SESSION BI01.01: Flexible Textbooks for the Materials Community I
Session Chair: Scott Beckman
Tuesday Morning, November 30, 2021
Sheraton, 2nd Floor, Grand Ballroom

10:30 AM *BI01.01.01
Materials Education and the Need for Modular, Flexible Textbooks M. Stanley Whittingham; Binghamton University, The State University of New York, United States

A challenge in teaching materials science is the rapid pace at which the field is changing and the different audiences that want educated. Two decades ago Binghamton planned an MS in MS&E that could be taken on-line with all the material on-line and could be taken at the student's pace. Today, there are continuous demands for a materials primer for advanced materials in the energy field, or for biomaterials. To satisfy those audiences an open-source textbook that could be readily modified and where modules could be plucked out to suit the audience level is needed. At Binghamton, we have begun such an effort in the areas of materials for energy storage and for electronics packaging. However, to achieve success a coordinated effort across several universities is necessary.

11:00 AM BI01.02.01
Spotlight Talk—Integrating Interactive Computing Experiences into Materials Science and Engineering Curricula Using Open-Source Jupyter Authoring Tools Enze Chen[1], Michelle H. Wilkerson[1] and Mark Asta[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

The ability for computational models and informatics techniques to rapidly provide scientific insights has led to their adoption across all areas of materials research, and there now exists tremendous opportunity to integrate these tools into materials science curricula [1]. However, even as advances in computing have made such tools accessible for teaching and learning, barriers to integration still exist partly due to the incoherent interface between research software (e.g., C++, Python, Julia) and curriculum design platforms (e.g., HTML, JavaScript, Microsoft Office). We show how the Jupyter Book platform [2] can be used to bridge this divide and create a digital textbook that synthesizes multiple sources of content, including rich computational narratives in Jupyter notebooks [3] that are widely used in the materials research community. The software is open source and the final textbook is accessible for not only readers, who engage with it dynamically in an internet browser or statically as a PDF, but also authors, who compile it directly from familiar file formats like Markdown and Jupyter notebooks.

We share our experience using Jupyter Book to design an open-source, introductory materials informatics curriculum [4] for a remote summer research internship at Lawrence Berkeley National Laboratory for UC Berkeley undergraduates in engineering. To accommodate their relative inexperience with programming and materials science, we support the Python programming exercises with prose, graphics, slides, polls, and discussion questions, all of which are seamlessly embedded into a common web interface as a digital textbook. In this way, the textbook is a one-stop-shop where the course information can be easily organized, accessed, and perused, which facilitates remote learning, user experience, and expansion to larger audiences. Most prominently, Jupyter Books have interactive programming capabilities, which we enable through the JupyterHub cloud infrastructure [5], that provide active learning opportunities in these digital spaces for students to interrogate the code, test their own hypotheses, and deepen their comprehension of the material. Through a combination of group-based exercises and self-directed research projects on data-driven design of photoactive materials, students are engaged in authentic learning experiences that demonstrate the broad utility of the Jupyter ecosystem in sustaining the growth of materials science education into new frontiers.

Spotlight Talk—Interactive, Reactive, Web-Based Media for Sharing and Exploring Materials Knowledge Michael Deagen and Linda Schadler; University of Vermont, United States

An open-source digital textbook presents an opportunity to envision dynamic, model-based representations of materials knowledge unbounded by many of the limitations of traditional print media. With an emphasis on reactive computational notebooks that run in-browser, we discuss the ideation and development of supplementary modules, exercises, and other learning activities for students entering the field of materials science and engineering in the 21st century. Authors of these notebooks—which blend code, prose, and other digital media—can demonstrate foundational concepts with parameterized explanations that allow readers to actively delve into models through embedded interactive elements. By facilitating exploration of domain models through a combination of *enactive*, *iconic*, and *symbolic* representations (Bruner, 1966), these interactive environments promote the formation of robust mental models around a given topic. While platforms such as *Observable* illustrate the state-of-the-art, they embody a decades-long trend toward literate programming, computational essays, "exploranations," and other forms of dynamic expression with computational media. In addition to the pedagogical advantages of this approach with respect to reproducibility and modularity, we examine some of the practical considerations around managing scope, editorial quality, and maintenance of these notebooks.

SESSION BI01.02: Poster Session I

Spotlight Talk—Interactive, Reactive, Web-Based Media for Sharing and Exploring Materials Knowledge Michael Deagen and Linda Schadler; University of Vermont, United States

An open-source digital textbook presents an opportunity to envision dynamic, model-based representations of materials knowledge unbounded by many of the limitations of traditional print media. With an emphasis on reactive computational notebooks that run in-browser, we discuss the ideation and development of supplementary modules, exercises, and other learning activities for students entering the field of materials science and engineering in the 21st century. Authors of these notebooks—which blend code, prose, and other digital media—can demonstrate foundational concepts with parameterized explanations that allow readers to actively delve into models through embedded interactive elements. By facilitating exploration of domain models through a combination of *enactive*, *iconic*, and *symbolic* representations (Bruner, 1966), these interactive environments promote the formation of robust mental models around a given topic. While platforms such as *Observable* illustrate the state-of-the-art, they embody a decades-long trend toward literate programming, computational essays, "exploranations," and other forms of dynamic expression with computational media. In addition to the pedagogical advantages of this approach with respect to reproducibility and modularity, we examine some of the practical considerations around managing scope, editorial quality, and maintenance of these notebooks.

BI01.02.03
Functional Materials—Electronic, Magnetic, Optic, Thermal and Elastic Scott Beckman; Washington State University, United States

The purpose of this session is to discuss the administrative and academic details needed to coordinate writing a chapter addressing functional materials,

which may include the electronic, magnetic, optic, thermal, and elastic properties and their cross-interactions. Our goal is to organize a working group that can engage in the writing and editing of content and create a rough outline for the chapter that will guide the development of content.

BI01.02.04
Teaching Materials Science Concepts Using a Web-Based Force-Directed Graph Framework George Varnavides, Amina Matt and W. C. Carter; Massachusetts Institute of Technology, United States

Recent developments in just-in-time compilers for dynamic languages have significantly improved the performance of web-based physics engines. Combined with the prevalence of interactive visualizations and the level of maturity of Document Object Model (DOM) manipulation libraries[1], this provides a unique opportunity to leverage such client-side physics engines for education. Force-directed graph layouts describe a broad class of algorithms which attempt to visualize the relationships between nodes in undirected graphs and hierarchical trees, via means of a physical simulation[2,3]. Such graph layouts have recently enjoyed increased popularity in the domain of information visualization, given the rise of interactive visualizations and advancements in just-in-time compilers for Javascript[4].

In this talk, we explore the use of physical simulations interactively on the client-side in the context of undergraduate education. We present an extension module to a popular open-source force-directed graph layout library which uses energy-conserving velocity Verlet integration to teach materials science concepts based on the Lennard Jones interatomic potential[5]. We find the ability to seamlessly integrate our numerical integrator with interaction techniques familiar to users, such as clicking, dragging, and brushing to improve the pedagogy of the simulations. The interactive exposition is deployed using a reactive notebook environment, which effectively intertwines textual explanations with multiple interactive visualizations[6].

BI01.02.08
Materials—A More Central Science Ilija Rasovic; University of Birmingham, United Kingdom

Chemistry has long rested on its laurels as “the central science”: the fulcrum about which all scientific endeavours pivot. Yet this view is based on the (arguably outdated) delineation of long-established traditional scientific disciplines and their associated *epistemological* hierarchy. This is limiting, for it doesn’t take into account the *technological* dimension of scientific research (not to mention the final element of the Aristotelian triumvirate: *phronesis*). Were we to do so, I contend that Materials Science and Engineering (MSE) would be a more viable candidate for “the central science”. This is not only important for raising the profile of the subject, but also for shaping what should be included in an undergraduate introductory text.

MSE, as a formalised subject with dedicated university departments, is a young discipline. It emerged out of the chaos of the Second World War to become the primary innovation and technology driver, with the recognition that the material realisation of advanced scientific, technological and, indeed, societal visions could not be achieved without dedicated research on understanding materials themselves. This understanding fundamentally boils down to the relationship between processing, structure and properties. As such, the subject inherently demands an intimate relationship with a vast array of characterisation techniques. It covers a huge range of length scales and spans all technology readiness levels. It is this explicit link between fundamental scientific understanding (*episteme*) and technological implementation (*techne*)—and the complete embedding of the subject in the tangible, physical, *material* world—that sets MSE apart from all other physical sciences.

This research endeavour unified scientists and engineers from across disciplines—physics; chemistry; mineralogy; chemical, mechanical and electrical engineering—giving rise to a highly interdisciplinary field that continues to this day to sprawl across boundaries. Indeed, it now defines itself adjacent to a plethora of even more diverse disciplines—computer science, medicine, the life sciences, sustainability, conservation, archaeology, and more—and its methodologies are propelling the establishment of a crucial new discipline in its own right: nanoscience and nanotechnology.

None of the above is news to an audience of materials science researchers and academic staff. But it would be remiss to assume that undergraduates had such a holistic overview and appreciation of the centrality of MSE in the networks of modern scientific research and contemporary human existence. This is especially true when considering audiences such as first-generation students and those majoring in other disciplines but who might require knowledge of some aspect of MSE. I anticipate that such knowledge would help *all* students to understand better their chosen subject and succeed in their MSE education. As such, I would like to take this opportunity to provoke discussion around how an open-access introductory undergraduate textbook can best incorporate such insights. I will offer some initial thoughts on how this might be achieved through, for example, the structure and content of the text, as well as embedding examples and problems.

SESSION BI01.03: Morning Session—Flexible Textbooks for the Materials Community II/Panel Discussion, Needs and Best Practices
Session Chairs: Kevin Jones and Steven Yalisove
Tuesday Morning, December 7, 2021
BI01-Virtual

8:30 AM *BI01.03.01
Materials Education and the Need for Modular, Flexible Textbooks M. Stanley Whittingham; Binghamton University, The State University of New York, United States

A challenge in teaching materials science is the rapid pace at which the field is changing and the different audiences that want educated. Two decades ago Binghamton planned an MS in MS&E that could be taken on-line with all the material on-line and could be taken at the student’s pace. Today, there are continuous demands for a materials primer for advanced materials in the energy field, or for biomaterials. To satisfy those audiences an open-source textbook that could be readily modified and where modules could be plucked out to suit the audience level is needed. At Binghamton, we have begun such an effort in the areas of materials for energy storage and for electronics packaging. However, to achieve success a coordinated effort across several

universities is necessary.

Open Source Presentation of Topics in Electronic Properties of Materials and Their Applications Angus Rockett; Colorado School of Mines, United States

A key element of materials is their electronic properties. However, this topic is rarely covered in detail in conventional introductory materials textbooks and there is a general lack of good coverage even in more advanced books. The topic as covered in Materials departments but without good textbook support includes the following: fundamental concepts in electronic structure, conduction (electricity, light, heat, ions, superconductivity, etc), magnetism and magnetic properties, dielectric properties, and semiconductors. These should be accompanied by applications of each of these concepts. A particular advantage of an open source textbook is that additional background can be added as needed. This is particularly important to the topic of electronic properties as it relies significantly on physics and chemistry concepts.

10:10 AM BREAK

10:30 AM *BI01.04.03
Filling the Capability Gap in Materials, Processing and Manufacturing Glenn Daehn; The Ohio State University, United States

Critical issues of supply chain, sustainability and jobs are all directly tied to the United States' ability to manufacture what it needs and uses. Its widely recognized that even if through economic means like tariffs and taxes US-based manufacturing were completely competitive with overseas manufacturing, the US does not have the talent needed to rapidly ramp up manufacturing. The inability to execute an effective manufacturing policy have led to a shortage of essential workers in welding, machining, equipment maintenance and installation, leading to bottlenecks in new technology deployment and innovation in the US. Multiple studies and technical society initiatives have focused on this problem, but with only modest success.

There are bright spots that we will focus on. The ASM Materials Education Foundation has successfully provided professional development to K-12 teachers at scale, leading to many new materials courses in high schools, and the broader problem is well understood. I will issue a call to action to bring together the stakeholders, largely through the technical societies to coordinate on one roadmap and use collective action to plow through the roadblocks.

10:50 AM *BI01.04.05
Growing Materials Science in Africa Samuel Chigome; Botswana Institute for Technology Research and Innovation, Botswana

Africa is the world's second largest and second most populous continent in the world. Generally, it has a rich concentration of a wide range of natural resources such as oil, copper, diamonds, bauxite, lithium, gold, graphite, iron ore, coal, hardwood forests, tropical fruits among others. It is estimated that 30% of the earth's mineral resources are found in Africa. However, there is underutilization of the resources partly because materials science has not been embraced effectively across the continent. This is evidenced by the fact that there some countries that do not have materials science programmes at any of their Universities.

The presentation will give an overview of the status of materials science in Africa, the efforts of the African Materials Research Society to close the materials science development gaps and the need for open access to materials science literature.

Approaches for Data Management and Version Control in Materials Science Marcus D. Hanwell; Brookhaven National Laboratory, United States

Research in materials science in the modern age involves far more data and software code than ever before. This makes it ever more important that researchers in materials science develop a good grasp of approaches for data management for their data and version control for their software code, scripts and other artifacts. There are also circumstances where data itself may need to be version controlled which presents unique challenges, along with the challenges of expressing the interplay between data and the software code/scripts used to analyze it.

An overview of some of the existing approaches to data management will be presented, along with discussions of the use of metadata, data, and programming interfaces that can be used to expose these things to the wider world. Approaches for small, medium and large data will be discussed including how data management approaches can document the links between raw data, reduced data and analyzed/derived data. The use of licenses to encourage sharing will be discussed along with the pros and cons of different licensing schemes.

Approaches to version control will look at pragmatic approaches to version control using mainstream version control projects, command-line, graphical interfaces and some embedded integrations in code editors. The interplay of version control and data along with some practical advice on different approaches there, along with the importance of licensing, documentation, and using standard development practices. Some discussion of licensing, distribution, archiving and the generation of digital object identifiers and similar using integrations with platforms/minting of identifiers to increase the citability of data and code.

Organizations to encourage better data management are an important component of the community, along with those that encourage better coding practices in the sciences and alternative career paths to better address these areas. It is important to consider how the community can better scope proposals and projects in order to fully cover not only the capital equipment costs, but also the data management and software/coding requirements to fully support instruments/projects is an important emerging area.

9:00 PM BI01.07.01
Materials Science—Who Cares? Why Should You? Mark Atwater; Liberty University, United States

I had no plan to be a materials science educator and researcher. It was only after seeing, experiencing, and applying the concepts that I even became interested. Too often we assume others have the natural inclinations we have to study and be motivated by the fundamentals of materials, and we under emphasize the reasons we became interested and still are. As an educator in manufacturing, mechanical, and materials engineering, I have sought to incorporate the principles of materials science within broader contexts so that there is reason for each of my students to care. Distilling concepts to ensure the weakest student understands and highlighting current research to give the strongest student opportunity for growth is a difficult but valuable approach

to presenting such a diverse topic. This presentation has three suggestions for future materials education: 1) It should be relatable, 2) it should be unique, and 3) it should accommodate both the student and professor. The basis for these aspects comes from my own experience writing an introductory materials and manufacturing textbook including more than 500 figures of original artwork and photography. I will share the struggles and successes I encountered along the way, and how that may help shape open-source materials education initiatives.

9:05 PM BI01.07.02
A Text Book on Materials Degradation on Earth and Outer Space Kalathur S. Santhanam; Rochester Institute of Technology, United States

The development of innumerable number of technologies of the twenty first century is based on the knowledge generated through the subject of Materials Science and Engineering, paving the way for our comfortable living. The materials are classified into the following categories. a) Metals b) Ceramics c) Polymers and d) Composites. A number of books (1-4) have been written on these materials for teaching undergraduate and graduate level courses. Our understanding of their behavior has been increasing over the years by constant research activities; this has resulted in the discovery and development of nanomaterials. The planned text book is an e-book with power point illustrations with vocal lectures. The book addresses a basic question on the stability of the materials; do they remain in the same virgin state over a long period of time or degrade with time. If they do not remain in virgin state, what are the causes for the change and how to overcome this problem. Our curiosity has driven us to explore interstellar planets which requires utilization of the above mentioned materials driving us to understand the behavior of materials in different atmospheric conditions. Will their behavior on our planet (earth) different from outer interstellar space due to the presence of meteorites and high energy radiation such as X-rays, g-rays and ultraviolet rays. On earth, we have besides moisture, atmospheric gases like oxygen, nitrogen and carbon dioxide and sunlight that are free from high energy radiation except for small quantities of ultra violet, visible and infra red radiations. In addition, there is hydrodynamical and mechanical effects that would be imposed on the materials. With metals, there has been well focused degradation processes (3,4) that are based on electrochemical theories providing solutions to greater stability of metals. Today, we have durable materials starting from microelectronics chips to large scale industrial processes for the betterment of humanity. Polymers fall into a different class and the degradation occurs by a) swelling and distortion b) bond rupture caused by radiation/chemical/thermal processes c) weathering d) mechanical oxidation and e) biodegradation. The mechanism of degradation is complex and contrasts metals and ceramics. The composites provide unique answers to many of the problems faced with metals and polymers; here composites with nanomaterials appear to offer distinctive advantages (5). Overall, the text book amalgamates the behavior of materials on earth and in outer space, in a combined fashion to bring the relative merits of the earth and outer space.

Late News: Incorporating nanoHUB's Free Simulation Apps for Materials Science Education into an Open Source Online Textbook Tanya A. Faltens and Alejandro Strachan; Purdue University, United States

Simulation plays a valuable role in engineering education, allowing students to explore phenomena and gain a greater comprehension of physical systems. Cloud-based simulation can also level the playing field by making powerful simulation tools available to students across a variety of institutions. nanoHUB provides free access to a wide range of simulation tools and computational resources that can be accessed online by users from around the world. Via easy-to-use nanoHUB apps, computational scientists can put powerful scientific software in the hands of instructors and students. This frictionless access lowers access barriers and accelerates innovation. Importantly, nanoHUB apps can be accessed via a standard web-browser and run in the cloud, so no downloading or installation of software for classroom use is required. With recent developments, nanoHUB apps can now be consumed as a web-service and be seamlessly incorporated into online courses and textbooks.
While many powerful, research-grade computational engines such as LAMMPS, OOF2 and Quantum Espresso are installed and available in nanoHUB, they are made accessible to a wide range of users, from beginner to advanced, through apps that are designed with interactive graphical user interfaces. Students can select input parameters and generate engaging images, atomic-level visualizations, graphs, trajectories, animations, and other types of data to explore and analyze, and thus engage more interactively in their learning. There are nanoHUB apps designed to explore a wide range of materials science topics, including, but not limited to: bonding, crystal and electronic structure, polymer structures, tensile testing, dislocations, plastic deformation, crack propagation, thermal transport, phase transformations, phase diagrams, microstructural analysis, optical properties, and magnetic properties.
nanoHUB provides instructor-friendly features such as the ability to share a simulation session with an entire class, or smaller groups within a class, and assign control of the shared simulation to any student. Caching of simulation runs allows the rapid retrieval of simulation results if a specific set of inputs has previously been run, significantly reducing the time required. Jupyter notebooks in nanoHUB come with a wide range of libraries and packages to provide a powerful platform for interactive computing. These tools have been used to deploy learning modules in data science and machine learning in the field of materials.
This presentation will demonstrate some of the interactive nanoHUB apps that have been used to teach materials science skills and concepts, illustrate nanoHUB features that are beneficial for the classroom use of simulation apps, and show how nanoHUB apps can be incorporated into an online electronic materials science textbook.

9:15 PM BI01.07.04
Teaching Basic Crystallography and Diffraction Using Open Access Structure Visualization Software Matt Beekman; California Polytechnic State University, United States

The understanding of basic concepts in crystallography and diffraction is foundational for the study of solid-state physics, chemistry, and materials science. In this talk, I will describe how open access structure visualization software, such as VESTA (https://jp-minerals.org/vesta/en/), can be used to help make learning the fundamentals of crystallography and X-ray diffraction active, engaging, and effective. The ability for 3D visualization of crystal structures, bonding, lattice planes, and simulation of powder X-ray diffraction patterns in a single software package allows students to discover and explore important concepts such as Bragg's law, symmetry, Miller indices, systematic absences, and the relation between the location and type of atoms in the unit cell influence and relative intensity in the diffraction pattern. Learning modules using such open access software give students familiarity with tools that are also used in authentic research and could be readily integrated with an open access introductory textbook.

The Importance of Being a "Bad Scientist"—Towards a More Inclusive Future for Women in Materials Science Julia R. Greer[1,2]; [1]California Institute of Technology, United States; [2]Kavli Nanoscience Institute, United States

I am a Professor of Mat Sci, Mechanics, and Medical Engineering at Caltech, and apparently I am a bad scientist. At least that's what my advisor told me when I was a Master's student at Stanford. Is there anything you are bad at? Because it turns out that sometimes being told that you are bad at something can make you excel at that very thing. I finished my Ph.D. degree at Stanford and spent a couple of years working at Intel, after which I had decided that if I were a bad scientist, at the very least I should be one with a Ph.D. I was lucky enough to become a Ph.D. student at Stanford in a research group of Prof. William D. Nix, affectionately known as "the Boss." At that time, Stanford's Materials Science department did not have a single woman faculty member. Together with the Boss we discovered that tiny little crystals of common metals – like gold, copper, and nickel, which we know to be quite malleable – become exceptionally strong when their dimensions are reduced to ~ 200nm, or ~1000^{th} of your hair diameter. We coined this phenomenon a "smaller is stronger" size effect. Working with Bill Nix had a tremendous impact on my life; to this day, he is quite possibly the most influential person in my professional career – he saw me transform from being a young "bad scientist" into a decent thinker. Most importantly, he believed in me, as he did in all of his graduate students, many of whom were women. And we rose to the occasion.
At the end of my third year in graduate school, I did everything backwards: I first had two faculty interviews for professorships at Caltech and MIT, I then interviewed for a post-doc, and finally defended my Ph.D. dissertation on May 16, 2005.
I built my professorial career at Caltech in Materials Science "option" (in the Division of Engineering and Applied Sciences) to study all things nano (materials and architectures) – much because of our discovery during my Ph.D. that materials behave differently at nano-scale. In the back of my mind, I had always wondered if there was a way to somehow harness these unique properties offered by nanomaterials and proliferate them onto larger scale so that we can have materials that behave as though they were nanomaterials but they look like our regular, macroscopic objects.
Fast forward a decade – I am now an endowed, chaired professor at Caltech, having accumulated multiple national and international recognitions and awards. I run a research group with 20+ incredibly smart, talented, and motivated Ph.D. students, undergraduate students, and post-docs. In the course of my career, have graduated 29 Ph.D. students, 7 of whom are tenure-track professors at US universities (not counting post-docs). And what gets me going every morning is that I know that my work, in part, that in the world where our children will live there will be no need for hearing aids because we will be able to synthetically "write" the cochlear bone directly into the ear, where the batteries their iPhone 83's will be able to hold charge for a year without needing re-charging, where balloons will not have to be filled up with He or any other gas but instead will be evacuated to make vacuum balloons, and where chocolate will have 100% taste, 99.9% air, and 0.01% calories. My success comes *from* being a woman, not *in spite* of being a woman. One of my key missions in life is to inspire as many young women to pursue a career in science, and especially in materials science, through mentoring, encouragement, and passing on the legacy of Bill Nix.

11:00 AM *BI02.01.02
Perspectives on a Career in Electrochemistry and Hydrogen—Translating R&D into Commercial Products Katherine Ayers; Nel Hydrogen, United

States

To reach global sustainability goals, renewable sources of hydrogen are urgently needed. Regardless of the debate over various electrochemical energy solutions and the end mix for the electrical and transportation sectors, even decarbonizing many existing chemical manufacturing processes is a large challenge directly related to existing hydrogen generation. Most industrially produced hydrogen is used for manufacturing chemicals such as ammonia, methanol, ethylene, and other hydrocarbons, and this hydrogen currently comes from fossil sources. Any effort to convert this industrial hydrogen stream to a fully renewable resource at scale will involve significant deployment of existing commercial technologies in the near term (5-10 years), while emerging technologies may play a larger role in the future.

Both liquid alkaline and proton exchange membrane-based electrolyzers have been scaled to multi-megawatt systems and are growing business segments. Both also have continued room for cost reduction and efficiency improvements, especially the PEM technology. However, fundamental understanding and process development are required to get to the targets. While most of the cell stack materials in fuel cells have been optimized for the application, electrolyzers still largely adapt existing materials for hydrogen generation. In addition, significant work has been done in developing roll to roll manufacturing methods and related quality control for PEM fuel cells, which has not yet been translated to electrolysis. Much of the learning from fuel cells can be leveraged, but needs to be applied to electrolyzer specific requirements and materials.

Collaborations will be a major element in this transition. At this stage of development, close interaction between the supply chain, electrolyzer manufacturers, and project developers all contribute to advancing towards the needed cost and performance levels. Fundamental research conducted by academia and National Labs also play a critical role. Leveraging contacts and networks built over several years in electrochemical technologies helps to bring these partners together. As a female in the field, understanding partners that value diversity and teamwork is an especially important part of this network building.

Major areas of research and development for PEM electrolysis include the polymer membrane, catalyst thrifting, automated component fabrication and assembly, and porous transport layer development. In this talk, some historical perspective on development of alkaline and PEM electrolysis will be described, with details presented on paths forward, especially in the PEM systems. Career experiences in the electrochemistry field including how to manage obstacles and opportunities from the perspective of a female scientist will also be discussed.

1:30 PM *BI02.02.01
Superprotonic Solid Acids for Sustainable Energy Technologies Sossina M. Haile; Northwestern University, United States

The compound CsH_2PO_4 (cesium dihydrogen phosphate) has emerged as a viable electrolyte for intermediate temperature electrochemical cells, devices for interconversion between electricity and value-added chemical compounds. Cesium dihydrogen phosphate is a member of the general class of materials known as solid acids or acid salts, in which polyanion groups are linked together via hydrogen bonds and monoatomic cations provide overall charge balance. Several such solid acids display a superprotonic transition, at which the material transforms to a high conductivity phase with a high degree of polyanion rotational disorder. At the transition the conductivity jumps by as much as 5 orders of magnitude and the activation energy for proton transport drops to 0.35 eV or less. In the case of CsH_2PO_4 the transition occurs at 228 °C and the conductivity reaches ~ 10^{-2} S/cm at 240 °C, enabling electrochemical device operation at temperatures between 230 and 260 °C. The physical characteristics of CsH_2PO_4 imply a number of realized and potential advantages for their application in fuel cells, electrolyzers, and electrochemical hydrogen pumps relative to polymer, solid oxide, and liquid electrolyte alternatives. We present here an overview of the transport characteristics of superprotonic solid acids and the current status of electrochemical technologies based on these electrolytes.

2:00 PM *BI02.02.02
Becomeing WISE—Women In Science and Engineering Y. Shirley Meng; University of California, San Diego, United States

I will share my personal perspective on the challenge and joy of being a woman in science and engineering. High energy long life rechargeable battery is considered as key enabling technology for deep de-carbonization. Energy storage in the electrochemical form is attractive because of its high efficiency and fast response time. Besides the technological importance, electrochemical devices also provide a unique platform for fundamental and applied materials research since ***ion*** movement is often accompanied by inherent complex phenomena related to phase changes, electronic structure changes and defect generation. In this seminar, I will discuss a few new perspectives for energy storage materials including new fast ion conductors, new intercalation compounds and their interfacial engineering. With recent advances in characterization tools and computational methods, we are able to explore ionic mobility, charge transfer and phase transformations in electrode materials *in-operando*, and map out the structure-properties relations in functional materials for next generation energy storage and conversion. Moreover, I will discuss a few future priority research directions for electrochemical energy storage.

2:30 PM *BI02.02.03
Nucleating a New Culture in STEM Debra R. Rolison; U.S. Naval Research Laboratory, United States

The research-intensive STEM (science/technology/engineering/math) environment—for all its renowned innovation and productivity—has only glacially incorporated the STEM talent endemic to humankind. And science really is too important to be left just to men [1]. Besides, we have never run the control experiment to assess just how well science and society will be served by inclusion, retention, and celebration of the STEM talent endemic to humankind. In short: we need a better culture. We have four mechanistic levers to work the problem: Revolution (such as when I proposed Title IX assessments of STEM departments in 2000 [2,3] and the General Accountability Office agreed in 2004); Subversion (always in fashion); Climate Change (creating a human-centric, innovative microclimate); and Market Forces (steering the talent and the funds to healthy, productive microclimates). Our team at the U.S. Naval Research Laboratory* has created such a microclimate. A key component of our success (recognized by awards and eager collaborators) is inclusion of full-time undergraduate researchers who step away from campus to spend six-to-twelve months working with a scrum (because we love disordered materials) of Ph.D. staff and postdoctoral associates on frontier research in nanomaterials, energy storage and conversion, catalysis, and chemical threat

mitigation. And we have great fun doing so.

* Rolison heads the Advanced Electrochemical Materials Section at the U.S. Naval Research Laboratory (NRL). The views are those of the author and are not necessarily those of the NRL or the U. S. Department of Defense.

3:00 PM *BI02.02.04
Understanding Dynamics at Solid-Solid and Solid-Liquid Interfaces for Separations and Energy Storage Kelsey B. Hatzell; Princeton University, United States

Understanding transport mechanisms in geometrically confined layered conducting inorganic membranes and solid electrolytes is paramount for next generation batteries and separation application. Ion transport is widely studied in an array of applications from batteries, to colloid science, to biological applications, and separations. Each of these applications rely on ion mobility in confined regions where the pore sizes are comparable to the Debye screening length. At these dimensions, biophysicists have observed efficient transport and selectivity mechanisms. Yet, it is still not understood how water and ions move in structural domains between 1-10 nm. Electrically tunable solid-state nanochannels may offer additional pathways for tailoring transport and controlling fundamental interactions that govern separations processes (desolvation, adsorption, selectivity, etc.). This talk intends to describe the role long-range mirostructural (tortuosity, constriction, etc.) and short-range (electric double layer, confined water) structural properties impact transport in solid electrolytes and separation membranes. To accomplish this goal, this talk will discuss a range of non-equilbrium techniques (spectroscopy, imaging, etc.) to probe solid|liquid and solid-solid interfaces in order to directly observe water and ion transport processes. The talk will also give a broader lens on women in engineering and tools to finding your community.

3:30 PM BREAK

Microwave Sintering Faux Moondust for NASA Holly Shulman[1,2]; [1]Alfred University, United States; [2]DrHollyShulman, LLC, United States

For the symposium subject of "Women in Materials Science", my experiences as a scientist contracting with NASA may be of interest. My first interaction with NASA was through my previous company, Ceralink Inc., in 2010. I founded Ceralink in 2000 to provide feasibility and scale up studies for energy saving processes, including the use of microwave energy. Ceralink demonstrated feasibility of microwave sintering for lunar and Martian regolith sintering through SBIR grants (Small Business Innovative Research). Ceralink's work resulted in the largest dense samples of microwave sintered lunar simulant (JSC-1A) to date. NASA is moving forward with construction on the moon and invited me to define a scope of work to lead the Microwave Sintering team. In my current role as a Professor of Ceramic Engineering at Alfred University, I am engaging undergraduate and graduate engineering students in this mission. This includes the development of synthetic lunar minerals, as well as process design for energy efficient and uniform microwave heating. I would be delighted to share some stories of getting out of my own way, accepting my position as a world expert in microwave and materials and interactions, and getting comfortable with how much I don't know and don't have to know to still be a valuable member of an amazing NASA team.

4:30 PM BI02.03.02
A Sustainable Future for Materials Science and Engineering—Enabling Scalable Manufacturing of Polymer Nanocomposites and Addressing Underrepresentation of Women in the Field Cecile Chazot and John Hart; Massachusetts Institute of Technology, United States

Polymer nanocomposites have been proposed as next-generation lightweight structural materials for applications ranging from aerospace to automotive and sports equipment. However, their processing often requires high temperatures for hours (or sometimes days), contributing to their energy footprint.[1] Additionally nanocomposite manufacturing techniques, such as dispersion of nanofillers in polymer solutions and resin infusion in nanoporous assemblies, often result in composite systems with heterogeneous morphologies and therefore reduced mechanical properties. We present a scalable, low-temperature nanocomposite manufacturing method called in-situ interfacial polymerization (ISIP), which is based on interfacial polycondensation of high-performance polymers in nanoporous assemblies. For example, we demonstrate that dense carbon nanotube (CNT)-polymer composites can be obtained by ISIP within CNT networks.[2] Uniform aramid-CNT composite sheets obtained by this method have a Young's modulus of 31 GPa and a tensile strength of 776 MPa, which is a two-fold increase compared to the pristine CNT sheets. We also present how ISIP can be extended to a broad range of polymers and matrices including nanofiber mats and 3D printed lattices. A macrokinetics model describing the simultaneous fluid flow and polymerization reaction is used to predict final composite morphology and performance. We also demonstrate the implementation of ISIP as a roll-to-roll process, where the nanoporous substrate is continuously drawn through the series of liquid immersion steps to produce the final composite fiber.

We also share the personal experience of a woman in STEM and Materials Science and Engineering (MSE) from technical high school in France to graduate school in the United States. While women represent 44% of the total workforce in the US, they constitute 39% of materials scientists and chemists, and only 16% of materials engineers.[3,4] Notably, the proportion of women decreases with increasing degree level in higher education in MSE in both France and the US. We will put the underrepresentation at the highest level of the field in relation with the social psychology topic of stereotype threat: a type of social identity threat that occurs when one fears being judged in terms of a group-based stereotype.[5,6] Last, we will discuss current ongoing initiatives at MIT targeted at mitigating stereotype threat and reducing these inequalities in the laboratory and the classroom.

Hynes, Level 1, Room 107

10:30 AM *BI02.04.01
Semiconductor Quantum Dots—A Journey from the Flask to Photonic Devices Jennifer Hollingsworth; Los Alamos National Laboratory, United States

Solution-processed quantum dots (QDs) are finding real-world applications in a wide-range of technologies from displays and lighting to photovoltaics and photodetectors. We take advantage of an expanded "structural toolbox" to synthesize QDs with novel and optimized photophysical properties relevant for device implementation. We use advanced heterostructuring that employs interfacial alloying, bandgap engineering, thick ("giant") or asymmetric shell growth, etc. In this way, we have synthesized QDs for which non-radiative processes, such as blinking, Auger recombination and photobleaching, have been suppressed or even "turned off" at room temperature,[1-7] or at elevated temperatures while exposed to atmospheric oxygen.[8-9] This has required simultaneous development of new methods for evaluating correlations between synthesis, resulting nanostructure and realized functionality toward the ideal of a materials-by-design approach to the next generation of useful QDs. In this talk, I will review highlights of our work in this area, as well as some of the enabled device demonstrations. I will also discuss the integration of QDs with other functional nanomaterials for multifunctionality or emergent properties, as well as into devices, especially scanning-probe-enabled fabrication of single-photon sources.[10]
The journey from materials discovery to demonstrated application is long and complex, but equally so are the personal journeys of the scientists and engineers pursuing this path. In the theme of this symposium, I will conclude my presentation with some observations, concerns and aspirations for women in science made over the course of more than 20 years as a national lab technical staff member.

11:00 AM *BI02.04.02
Colloidal Semiconductor Nanocrystals—(Un)Conventional and Quantum Materials and Devices Cherie R. Kagan; University of Pennsylvania, United States

Colloidal semiconductor nanocrystals (NCs) are typically 2-20 nm diameter fragments of the bulk solid. They are known as "artificial atoms" or quantum dots since electrons, holes, and excitons are quantum-mechanically confined and occupy discrete electronic states. The research community has celebrated >30 years of study of the synthesis, assembly, structure, properties, and applications of colloidal semiconductors NCs, and I have enjoyed the opportunity to contribute to the field in my career. Advances in wet-chemical synthetic methods enable the preparation of NCs tailorable in size, shape, composition, and surface chemistry. As colloids, these NCs are readily dispersed in solvents and deposited using solution-based methods. They can self-assemble to form glassy or crystalline NC solids or be directed to assemble to deterministically position single or countable numbers of NCs. I will focus on routes to design solid-state NC materials by manipulating the NC surface chemistry to strengthen electronic coupling, by exchanging the ligands used in synthesis for more compact chemistries, and NC doping, by introducing atoms and ions that serve as impurities or modify stoichiometry. Ultimately, I will connect NC material design to their physical properties and their application in (un)conventional electronic and optoelectronic devices. I will also give an outlook on the opportunity to exploit NCs as platforms for quantum information science, in particular as optically addressable qubits.

11:30 AM BI02.04.03
A Bioinspired, Bioinorganic Approach to Materials Design—Using Fe and V Coordination to Create Photoresponsive Materials Alexis D. Ostrowski; Bowling Green State Univ, United States

In bioinorganic chemistry, metal ions play important roles in the structure and function of a variety of systems. Using this as inspiration, our approach is to design materials that exploit metal coordination bonding to create materials with unique properties. Of particular interest, are materials that coordinate Fe and V ions, since once coordinated, the metal-ligand bonding in the material can be controlled with light using photochemical processes Both Fe(III) and V(V) coordination in polysaccharide materials can be used to create hydrogels. Once irradiated, photo-induced charge transfer processes change the Fe and V coordination environments in the gel, and disrupting the intermolecular forces in the material, changing the viscosity and modulus of the gels. These photoresponsive materials can be used for a variety of applications, including encapsulation and delivery of bioactive molecules or nutrients.

11:45 AM BI02.04.04
Designing Nanoparticles for Self-Assembly of Novel Photonic Materials Rose K. Cersonsky[1,2], James Antonaglia[1], Bradley D. Dice[1] and Sharon C. Glotzer[1]; [1]University of Michigan, United States; [2]École Polytechnique Fédérale de Lausanne, Switzerland

The design of new materials has often relied on crystal structure as a primary source for design complexity and innovation, requiring new crystal structures and new manners of constructing and synthesizing these structures. Within the photonics community, where the goal is a photonic crystal, i.e., a crystal that reflects a range of wavelengths, the literature points to a handful of targets, most commonly the diamond or inverse opal structures. Nanoparticle self-assembly, or the spontaneous emergence of order due to particle interactions, has been identified as a favorable synthesis route, as photonic nanocrystals reflect wavelengths within the visible range due to the scale-covariance of photonic band structures. Yet, the effort to self-assemble photonic crystals has been fraught with obstacles — from difficulty synthesizing diamond to the degradation of photonic band gaps based upon thermal noise within the assembly. This begs the question: if we look beyond the known set of photonic crystal structures, which other structures are worth targeting? We discuss the unexpectedly diverse range of crystallographic structures that will support a photonic band gap, as determined by more than 150,000 photonic band structure calculations. These calculations identify nearly 300 previously unstudied targets for photonic crystals—including targets achievable via colloidal self-assembly [1]. We demonstrate avenues to predict the polyhedral nanoparticles that can cleanly self-assemble these targets and the implications, both good and bad, that small changes to nanoparticle shape have on the resulting crystal's behavior [2-4].

Finally, we discuss the topic of scientific communication, which is fundamental in encouraging underrepresented populations in STEM by deterring the imposter syndrome for those who may glean a sense of "otherness" from poorly communicated work. We will focus on two programs at the University of Michigan to connect higher education institutions with primary and secondary school educators [5],[6]. These programs facilitate and promote discourse between graduate students and K-12 STEM educators, pushing students to communicate and contextualize their research and extending access to cutting-edge science to populations typically harder to reach via other outreach efforts.

1:30 PM *BI02.05.02
Barriers to Electrons in Nanocrystal Films and Barriers Arising from Gender Stereotypes Delia Milliron; The University of Texas at Austin, United States

Colloidal nanocrystals are attractive as solution-processable precursors to make conductive thin films for electronic and optoelectronic devices. However, in most cases electrons move through nanocrystal films by thermally activated hopping, behaving as insulators even when the nanocrystals themselves are metallic. We synthesize indium tin oxide transparent conducting nanocrystals to fabricate conductive thin films and show how the contact resistance between them controls the metal-insulator transition. Our results establish a "phase diagram" for electron transport, mapping conditions for hopping, thermally activated granular metallic, and classical metallic conduction.

From the perspective I now have – participating regularly in faculty recruiting, promotion, and mentorship – I have started to see experiences from my own early career in a broader context. Reflecting on these, I'll talk briefly about the ways that prevalent stereotypes present barriers to the development and advancement of women and people from underrepresented groups in STEM.

2:00 PM *BI02.05.03
Rethinking our Approach to Developing Inorganic Nanoparticles for *In Vivo* Imaging Allison M. Dennis; Boston University, United States

Although semiconductor quantum dots (QDs) are excellent fluorophores for biosensing and biomedical imaging, their translation to clinical applications is stymied by toxicity concerns. While materials developed for optoelectronic applications such as displays and photovoltaics exhibit excellent photophysical properties, their elemental composition is often contraindicated for use in human subjects. The current solution to elemental toxicity is to cap the core nanoparticle in a shell, usually of zinc sulfide, to prevent the release of the offending elements into the biological environment. This sequestration approach also results in the accumulation and persistence of the nanoparticles in the liver, an outcome that would preclude FDA approval for a diagnostic contrast agent. This combination of toxic compositions and bioaccumulation is a persistent barrier to the clinical translation of semiconductor nanoparticles.

In our new approach to developing inorganic nanoparticles for biomedical imaging and in vivo biosensing applications, we have shifted our focus to consider biological interactions first and optical properties second to identify the best materials for the application. Developing inorganic nanomaterials that can be used as contrast agents in humans requires addressing issues of toxicity, bioaccumulation, and function. We are inspired by the composition of the only FDA-approved inorganic nanoparticle: iron oxide. Iron oxide nanoparticles degrade in vivo into biocompatible and bioessential elements, coincidentally treating the patient's anemia. To develop biocompatible inorganic nanoparticles (bioNPs), we are synthesizing nanocrystals comprising bioessential elements and assessing their optical properties, degradation, and nanotoxicity. These iron- and copper-based semiconductors are often understudied with regards to both their optoelectronic properties and biocompatibility. For example, we have demonstrated that while copper indium

sulfide (CIS) QDs exhibit appropriate optical properties for in vivo luminescence imaging, ZnS shell-free CIS particles degrade rapidly with high toxicity in mice. Alloying zinc into the particles (CISZ) improves their optical properties, maintains a reasonable degradation rate, and substantially reduces toxicity. In comparison, copper iron sulfide nanoparticles (chalcopyrite or bornite; abbreviated CFS) biodegrade and exhibit localized surface plasmon resonance (LSPR) in the NIR, showing promise for photoacoustic imaging and photothermal therapy applications. As we expand the compositions of the bioNPs tested, we are developing a framework to relate the degradation rate and degradation products to toxicity. This information is being used together with the optoelectronic properties of the new materials to change the way we develop semiconductor nanoparticles for in vivo applications.

Advancement of Battery Technology for EVs Mei Cai; General Motors, United States

Despite the current battery technology evolution, battery chemistries have not changed much in the last two decades. Highly emerged EV market evokes the demands on advanced batteries with high energy density. Among the future chemistries, lithium metal batteries have great advantages over state-of-the-art lithium ion batteries in term of energy density and cost, which bring huge opportunity for long-range and low-cost electrical vehicles in the future. However, automotive industry has critical requirements on specific characteristics of battery cells. In this talk, I will discuss the requirements for future electrical vehicle application and the impact of Li-metal batteries on automotive industry. As a women scientist working in the automotive industry, I will also describe the range of opportunities available to women in this field. Some concerns and challenges will also be discussed.

9:30 AM *BI02.07.02
Using Multidisciplinary Science to Drive Healthcare Innovations Molly Stevens; Imperial College London, United Kingdom

This talk will provide an overview of our multidisciplinary approach to elucidate the interfaces between living and non-living matter, and how we use this fundamental knowledge to design innovative materials and technologies with impactful applications in regenerative medicine, advanced therapeutic delivery and disease diagnostics.
We engineer simple conceptually novel biosensing approaches using designer bio-nanomaterials for ultrasensitive diagnostic assays that are simple, cost-effective and easy deploy to the point-of-care. We are exploiting the sensing capabilities of nanoparticles to engineer paper-based lateral flow immunoassays (LFIAs) for the detection of infectious diseases such as HIV [2], Ebola, tuberculosis and Covid-19, and we can integrate our assays with smartphone technology for patient self-monitoring, geographical tagging and epidemic surveillance [3]. Harnessing our knowledge of the bio-interfaces, we also engineer complex 3D architectures with spatially arranged biochemical cues and cell interfacing nanoneedles for multiplexed intracellular biosensing at sub-cellular resolution and modulation of biological processes [4].
I will also speak about the breakthroughs, innovations and aspirations that shape who we are and what we do, and how we strive to create an inclusive and stimulating environment where science and scientists flourish.

Emerging Nanophotonic Platforms for Infectious Disease Diagnostics—Re-Imagining the Conventional Microbiology Toolkit Jennifer A. Dionne; Stanford University, United States

We present our research, education, outreach, and translational work to control light at the nanoscale for infectious disease diagnostics, including detecting bacteria at low concentration, screening for viral gene sequences, and visualizing in-vivo inter-cellular forces. First, we combine Raman spectroscopy and deep learning to accurately classify bacteria by both species and antibiotic resistance in a single step. We design a convolutional neural network (CNN) for spectral data and train it to identify 30 of the most common bacterial strains from single-cell Raman spectra, achieving antibiotic treatment identification accuracies exceeding 99% and species identification accuracies similar to leading mass spectrometry identification techniques. Our combined Raman-CNN system represents a proof-of-concept for rapid, culture-free identification of bacterial isolates and antibiotic resistance. Second, we describe resonant nanophotonic surfaces, known as "metasurfaces" that enable multiplexed detection of SARS-CoV-2 gene sequences. Our metasurfaces utilize guided mode resonances excited in high refractive index nanostructures. The high quality factor modes produce a large amplification of the electromagnetic field near the nanostructures that increase the response to targeted binding of nucleic acids; simultaneously, the optical signal is beam-steered for multiplexed detection. We describe how this platform can be manufactured at scale for portable, low-cost assays. Finally, we introduce a new class of *in vivo* optical probes to monitor biological forces with high spatial resolution. Our design is based on upconverting nanoparticles that, when excited in the near-infrared, emit light of a different color and intensity in response to nano-to-microNewton forces. The nanoparticles are sub-30nm in size, do not bleach or photoblink, and can enable deep tissue imaging with minimal tissue autofluorescence. We present the design, synthesis, and characterization of these nanoparticles both in vitro and in vivo, focusing on the forces generated by the roundworm *C. elegans* as it feeds and digests its bacterial food. Beyond the rigor of research, I also describe how I am reliving my childhood with my two young sons, and exploring the country as an avid cyclist and long-distance runner.

11:30 AM BI02.08.03
A Computational Framework for Studying CoCrFeNiTi High Entropy Alloys—My Path to Computational Materials Science as a Young Egyptian Woman Geraldine Anis[1], Mostafa Youssef[1], Moataz Attallah[2] and Hanadi Salem[1]; [1]The American University in Cairo, Egypt; [2]University of Birmingham, United Kingdom

In my presentation, I will talk about my academic journey as a young Egyptian woman and the path that led me to studying and working in computational materials science. I will describe our recent work on a multiscale modeling and simulation study of a high entropy alloy (HEA) system by combining continuum level thermodynamic modeling, atomic scale quasi-random structures, and electronic structure density functional theory (DFT). The main aim of this study is to provide a framework that can aid with and potentially accelerate the exploration of the massive HEA composition space through guiding experimental efforts.

Computational phase diagrams of four subsystems of the CoCrFeNiTi HEA system were constructed using the calculation of phase diagrams (CALPHAD) method. Our efforts were focused on the single phase face-centered cubic (FCC) regions in the obtained diagrams, due to the potentially favorable properties of alloys with this structure. A thermodynamic analysis was also carried out, in which we studied the variations in the mixing enthalpies and entropies within the studied systems. From our analysis, we were able to determine the main stabilizing factor (enthalpy vs. entropy) of the single FCC phase as a function of temperature. Furthermore, we tested the possibility of changing the thermodynamic phase diagram of this alloy system upon dissolution of impurities such as carbon and oxygen.

The constructed phase diagrams were then used to guide composition selection for an alloy to study its mechanical properties using first-principles DFT calculations. The selected alloy with composition $CoCrFeNi_{1.75}Ti_{0.25}$ was modeled using the special quasi-random structure (SQS) approach and DFT calculations were used to determine the elastic constants matrix of this alloy composition in addition to its stress-strain response under a uniaxial load. Additionally, we analyzed the hypothesis of sluggish diffusion in HEA via computing the formation energies of all possible vacancies in the alloy. Our coupled CALPHAD-SQS-DFT approach provides a general methodology for understanding the thermodynamics and mechanics of non-equiatomic HEAs.

In addition to the technical aspects related to the HEA work, I will be sharing my experience and some aspects of my personal life, with an emphasis on the things that have helped me overcome the obstacles that women in STEM face. My interest in materials science was sparked early on when I was still an undergraduate student, which led me to volunteer as a research assistant on a project focused on synthesizing and characterizing aluminum-graphene composites. Although I started my M.Sc. thesis as an experimentalist working on studying HEAs, the Covid-19 pandemic imposed a shift of my project to a fully computational study, after which I successfully obtained my M.Sc. degree. Upon finishing my thesis and facing a delay in my PhD plans due to the Covid-19 pandemic, I worked on a research project at the interface between materials science and biochemistry in which I employed molecular dynamics simulations to study the effect of certain small molecules on the binding affinity of the SARS-CoV-2 virus to the ACE2 human enzyme.

Finally, I will conclude my presentation with a discussion of my future plans, which include obtaining a PhD degree in modeling of heterogeneous systems, as well as how my goals have been shaped by my experiences and previous research.

1:00 PM *BI02.09.01
The Growing Role of Women in Materials Science—Personal Experiences and My Recent Research in Oxide Thin Films Judith L. MacManus-Driscoll; University of Cambridge, United Kingdom

Women have, throughout history, played an important role in materials science. In recent times, our role has grown strongly and we have become more prominent. So things are improving, but I believe we still face many challenges, some well recognized and spoken about openly, but others that are more hidden and hence not addressed or spoken about. Based on my own experiences, I will try to address some of challenges I have faced and will discuss how I have (or have tried to) overcome them. I will move on from here to show examples of my recent work demonstrating the important role of materials science in the engineering of oxide electronic thin films for low power electronics and energy applications.

1:30 PM *BI02.09.02
Imaging, Understanding and Controlling of Nanoscale Materials Transformations Haimei Zheng[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

The development of liquid cells for transmission electron microscopy (TEM) has enabled breakthroughs in our ability to follow nanoscale structural, morphological, or chemical changes during materials growth and applications. Time-resolved high-resolution imaging and chemical analysis through liquids have opened the opportunity to capture nanoscale dynamic processes of materials, including reaction intermediates and the transformation pathways. In this talk, I will present a series of work in my group on liquid cell developments and in situ liquid cell TEM study of nanocrystal growth and transformations, lithium dendrite formation and suppression and using liquid cell TEM in other studies on materials dynamics. The understanding garnered accelerates the discovery of novel materials for applications in energy storage, catalysis, and other functional devices.

2:00 PM *BI02.09.03
Empowering Women's Leadership in the Energy Sector Mihrimah Ozkan; University of California, Riverside, United States

The Energy sector has low diversity and gender equality into its workspaces and boardrooms. Based on some statistics, only 14% of energy engineers are women. This testifies that we need to take serious steps to improve the gender diversity in the energy sector. Women at leadership positions, in boardrooms and in factory floors can be achieved in two ways: 1) male dominant hiring managers can help to promote women engineers for the leadership positions, 2) mentoring and supporting younger women generations in engineering and helping them to become more visible and confident. In my presentation, I will focus on my research about Li-ion batteries and their applications in electric vehicles and my journey as a women academic engineer being the first women tenure-track faculty hired for the engineering college in 2001, and also being the only women full-professor in the engineering college today.

2:30 PM *BI02.09.04
Engineering an Inclusive Future Aditi Risbud Bartl; Stanford University, United States

At the UC Davis College of Engineering, we've launched a new commmunications platform titled Engineering an Inclusive Future: https://engineering.ucdavis.edu/engineering-inclusive-future. This new platform highlights how much we've done—and how much more we will be doing—to move the College of Engineering toward "inclusion excellence," in which all members of a community are encouraged and supported to work, study and learn in a way that allows each of us to reach our full potential. For this effort, I wanted to take a chance and show not just our best work but areas where we can improve, so we've employed first-person storytelling from our students, faculty, staff and postdocs. We post one to two stories a month and share these on our social media channels. Sometimes these stories are less than rosy, but this transparency helps stimulate conversation and reveals a deeper need to discuss challenges faced by women and underrepresented groups across our constituencies.

In addition, I've been part of a larger effort in collaboration with colleagues at the Northern California UC campuses (Davis, Berkeley, Santa Cruz, San Francisco), as well as Berkeley Lab, titled Imagining an Anti-Racist UC: https://www.ucop.edu/human-resources/coro/2020_forms/coro_nor-cal_2020_executive_summary.pdf. This effort aims to facilitate learning, reflection and performance assessment processes with respect to anti-racism among UC supervisors/leaders. Despite being the third largest employer in California, the racial/ethnic demographics of our senior professionals and management do not reflect the racial/ethnic demographics of the UC workforce, or our state.

To address this need, we developed an Anti-Racism Learning and Reflection Tool that establishes guiding anti-racism principles and practices that can be applied uniformly across the UC system by leaders, supervisors and managers to better communicate and carry out anti-racist core values and cultivate a climate of belonging for our staff. While each UC campus has a performance review process and evaluation tool that includes consideration of diversity, equity and inclusion, these materials do not currently incorporate a focus on anti-racist principles and practices. This tool aims to support the life-long learning of managers by offering a framework for them to advance racial equity principles and practices in hiring, performance review, promotion, and workplace climates for staff. I will present this tool and share learnings from its implementation at UC Davis.

SESSION Tutorial CH01: Electrochemical Impedance Spectroscopy Applied to Interfacial Battery Investigation
Session Chairs: Sylvain Franger, Fabio La Mantia and Claire Villevieille
Monday Morning, November 29, 2021
Virtual

8:30 AM
Electrochemical Impedance Spectroscopy (EIS) Applied to Battery Characterization Sylvain Franger; Université Paris-Saclay, France

EIS is one of the most practical in situ analysis technique, which can discriminate electrochemical processes by their time constant. EIS gives information from the electrode/electrolyte interface (MHz) to the bulk electrode (µHz). The frequency region scanned mainly concerns ionic mobility and is thus well adapted to evidence matter transport limitations (both in electrolyte and in active materials).
In that way, EIS is particularly interesting to check the interface since it is a non-destructive investigation method, giving access to several electrochemical parameters of major interest (charge transfer, passivation film, adsorption, corrosion, ionic diffusion...).
However, interpreting EIS data still requires specific attention.

For that purpose, in this tutorial, some fundamentals of Electrochemical Impedance Spectroscopy will be reminded.
Different examples (from liquid-based and solid-state batteries) will be shown in order to illustrate the tutorial's theoretical aspects.

The goal of this tutorial is actually to give some keys for:
convenient experimental set-up in order to record unambiguous EIS data
use of adequate EIS signal (a special attention will be given to GEIS and PEIS)
data analysis through the use of both Nyquist and Bode diagrams
understanding the interest and limits of equivalent electrical circuit models

10:00 AM BREAK

10:15 AM
Dynamic Impedance Spectroscopy for Operando Battery Materials Characterization Fabio La Mantia; Universität Bremen, Germany

Electrochemical impedance spectroscopy is a very powerful tool, however its actual implementation in standard electrochemical instrumentation does not allow looking into the dynamic behavior of the electrochemical systems. For this reason, classic impedance spectroscopy fails for the investigation of aging of materials, corrosion, self-oscillation, poisoning and others. In order to achieve an understanding of the effect of such degradation mechanisms on the materials and their electrochemical properties, it is necessary to use a methodology, which is able to look at systems while they are changing. The tutorial will start by introducing the concept of dynamic impedance and its connection to the Volterra series of the electrochemical system will be given. An overview of the experimental methodologies for the measurement and extraction of dynamic impedance spectra will follow, accompanied by an analysis of the experimental artefacts related to the electrochemical instrumentation. Different examples of dynamic impedance spectra acquired for different electrochemical reactions will be shown: redox couple in solution; intercalation of ions in host structures; hydrogen evolution on platinum electrodes. The data will be analyzed using at first a statistical approach based on the concept of Pade' approximants, using as weighting factor the theoretical variance of the admittance. The connection between equivalent circuits and Pade' approximants will be explored, as well as their connection to the Kramers-Kronig transformations. Finally, a physico-chemical model will be established in order to describe the phenomena occurring during the electrochemical reaction and the dynamic impedance spectra will be fitted using such model, in order to quantify the kinetic constants of the reaction. The tutorial will close with an summary of the main important points and an overview of the possible applications in the field of energy storage and energy conversion.

SESSION CH01.01: Cathode Materials Investigation
Session Chairs: Joshua Gallaway and Brett Lucht
Tuesday Morning, November 30, 2021
Hynes, Level 3, Room 304

10:30 AM *CH01.01.01
Nanostructure Formation as a Signature of Oxygen Redox in Li-Rich Cathodes Karena Chapman[1], Antonin Grenier[1], Gabrielle Kamm[1], Y. Shirley Meng[2], Yixuan Li[2] and Hyeseung Chung[2]; [1]Stony Brook University, United States; [2]University of California, San Diego, United States

Lithium-rich nickel manganese cobalt oxide (LRNMC) is being explored as an alternative to stoichiometric nickel manganese cobalt oxide (NMC) cathode materials due to its higher, initially accessible, energy-storage capacity. This higher capacity has been associated with reversible O oxidation, however, the mechanism through which the change in O chemistry is accommodated by the surrounding cathode structure remains incomplete, making it challenging to design strategies to mitigate poor electrode performance resulting from extended cycling. Focusing on LRNMC cathodes, we identify nanoscale domains of lower electron density within the cathode as a structural consequence of O oxidation using small-angle X-ray scattering (SAXS) and operando X-ray diffraction (XRD). A feature observed in the small angle scattering region suggest the formation of nanopores, which first appear during O oxidation, and is partially reversible. This feature is not present in traditional cathode materials, including stoichiometric NMC and lithium nickel cobalt aluminum oxide (NCA), but appears to be common to other Li-rich systems tested here, Li_2RuO_3 and $Li_{1.3}Nb_{0.3}Mn_{0.4}O_2$.

11:00 AM CH01.01.02
Regeneration of Degraded Li-rich Layered Oxide Materials Through Heat Treatment-Induced Transition Metal Reordering Yixuan Li[1], Mateusz Zuba[2], Shuang Bai[1], Zachary Lebens-Higgins[2], Bao Qiu[3], Zhaoping Liu[3], Minghao Zhang[1], Louis Piper[2] and Y. Shirley Meng[1]; [1]University of California, San Diego, United States; [2]Binghamton University, United States; [3]Ningbo Institute of Materials Technology and Engineering, Chinese Academy of Sciences, China

Lithium-rich layered oxides (LRLO) have drawn great attention recently as a high energy density cathode material. However, the practical deployment of these materials is hindered by voltage and capacity decay during electrochemical cycling. Applying mild thermal energy to cycled LRLO materials allows to recover the voltage profile and to alleviate the voltage decay problem in the following cycling. In this work, a detailed mechanism study of the voltage

and structure recovery is conducted through various analytical tools. The recovery of the lattice structure is investigated through in-situ neutron powder diffraction and synchrotron X-ray diffraction. The reordering of the transition metal environment is explored by in-situ extended X-ray absorption fine structure and pair distribution function. A transition metal reordering pathway is proposed and evaluated through computation methodology. Heat treatment provides the necessary energy for the transition metal to overcome the kinetic barrier to move from the honeycomb center to the honeycomb vertex and recover the honeycomb ordering in the transition metal layer. An ambient-air relithiation using Li^+ molten salt was also conducted along with the heat treatment to the cycled LRLO cathode and lead to a material regeneration in both the voltage and capacity. This work identifies the transition metal reordering as the key factor under the structure recovery of degraded LRLO materials. It opens a door for promising strategies to mitigate the voltage and capacity degradation problem in LRLO and provides the potential routes to recycle degraded LRLO materials.

11:15 AM CH01.01.04
Late News: Established and Emerging Methodologies for *Operando* X-Ray Total Scattering and Pair Distribution Function Analysis for Rechargeable Batteries Martin A. Karlsen[1], Simon J. Billinge[2,3] and Dorthe B. Ravnsbæk[1]; [1]University of Southern Denmark, Denmark; [2]Columbia University, United States; [3]Brookhaven National Laboratory, United States

The inevitable and necessary green transition towards sustainable energy sources depends completely on the ability to store energy. One possibility is to store the excess energy from renewable energy sources electrochemically in rechargeable batteries. A possibility that has also been realized for the substitution of combustion engines in vehicles.

To develop the rechargeable batteries of tomorrow, fundamental understanding of relations between material structure and properties is essential. Here, *operando* experiments are essential, as they provide insight into material behavior under the true dynamic conditions relevant for real applications. For the material structure at the atomic and nano length scales, x-rays, neutrons, and electrons are excellent probes.

If materials are crystalline and well-ordered on the atomic and nano length scales, traditional diffraction methods are ideal to probe the long-range order of the material structure, as the relevant information lies in the Bragg peaks. In recent years, it has been realized that crystallinity is not a given for all battery materials at all states-of-charge or at all stages of a battery's lifetime. However, for non-crystalline materials, whether they are nanocrystalline, disordered, or even amorphous, the more traditional diffraction methods fall short. Now, the relevant information does not lie *in* the Bragg peaks but *underneath* them in the diffuse scattering.

To probe the material structure of crystallographically challenged materials, total scattering experiments, which involve both the Bragg and diffuse scattering, hold the key. From total scattering data, the reduced atomic pair distribution function (PDF) can be obtained, which takes the scattering data from reciprocal space and into real space. The PDF can be thought of as a probability distribution of the interatomic distances in the material and the very local structure down to nearest-neighbor distances in materials can now be probed. Everything is seen in the PDF, which is a blessing as well as a curse for battery scientists, as batteries are multicomponent systems with complicated PDFs, which calls for battery-specific PDF methodologies.

This contribution will address how to obtain *operando* PDFs for battery materials during cycling and especially how to analyze data.

In our studies, we utilize model-dependent PDF analysis, sometimes referred to as 'real-space Rietveld refinement', via a least-square optimization method, like Rietveld refinement, where an input model is refined against experimental data, such that the residual between the two is minimized. The user-friendly PDFgui and the more versatile and advanced DiffPy Complex Modelling Interface (DiffPy-CMI) software are two examples on tools to conduct model-dependent, quantitative PDF analysis. In addition, we employ novel tools for model-free PDF analysis.

During summer 2021, 'PDF in the cloud' (PDFitc) was launched at 'pdfitc.org', where multiple apps for PDF analysis are available to users. This includes the model-free 'similarityMapping' app, which is a statistical analysis based on Pearson correlation. During fall 2021, another model-free statistical method will become available as an app: non-negative matrix factorization (NMF), which is somewhat like principal component analysis (PCA). Automated methods are also starting to enter the ballpark of PDF analysis. The 'structureMining', 'spacegroupMining', and 'clusterMining' apps at PDFitc mine structural databases and guide users in their PDF analyses to enable the users to explore the atomic level structure of their materials.

11:30 AM CH01.01.05
Operando Single Particle Diffraction of $Na_x[Ni_{1/3}Mn_{2/3}]O_2$ Jason J. Huang[1], Daniel B. Weinstock[1], Hayley Hirsch[2], Ryan Bouck[1], Oleg Gorobtsov[1], Malia Okamura[3], Ross Harder[4], Wonsuk Cha[4], Jacob Ruff[1], Y. Shirley Meng[2] and Andrej Singer[1]; [1]Cornell University, United States; [2]University of California, San Diego, United States; [3]Carnegie Mellon University, United States; [4]Argonne National Laboratory, United States

The prevalence of both structural and sodium-ion ordering phase transitions in sodium-ion intercalation materials limits their useful cycle life. The multitude of transitions creates complex phase behavior that is difficult to investigate, especially on the single nanoparticle scale and under operating conditions. Here, we develop operando single particle x-ray diffraction to observe single particle rotation, interlayer spacing, and layer misorientation. We apply the technique, during charge, to a model P2-type sodium ion cathode material, $Na_x[Ni_{1/3}Mn_{2/3}]O_2$ (NNMO), where $0<x<2/3$, which exhibits the detrimental P2-O2 transition. From operando observations of single particle misorientation and layer spacing changes, we propose a model for the phase evolution of NNMO that includes a localized to correlated Jahn-Teller distortion phase transformation. Through this work, the proposed model can serve to guide further characterization of NNMO and other materials with P2-O2 type transitions, and operando single particle x-ray diffraction has the demonstrated potential to be used in other systems to reveal phase behavior at the nanoscale.

11:45 AM CH01.01.06
The Impact of Alkali-Ion Intercalation on Redox Chemistry and Mechanical Deformations—Case Study on Intercalation of Li, Na and K Ions into $FePO_4$ Cathode Bertan Ozdogru and Omer O. Capraz; Oklahoma State University, United States

Development of cathode structures suitable for Na-ion and K-ion batteries is still one of the major challenges on the way to the design of next-generation alkali metal-ion batteries. Although Li, Na and K belong to the same alkali metal group with a single charge in their cation form, intercalation of Na^+ and K^+ ions in electrodes is difficult since ionic radii of Na^+ (0.98 Å) and K^+ (1.38 Å) are larger than that of Li^+ (0.69Å). Therefore, physical, and electrochemical behavior of the cathode materials in response to Na^+ and K^+ ion intercalation is expected to be fundamentally different than the response to Li^+ ion. However, there is not much known about how electrochemical reactions and transport of ions take place in cathode materials with different alkali metal ions. There have been several studies focusing on electrochemical characterization and investigation of the structural changes in the electrode materials. Lack of insight into these reaction-transport mechanisms limits the design of novel cathode materials for Na-ion and K-ion batteries. Comparative studies between Li-ion, Na-ion and K-ion battery cathodes are critical to identify fundamental similarities and differences during intercalation. Even modest expansions in brittle cathodes can cause particle fracturing in a larger crystalline-size scale. Intercalation of larger ions can cause structural collapse and amorphization induced by continuous strains and distortions. Although the amorphization in the structure can be easily

identified by conventional diffraction or electron microscopy techniques, quantitative analysis of the physical changes in the structure during and after amorphization while cycling the battery electrode is critical.

In the first part of the talk, we will first report the utilization of in situ digital image correlation and in-operando X-ray diffraction (XRD) techniques to probe dynamic changes in the amorphous phase of iron phosphate during potassium intercalation[1]. A new experimental approach allows to monitor dynamic physical and structural changes in the amorphous phase of the electrodes. In-operando XRD demonstrates amorphization in the electrode's nanostructure during the first charge / discharge cycle. In situ strain analysis detects the reversible deformations associated with redox reactions in the amorphous phases. This method offers new insights to study mechanics of ion intercalation in the amorphous nanostructures.

In the second part of the talk, we will compare the electrochemical and mechanical response of the iron phosphate cathodes upon Li, Na and K ion intercalation by using electrochemical techniques and *in situ* digital image correlation. Iron phosphate model electrodes were prepared by electrochemical displacement technique in order to ensure identical morphology, structure and chemistry in the pristine iron phosphate electrodes. Strain evolution during Li and Na intercalation results in more linear dependence on the state of charge / discharge. However, strains generated in the eletrode shows nonlinear behavior during insertion / extraction of K ions. Interestingly, when the same amount of K and Na ions are intercalated, similar chemomechanical expansions were observed. However, strain rate calculations showed that K ion intercalation results in a progressive increase in the strain rate, whereas Li and Na intercalation induce nearly constant strain rates. Potential-dependent behaviors also demonstrate more sluggish redox reactions during K intercalation, compared to the Li and Na intercalation. These observations provide a fundamental insight into the impact of alkali ions on the redox chemistry and associated chemomechanical deformations.

SESSION CH01.02: Electrolyte Characterization
Session Chair: Karena Chapman
Tuesday Afternoon, November 30, 2021
Hynes, Level 3, Room 304

1:30 PM *CH01.02.01
Electrolyte Oxidation and the Role of Acidic Fluorophosphates in Capacity Loss for Lithium–Ion Batteries Brett Lucht; University of Rhode Island, United States

Cycling lithiated metal oxides to high potential (>4.5 V vs Li) is of significant interest for the next generation of lithium ion batteries. Cathodes cycled to high potential suffer from rapid capacity fade due to a combination of thickening of the anode solid electrolyte interphase (SEI) and impedance growth on the cathode. While transition metal catalyzed degradation of the anode SEI has been widely proposed as a primary source of capacity loss, we propose a related acid induced degradation of the anode SEI. A systematic investigation of LMO, LNMO, NMC622, and MNC811 cathodes will be presented. The role of potential on the generation of soluble acidic fluorophosphates crossover species and the impact of these species on the structure and stability of the SEI will be presented.

2:00 PM CH01.02.02
***In Operando* Visualization and Data-Driven Modeling of Ion Transport in Electrolytes for Lithium Metal Batteries** Yuan Yang; Columbia University, United States

In-operando Visualization of ion transport in electrolyte provides fundamental understandings of electrolyte dynamics and electrolyte-electrode interaction, shedding light on material designs to enhance device performance, such as batteries and fuel cells. However, this task is extremely challenging for existing techniques, since it is difficult to capture the low ionic concentration (<1 M) and the fast dynamics (1-10 s) of the electrolyte. Here we show that an emerging Stimulated Raman Scattering (SRS) microscopy offers the required spatial (sub-micrometer optical resolution), temporal (faster than 1 s per frame) and chemical (around mM) sensitivities to address this challenge.

The SRS microscopy has been used to study ion depletion and lithium dendrite growth in both liquid and polymer electrolyte, and distinct behaviors are observed. In liquid electrolyte, we observe a three-stage lithium deposition process, each corresponding to no-depletion, partial-depletion and full-depletion regime of Li+, respectively. A positive feedback mechanism between the inhomogeneous growth of lithium and the local ionic concentration or flux. In polymer electrolyte, we clearly see phase separation due to ion depletion and observe the accompanying transport of plasticizer inside, which was not observed in the past. These new understanding also leads to new strategies to suppress lithium dendrites. Moreover, the high-speed image acquisition also enables data-driven modeling to understand the relation between local material properties (e.g. salt concentration) and dendrite growth. A neural network modeling is built to understand how different factors affect dendrite growth.

2:15 PM CH01.02.03
***Operando* AFM and Electrochemical Characterization of the Growth of the Solid Electrolyte Interphase** Harry Thaman[1,2], Che-Ning Yeh[1], Justin Rose[1] and William C. Chueh[1]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

Understanding the formation and operation of the solid electrolyte interphase (SEI) is critical to the development of lithium metal batteries because of the continuous evolution of new surface area which necessitates a rapidly passivating SEI to minimize capacity loss. However, because of the highly sensitive, heterogeneous, and continuously evolving nature of the SEI, it remains challenging to develop a fundamental understanding of how SEI morphology relates to key metrics such as ionic conductivity and formation rate. To probe the role of these parameters in the SEI evolution, we combine operando atomic force microscopy (AFM) with electrochemical characterization to extract the relationships between the SEI's roughness and it's efficacy at forming a self-passivating layer.
Using a combination of electrochemical impedance spectroscopy (EIS) and capacity measurement during constant voltage holds, we observe formation process in which the initially deposited SEI substantially increases the ionic impedance while subsequently grown SEI produces limited impedance increases despite consuming significant amounts of lithium. These observations are supported by operando AFM measurements taken during the SEI formation process. The AFM topography measurements reveal a two part SEI microstructure composed of a compact film interspersed with large nuclei

that make up a substantial fraction of the SEI volume but cover relatively little of the surface area. This observation matches our electrochemical observation of SEI composed of both passivating and non-passivating components.
To further investigate the morphology and composition of the SEI layer, we leverage the AFM system to scrape away the soft outer layer of the solid electrolyte interphase and quantify roughness and thickness properties of both the inner and outer layers of the SEI to further understand the role the SEI components play in the previously measured EIS and SEI growth rate measurements. Ultimately, by relating electrochemical properties of the SEI - both in steady state and EIS measurement modes - to its morphology and thickness we provide correlations between easily measured average electrochemical properties and critical but hard-to-measure nanoscale properties that we hope will inform the development of advanced electrolytes and formation protocols for anode free and lithium metal batteries.

***In Situ* Characterization of Solid Liquid Interface by Infrared Nanospectroscopy** Xiao Zhao[1,2], Yi-Hsien Lu[1] and Miquel Salmeron[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

The solid-liquid interface plays a crucial role in many natural process and practical applications, such as corrosion, electrochemical catalysis and energy storage. Fundamental insights of solid-liquid interface are necessary to understand these processes, but currently these studies are hampered by the shortage of appropriate characterization tools. Extensive efforts have been made to develop or improve *in-situ* or *operando* characterization techniques to study the information of solid phase near interface, while the knowledge on the liquid layers at interface, including ion concentration, double layer structure and speciation, is still limited.
Here we present a new nondestructive methodology that enables molecular study of liquid layer near interface with nanoscale spatial resolution. It is based on Fourier transform infrared nanospectroscopy (nano-FTIR), where the infrared (IR) field is plasmonically enhanced near the tip apex of an atomic force microscope (AFM). Ultra-thin freestanding membrane (single layer graphene or 2-5nm thick metal oxide film grown by atomic layer deposition (ALD)) separates AFM tip and electrolyte while acting as working electrode. We illustrate this method by comparing interface-sensitive nano-FTIR spectra with bulk-sensitive spectra obtained by ATR-FTIR and demonstrate its capability to determine changes in chemical composition and molecular structure near solid-liquid interface under electrochemical condition. These membranes can be further functionalized with synthesized nanoparticles to study the catalytic microenvironment under electrochemical condition. This platform developed and presented here will open up new avenues for the study of catalytic, electrochemical, geochemical, and other reactions at interfaces in practical conditions.

Energy Dispersive X-Ray Diffraction (EDXRD) as a Synchrotron Technique for Spatially-Resolved *Operando* Study of Buried Materials and Interfaces Within Batteries Joshua W. Gallaway; Northeastern University, United States

Energy dispersive X-ray diffraction (EDXRD) from a high energy source enables operando study of battery materials within their real-world form factor and containment. This is thanks to the (a) use of a highly penetrating incident X-ray white beam (20-200 keV) and (b) placement of the detector and sample to define a well-controlled diffraction gauge volume in space. The shape of this gauge volume allows spatial resolution of ten of microns when positioned inside a battery, and movement of the battery along a scanning direction allows construction of diffraction profiles across electrodes, all with time resolution of tens of seconds. This technique can identify formation of new phases as well as map fine changes in active material lattice parameters, the latter of which is equivalent to obtaining spatially resolved state-of-charge information in the case of intercalation electrodes. Because development of both high energy density and low cost batteries is enabled by designs with thick electrodes, the types of material profiles provided by EDXRD are highly relevant for the present day thrust of battery engineering. Thick electrodes, while desirable, bring extra challenges because they can cause inhomogeneities within the battery that lead to uneven active material utilization and/or battery failure. While the fundamental electrochemistry of battery active materials can be known from laboratory experiments, system-level phenomena not necessarily inherent to the active materials can have an equally profound impact on battery performance. EDXRD is a powerful tool for probing this information, with no need to adjust the cell construction, which could alter the resultant electrochemistry. Due to its highly penetrating nature, EDXRD is also ideally suited for collecting operando data from within batteries at high temperature or under high pressure. Some current solid-state battery designs require high cell compression to ensure good interfacial contact, and this makes operando data collection challenging using techniques other than EDXRD.

This talk will address the fundamentals of EDXRD, as well as provide examples of its use to establish mechanistic knowledge in several types of batteries, including (1) rechargeable alkaline batteries with electrodes of thicknesses of >1mm, (2) sulfide all solid-state batteries tested under high compression, and (3) multivalant ion batteries tested at elevated temperature within unmodified coin cells. In alkaline rechargeable batteries, EDXRD was used to establish a catalytic effect by Bi-containing additives to favor formation of rechargeable $Mn(OH)_2$ over terminal Mn_3O_4. In all solid-state batteries, EDXRD demonstrated a crystalline instability of a sulfide solid-state electrolyte, $Li_{6.6}Ge_{0.6}Sb_{0.4}S_5I$ (LGSSI), which was observed only in the cathode and not elsewhere in the cell. This was due to reduction of the LGSSI when in contact with active material and conductive carbon in the cathode during discharge. It was also shown that this crystalline change was reversible if the cell lower voltage limit was correctly chosen. Finally, operando observation of the intercalation reaction of both Al^{3+} and Zn^{2+} was collected for Chevrel Mo_6S_8 and Mo_6Se_8 cathode hosts. This was accomplished from within unaltered, sealed coin cells, which was important as previous literature has suggested that the fully intercalated species can be inadvertently oxidized during destructive sample preparation.

***In Situ* and *Operando* Characterization of Capacity and Efficiency Limiting Phenomena in Electrochemical Energy Storage Systems** Amy Marschilok[1,2], Esther S. Takeuchi[1,2] and Kenneth Takeuchi[1,2]; [1]Stony Brook University, United States; [2]Brookhaven National Laboratory, United States

Parasitic side reactions can limit the capacity and efficiency of the energy storage system, via formation of resistive interfaces and consumption of redox active material/s. Transport limitations can also impact functional capacity of systems, and can mainfest at different states of (dis)charge and as a function of time over extended cycling. In this presentation, insights in elucidating and quantifying productive and parasitic processes from complementary in situ, and operando spectroscopy, diffraction and electrochemistry studies will be highlighted.

Looking into Key Components for Next Generation Batteries with *Operando* X-Ray Tomography Aleksandar Matic, Matthew Sadd and Shizhao Xiong; Chalmers University of Technology, Sweden

New configurations and chemistries for next generation batteries are currently in focus as a response to needs from sustainable energy technologies and transport applications. The electrochemical mechanism for next generation batteries is often based on conversion reactions and transport of active material, which is different from the "Rocking Chair" concept in current state-of-the-art, the Li-ion battery. To probe these processes *operando* computed X-ray tomography is a powerful technique which allows nondestructive and quantitative imaging in 3D of materials and components during operation. A particular advantage is the possibility to quantitatively correlate the 3D morphology to electrochemical data recorded simultaneously if the whole cell can be within the field of view. With the high flux of 3rd and 4th generation synchrotron sources rapid acquisition (sub minute for a full tomogram with sub µm resolution) opens the possibility for *operando* studies, even at high discharge rates.

In this contribution we show how X-ray tomography can be used to provide insights on processes in Li-sulfur (LiS) cells and the Li-plating process in Li-metal batteries, two promising next generation battery concepts. In LiS-cells the electrochemical conversion of elemental sulfur delivers a very high theoretical specific capacity (1672 mAh/g). The conversion takes place through a series of soluble intermediate polysulfide species (Li_2S_n) whereas the end product, Li_2S, is insoluble in the common electrolytes used [1]. This mechanism leads to continuous dissolution/precipitation processes during cycling which are closely related to the difficulty in reaching a high specific capacity in practice due to poor active material utilization. This can be related to elemental sulfur in the cathode not being converted, dissolved polysulfides diffusing out of the cathode and not being further converted, or Li_2S forming a continuous insulating layer that blocks access to the conducting part of the cathode matrix and stops the conversion reaction. With an operando X-ray tomography experiment we are able to directly follow the dissolution/precipitation processes at discharge with the whole cathode within field of view using a capillary *operando* cell. This enables us to quantitatively correlate the sulfur conversion/dissolution process to the charge delivered by the cell. In a multi-modal approach we also follow the diffusion of polysulfides species in the electrolyte with an *operando* optical imaging experiment in the same cell.

Common for several of the high-capacity concepts is the use of Li-metal as the anode. However, preferred electrodeposition of Li-metal can lead to a mossy or dendritic morphology, as a result of depletion of Li-ions at the electrode surface [2,3]. In combination with the high reactivity of Li this results in a continuous breakdown of the electrolyte during cycling and the formation of "dead Li", manifesting in a low coulombic efficiency. These phenomena are accelerated at low operating temperatures, in dilute electrolytes or high applied current densities. To build an understanding of the plating process we use *operando* X-ray tomography to reveal the 3D-geometry and kinetics of dendrite growth during cycling to build a connection between the properties of the new electrolytes, and the microstructure formed on the Li-metal anode. These results are correlated to phase-field modelling to provide a mechanistic understanding of the plating process.

4:30 PM CH01.03.02
Unveiling the Relation Between Electrochemical Performance and Nanostructure of Fuel Cell Electrode Materials via Scanning SAXS and Ptychographic X-Ray Nanotomography Christian Appel[1], Katharina Jeschonek[2], Kai Brunnengräber[2], Bastian J.M. Etzold[2], Marianne Liebi[3,4] and Manuel Guizar-Sicairos[1]; [1]Paul Scherrer Institute, Switzerland; [2]Technische Universität Darmstadt, Germany; [3]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [4]Chalmers University of Technology, Sweden

Future energy solution require development of advanced composite materials. Such materials are for example catalyst layers of polymer electrolyte membrane fuel cells (PEMFCs) where electricity is generated by electrochemical reactions that take place in a complex environment. These layers are porous materials built up from three different components; chemically active sites, electron conducting support and proton conducting binder. This study focusses on investigating Pt nanoparticles on carbon black support (PTC, HiSPEC 3000), spray-coated on a polymer membrane with varying amounts of binder (PTFE – ionomer) but an equal loading of catalyst (m_{Pt} = 0.2 mg/m^2).

The meso and nanoscale structure of the catalyst is investigated by a correlative approach based on two techniques; scanning small-angle X-ray scattering (SAXS) and ptychographic X-ray computed nanotomography (PXCT). From scanning SAXS we obtain statistical information about the nanostructure, in the range of 1 to 300 nm, probed in local areas of 10x10 µm^2 which correspond to the scanning step size over macroscopic areas of 1x1 mm^2. X-ray fluorescence spectra were simultaneously collected, with which we can then map the Pt content in the layers based on the Pt-M_α emission line at 2.05 keV. 2D maps of X-ray scattering and XRF, integrated over a specific q-range and energy-range, respectively, were processed and allow quantification of sample homogeneity in terms of nanostructure and Pt distribution across the macroscopic length scale. This data was further used to choose specific representative areas to mill out cylindrical 20 µm sized pillars using FIB/SEM. These pillars were investigated under cryogenic temperatures to avoid radiation damage with the OMNY setup at the cSAXS beamline to reveal the 3D nanostructure with PXCT down to a 3D half-period resolution of 26 nm.

PXCT measures the 3D electron density from 20 µm down to 26 nm, which perfectly bridges the gap between the macroscopic domains probed by scanning SAXS (1 mm to 10 µm), and the statistically averaged information of the nanoscale probed by SAXS (1 nm to 300 nm) for local areas of 10x10 µm^2. PXCT measurements alone are already able to provide valuable information to distinguish structural features of the three different catalysts. Threshold segmentation reveals differences in the pore size distribution as well as connectivity of pores. This information is crucial for a better understanding of gas and liquid transport mechanisms within the catalyst. However PXCT cannot reveal the chemically active sites due to limitations in spatial resolution, namely the Pt nanoparticles of 2-3 nm diameter where the electrochemical reaction takes place. In this work, we explore different approaches to correlate the imaging data from PXCT with the statistical data from SAXS and XRF. Our vision is to generate 3D representative models for catalyst layers based on its imaged structure by PXCT, but further complemented with statistical data from SAXS and XRF measured from the exact same sample. Such models are strongly desired in flow simulations on PEMFCs to further understand limiting factors for their performance. In addition, our study also explores novel routes in correlative data analysis combining imaging with scattering experiments. These insights may further lead to new approaches and studies in investigating porous materials.

***In Situ* XANES of Non-Stoichiometric Vanadium Oxide During Electrochemical Cycling of Aqueous Zn-Ion Battery** Christopher J. Patridge; D'youville College, United States

Multivalent ion batteries represent a unique approach to increasing energy capacity for electrochemical storage. While Li-ion batteries (LIB) are the dominant technology that continues to advance with novel architectures and engineering, there still exists serious issues of thermal sensitivity and runaway. Aqueous systems would significantly reduce these thermal concerns and also drop the economic costs associated with the organic solvents that compose the electrolytes in LIBs. The Zn ion (+2) gives twice the capacity and the ionic radii (0.78 angstroms) matches closely to the Li ion. The increased electronic/structural disruption imposed by intercalating a +2 ion finds some relief by co-intercalation of H_2O along with sandwich layered structures often associated with the multitude of vanadium oxide polymorphs.
Synchrotron work at NSLS-II BM-6 looked at the XANES and EXAFS dependence on voltage. Using crystal structure data for the material, theoretical XAFS scattering was compared to the experimental data to establish possible local site occupancy for the intercalated Zn ion. Further in-situ experiments on both $Zn_{0.25}V_2O_5$ and $Ca_{0.25}V_2O_5$ were performed using a novel electrochemical cell. Both materials exhibit a clear change in the local geometry and oxidation state of the vanadium in the active material with early cycle reversibility. Integrated XANES difference spectra are correlated with the approximate shift of vanadium from a nominal oxidation state of +4.75 down to +4.00 if assuming an approximate fully discharged state stoichiometry of $Zn_1V_2O_5$ or $Ca_{0.25}V_2O_5$.

Kelvin Probe Force Microscopy Provides New Insights into Electrochemical Reactions via Suspended Graphene Irit Rosenhek Goldian[1], Salma Khatun[1], Sidney R. Cohen[1], Sa'ar Shor Peled[1], Robert S. Weatherup[2] and Baran Eren[1]; [1]Weizmann Institute of Science, Israel; [2]University of Oxford, United Kingdom

Probing processes at electrode-electrolyte interfaces promises new insights into electrochemical reactions, which are inherent to many sustainable energy storage and conversion technologies.
Kelvin Probe Force Microscopy (KPFM) is widely used to map work function (surface potential) variations at the nanoscale in ambient or vacuum conditions. KPFM could be of great importance for electrochemical systems, but is impractical in polar liquids due to screening and interference from surrounding fluid. Capping a liquid-cell by free-standing single-layer graphene (SLG) serving as the working electrode, enables a stable KPFM measurement on the SLG working electrode to monitor its Fermi-level shift and is sensitive to processes occurring at the liquid-solid interface. The graphene-membrane physically separates the scanning tip from the conducting solution. With KPFM, localized information can be obtained for single SLG regions, unlike techniques like cyclic voltammetry (CV), where the signal is averaged over the entire reactor-cell.
We have applied this approach to study small electrochemical cells of 500 nm diameter capped by SLG under electrochemical reaction conditions. We used a polymer-free transfer method in order to avoid the presence of polymer residues that would alter the measured WF and the interfacial activity of the graphene. Measurement at different alkaline pH values enabled investigation of the influence of the electrical double layer (edl). This method enabled us to perform statistical measurements by monitoring several cells, following them through a few cycles while correlating the different signals recorded simultaneously (Topography, phase, KPFM).
Our experimental results correlate well with a simple electrochemical gating model, shedding light on the interplay between electronic and electrochemical doping (through redox of water) processes in the suspended graphene. The observed topographical changes in the suspended graphene in the form of bulging are attributed to electro-wetting of graphene induced by charge-carrier doping.
The experimental approach and results presented here serve as a benchmark for future studies of the electrochemical behavior of two-dimensional materials both in aqueous and organic electrolytes, and the underlying mechanisms of doping.

Li Deposition in a Highly Concentrated Electrolyte Studied by *In Situ* Neutron Reflectometry Josef Rizell[1], Anton Zubayer[2], Matthew Sadd[1], Filippa Lundin[1], Nataliia Mozhzhukhina[1], Alexei Vorobiev[3,4], Shizhao Xiong[1] and Aleksandar Matic[1]; [1]Chalmers University of Technology, Sweden; [2]Linköping University, Sweden; [3]Uppsala University, Sweden; [4]Institut Laue-Langevin, France

Li-metal has a theoretical specific capacity of 3860 mAh/g, ten times larger than that of graphite (372 mAh/g). In combination with the low reduction potential of Li, this entails Li-metal batteries (LMB) with significantly higher energy densities compared to Li-ion batteries. **[1]** However, the long-term cycling of LMBs is hindered by several parasitic effects linked to Li deposition. In the worst case scenario, uncontrolled Li-plating results in dendrites that can pierce the separator and short circuit the cell. Lithium plated in a dendritic morphology is also more prone to lose contact with the electrode, forming so called dead Li, leading to loss of active material and poor columbic efficiency. Furthermore, uneven Li-morphologies expose more fresh Li to the electrolyte, leading to continuous electrolyte consumption in side reactions.

To stabilize the Li-metal anode, one of several routes is to tune the electrolyte composition. Recently, we have shown that electrolytes with higher salt concentrations can enable stable cycling and uniform Li-plating **[2]**. This improvement in electrochemical performance can be rationalized by (1) a mitigated risk of Li-ion depletion at the electrode surface (Li-ion depletion would cause rapid dendrite growth) (2) the tendency for these electrolytes to form a stable surface layer at the anode. However, more work is needed to fully understand the mechanism for the improved efficiency of Li-plating in highly concentrated electrolytes.

Due to the very low potential of the anode during Li plating, the electrolyte will tend to decompose on the electrode surface to form a surface layer, the solid electrolyte interphase (SEI). This layer is an important factor for efficient Li plating and stripping. **[3]** However, the sensitivity of the SEI makes several characterization methods elusive. Any ex situ characterization, like x-ray photoelectron spectroscopy, is associated with large uncertainties regarding the stability of the SEI under a change of environment.

Instead, in situ and operando characterization of the SEI layer becomes important for building a better understanding of its role in Li deposition. In this contribution we report on a neutron reflectometry study of SEI formation and early stages of Li-metal plating, performed with the reflectometer SuperADAM at ILL. Due to the weak interaction of neutrons with matter it is possible to build an in-situ sample environment where the neutron beam can enter the cell through the back side of the working electrode. Using a custom made Li-Cu cell, we probe the formation of surface layers on the Cu working electrode. By measuring the reflectivity as a function of momentum transfer, we detect the changes in the neutron scattering length density arising as a result of a changing surface layer, thickness and composition, on the working electrode. In this study we compare Li deposition in a highly concentrated electrolyte (4M salt concentration) with an electrolyte with conventional salt concentration (1M) and discuss how the electrode/electrolyte interface evolves and influences the Li deposition.

Direct Insight into Electrochemical Processes in Alkali-Ion Cathodes from *Operando* Electron Spin Probes Howie Nguyen, Daniil Kitchaev, Emily Foley, Allyson Ee, Yuefan Ji and Raphaele J. Clement; University of California, Santa Barbara, United States

Operando electron paramagnetic resonance (EPR) enables to monitor the evolution of the local crystal and electronic structure of lithium-ion electrodes in real time, by following changes in EPR spectral linewidth and intensity.[1] These spectral changes are induced by the evolving magnetic-exchange interactions between transition metal species in the electrode material during battery operation. However, ambiguities can still arise as to the exact interpretation of *operando* EPR datasets since different charge-compensation reactions can lead to similar trends in linewidth and intensity. Additionally, traditional EPR detection is limited to transition metal species with spin-allowed transitions (spin ½ species) and favorable spin relaxation times. We address these shortcomings by conducting *operando* EPR in tandem with *operando* magnetometry, where the bulk magnetic susceptibility is used as an additional filter to parse out different local redox processes. This combined *operando* electron spin probe approach is applied to the $LiNi_{0.5}Mn_{0.5}O_2$ cathode, and complemented with DFT calculations of magnetic J-couplings. EPR results show an evolving signal that disappears at high potentials and Mn dissolution after the initial cycle. *Operando* magnetometry is used to decipher electrode changes during the regions of undetectable EPR. Other applications of our *operando* magnetometry cell include probing reaction mechanisms and estimating irreversibility in the conversion-type Na_3FeF_6 cathode. Magnetic susceptibility changes during cycling suggest Na-ion initially intercalates into carbon additives before the active material is converted into NaF and Fe. The reaction products are unable to convert back to Na_3FeF_6 as indicated by an irreversible change in magnetic susceptibility. Furthermore, the instability of this system is highlighted by a growing magnetic susceptibility during a relaxation period after cycling.

Isothermal Microcalorimetry Characterization of Lithium Battery Storage Materials and Mechanisms Wenzao Li[1], Lisa Housel[2], Calvin D. Quilty[1], Mallory Vila[1], Lei Wang[2], Christopher Tang[1], David Bock[2], Kenneth Takeuchi[1,2], Esther S. Takeuchi[1,2] and Amy Marschilok[1,2]; [1]Stony Brook University, United States; [2]Brookhaven National Laboratory, United States

Li ion batteries, one of the most popular energy conversion and storage devices, are widely applied as power sources for electronics, electric vehicles, and medical devices. However, when current flows through Li ion batteries upon charge or discharge, heat is triggered and can lead to many undesirable consequences: (1) heat is considered wasted energy that is typically not converted to useful electrical work; (2) heat could provoke a local temperature increase within the battery that accelerates the ageing of electrodes and electrolyte for those with poor thermal stability; (3) the accumulation of heat, especially in large-scale battery packs, may cause safety hazards. Therefore, monitoring thermal behavior of Li ion batteries under load currents is an insightful way to understand electrochemical mechanisms, diagnose batteries' failure mechanisms, and navigate safety management.
Operando isothermal microcalorimetry (IMC) is a precise characterization method that can measure the real-time heat flow dissipated from batteries while cells are undergoing synchronous electrochemical cycling. We applied the IMC method to investigate multiple lithium storage systems covering both conversion and insertion type electrode materials. Heat flow features visualized by the IMC provide information on the kinetics and thermodynamics of electrode materials' chemistry and electrode-electrolyte interactions. Among sources of cell's heat generation, the heat flow associated with parasitic reactions can be quantified as an indicator of interfacial reactions, mainly the formation and evolution of the SEI. Further, the structural change of electrode materials was also found to be a factor governing the heat generation. These results inspire us to pave new ways of understanding phase evolution of Li storage materials via thermodynamics.

SESSION CH01.05: Multiscale Techniques

Insights into Battery Processes from the Perspective of the Electron Spin Howie Nguyen, Emily Foley, Daniil Kitchaev, Allyson Ee, Yuefan Ji and Raphaele J. Clement; University of California, Santa Barbara, United States

Advances in rechargeable batteries rely on the discovery of high power, high energy density electrode materials, but also on mitigating degradation mechanisms. Understanding how a battery works and why it fails requires the development of cutting-edge characterization tools capable of monitoring structural changes and redox reactions at the surface and in the bulk of the electrodes as the battery is (dis)charged. The fundamental insights thereby

gained are key to designing new compounds for high performance batteries.
Electron paramagnetic resonance (EPR) and magnetometry offer a rare perspective on structural and redox processes from the standpoint of electron spins and magnetic interactions between redox-active species, holding promise for breakthroughs in our understanding of charge-discharge phenomena in battery materials. Our group has recently developed *operando* EPR and magnetometry cells to investigate such processes in real time. In this talk, I will briefly discuss when EPR and magnetometry are best used and how *operando* datasets are analyzed. Specifically, our recent work has shown that the interpretation of the broad EPR spectra obtained on paramagnetically-concentrated electrodes is challenging and requires the tandem use of magnetometry.[1] I will also present our recent (and preliminary) work on both intercalation and conversion electrodes using these powerful tools.

***Operando* Surface Enhanced Raman Spectroelectrochemistry for Mechanistic Understanding of Energy Storage in Lithium/Sodium/Potassium Ion-Batteries Containing Few-Layered 2D Anodes** Mariusz Radtke and Christian Hess; Technical University of Darmstadt, Germany

Reaction mechanisms underlying energy storage and intercalation in lithium/sodium/potassium-ion batteries (LIB, NIB, KIB) were investigated in few layers 2D FeS_2, SnS_2, TiS_2 and MoS_2 by means of *operando* surface enhanced Raman spectroelectrochemistry (SERSEC).

The few-layers 2D materials were prepared by anodic exfoliation from bulk in mild K_2SO_4 media and characterized by HRTEM, XPS, Raman and EDX. Each sample exhibited similar Raman signature of two most prominent modes- A_{1g} and E_g, which were basis for the *operando* experiments. During the *operando* SERSEC A_{1g} mode in SnS_2 exhibited considerable red shift by 20 cm^{-1} in the anodic oxidation scan, due to the generation of Sn-S-Li bond, as evaluated by the post-mortem XPS after the reaction. On the contrary the intercalation of Li^+-ion in FeS_2, TiS_2 and MoS_2 was purely physical, as based on ion insertion between the the layers of 2D materials.

All *operando* electrochemical and SERSEC measurements were performed in a specially-designed spectroelectrochemical cell equipped with borosilicate windows modified with mercaptosilicate gold clusters of varying sizes attached covalently to the window, which were able to create hot-spots with localized plasmon resonances (LPR). The clusters were designed to be electrochemically inert (silicate shell) and LPR Raman active (gold core), as proven by the electrochemical DPV scan. The MALDI-TOF/TOF MS analysis has revealed that the gold clusters were created in mostly icosahedral shapes, as based on m/z analysis. The electrochemically inert borosilicate windows have allowed for performing of highly precise operando experiments (analytical enhancement factor: 4282).

In addition we discuss the potential of expanding SERSEC with the spectroscopic LPR windows by introduction of e.g. time-resolved *operando* 4D and 5D electrochemical impedance spectroscopy (EIS) for exact Raman mapping of bulk RedOx reactions with spatial resolution at the Abbé limit.

Elucidating the Role of Halides and Iron During Radiolysis Driven Oxidative Etching of Gold Nanocrystals Using Liquid Cell TEM and Pulse Radiolysis Michelle Crook[1], Christian Laube[1], Ivan Moreno-Hernandez[1], Axel Kahnt[2], Stefan Zahn[2], Justin C. Ondry[1], Aijia Liu[1] and A. Paul Alivisatos[1]; [1]University of California, Berkeley, United States; [2]Leibniz Institute of Surface Engineering (IOM), Germany

Graphene liquid cell transmission electron microscopy (TEM) has enabled the observation of a variety of nanoscale transformations. Yet understanding the chemistry of the liquid cell solution and its impact on the observed transformations remains an important step towards translating insights from liquid cell TEM to bench-top chemistry. Gold nanocrystal etching can be used as a model system to probe the reactivity of the solution. $FeCl_3$ has been widely used to promote gold oxidation in bulk and liquid cell TEM studies, but the roles of the halide and iron species have not been fully elucidated. In this work, we observed the etching trajectories of gold nanocrystals in different iron halide solutions. We observed an increase in gold nanocrystal etch rate going from Cl^-- to Br^-- to I^--containing solutions. This is consistent with a mechanism in which the dominant role of halides is as complexation agents for oxidized gold species. Additionally, the mechanism through which $FeCl_3$ induces etching in liquid cell TEM remains unclear. Ground state bleaching of the Fe(III) absorption band observed through pulse radiolysis indicates that iron may react with Cl_2^- radicals to form an oxidized transient species under irradiation. Complete active space self-consistent field (CASSCF) calculations indicate that the $FeCl_3$ complex is oxidized to an Fe species with an OH radical ligand. Together our data indicates that an oxidized Fe species may be the active oxidant, while halides modulate the etch rate by tuning the reduction potential of gold nanocrystals.

Nanoscale Chemical and Structural Analysis During *In Situ* Scanning/Transmission Electron Microscopy in Liquids Rui F. Serra-Maia[1], Pawan Kumar[1], Andrew C. Meng[1], Alexandre Foucher[1], Yijin Kang[2], Deep M. Jariwala[1], Khim Karki[3] and Eric A. Stach[1,3]; [1]University of Pennsylvania, United States; [2]Northwestern University, United States; [3]Hummingbird Scientific, United States

Liquid-cell scanning/transmission electron microscopy (S/TEM)has emerged as an effective in-situ / operando approach to characterize electrochemical systems. This approach confines both the sample of interest, electrolyte and microfabricated electrodes between two silicon nitride membranes to allow materials characterization in aqueous environments. While powerful, the thickness of the liquid layer and the nitride membranes inhibits high-resolution characterization. We will show that it is possible to overcome these limits to a great extent by utilizing electrochemical water splitting to generate a gas bubble that reduces the liquid to a film that is approximately 30 nm thick and which remains on the sample. This reduction in liquid thickness permits the acquisition of atomically resolved S/TEM images, electron diffraction patterns, and electron energy loss spectra with sufficiently high signal to noise to allow characterization of valence. After high-resolution characterization, the gas bubble can be eliminated by water oxidation. This allows us to alternate between a full cell and thin-film condition so that we can obtain optimal electrochemical cycling (full cell) and intermittent, controllable analytical characterization. We will show how we use this method to advance our understanding of several different electrochemically driven processes, including dealloying of nanoporous AuAg alloys and CO2-driven shape changes in copper nanoparticle systems.

SESSION CH01.06: Spectroscopy Techniques I

Exploring Complex Oxide Structural Motifs in Lithium-Ion Battery Anodes with Diffraction and Spectroscopy Kent J. Griffith, G. J. Snyder and Kenneth R. Poeppelmeier; Northwestern University, United States

Complex early transition metal oxides have emerged as leading candidates for fast charging lithium-ion battery anode materials. Framework crystal structures with frustrated topologies are good electrode candidates because they may intercalate large quantities of guest ions with minimal structural response. Starting from the empty perovskite (ReO_3) framework, shear planes and filled pentagonal columns are examples of motifs that decrease the structural degrees of freedom. As a consequence, many early transition metal oxide shear and bronze structures do not readily undergo the tilts and distortions that lead to phase transitions and/or the clamping of lithium diffusion pathways that occur in a purely corner-shared polyhedral network.

In this work, we explore the relationship between composition, crystal structure, and reduction pathway in a variety of mixed transition metal and main group oxides. The electrochemical properties of a series of sodium and lithium niobates are studied as new fast-charging lithium-ion battery electrode materials. High-resolution neutron diffraction is used to resolve structural questions in the host materials related to sodium disorder, space group subtleties, lithium positions, and second-order Jahn–Teller distortions of the d^0 Nb^{5+} redox centers. Structural evolution is followed in real-time at rapid discharge/charge rates with *operando* synchrotron X-ray diffraction, collecting high-resolution diffraction patterns in a few seconds. The structure models from diffraction are informed by the local structure perspective from solid-state NMR spectroscopy and *operando* X-ray absorption spectroscopy (XANES and EXAFS), while the structural (meta)stability and ionic properties are probed through density functional theory (DFT) calculations. A comprehensive picture of the charge storage mechanisms in these complex oxides are described. Prospects for tunability and implications for charge rate and structural stability will be discussed.

2:00 PM CH01.06.02
Quantifying Electron-Beam Induced Electrochemistry Using *In Situ* KPFM Evgheni Strelcov[1,2], William McGehee[1], Vladimir Oleshko[1], Nikolai Zhitenev[1], Jabez McClelland[1] and Andrei Kolmakov[1]; [1]National Institute of Standards and Technology, United States; [2]University of Maryland, United States

Nanoscale characterization of solid-state electrochemical devices is crucial for understanding functional mechanisms and limiting factors in device operation. Many characterization techniques use electron microscopy and associated electron and X-ray spectroscopies, but these techniques are limited by electron- or X-ray-radiation-induced modification of the device. While the standard solution to this problem is to limit the irradiation dose to a minimum, we demonstrate the utility of some electron-beam-induced changes to probe nanoscale electrochemistry. Careful selection of electron beam parameters allows the employment of the electron beam not just as a probe, but as an active electron source to create a nanoscopic virtual anode and cathode to study *in situ* and *in vacuo* solid-state electrochemistry. We quantify electron-beam-induced variation in surface potential in electrochemical systems using *in situ* Kelvin probe force microscopy. Correlation of the surface potential and material's work function changes with the electron beam dose and energy as well as with the amount of the reaction products, revealing details of the electrochemical transformation mechanisms. We compare local oxidation and reduction in several systems, including lithiated silicon, a Li-ion conductor, metallic lithium, magnesium and platinum, to establish the transformation mechanism.

2:15 PM CH01.06.03
Illuminating Porous Electrodes via 4D *In Situ* Fluorescent Electrochemical Microscopy Anton M. Graf[1], Thomas Cochard[1], Meisam Bahari[1], Shmuel Rubinstein[2] and Michael Aziz[1]; [1]Harvard University, United States; [2]The Hebrew University of Jerusalem, Israel

Porous electrodes are a crucial hardware for many sustainable electrochemical energy devices. They are broadly used in redox flow batteries and fuel cells as well as in electrochemical synthesis and separation. Although porous electrodes with many different internal fibre architectures have been studied, there is no clear consensus as to what structural features affect electrode performance. Recent results revealing heterogeneities on length scales an order of magnitude greater than the pore size challenge the common assumption that transport in porous electrodes can be approximated by a homogeneous Darcy-like permeability, particularly at the length scales relevant to many electrochemical systems. [1]
In this study, we investigate various porous electrodes with different fibre architectures by visualization of the electrolyte charging process *via in-situ* confocal microscopy at length scales down to the single digit micron scale. We present fluorescent electrochemical microscopy, a strategy to couple confocal fluorescence microscopy with electrochemical monitoring as a new analytical method to investigate electrochemical flow systems *in operando*. The fluorescent signature of quinone electrolytes differs for the charged and discharged redox states, which enables us to map the local state of charge in three spatial and one temporal dimension (4D imaging). In addition, we use 4D fluorescent particle tracking to evaluate local velocity fields, fluid streamlines, and spatial heterogeneities. The correlation between flow fields and electrochemical concentration maps shows that not only the surface area limits the electrode efficiency but also the fibre arrangement affecting the overall electrolyte flow.

***In Situ* and *Operando* Neutron Powder Diffraction at the ILL on Li-Ion Batteries—How Can We Help You?** Emmanuelle Suard; Institut Laue Langevin, France

Li-ion batteries structure and purity have been characterized ex-situ classically by neutron powder diffraction for a long time. More recently, there has been a huge effort to provide scientists with a tool to study Li-ion batteries operando, in order to obtain better insights of the processes involved during charge and discharge. Several electrochemical cells have been developed in various facilities [1]
At the ILL, we have designed our own custom-made electrochemical cell to respond to some specific requirements (cell fully transparent to neutrons, sample amount between 100mg to 300mg, easy to use, extremely good quality neutron powder diffraction patterns) #ILLBAT1 [2].

We showed that this cell could function properly electrochemically, whilst enabling, at the same time, the acquisition of NPD patterns of high quality for Rietveld structural refinements using D20 at the ILL. We have used this cell to study different classes of materials and it has proven very effective. We therefore decided to give users access to this new, powerful tool.

The next step was the development of similar electrochemical cells for operando studies on all-solid-state lithium batteries. This cell #ILLBAT2 has a similar design as the original one, the main difference being that it can be used at non-ambiant temperature (either high or low temperature) [3].

We are now still working on improving our cells in order to fullfill our users requests. ILLBAT#3 is a cell designed to work on ASSB as ILLBAT#2, but its specificity is that it will be possible to maintain a high pressure on the sample while measuring. And finally a cylindrical cell will also be soon available. All made in TiZy alloys. These two lasts cells are still prototypes but they will be soon available for our users community.

In parallel, in order to give more beamtime available for such studies we are developping the possibility to perform operando experiments using such cells on D19 which is a single-crystal diffractometer with a large bi-dimensionnal detector. The results of the preliminary tests are extremely possitive and there is no doubt that D19 will be a good alternative to D20.

Finaly, to give the best possible experimental conditions to our users, we are now building a Small Electrochemistry Laboratory (SEL) near D20, for the purpose of preparing these cells in a clean environment.

Of course, Operando experiments are not the only measurements using NPD. In-situ experiments using furnaces, cryostats are also common to study phase transformations or follow the phase diagram depending during the synthesis.

This conference is an opportunity to present the possibilities offered by the ILL to characterize the crystallographic structure and monitor the Li atoms position and content either *operando* or in-situ in Li-ion batteries using Neutron Powder Diffraction

CELLS-ALBA Synchrotron, a Versatile Facility Offering Wide Panel of *In Situ* and/or *Operando* Synchrotron Techniques Applied to Electrochemical Systems Francois Fauth; CELLS-ALBA synchrotron, Spain

CELLS-ALBA is the Spanish synchrotron located in the Barcelona area. The facility started in 2011 and is now prospecting machine upgrade. Along last years, several synchrotron techniques were applied using *In Situ* data collection on Operando electrochemical systems. Synchrotron X-ray Powder Diffraction (SXRPD) performed on BL04-MSPD has been the most productive tool in the study of new electrode materials and in particular the realized crystallographic phases settling in during (des-)insertion of alakline ions. Typical example is the $Na_3V_2(PO_4)_2F_3$ system for which the high angular resolution allowed whol structure determination of all occuring phases in the charge/discharge process [1]. The same system was studied using hard X-ray Absorption (XAS) techniques on the BL22-CLEASS beamline highlighting the electronic configuration of the V pairs when desinserting two Na^+ [2]. The presentation will cover selected examples for which both SXRPD and XAS has been applied to electrochemical systems as well an insight to the presently commissioned BL16-NOTOS beamline principally offering the possibility to collect both SXRPD and XAS data "quasi" simultaneously. Soft X-ray spectroscopy and Imaging techniques have been applied using the BL09-MISTRAL beamline in the study of Ca intercalation in TiS_2. Differential absorbtion tomography allowed reconstruction in direct space of Ca distribution at several steps of intercalation.[3] In the same trend of multivalent based batteries, the identification, quantification and morphology of materials built at solid electrolyte interphase (SEI) has been tackled by InfraRed (IR) spectroscopy techniques on BL01-MIRAS beamline [4]. So far soft X-ray techniques are only availbale on *Ex Situ* prepared samples but development of *In SItu* cells is ongoing at ALBA. Deteils on devlopment will be presented.
The move towards All Solid State batteries focus now the search on solid electrolytes exhibiting high ionic conductivity and stable crystal structures. Temperature dependent SXRPD sounds a valuable technique in the understanding of such materials as demonstrated in studies of Na_3PS_4 [5] and $Li_6Zn(P_2O_7)_2$ [6] performed on BL04-MSPD.
Another approach in optimization and better understanding of cathode material production involves *In Situ* synthesis studies as recently exemplified in temperature dependent SXRPD under controlled gas atmosphere performed during synthesis of $LiNiO_2$ [7] and Ni-rich layered $Li(NiCoMn)O_2$ oxides [8].

Resolving Structural Deterioration in Ni-Rich Layered Cathode Materials at Higher Operating Potentials in *Operando* Anastasiia Mikheenkova[1], Olof Gustafsson[1], Casimir Misiewicz[1], William Brant[1], Matthew Lacey[2], Maria Hahlin[1] and Erik Berg[1]; [1]Uppsala University, Sweden; [2]Scania CV AB, Sweden

Aiming for high capacity and high energy density batteries, combined with the strive to reduce the use of Co has resulted in significant demand for Ni-rich cathode layered materials ($Li[Ni_{1-x}Co_xAl_y]O_2$, so-called NCA, and $Li[Ni_{1-x}Mn_xCo_y]O_2$, so-called NMC) on the EV market. Structure driven deterioration together with mechanical degradation hinder the full potential of the NCA and NMC materials. During cycling to higher voltages (above 4.2 V) the layered oxide materials exhibit significant reactivity of the active material with electrolyte with further gas evolution[1]. Along with studies demonstrating structural fatigue facilitating rapid degradation while reaching high potentials, the high relevance of studies focused on the dependence of oxygen release and structural degradation is justifyed[2]. We will present insights into the relation of structural changes coupled with gas evolution and advanced electrochemical characterisation that expand understanding of the limits of Ni-rich cathode material and clarify strategies for surmounting these limits. Specifically, the current study is focused on investigating the origins of NCA cathode material degradation at higher operating potentials in commercial electrodes. We use a combination of intermittent current interruption technique[3] with *operando* XRD and *operando* gas analysis on electrodes extracted from commercial cells (Tesla Model 3 18650 cylindrical cells). This work allows to expound the degradation processes in Ni-rich layered oxides at high operating potentials.

Li_xMoO_2 and Na_xMoO_2 Systems Studied by *Operando* Pair Distribution Function Analysis During Lithium or Sodium Electrochemical (De)Intercalation Marie Guignard and Matthew Suchomel; Institute of Condensed Matter Chemistry of Bordeaux (ICMCB), France

For many years already, we have shown that the electrochemical intercalation and deintercalation of alkali ions in a battery is a very powerful technique for determining phase diagrams in MO_2-AMO_2 systems (where A is an alkali ion and M is a 3d or 4d transition metal ion) by combining in situ powder X-ray diffraction and electrochemistry. In the molybdenum systems MoO_2-$LiMoO_2$ and MoO_2-$NaMoO_2$, it has been found that many phase transitions occur during the deintercalation of alkali ions without being able to determine the origin. We proposed that these phase transitions arose in part from the rearrangement of molybdenum atoms in MoO_2 sheets formed of MoO6 octahedra.

In order to validate this hypothesis, we performed operando pair distribution function analysis (PDF) experiments during battery cycling using $Li_{2/3}MoO_2$ and $Na_{2/3}MoO_2$ phases as positive electrode materials in lithium batteries and sodium, respectively. These experiments were performed at the XPDF beamline of the Diamond synchrotron using the electrochemical cells specifically dedicated to PDF analysis designed by Diamond. These experiments confirmed that molybdenum atoms shifted slightly from the center of MoO_6 octahedra during electrochemical (de)intercalation of alkali ions and thus formed short (approximately 2.5 Å) and long (approximately 3.2 Å) Mo-Mo bonds. The length and the distribution of the different Mo-Mo bonds have been analyzed. We concluded that different geometries of molybdenum clusters can be observed in the Li_xMoO_2 and Na_xMoO_2 phases during the alkali electrochemical deintercalation (for example, zig-zag chains or diamond-like chains).

9:30 AM *CH01.11.05
***Operando* Characterization of Silicon-Based Battery Anodes by Neutron and Synchrotron Techniques** Sandrine Lyonnard; CEA-IRIG, France

Understanding lithiation and ageing mechanisms in Li-ion batteries requires ad hoc tools to probe the real-time evolution of active materials during charge and discharge of a battery. Neutron & synchrotron techniques have been widely employed to probe the structural, morphological and chemical changes occurring in electrodes, as both high energy X-rays and neutrons can deeply penetrate into matter, therefore enabling to monitor key processes in realistic devices with ultimate space and time resolutions. Recently, composite anodes made of (nano)silicon and graphite have attracted attention due to the high specific capacity of silicon. However, these are extremely complex materials where the volume changes due to silicon alloying with lithium generate ageing on the long-term, therefore hindering their potential use towards viable high energy density anodes. We will present in this talk a toolkit of techniques employed to quantify strain in crystalline silicon by operando synchrotron XRD [1], nanoscale morphological changes in composite anodes by synchrotron SAXS and SANS [2,3], 3D lithiation heterogeneities and microstructural ageing by SAXS/WAXS synchrotron tomography and synchrotron mXCT [4]. These investigations established the details of core-shell lithiation mechanism as well as the correlations between electrochemistry, materials design and ageing process, allowing to highlight the key features for a better engineering of novel silicon-based anodes.

10:30 AM *CH01.12.01
Towards Holistic Understanding of Electrochemical Energy Conversion and Storage Systems Using High Energy X-Rays Jakub Drnec; ESRF, France

Complete physico-chemical operando characterization of electrochemical devices in whole, or it's constituent materials separately, is necessary to guide the development and to improve the performance. High brilliance synchrotron X-ray sources play a crucial role in this respect as they act as a probe with relatively high penetration power and low damage potential. Synchrotron sources will undergo major upgrades in next decade and will provide even higher brilliance and, more importantly, coherence. These upgrades will be particularly advantageous for beamlines providing high energy X-rays as they will allow use of advanced scattering techniques with highly penetrating probe. Therefore, the techniques typically used for ex-situ measurements or at lower X-ray energies could be used on materials in liquid half-cells and operating electrochemical devices. In this contribution the new possibilities of using high energy, high intensity, coherent X-rays to probe model systems and whole electrochemical devices will be presented. The focus will be on defects tracking, local structure determination and correlative multimodal characterization using advanced WAXS, SAXS and surface scattering techniques.
To study fuel cells or batteries as a whole, elastic scattering techniques such as wide angle and small angle scattering are typically employed, as they can provide important complementary information to more standard X-ray imaging and tomography. The advantage is that the chemical contrast and sensitivity at atomic and nm scales is superior. Coupling these technique with the tomographic reconstruction (XRD-CT and SAXS-CT) is much less common as it requires bright synchrotron sources, fast 2D detectors and advanced instrumentation [1]. However, such combination allows spatial reconstruction of materials important atomic parameters in operando conditions. This will be demonstrated on imaging of standard 5 cm2 PEM fuel cell during operation. Furthermore, local atomic and mesoscale structure, together with defect content, can also be determined by using Rietveld fitting, Pair Distribution Function (PDF) analysis and advanced SAXS theory. This in principle allows holistic investigations of interfaces at the device level, specification of defects' role in catalysis and determination of interplay between different phases during operation. These are critical questions needed to be answered in order to incorporate novel materials into the electrochemical devices. Examples will be given on studies of the defectous ORR catalysts [2,3] and amorphous Li-ion anodes.
HESXRD (High Energy Surface X-ray Diffraction) [4] and TDS (Transmission Surface Diffraction) [5] provide ideal tools to study structural changes during reaction conditions on single crystal model electrodes. The main advantage of both techniques is the possibility to follow the surface structural changes precisely with atomic resolution. While HESXRD is ideally used to determine exact atomic position, the TSD is easier from experimental perspective and allows studies with high spatial resolution. Advantages and disadvantages of both approaches will be discussed and examples of measurements on ORR and OER catalysts will be given. The future possibility to use high energy coherent beams will open new opportunities for both techniques to study single defects and surface dynamics in operando conditions.

Advances in *In Situ* Liquid Phase TEM to Study Electrochemical Processes in Li-Ion Batteries and Beyond Yevheniy Pivak, Hongyu Sun, Anne F. Beker and Hugo H. Pérez Garza; Denssolutions, Netherlands

In situ liquid phase transmission electron microscopy (LPTEM) is a promising technique to visualize and study real-time dynamic processes happening during electrochemical cycling of Li-, Zn-, Na- and other types of ion batteries. The in situ LPTEM allows to reveal morphological and structural changes occuring in the sample in a liquid environemnt and to correlate it with the electrochemistry. On the other hand, this method has a number of drawbacks which reduces its success rate and limits wide practical application. First of all, high resolution (~ nm scale) and analytical capabilities (Electron Diffraction-ED, Energy Dispersive X-ray Spectroscopy-EDXS and Electron Energy Loss Spectroscopy-EELS) are substiantilly hindered by the uncotrlled thick liquid layer ($\geq$ 500 nm). Furthremore, the current designs of the liquid flow cells used for in situ liquid phase TEM have no direct control over the liquid flow as they possess multiple fluidic pathways with considrably higher fluidic resistance in the sample area. This prevents measuring the flow rate around the sample and studying the effect of the flow on the dendrite growth. Furthermore, bubbles, often created in the imaging area while performing electrochemical cycling abort the whole experiment as these are impossible to remove from the current liquid cells.

To solve the above-mentioned limitations and to increase the success rate, we revolutionazed the design of the liquid cell. Unlike existing solutions, where the liquid inlet and the outlet are located in the TEM holder, the new design has the liquid inlet/outlet directly in the liquid cell. The spacers inside the cell guide the liquid from the inlet to the outlet, forming a fluidic channel that goes through the imaging area. This innovation made it possible to have a direct flow control over the sample. In combination with a new type of liquid delivery system based on pressure-driven flow, the new liquid cell has a well-defined flow direction, allows to control the pressure of the liquid inside the cell and thus the liquid thickness, enables quantification of liquid flow rates, enables bubbles removal and much more.
In this work we are going to present the design of the new liquid cell together with the new liquid delivery setup and show how this new system can be used to remove bubbles from the region of interst by means of the liquid flow or the liquid pressure, how it is possible to minimize the effect of the electron beam with the flow, how to make high resolution imaging and enable elemental mapping in liquid and how to define the mass transport in the electrochemical cell and to study kinetics of redox reactions.

Unriddling the Complex Battery Chemistry by Rationally Designed High-Performance Liquid Electrolytes Isidora Cekic-Laskovic; Helmholtz-Institute Muenster, IEK-12 Forschungszentrum Juelich, Germany

Materials science in the field of batteries as dominating electrochemical energy storage systems is forced to follow a systems approach as the interactions between active materials, the electrolyte, the separator and various inactive materials (binder, current collector, conductive fillers, cell housing, etc.), are of similar or even higher importance as the properties and performance parameters of the individual materials. Successful operation of batteries relies significantly on a series of interrelated mechanisms, some involving instability of the constituting components induced by charge/discharge cycles and some also encompassing formation/reaction of metastable phases. With this in line, the ability to achieve long-term stability requires careful elucidation of the physical and chemical processes governing charge/discharge cycling and storage. The key performance requirements of a battery for different applications might look very similar at first sight, however, each application calls for different requirement prioritization. Frequently, they conflict with one another and call for inevitable trade-offs. The objective of advanced battery research and development relates to obtaining the best compromise among the determined goals, followed by a decision whether the balanced system should be implemented instead of a competing technology. In all types of batteries, electrolyte as the only component in direct contact with all other active and inactive parts, plays a key role in terms of overall performance, life and safety. Chemistry of liquid electrolytes and their interaction with anode and cathode materials is complex and yet not fully understood, thus representing a delicate balance of various properties. Despite our limited knowledge, modern needs for battery electrolytes require the development of sophisticated electrolyte solutions with multifunctional components, able to simultaneously fulfill several duties. Typical requirements include combined roles as salt dissolution

enhancers, viscosity decreasers, flame-retardants or effective electrolyte interphase formers at the electrodes. The introduction of these modern components can be regarded as a paradigm shift in order to increase the efficiency and safety of lithium-based and post-lithium-based batteries, when compared with nowadays technologies.
This talk is an invitation to a journey of the scientific development, technology as well as engineering of selected classes of advanced liquid electrolytes for lithium-based batteries under systematic approach that allows to understand the structure-property-performance relationships of the selected compounds/formulations, their impact on the overall battery chemistry, performance and safety, thus helping to further tailor relevant properties of electrolyte components/formulations for targeted applications.

11:45 AM CH01.12.04
Operando GCMS Gas Analysis for Monitoring Complex Electrolyte Decomposition Products in Lithium–Ion Batteries Jürgen Kahr[1], Christiane Groher[1], Maria Antoniadou[2], Erwin Rosenberg[2] and Marcus Jahn[1]; [1]AIT, Austria; [2]Technische Universität Wien, Austria

Lithium Ion Batteries (LIB) find not only wide use in portable devices and consumer electronics, but also attract increasing attention in stationary energy storage and the automotive sector. In this regard, LIBs play a significant role as intermediate energy storage due to their high volumetric and gravimetric energy, high power density, and long cycle life. With respect to larger battery packs safety became a major concern and attracted increasing research interest in this field.

To achieve the required performance, the interaction of novel anode and high-voltage cathode materials with the electrolyte is of paramount interest. Safety and performance issues arise from degradation reactions of the conducting salt and electrolyte solvent, due to the formation of flammable, corrosive and toxic gas species. Particularly, the safety must be assessed with respect to the formation of volatile and reactive species during cell operation which can negatively alter cell components. Gas chromatography / mass spectroscopy (GC/MS) has proven to be a reliable tool for species detection. Unfortunately, conventional GC systems lack time resolution for operando gas analysis regarding fast processes, for example battery failure. Therefore, developing operando testing methods with improved time resolution is key to giving insight into electrolyte alterations during battery operation.

Here one of them, an operando GC/MS for LIBs is presented as a gas monitoring technique for volatile organic species arising from the decomposition of conventional LIB electrolytes. The combination of a continuous sampling technique with GC/MS allows an increased time resolution for the analysis of products from fast decomposition processes. Commercially produced NMC-based pouch cells and coin cell-sized batteries were monitored with respect to evolving gas species during battery operation. Especially, the degradation products of organic carbonate- based electrolytes, such as derivatives that appear in the presence of decomposed $LiPF_6$, have been evaluated in respect to the cell potential.

The author gratefully acknowledges the FFG (Austrian Research Promotion Agency) for funding this research within project No. 879613.

Investigating Li Metal Anodes with *Operando* Neutron Depth Profiling and Solid-State NMR Marnix Wagemaker, Ming Liu, Qidi Wang, Chao Wang, Tomas Verhallen and Swapna Ganapathy; Delft Univ of Technology, Netherlands

Li-metal is the ultimate anode for Li-batteries from the perspective of energy density. However, reversible cycling is challenged by dendrite formation and the irreversible reactions with the electrolyte, a topic that is intensively investigated for many decades. Here we show the use of operando Neutron Depth Profiling (NDP) and Solid State NMR to monitor the some of the espects of Li-metal deposition. Neutron Depth Profiling provides the Li density profile perpendicular to the electrode place in modified pouch cells. Solid state NMR is able to monitor the evolution of dead Li metal in a full cell geometry, as well as the nature of the deposited Li metal. Both techniques are applied to different solution strategies, such as electrolyte/solvent additives and a host scaffold for Li metal plating. Operando NDP is employed on a regular LiPF6 EC/DMC electrolyte [1], to illustrate the NDP principle and the type of data that can be extracted, as well as on an amide electrolyte [2], highlighting how this changes the Li metal plating and stripping. Operando 7Li solid state NMR on full anodeless cells is performed [3], with and without a high dielectric scaffold that is intended to induce more compact Li metal growth. These examples provide insight in the underlying mechanism of these strategies, illustrating the value of these operando techniques in Li metal studies.

SESSION CH01.13: Interfacial Characterizations
Session Chairs: Jordi Cabana and Jakub Drnec
Monday Afternoon, December 6, 2021
CH01-Virtual

1:00 PM *CH01.13.01
Using X-Rays to Locate Chemical Phenomena in Battery Materials Jordi Cabana; University of Illinois at Chicago, United States

The evolution of local chemistry determines the performance of electrodes and electrolytes used in batteries because limitations can be tracked to slow kinetics and transport, and irreversibilities in the storage reaction. Tools that provide insight into local chemistry are critical for identifying the underpinnings of electrochemical function. This information must be resolved within architectures, from individual particles to microscale domains, to pinpoint the relationship between local phenomena and their role in macroscopic metrics and degradation. Technical developments in X-ray microscopy and mapping have built a flexible suite of tools that combine the desired spatial resolution and 3D capabilities with a suite of possible contrasts mechanisms, such as diffraction and spectroscopy. In this talk, we will discuss our recent research that demonstrates the diversity of length scales at which important chemical heterogeneity can be induced in battery electrodes. For this purpose, the systems of study will be the leading cathodes for Li-ion batteries, but the insight is expected to be generalizable to “beyond” technologies, such as Na-ion or Mg. We will highlight the new fundamental insight generated by the tools. The mechanisms of transformation will be related to their impact on material and architecture properties. Along the way, we will also provide a glimpse into the future by showing how emerging synchrotron techniques can enhance the impact of X-ray microscopy in fundamental battery science. Particularly, in the spirit of this Symposium, we will discuss the prospects of probing time-resolved phenomena using operando measurements to avoid uncertainty due to relaxation under open circuit conditions.

1:30 PM CH01.13.02
Imaging Phase Segregation in Nanostructured Li_xCoO_2 Islands with Conductive Atomic Force Microscopy Elliot J. Fuller[1], David Ashby[1], Celia Polop[2], Enrique Vasco[3], Joshua Sugar[3] and A. A. Talin[1]; [1]Sandia National Laboratories, United States; [2]Universidad Autónoma de Madrid, Spain; [3]Instituto de Ciencia de Materiales de Madrid, Spain

Li_xCoO_2 (LCO) is a common battery cathode material that exhibits phase transformations that are significantly complicated by the coupling of correlated electronic effects, strain and diffusional anisotropy. At compositions $0.96<x<1$ LCO remains insulating, while at compositions $x<0.75$ it is metallic. Between these two compositions, the insulating and metallic phases coexist. While the bulk phase diagram has been studied extensively [1, 2], it remains unclear how the electronic and structural phases scale to nanometer particle dimensions, and the effects of strain and diffusional anisotropy on the phase morphology [3]. We have investigated nanoscale, epitaxial $LiCoO_2$ islands grown by pulsed laser deposition onto $SrTiO_3$ substrates. After charge cycling of the islands, conductive atomic force microscopy (c-AFM) is used to image the spatial distribution of conductive and insulating phases at various states of charge and under strain conditions. Above island thicknesses of 25 nm, we resolve a diffusion-limited intercalation wavefront propagating along the Li-planes. Thinner islands (~11nm) are found to exhibit a striping pattern which suggests the surface energy plays a critical role in the phase morphology when particles are scaled below a critical dimension. The effects of strain are investigated through the application of force with the c-AFM tip. Above a critical force threshold, the insulating regions of the islands are found to undergo an insulator-metal transition. The results suggest that the morphology of phase segregation and strain play a critical role in charge-cycling of nanoscale particles.

1:45 PM CH01.13.03
***In Situ* X-Ray Multimodal Characterization for Insights into Synthesis/Processing of High-Ni Cathode Materials** Sizhan Liu, Jianming Bai and Feng Wang; Brookhaven National Laboratory, United States

Driven by the increasing need for energy storage, especially for electric vehicles and electronic devices, the technological advancements of lithium-ion batteries (LIBs) are urgently in demand to increase energy density while reducing the cost. Battery performance is largely determined by the phase constitution and properties of electrodes and electrolytes and, therefore, can be advanced by synthesis/processing, in making certain phases with controlled structure and material properties. This is particularly true for high-Ni layered oxides, $LiNi_xMn_yCo_{1-x-y}O_2$ (NMC; $x>0.7$), the most promising low-cost, high energy density cathodes for next-generation LIBs. In such cathode materials, the increasingly high Ni loading worsens the surface instability and, consequently, lowers the cells' lifespan and brings issues to materials production and storage, posing a practical challenge to their commercial deployment. In this work, a multimodal *in situ* synchrotron X-ray characterization approach is employed to investigate the thermodynamic and kinetic pathways in the synthesis/processing of high-Ni NMC materials. A combination of *in situ* X-ray diffraction, total scattering (coupled with pair distribution function analysis), X-ray absorption spectroscopy, and imaging is applied to tracking structural/chemical evolution at short, intermediate, and long-range ordering of intermediates in preparing NMC811, $LiNiO_2$, and other layered oxides from their hydroxide counterparts. Results of our recent studies reveal the strong composition dependence of the structure and morphology evolution as a result of the preferential oxidation of Mn/Co over Ni. We show Mn and Co play an important role in facilitating Li/O incorporation, consequently leading to more continuous structural ordering and crystal growth in Mn/Co containing high-Ni NMC compared to the pure $LiNiO_2$. Those findings shed light on the rational design of synthesis/processing in preparing high-Ni layered cathodes of optimized performance for next-generation LIBs.

2:00 PM CH01.13.04
Advancing Nondestructive *In Situ* Characterizations of Buried Electrochemical Interfaces—Infrared Nanospectroscopy at Electrode/Liquid-Electrolyte and Electrode/Polymer-Electrolyte Interfaces Jonathan Larson, Xin He, Hans Bechtel and Robert Kostecki; Lawrence Berkeley National Laboratory, United States

Paving new pathways for in situ and/or operando characterizations of buried and intact electrochemical interfaces is critically important for, in the least, (i) advancing basic energy storage science and for (ii) optimizing the efficacy of engineered interfaces/interphases in batteries. In this talk, we first present a brief overview of near-field based infrared nanospectroscopy (true nanoscale Fourier transform infrared spectroscopy) and nanoimaging. We follow this by sharing how we have demonstrated such techniques can be utilized to study graphene/liquid-electrolyte interfaces, with sensitivity to even species within the electric double layer. Finally, we discuss our most recent data in which we extend such near-field methods to characterize buried and intact electrode/electrolyte interface evolution in solid-state polymer battery (SPB) devices, *in situ*. The SPB devices are capped with graphene, which operates as both infrared transparent window and current collector for Li plating and stripping (similar in function to anode-less batteries). *In situ* infrared imaging and spectroscopic measurements are performed at pristine, heated, plated, and stripped interfaces, where we find that the interfacial solid-state polymer-electrolyte (SPE) intrinsically possesses nanoscale heterogeneities that contribute to plating inhomogeneities on a similar length scale. Additionally, we find that a mosaic-like solid-electrolyte interphase forms at the Li/SPE interface consisting of decomposition products amongst SPE. Our approach paves a way for SPB optimization (or other chemistries), by providing a method for unprecedented nanoscale measurements of crystallinity, structure, conductivity, and chemistry of intact and buried electrochemical interfaces in their native environments.

2:15 PM CH01.13.05
***In Situ/Operando* Soft X-Ray Absorption Spectroscopy Probing of the Electrode/Electrolyte Interfacial Dynamics Influenced by the Electrolyte Anions and Cations** Feipeng Yang[1], Xuefei Feng[1], Hui Li[1], Scott A. McClary[2], Ana Sanz-Matias[1], Nathan M. Hahn[2], David Prendergast[1], Kevin Zavadil[2] and Jinghua Guo[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]Sandia National Laboratories, United States

There is considerable interest in the study of electrochemical processes in calcium batteries since the demonstration of room temperature plating and stripping of calcium with high capacities and low polarization using $Ca(BH_4)_2$ as the electrolyte. The greater polarizability of Ca^{2+} over Mg^{2+} represents greater configurational flexibility, facilitating ionic cluster formation and rapid delivery of Ca^{2+} ions to the electrode interface. To promote the development of calcium batteries, it is critical to probe the solvation and charge transfer mechanism at the electrode/electrolyte interface. It has been reported that when $Ca(BH_4)_2$ is substituted by the weakly coordinated calcium hexafluoroisopropoxyborate ($Ca(Bhfip)_2$), ionic conductivity increases by an order of magnitude, which demonstrates the strong coordination of BH_4^- compared to Ca^{2+} in THF. In this work, the coordination of Ca^{2+} at this electrolyte/electrode interface as a function of the type of anions is probed by the in-situ/operando soft X-ray absorption (XAS) spectroscopy under operando electrochemical conditions. The total electron yield (TEY) mode XAS is sensitive to the interfacial speciation under in-situ and operando conditions. It was observed that the $Ca(Bhfip)_2$ in THF shows a small shoulder on the right side of the L_2-edge and a pre-edge peak on the left side of the L_2-edge peak. A less prominent pre-edge peak is also observed on the left side of the L_3-edge peak. These signatures become more prominent when the potential is swept negatively and are not reversible when the potential is swept positively in a cyclic voltammetry cycle. On the other hand, the $Ca(BH_4)_2$ in THF is more reversible, and no shoulder peak on the right side of the L_2-edge peak was observed. The effect of cations was also compared by investigation

of the calcium L-edge and fluorine K-edge TEY mode XAS from the 0.5M calcium bis(trifluoromethanesulfonyl)imide ($Ca(TFSI)_2$) in THF vs. 0.45M $Ca(TFSI)_2$ + 0.05M LiTFSI in THF. The TEY-XAS spectra from these operando studies indicate their differences in the Ca^{2+} coordination chemistry at the electrode/electrolyte interface as a result of the anions and cations, and will path the way for the future development of electrolytes for calcium batteries.

2:30 PM CH01.13.06
***In Situ* and *Operando* XPS Studies of the Si-Anode Solid-Electrolyte Interphase** Sarah Frisco, Yeyoung Ha, David Moore, Andrew Colclasure and Glenn Teeter; National Renewable Energy Laboratory, United States

Laboratory-based x-ray photoelectron spectroscopy (XPS) is a ubiquitous, powerful technique for analyzing surfaces and interfaces to reveal compositions and chemical states. Beyond these typical applications, in recent years there has been growing interest around *in situ* and *operando* XPS approaches that can elucidate dynamic interfacial phenomena, including charge- and mass-transfer processes relevant to renewable technologies including lithium-ion batteries (LIBs). This presentation will discuss recent efforts to develop and apply *in situ* and *operando* approaches to probe interfacial charge transfer and phase transformations relevant to the formation and evolution of the solid-electrolyte interphase (SEI) in silicon-anode LIBs. These experiments are enabled by the so-called virtual electrode (VE) approach [1,2], in which electrochemical currents are driven during VE-XPS measurements on exposed interfaces via a combination of low-energy Li^+ion and electron guns and ultraviolet-based photoemission. Key recent findings that will be discussed include: (i) conversion of native SiO_x to Li_ySiO_x phases; (ii) lithium-induced band-alignment shifts at the SiO_x|silicon interface; (iii) observed correlations between lithium chemical potential (m_{Li}) and ionic vs. electronic conductivities of SEI constituent phases such as LiF and Li_2CO_3; and (iv) *in situ* reduction of ethylene carbonate (EC) on various model-system electrodes.

2:45 PM CH01.13.07
Operando Spectroscopic Ellipsometry—A Non-Destructive Optical Technique Offering Insights into Lithium Intercalation and Solid Electrolyte Interphase Formation Juan Carlos Gonzalez-Rosillo[1], Valerie Siller[1], Marc Nuñez Eroles[1], Michel Stchakovsky[2], Alex Morata[1] and Albert Tarancon[1,3]; [1]Catalonia Institute of Energy Research, Spain; [2]HORIBA Scientific, France; [3]ICREA, Spain

Vast efforts have been devoted over the last decade to develop new techniques and approaches to obtain critical information about interfacial phenomena during device operation to establish direct correlations towards their electrochemical performance. However, the sophistication of some of the most powerful techniques, such as isotopic ion exchange methods, in situ TEM and synchrotron radiation based techniques, limits the routine access to essential information for developing next-generation batteries. In addition, commonly available techniques have also been explored including X-ray diffraction, atomic force microscopy, Raman spectroscopy and Fourier transform infrared (FTIR) spectroscopy showing different compromises between spatial and time resolutions. Surprisingly, and despite the well-known capabilities of Spectroscopic Ellipsometry (SE) to infer the properties of thin film systems (including multilayers), the use of this affordable, non-destructive technique in the field of Li-ion batteries is very limited. In short, SE measures the change in the polarization state of a light beam reflected in the sample. By comparing with a suitable model, the relevant optical properties of the material, such as the dielectric function and extinction coefficients, are extracted as a function of the wavelength. This technique is typically sensitive to parameters such as crystallinity, materials ratio in mixtures, roughness, structure of the interfaces, etc

In this talk, we will discuss the basic theory and our implementation of Spectroscopic Ellipsometry to perform operando experiments thanks to its fast response and the strong effect of the oxidation state on the optical properties of the films. We will exemplify the power of the technique with two examples. First, we have used SE to monitor Li^+ transport properties through real-time tracking of the valence changes associated with lithium insertion and extraction along $LiMn_2O_4$ thin films and interfaces[1]. Second, we have employed SE to interrogate the formation of a Solid Electrolyte Interphase (SEI) during the first cycle on spinel-based anode and cathodes over the extended voltage range. Here, we link the changes in the optical properties of the films with the capacity losses associated with the first cycle, and provide guidelines for SEI-resistant coatings at the cathode and anode interfaces[2].

SESSION CH01.14: Dynamic Investigations
Session Chairs: Jordi Cabana and Y. Shirley Meng
Monday Afternoon, December 6, 2021
CH01-Virtual

4:00 PM *CH01.14.01
***Operando* Studies of Lithium-Ion Battery Electrodes Under Fast Charge Conditions** Daniel Abraham; Argonne National Laboratory, United States

Fast charging of lithium-ion batteries (LIBs), being developed for electric vehicles, is needed to meet customer demands of time-parity with today's gasoline-powered cars. The U.S. Department of Energy (DOE) has set a target charging time of 15 minutes (4C rate) as a near-term goal, further indicating that a 10-minute charge (6C rate) could be a long-term goal. This talk will present an overview of fast charge studies being conducted at Argonne National Laboratory as part of projects funded by the U.S. DOE. In-situ and operando methods to examine electrode and cell behavior will be discussed: results from cells containing layered oxide cathodes and graphite anodes will be highlighted. The use of a microprobe reference electrode to monitor the onset of Li plating conditions and to determine develop cycling protocols that minimize cell performance degradation will be presented. X-ray methodologies to characterize spatial distribution of the active materials and investigate lithium concentration gradients that develop in electrodes will be examined. The heterogeneities that develop and persist in the electrodes cause non-uniform degradation across the electrodes thus making it a challenge to predict cell life.

4:30 PM CH01.14.03
***In Situ* Dynamic Measurements of Ti_3C_2 MXene Thin Films During Voltage Cycling at Variable Sweep Rates** Thomas Sobyra[1], Tyler Mathis[2], Yury

Gogotsi[2] and Paul Fenter[1]; [1]Argonne National Laboratory, United States; [2]Drexel University, United States

X-ray reflectivity and crystal truncation rod measurements, performed at the Advanced Photon Source at Argonne National Laboratory, monitored structural changes of Ti_3C_2 MXene films as a function of applied potential between 0.3 and −0.7 V in an aqueous 0.1 M Li_2SO_4/H_2O electrolyte. Static measurements show negative potential sweeps lead to a contraction in the interlayer spacing of 1.2 Å upon Li insertion and a net loss of electron density between the layers (Sobyra et al. *ACS AMI*, **2021**, Under Review). The layer spacing changes continuously, except for an additional discrete contraction that occurs near −0.35 V having the characteristics of a first-order transition. The continuous change in the MXene layer spacing is associated with the capacitive charge, while the discrete change in structure correlated with the weak feature in the cyclic voltammogram at −0.35 V can be interpreted as either a pseudocapacitive charging process or a potential-dependent change in capacity.

New dynamic *in-situ* measurements observe the change in lattice spacing and MXene layer widths in real-time as a function of sweep rate to provide insight into the mechanisms of intercalation as the system is forced to respond to the rapidly changing environment. Potential sweep rates were varied from 1 mV/s to 500 mV/s. The Ti_3C_2 MXene response at slow sweep rates, less than 10 mV/s is similar to the static charging, but at faster rates, the system shows less contraction in the Ti_3C_2 layer spacing as the Li insertion becomes transport limited.

Analysis of the MXene electrochemical response reveals a charging mechanism that is sweep rate-dependent and not diffusion-limited as the Li^+ ions diffuse slower than the bulk diffusion rate through the interlayer spacing. These measurements with varying sweep rates, in conjunction with the dynamic X-ray measurements, confirm the rapid change in layer spacing that occurs below −0.3 V is directly associated with the broad redox peak seen in the cyclic voltammogram.

4:45 PM *CH01.14.04
***In Situ* Magnetic Resonance Studies of Electrochemical Processes in Li-Ion Cells Using Novel Probes** Gillian R. Goward[1], Kevin Sanders[1], Amanda A. Ciezki[1], Zoya Sadighi[1], Annica Freytag[1], Andres Ramírez Aguilera[2] and Bruce J. Balcom[2]; [1]McMaster University, Canada; [2]University of New Brunswick, Canada

Magnetic resonance tools for *in situ* and *in operando* investigations of electrochemical processes have provided many new insights into electrochemical processes in lithium ion batteries. We have recently reported the application of a parallel-plate NMR probe to monitor Li metal deposition on a graphite anode during the charging of a single layer prismatic cell.[1] The probe provides an enhanced sensitivity and an ideal orientation of the cell relative to the applied electromagnetic fields, and allows the quantification of the lithiation of the graphite anode throughout the duration of cell charging.
A new version of this parallel-plate resonator for ^{7}Li ion cell studies is introduced along with a removable cartridge-like electrochemical cell for studies of LIBs.[2] This geometry separates the RF probe from the electrochemical cell permitting charge/discharge of the cell outside the magnet and introduces the possibility of multiplexing samples. The cell and RF probe dramatically increase the sample volume compared to traditional MR compatible battery designs. The cell and RF probe may be employed for spectroscopy, imaging, and relaxation studies.
Here we report the application of this probe, together with a custom electrochemical cell assembly, to monitor Li plating on a graphite anode of a full-cell LIB using *in operando* NMR spectroscopy and imaging. We are able to quantify the amount of Li metal deposited on the anode surface and correlate it to the relative amounts of Li species within the graphite anode with high time resolution relative to the high charging rate of 1C. Our data demonstrate that most of the Li metal deposited on the anode surface can be intercalated into graphite during rest periods when no current is applied, and that the formation of Li metal correlates to the loss of capacity of the cell over multiple high-rate charge cycles. Moreover, we demonstrate that this methodology can be extended to a variety of battery chemistries, with an emphasis on full-cell behaviour.
Finally, we demonstrate a magic-angle spinning (MAS) based *in situ* electrochemical NMR method that offers significantly improved resolution over conventional static NMR experiments. We demonstrate that it is possible to monitor both the anode and cathode simultaneously making it possible to track the Li distribution in a full cell.[3] The state of charge, metallic Li plating and SEI formation was captured for the first charge/discharge cycle of a full electrochemical cell using conventional liquid electrolytes. The use of a polymer electrolyte membrane offers improvements over the original design.

5:15 PM CH01.14.05
Structural Dynamics of Metallic Nanocatalysts for Fuel Cells by *In Situ* Total X-Ray Scattering Valeri Petkov; Central Michigan University, United States

Many catalysts for energy related applications, in particular metallic nanoalloys, undergo atomic-level changes during electrochemical reactions. The nature and dynamics of the changes and their impact on the catalyst performance, however, are not well understood. This is largely because they are studied on model nanocatalysts under controlled laboratory conditions. We will present results from recent studies [1, 2, 3] on the dynamic behavior of metallic nanoalloy catalysts inside an operating proton exchange membrane fuel cell. Results show that the nanocatalyst change profoundly, from their initial state to the active form and further along the cell operation. Their electrocatalytic activity also changes, as reflected by the cell's performance. We will also show that the rate and magnitude of the changes may be rationalized when the limits of traditional relationships used to connect the composition and structure of nanoalloys with their electrocatalytic activity and stability, such as Vegard's law, are taken into account. The new insight into the atomic-level evolution of nanoalloy electrocatalysts is likely to inspire new efforts to stabilize transient structure states beneficial to their activity and stability under operating conditions, if not synthesize them directly.

5:30 PM CH01.14.06
***In Operando* Study of Electrochemical Strain and Charge Storage in Nanosheet Oxide Electrodes** Scott T. Misture, Madeleine N. Flint, Peter Metz, Peng Gao and Robert Koch; Alfred University, United States

MnO_2 nanosheets demonstrate an interesting response to reduction of Mn^{4+} to Mn^{3+}, where Jahn-Teller distorted Mn^{3+} is displaced out of the plane of the nanosheet forming a "surface Frenkel" defect. Atomic scale point defects enhance capacitance beyond 300F/g while lowering charge transfer resistance of δ-MnO_2 nanosheets by a factor of 10. X-ray total scattering was teamed with X-ray absorption spectroscopy and Raman spectroscopy probe the local

atomic structure, defect chemistry, and strain during electrochemical cycling. All methods employed in-situ or real-time in-operando study using custom sample environment cells and porous agglomerated nanosheet active materials. Specimens prepared by exfoliation of pristine powder grains to form nanosheet clusters with 2-5 individual layers were processed into nanosheet floccules, which are of high surface area (over 200 square meters per gram) and can be deposited as thick films using electrophoretic deposition. The result of the studies is a description of the charging mechanism in high surface area MnO2 nanosheet electrodes and related nanosheet oxides: in-plane strains of up to 0.7% occur during charging, accompanied by Mn reduction. The initial number of Mn3+ defects determines the magnitude of the charge stored and consequently the electrochemical strain. In-situ XANES showed 16% of the Mn in MnO_2 reduced from Mn^{4+} to Mn^{3+} during electrochemical cycling. In agreement, in-situ Raman spectra demonstrate an increase in the number of Jahn-Teller distorted MnO_6 octahedra in the charged state as well as changes in the polarizability of vibrational modes that are affected by interlayer cations and interlayer water, though there is only very limited restacking of a few nanosheets. The excellent cycling stability of the nanosheet electrodes vs. bulk solids is attributed to the free space in the floccules that allows electrochemically-driven expansion and contraction without degrading the charge transfer pathways and without microcracking the active electrode. Another new discovery is Mn3+ defects also induce enhanced mass transport, resulting in formation of tunnel-like fragments which disrupt the sheet-like motif. Heat treatments expedite this layer-to-tunnel conversion which has a profound impact on the electrochemical properties and cycling stability. At low scan rates the capacitance of δ-MnO_2 heat treated at 60°C is ~6 times larger than the 400°C samples indicating a change in the charge storage mechanism that cannot be detected by diffraction studies alone, and requires PDF analyses. Kinetic analysis paired with PDF refinements demonstrate tunnel formation hinders the intercalative ion diffusion, reaching a percolation threshold around 25-30% tunnel structured MnO_2.

6:30 PM *CH01.15.01
Advanced Neutron Characterisation of Rechargeable Batteries Vanessa K. Peterson[1,2]; [1]ANSTO, Australia; [2]University of Wollongong, Australia

The performance of rechargeable batteries is determined largely by materials structure- and dynamic-function relations. During battery function, materials undergo change, such as the experienced by electrode materials during the compositional change that occurs during battery cycling. Robust characterization methods that quantitatively and accurately capture structure- and dynamic-function relations across the relevant length and timescales for batteries are essential to the strategic design of materials with superior function.

Neutrons have attributes that make them exceptionally useful for this purpose. The predominantly nuclear interaction of neutrons with matter results in both high penetration, allowing the analysis of materials within whole commercial batteries, as well as an elemental sensitivity that is particularly well suited to battery materials composition.

This talk will give examples of neutron characterization of rechargeable battery materials, with a focus on instrumentation at the Australian Centre for Neutron Scattering, and much of which examines materials within whole batteries during operation. Examples using neutron powder diffraction,[1-5] neutron imaging,[6,7] small and ultra small angle neutron scattering,[8] and quasielastic neutron scattering,[9] will be presented.

7:00 PM CH01.15.02
***In Situ* TEM Corrosion Study and Anti-Corrosion Control of Pd@Pt Core-Shell Electrocatalysts** Fenglei Shi; Shanghai Jiao Tong University, China

Platinum (Pt)-based electrocatalysts are widely used in many fields such as energy, environment, medicine, and so on. The activity can be improved by composition, structure, morphology control while the performance degradation still occurs during the operation. Therefore, it is of great importance to investigate the degradation mechanism of the Pt-based electrocatalysts. Herein, we chose Pd@Pt core-shell structure, a promising electrocatalyst toward oxygen reduction reaction (ORR) as the study system. In-situ liquid cell transmission electron microscopy (LC-TEM) technique was utilized to explore the nanoscale corrosion kinetics of the electrocatalysts. The corrosion of Pd@Pt core-shell nanoparticles with different morphology like cube and octahedra were studied. The results indicate that the defects are the inducing factors of corrosion and the sequential corrosion process is controlled by both the local strain and evolving curvature. Strain plays a major role in the early process, and the local curvature dominates gradually in the later process. In addition, the sites with high surface energy like corners are the preferential etching areas. We sequentially designed and synthesized corner-protected Pd@Pt nanocubes and small size octahedral nanoparticles with fewer defects and smaller strains based on these insights in nanoscale corrosion behaviors. Both in-situ LC-TEM study and ex-situ stability tests confirmed that the newly designed electrocatalysts were much more corrosion-resistant.

***Operando* Visualization of Mass Transport Behavior in Electrolytes During Electrochemical Device Operation by Phase-Contrast X-Ray**

Imaging Daiko Takamatsu, Akio Yoneyama and Jun Hayakawa; Hitachi, Ltd., Japan

A fundamental understanding of mass transport properties in electrolytes during electrochemical reaction is important for optimal operation and design of energy conversion/storage devices, including batteries, fuel cells and water electrolysis. It is known that internal resistance of the lithium-ion batteries (LIBs) temporarily rises by repeating high-rate charge/discharge cycles and that it decreases by stopping the battery operation and rest. Because such a reversible resistance rise occurs only during the battery operation, this phenomenon is speculated to be related to the ion concentration distributions in the electrolyte. Such ion concentration distributions in the electrolyte give also serious effect on the performance of lead-acid batteries (LABs). The development of a vertical ion concentration gradient of sulfuric acid is called electrolyte stratification, which causes inhomogeneous current distribution in the vertical distribution of the electrodes by frequent charging-discharging, reducing the life of LABs. However, there are few techniques that can be used to quantitatively characterize ion concentration distribution that arise in electrolytes during the battery operation.
Phase-contrast X-ray imaging is a technique that can be used to visualize density differences by detecting the X-ray phase shift caused by an X-ray passing through a sample. The sensitivity of the phase-contrast X-ray imaging is about 1000 times higher than that of conventional X-ray absorption imaging in a hard X-ray region for light elements. Since the electrolytes of batteries are composed of light elements, the phase-contrast X-ray imaging is expected to be effective in visualizing small density differences in an electrolyte during battery operation. We have demonstrated that phase-contrast X-ray imaging technique can quantitatively visualize ion concentration distributions that arise in electrolytes during battery operation (cf. LIBs [1], LABs [2]).
Recently, hydrogen energy systems that use hydrogen as an energy carrier, such as fuel cells (hydrogen-to-power) and water electrolysis cells (power-to-hydrogen), is a growing interest to realize carbon emission-free energy technologies. Among the various types of hydrogen energy devices, the proton exchange membrane fuel cell (PEFC) and water electrolysis (PEM-WE), which use solid polymer membrane as electrolyte, have been used in practical applications. For further improvement of PEFC and PEM-WE performance, there are several obstacles to be solved include sluggish reaction kinetics, complex water management, limited lifetime due to membrane degradation. However, characterization of mass transport phenomena (e.g., ion transport, thermal transport, etc.) in polymer electrolyte membrane under device operating conditions remains insufficient because of the lack of suitable observation techniques. We have demonstrated that phase-contrast X-ray imaging can visualize the behavior of the water distribution of polymer electrolyte membranes during water electrolysis operations [3].
In this presentation, we will introduce operando phase-contrast X-ray imaging technique can quantitatively evaluate mass transport phenomena in the electrolyte simultaneously during electrochemical device operation with high temporal (a few seconds) and spatial (a few microns) resolutions.

Structural-Electrochemical Studies of Sodium-Ion Battery Positive Electrodes Neeraj Sharma; UNSW, Australia

A significant challenge in sodium-ion batteries relative to lithium-ion batteries is the larger size of the sodium cation especially for host structures. An ideal electrode should be able to reversibly insert/extract large quantities of sodium ions with minimal structural distortions or with distortions that can be managed. The positive electrode active material is a significant source of the sodium ions during battery function and can be one of the most expensive and toxic components. Layered transition metal (*TM*) oxides of the general formula, $Na_x TMO_2$ have shown excellent electrochemical properties but are plagued in part by the structural changes during battery function. Our work has utilized *in situ* and *operando* synchrotron X-ray diffraction to probe the relationship between structure and electrochemistry during battery function in this class of materials with a variety of compositions.

Here, the focus will be on Mn-rich compositions which represent one of the cheapest and least toxic candidates for positive electrodes. The parameter space covered in this talk will include the structural and phase evolution of - Mn-rich P2 $Na_{2/3}Fe_{1-y}Mn_yO_2$ highlighting the differences based on composition, P2-$Na_{2/3}Mn_{0.8}M_{0.1}M'_{0.1}O_2$ (*M* = Zn, Fe and *M'* = Cu, Al, Ti) showing how the choice of transition metals influences structural evolution, and P2/O3-$Na_{2/3}Li_{0.18}Mn_{0.8}Fe_{0.2}O_2$ illustrating the role of a multi-component electrode.

***Operando* Analysis of Lithium-Ion Battery Electrodes and Cells Featuring Neutron Diffraction** Hajime Arai, Tetsuya Omiya and Atsunori Ikezawa; Tokyo Institute of Technology, Japan

Operando analysis under both in-situ and non-equilibrium conditions offers information on how battery materials actually function during battery operation. The behavior of interest includes not only continuous status changes during discharging and charging but relaxation phenomena and even degradation.
The time resolutions of analytical methods limit their application to operando analysis; 6 min is required to observe each 10% change of battery materials during 1C rate operation. Electrochemical analysis generally shows high time resolutions but offers only limited physico-chemical information of the material. To support the phenomena observed by electrochemical analysis, a variety of operando methods have been proposed and applied such as X-ray diffraction, X-ray absorption and neutron magnetic resonances.
Operando analysis of practical cells has been difficult due to the limited penetration depths of the analytical probes. Neutron analysis can be applied to look through the practical cells while it generally lacks sufficient time resolutions. SPICA, a diffractometer installed at Material and Life Science Experimental Facility of Japan Proton Accelerator Research Complex [1], uses strong neutron beam to enable operando analysis of 18650 cells during battery operation up to 1C [2,3] to allow simultaneous observation of positive and negative electrodes.
In this study, we apply the operando neutron analysis to clarify the degradation behavior of commercially available 18650 lithium-ion cells under float-charging, cycling and the mixture of them. We first anticipated that occasional cycling releases the cell from continuous float-charging to decrease side reactions and thus prolong the life. Against our expectations, it turned out that there is a negative synergy effect on the cell life when the float-charging and cycling were mixed. The d*V*/d*Q* curve [4] of the degraded cell was totally different from the original one, showing the limitation of the d*V*/d*Q* analysis to clarify the origin of the degradation. Neutron diffraction analysis indicated that the serious degradation chiefly originated from the positive electrode side, with its resistance increase. This is in contrast to the soft degradation caused by either float-charging or cycling, which can be attributed to loss of lithium inventory due to side reactions at the negative electrode [5] (clarified by the d*V*/d*Q* curve analysis and the neutron diffraction).
It is noted that the degraded positive electrode showed reaction inhomogeneity during discharging, which has rarely been reported by neutron diffraction. Such reaction inhomogeneity can be ascribed to the ion transportation limitation, as shown by X-ray diffraction [6] and optical measurement [7]. We assume that the surface film formation caused by the float-charging was accelerated by the particle cracking due to cycling, and considerable ion transportation limitation finally resulted in the high resistance of the positive electrode. These results prove that operando neutron analysis is a powerful tool for clarifying the degradation mode of practical cells.

Understanding the Interplay of Electrode Microstructure, Crystallography and Performance Using Advanced X-Ray and Correlative Imaging Methods Paul Shearing[1,2]; [1]University College London, United Kingdom; [2]The Faraday Institution, United Kingdom

The past decade has seen the rapid development and proliferation of three-dimensional X-ray imaging tools applied to Li-ion batteries, providing a framework to improve the understanding of electrode morphology and its influence on transport processes, electrochemistry and mechanical behaviour. The non-destructive, and multi-scale characteristics of X-ray imaging tools provide benefits to quantify hierarchical complexity from the particle to the electrode and device level. Through the application of image-based modelling tools, it has become possible to simulate a range of phenomena using a computational framework derived directly from tomographic images. Here, we will review this progress and reflect on recent developments using multi-modal methods to understand the performance of Li-batteries: this includes XRD-CT to reconcile chemical, crystallographic and morphological behaviour, Bragg Coherent Diffraction Imaging to access sub-particle behaviour and complementary neutron and X-ray imaging techniques, leveraging the benefits of the alternative contrast modes possible.
In concert, the portfolio of imaging and modelling tools provides a platform to explore the performance, degradation and failure of Li-ion batteries and post Li-ion chemistries, including LiS and solid state batteries, which will also be presented here.

Revealing a Dissolution and Reprecipitation Process of Copper Catalysts During CO_2 Reduction Reaction Jan Vavra, Tzu-Hsien Shen, Dragos Stoian, Vasiliki Tileli and Raffaella Buonsanti; EPFL, Switzerland

Electrochemical CO_2 reduction reaction (CO_2RR) aims at reusing waste CO_2 and turning it into fuels and chemical feedstock. Ongoing development of catalysts focuses at reducing overpotentials and improving selectivity and stability. Cu is the most promising catalyst for multi-carbon products. Here, we describe a mechanism responsible for evolution of a Cu-based catalyst during CO_2RR by relying on in-situ techniques. Liquid cell electrochemical transmission electron microscopy is complemented by x-ray absorption near edge structure.

Metallic Cu nanospheres were shown to evolve into larger particles selective for C2 products during CO_2RR.[1] We describe a series of subsequent stages responsible for the catalyst reconstruction. Initially, the catalyst oxidizes to Cu_2O upon exposure to the cell environment at open circuit voltage, while releasing Cu ions into the electrolyte. During the cell startup, the dissolved Cu ions redeposit, while the bulk of the catalyst is reduced back to metallic Cu. Surprisingly, the catalyst dissolution and redeposition continues under cell operation at reductive potential, despite the absence of oxidized phases. We exclude a previously proposed process of particle migration and coalescence by resolving individual particles in an operating CO_2RR cell. The observed process is instead similar to Ostwald ripening and proceeds through a soluble intermediate.[2]

The observed dissolution/reprecipitation process does rationalize the reported evidence of catalyst activation[1] as well as the loss of initial selectivity in precision synthesized nanocrystals.[3] By understanding the processes responsible for CO_2RR catalyst reconstruction, we direct the efforts in synthesis of long-term stable catalysts and motivate future research aimed at controlling the redeposition to continuously refresh the catalysts active sites.

Atoms in Motion—Operando M-Ion Battery Monitoring Using X-Ray Techniques Damien Saurel, Marine Reynaud, María Jáuregui, Montserrat Galcerán and Montserrat Casas-Cabanas; CIC Energigune, Spain

The use of operando methods for the study of electrochemical processes occurring in energy storage systems has become increasingly popular in recent years. Operando experiments represent a powerful tool for the monitoring of internal processes upon battery cycling that provide valuable insights regarding the fundamental electrochemical redox mechanisms and ageing phenomena in battery materials. Nevertheless, obtaining high-quality, representative and exploitable data from *operando* measurements requires careful control of many experimental parameters (i.e. cell configuration, electrode preparation, optical/goniometer geometry, data acquisition protocols and data interpretation methodology).
In this talk we aim to share our experience and draw the attention into several aspects that we consider important for effective data acquisition and exploitation using both lab-scale and synchrotron powder X-ray diffraction (PXRD) and Small Angle X-ray Scattering (SAXS) instruments. The impact of several key factors, related to the cell design, the experimental setup as well as the sample and experiment preparation, will be discussed.[1] Next, several case studies will be shown to illustrate the effectiveness of operando experiments to understand the electrochemical signature of several Na-ion battery materials,[2-3] including asymetric reaction mechanisms and order-disorder transitions.

Visualizing Electrochemical Reactions at the Nano- and the Atomic Scale by *In Situ* TEM Huolin Xin, Chunyang Wang, Lili Han and Peichao Zou; University of California, Irvine, United States

Over the past decade, we have witnessed a rapid growth in liquid and gas phase, heating and electrochemistry holders for transmission electron microscopy. These holders have enabled direct imaging of material transformations in liquid and gaseous environments with submicron-scale to atomic-scale spatial resolution under operando conditions. In particular, research regarding electrode materials in lithium ion batteries and nanocatalysts in heterogeneous catalysis has greatly benefited from the emergence of these capabilities. In this talk, I will showcase the capability of direct nanoscale visualization of electrochemical nucleation, growth and degradation of electrode materials and electrocatalysts utilizing operando and in-situ TEM techniques and discuss the insights extracted from these experiments for improving the electrochemical devices.

***In Situ* NMR Guided Electrochemical Regeneration of Anthraquinone Flow Batteries** Yan Jing[1], Evan Wenbo Zhao[2], Marc-antonio Goulet[1], Meisam Bahari[1], Eric Fell[1], Shijian Jin[1], Erlendur Jónsson[2], Ali Davoodi[1], Min Wu[1], Clare Grey[2], Roy Gordon[1] and Michael Aziz[1]; [1]Harvard University, United States; [2]University of Cambridge, United Kingdom

Organic molecules used for aqueous redox flow batteries hold great promise in significantly lowering levelized costs of electricity storage and potentially outperforming their inorganic counterparts, representing one class of promising candidates for grid-scale electricity storage.[1] Short lifetime of aqueous organic redox flow batteries, caused by the instability of organic molecules, has been considered the biggest obstacle for successful commercialization. *In situ* NMR metrology offers a unique, non-invasive opportunity to observe dissolved redox-active organic molecules undergoing electrochemical reactions in an operating flow battery.[2]
2,6-Dihydroxyanthraquinone ($DHAQ^{2-}$) shows a fast instantaneous temporal fade rate (~5%/day) due to the instability of the reduced form ($DHAQ^{4-}$), which disproportionates to 2,6-dihydroxyanthrone (DHA) along with its tautomer, 2,6-dihydroxyanthranol (DHAL), and $DHAQ^{2-}$.[3] In the present work, we employ *in situ* NMR to observe reversible and irreversible reactions among these DHAQ-related species as we vary the cell voltage.
DHAQ (100 mM) was first charged at 30 mA/cm^2 and held at 1.7 V vs. $Fe(CN)_6^{3-/4-}$ (100 mM) in a full cell, then it was discharged at 30 mA/cm^2 while the voltage decreased from 0.9 V to a cut-off voltage of 0.5 V, followed by a voltage hold at 0.5 V for 7.4 hours. During the voltage hold at 1.7 V, ^{1}H NMR signals of $DHAQ^{4-}$ are visible; signals from DHA(L) were also observed. During discharge, the fast electron transfer between $DHAQ^{3-}$ radical and $DHAQ^{4-}$ anions causes the corresponding aromatic peak broadening, allowing the DHA^{2-} and $DHAL^{2-}$ signals to be revealed as they remain unaffected. During the voltage hold at 0.5 V, aromatic peaks of $DHAQ^{2-}$ and the new signals at 6.36, 6.41, 7.40 and 7.41 ppm grow in, accompanied by the decrease of signal intensities of DHA(L). The chemical shifts of these new signals were assigned to $(DHA)_2$. These results indicate that, at 0.5 V, DHA(L) can be electrochemically oxidized to $(DHA)_2$.
To determine whether $(DHA)_2$ can be further oxidized, the cell voltage was decreased from 0.1 V to −0.3 V, stepping in decrements of 0.1 V, holding for 2 hours at each voltage step. The intensity of the $(DHA)_2$ signals remains unchanged at 0.1 V and starts to decrease at 0 V, and the signals disappear completely at −0.2 V, accompanied by the increase of signal intensities of $DHAQ^{2-}$. This observation indicates that $(DHA)_2$ has been electrochemically oxidized to $DHAQ^{2-}$.
The concentration of $DHAQ^{2-}$ as a function of battery voltage has been quantified. It remains at 72 mM at 0.1 V, starts to increase to 80 mM, 95 mM and 100 mM at 0 V, −0.1 V and −0.2 V, respectively. A comparison of the initial concentration of $DHAQ^{2-}$ (*i.e.*, 100.4 mM 0.25 mM) with the concentration after electrochemical regeneration (*i.e.*, 99.9 mM 0.44 mM) indicates complete regeneration within the experimental resolution. This result demonstrates the circularity of the electrochemical reactions from DHAQ to DHA(L), to $(DHA)_2$ and back to DHAQ at different potentials.
The electrochemical regeneration technique rejuvenates not only DHAQ, but also the positive electrolyte – rebalancing the states of charge of both electrolytes without introducing extra ions. The strategy should extend to other water-soluble anthraquinones susceptible to anthrone formation; it may also be applicable for other redox-active organic molecules. The strategy could permit redox-active organic molecules to reach the combination of performance, cost, and lifetime necessary for AORFBs to become an attractive solution to the intermittent renewable electricity storage problem.

Fast X-Ray Operando Measurements "at Home" Jean-Noel Chotard, Vincent Seznec, Arina Nadeina, Tristan Lombard and Christian Masquelier; Lab de Reactivite Chimie-Solides, France

One of the weak point of batteries is their low cycling rate. It takes tens of minutes to charge a mobile phone (in the best cases) and even hours to charge an Electrical Vehicle and they fail delivering instant high power. **High rate materials**, i.e. materials able to be charge and discharge in the scale of the minutes or seconds, are of most interest. Some cathode materials such as $Na_3V_2(PO_4)_2F_3$ (NVPF) can be cycled at high rate (10C) with a limited loss of capacity [1]. A key point to develop such materials is the understanding of the cycling mechanisms involved. **Fast operando measurements are thus crucial**. Such measurements on electrode materials can easily be performed thanks to the high photons brilliance provided by third generation synchrotron light sources and the fast detection modes. In this field, the LRCS already demonstrated its ability to innovate by developing cells allowing concomitant measurement of the electrochemical and structural properties of electrode materials. Since the first operando-cell developed 15 years ago (for Lab X-ray diffraction), continuous improvements have been made. More recently, the cell was updated for transmission measurements in transmission mode [2] successfully used at both **SOLEIL (France) and ALBA (SPAIN) synchrotrons.** Additionally, this cell can be utilized for both absorption

(EXAF/XANES) and diffraction measurements. In parallel, a cell suitable for neutron diffraction has also been developed (collaboration between LRCS, the ICMCB in Bordeaux, France and the Laue Langevin Institute (ILL) in Grenoble) [3]. These various innovations shed lights on the reaction mechanism as well as Li/Na diffusion paths into the electrode material as demonstrated by some of our experiences in ALBA [4].
However, it is not easy to access large-scale facilities and beam time is rare. Being able to perform x-ray diffraction measurements in the time scale of a minute "at home" would indeed be a strong asset.
Thanks to a new diffractometer equipped with a Molybdenum rotating anode source, a highly efficient detector and a specific operando cell, those measurements are now doable in laboratories.
As it will be shown in this talk, fast measurements (less than a minute per diagram) can be performed allowing following the different phase changes during the charge or discharge of high rate electrode materials and identifying the formation of new metastable phases. Moreover, thanks to the high energy of the molybdenum radiation, we can do X-Ray diffraction in transmission mode through full All Solid State Batteries and study at the same time the anode and cathode.

1:30 PM CH01.17.02
Operando X-Ray Nano-CT Coupling with XANES for Monitoring the (De)Lithiation Dynamics Inside NMC Secondary Particle Tuan-Tu Nguyen[1], Zeliang Su[1], Vincent De Andrade[2], Charles Delacourt[1] and Arnaud Demortiere[1]; [1]CNRS RS2E/LRCS, France; [2]Argonne National Laboratory, United States

Over the last decades, with increasing energy demand along with the shift towards greener energy solutions, Li-ion batteries have gained attraction for energy storage applications.[1] Due to the high complexity in the hierarchical architecture of composite electrodes, it is extremely challenging to ensure a homogenous electrode structure. The non-uniform distribution of phases, leading to microstructural heterogeneities, has been shown to induce a non-uniform electrochemical behavior, which can deteriorate the performance, and cause macroscopic failures.[2,3] Therefore, the identification of these microstructural heterogeneities and understanding their effects on the dynamics of (de)lithiation is crucial to improve electrode design.

Lithium compositional distributions in composite electrodes can also be investigated using various techniques such as Raman microscopy,[4] X-ray diffraction,[5] or 2D X-ray absorption near-edge structure spectroscopy (XANES).[6] However, these methods have been restricted to low spatial resolution or spatially integrated signal along the depth direction and cannot accurately capture the spatial distributions and can lead to a limited interpretation of the mechanism.

Several works have combined XANES and X-ray tomography [7] to generate a rich data set that allows a direct correlation of the chemical information and the microstructure. Meirer *et al.*[8] used 3D XANES to probe the conversion of NiO to Ni metal in a partly reduced electrode. They found significant inhomogeneities in terms of chemical states across particles as well as evidence of fracturing caused by volume expansion during the reaction. More recently, Wang *et al.* [9] collected a 46-point spectrum across the iron K-edge of a $LiFePO_4$ cathode particle and developed a run-out correction system to enable automated tomography.

Here, we perform XANES coupled with transmission X-ray computed tomography at nanoscale in *operando* mode to investigate $LiNi_{0.5}Mn_{0.3}Co_{0.2}O_2$ (NMC) positive electrodes. In this work, we demonstrate that *operando* XANES-TXM nanoCT allows access to the Li distribution at nanoscale within the LiB electrodes during the operation. We also proposed a method that relies on just three energy levels located at pre-edge, edge, post-edge for minimization of radiation damage to the sample. Also, a specific electrochemical cell and a sample preparation process were introduced, which make the use of electrodes typical to those used in real-life applications possible.

Our experimental results unveil the non-uniformity of the Li repartition throughout the LiB porous electrodes during operation. As a result, there are regions being more active than the others as well as preference spots on the particle surface where the reactions are more likely to occur. The Li repartition across the electrode depth is adequately uniform, which indicates a negligible effect from porous electrode. In addition, some of the reconstructed slices also revealed that the lithiation process could also happen from internal pores of the AM particles. This observation also implies that the electrolyte along with the carbon conductive can penetrate some internal pores through the AM grain boundaries and allow the (de)lithiation process to occur from the inside of the NMC secondary particles. This multiscale insight can shed light to the optimization of the electrode design to improve the electrode performance.

Late News: Advances in Direct Detectors for *In Situ* Electron Microscopy Barnaby D. Levin; Direct Electron LP, United States

In situ transmission electron microscopy (TEM) experiments on electrochemical systems require highly sensitive detectors in order to minimize the electron beam dose incident on the specimen, and thereby minimize the potential effects of electron beam damage. Highly sensitive detectors are also advantageous for *in situ* and *operando* experiments that aim to observe phenomena on millisecond timescales, where electron beam dose per frame is necessarily limited[1].

Monolithic active pixel sensor (MAPS) based direct detectors such as the DE-12 and DE-16 offer higher detective quantum efficiency (DQE) and sensitivity compared to conventional, scintillator-coupled detectors, and have been employed in a variety of *in situ* TEM experiments[2-4], including studies of lithiation and delithiation[5], sodium electrodeposition[6], and CO_2 reduction[7]. More recently, Direct Electron has developed two new MAPS detectors, Apollo and Celeritas, that offer significant advances in the capability of direct detectors with potential applications to *in situ* experiments.

The event-based Apollo detector provides a fast-imaging speed whilst operating in an electron counting mode. Although MAPS based detectors achieve greater DQE than conventional TEM detectors when operating in charge integrating mode, DQE is further enhanced when performing electron counting. For frame-based MAPS based detectors, electron counting requires a very sparse signal per frame (~1 electron per 50 pixels), meaning that many frames must be summed to obtain interpretable images, effectively reducing imaging speed by one or two orders of magnitude. At the same time, enormous computational power is required to identify and count sparse events in individual frames. Instead of generating frames of data, event-based detectors only generate data from pixels in which an event occurs, causing intensity to exceed a threshold level. The generation of data from select pixels, rather than entire frames means fewer computational resources are needed to generate interpretable data, yielding a potential increase in speed. In the Apollo detector, events occur when pixels are excited by an electron hitting the sensor. These events are compiled into interpretable counting mode images, which are output at a rate of 60 images per second in 8192 x 8192 super-resolution mode.

The Celeritas detector offers very fast frame rates compared to previous TEM detectors. The physical sensor is 1024 x 1024 pixels with a 15 µm pixel size. At full frame size the frame rate exceeds 1950 fps, allowing phenomena to be observed with a time step of just 512 µs between images. With a reduced sub-area of 256 x 64 pixels, a frame rate of up to 87,000 fps can be achieved. This allows the Celeritas detector to be used to collect *in situ* 4D STEM datasets, where a time step of less than 0.2 seconds between entire 128 x 128 probe position datasets is possible. This is a comparable speed to conventional 2D STEM imaging and is one to two orders of magnitude faster than is currently possible with typical 4D STEM detectors.

The speed and sensitivity of the Celeritas and Apollo detectors may be advantageous for *in situ* electrochemical TEM experiments, such as studies of dendrite growth and formation, or of atomic structural fluctuations in electrocatalysts, where high-speed imaging will be valuable for understanding fundamental mechanisms.

Late News: Anisotropy of Lithium Metal Stripping Explored with *Operando* 3D Microscopy Adrian J. Sanchez, Eric Kazyak, Yuxin Chen, Jose Lasso and Neil P. Dasgupta; University of Michigan, United States

A promising pathway to surpass the energy storage capabilities of Li-ion is to incorporate a Lithium (Li) metal anode into a rechargeable battery. However, challenges, such as poor cycle life and safety concerns, severely hinder the performance of Li metal anodes. Dendritic growth has been shown to contribute to poor cycle life, but the impact pit formation has performance is not fully understood. In our previous work, we implemented *operando* video microscopy to study the nucleation of Li metal and demonstrated the impact pits have on Li metal cycling[1]. The edges of pits were observed to be "hot" spots for dendrite nucleation[1]. Furthermore, the size of the pits was observed to influence the reversibility of dendrites when nucleation occurred in a pit[1]. However, a mechanistic understanding of how pit formation influences dendrite nucleation and reversibility is lacking. To better understand how pits evolve and how this evolution impacts dendrites, we have enabled focus variation microscopy in our *operando* visualization platform[2]. This technique captures the areal surface topography of sample with sufficient temporal resolution for *operando* measurements.

Using this capability, we: (1) explore the morphological evolution of individual pits; (2) demonstrate the anisotropic expansion of pits; (3) correlate electrode surface microstructure and crystallographic orientation with stripping anisotropy; and (4) demonstrate pit faceting. The results of this study highlight the anisotropic nature of Li metal stripping and identify the critical role of electrode crystallographic orientation and microstructure on stripping. Furthermore, this study illuminates how the observed anisotropic stripping can promote dead Li formation and suggests potential pathways to improve reversibility.

Late News: *In Situ* Transmission Electron Microscopy of High-Temperature Corrosion by Chloride Salts Prachi Pragnya, Daniel Gall and Robert Hull; Rensselaer Polytechnic Institute, United States

Understanding high temperature corrosion of molten salt containment materials is of great importance to improve energy-efficiency and reduce cost of thermal energy storage systems used with concentrating solar power plants. We have developed and implemented an in situ high-temperature transmission electron microscopy (TEM) diffraction and imaging approach to monitor corrosion of Inconel-625 alloy by molten eutectic $MgCl_2$–NaCl–KCl with 3 ± 1 nm spatial resolution and sub-second temporal resolution in real time. The experimental setup uses a micro-environmental cell (MEC) assembly inside a TEM with a gas flow channel and substrate heating (25-1000 °C), manufactured by Hummingbird Scientific. We also developed procedures involving a mobile vacuum transfer vessel and encapsulation in inert gas in a glove box to avoid incorporation of significant H_2O and O_2 in a Mg-chloride based salt-stack to be used for controlled corrosion studies. Quantitative in situ diffraction pattern analysis is implemented using a numerical clustering algorithm and 2D Gaussian fit functions to determine diffraction spot intensities as a function of space and time. This facilitates determination of overall corrosion rates as well as quantitative observation of the evolution of individual grains, providing microscopic insight into the nucleation and growth of the corrosion process. Multi-layered salt films (25 nm $MgCl_2$, 13 nm NaCl, and 12 nm KCl) on50 nm-thick Inconel-625 layers on TEM heater-chips are assembled into a MEC for corrosion experiments at various temperatures and ambients inside a TEM. The isothermal corrosion rate for an anhydrous, unoxidized salt-stack is 25 ± 3 nm hr^{-1} (220 ± 30 µm $year^{-1}$) at 700 °C. It increases to 40 ± 2 nm hr^{-1} (350 ± 20 µm $year^{-1}$) at 800 °C. The corrosion rate at 700 °C increases five-

fold to 114 ± 19 nm hr^{-1} (1000 ± 170 μm $year^{-1}$) when the salt stack is air-exposed. These isothermal corrosion rates indicate that the molten chloride corrosion is significantly accelerated by salt hydration from air exposure. Real-time imaging of the microstructure suggests that corrosion is initiated at grain-boundaries.

Reaction Rate Constant Parameterization Methods for Simplified Electrochemical Lithium-Ion Models Alain Goussian[1], Sylvain Franger[1], Loïc Assaud[1] and Issam Baghdadi[2]; [1]Université Paris-Saclay, France; [2]Stellantis, France

The modeling of lithium ion batteries (LIB) requires to fulfill two main aspects to: i) finding a system of relevant equations and ii) defining adequate unambiguous parameters. Actually, the parameterization of an electrochemical LIB model could be time consuming and the choice of the inputs is thus crucial. However, among all the parameters needed for an accurate model, the kinetic rate constants is often forgotten in the literature, when it comes to identify its value and dependency, whereas it takes a major part in electrochemical processes. Moreover, this parameter is believed to have a huge sensitivity over the entire model. Thus, our study is exploring, suggesting and comparing different approaches to estimate this reaction rate constant value and its dependency over other state variables, in order to identify an efficient method to determine this important parameter while accelerating parameterization phase and getting a more trustful result of the overall model.

Solid-Liquid Interactions of Oxygen Evolving Oxide Catalysts Probed in Real-Time Tzu-Hsien Shen[1], Liam Spillane[2], Jiayu Peng[3], Yang Shao-Horn[3] and Vasiliki Tileli[1]; [1]Ecole Polytechnique Federale de Lausanne, Switzerland; [2]Gatan, United States; [3]Massachusetts Institute of Technology, United States

The improvement of the electrocatalyst performance for the oxygen evolution reaction (OER, $4OH^- \rightarrow O_2 + 2H_2O + 4e^-$) requires fundamental understanding of the active sites during operation [1]. Here, we use electrochemical liquid-phase transmission electron microscopy (TEM) in combination with electron energy-loss spectroscopy (EELS) to probe solid-liquid interfacial interactions of the OER catalysts in real-time. The wetting behavior of Co-oxide particles is revealed and the catalytic products during the oxygen evolution reaction are detected at a single particle level. Three different crystal structures were evaluated: the rocksalt CoO, the spinel Co_3O_4, and the highly OER-active perovskite $Ba_{0.5}Sr_{0.5}Co_{0.8}Fe_{0.2}O_{3-\delta}$ (BSCF) [2]. By analyzing the contrast of sequences of TEM images, the oxide surfaces are found to switch from hydrophobic to hydrophilic character under anodic potential due to electrowetting induced by OH^- accumulation at the interface [3]. The process is fully reversible and the extent of its stability is linked to the underlying $Co^{2+/3+}$ redox reaction as well as the oxyhydroxide phase transformation on the spinel surfaces [4]. At high anodic applied potential, the evolution of molecular oxygen, probed site-specifically from areas surrounding the single particles, enhances the apparent hydrophilicity of the surfaces. These observations, performed in real-time and at a single particle level, provide unique nanoscale insights into the solid-liquid interactions of catalysts in their native environment.

Mapping Lithium with *Operando* Synchrotron X-Ray and Neutron Imaging Techniques Ingo Manke[1], Markus Osenberg[1], Nikolay Kardjilov[1], Robert Bradbury[1], Wolfgang Zeier[2], Ohno Saneyuki[3], Alessandro Tengattini[4], André Hilger[1], Joachim Binder[5], Kang Dong[1] and Fu Sun[6]; [1]Helmhotz-Zentrum Berlin, Germany; [2]University Münster, Germany; [3]Kyushu University, Japan; [4]Universite Grenoble, France; [5]Karlsruhe Institute of Technology, Switzerland; [6]Chinese Academy of Sciences, China

The three-dimensional structure and morphology of the electrode has a strong influence on the performance characteristics of a battery. Optimizing 3D structure and morphology is one of the key issues in the development of battery materials. Good electrical conductivity and sufficient Li-ion transport must be ensured at every point of the entire electrode at all times. Furthermore, changes of the 3D structure during cycling are often a main reason for capacity fading. The 3D structure has to be stable over hundreds of cycles. Therefore, a well designed 3D structure is essential for improving storage capacities and longevity. Radiographic and tomographic measurement techniques based on (synchrotron) X-rays and neutrons are ideally suited to obtain detailed information on the electrode structures. If properly used these techniques are non-destructive and allow for operando studies of structural changes during cycling in the cell.
This presentation will give an overview of recent developments in the field of operando imaging on batteries at Helmholtz-Zentrum Berlin (HZB) with a special focus on lithium mapping. To study the distribution of lithium and/or the lithiation process in a battery electrode different imaging techniques are of particular importance: 1. Synchrotron X-ray phase contrast imaging is well suited for analysis of lithium degradation when no strong X-ray absorbers are nearby. The high spatial resolutions allow studying small effects at interfaces of Li anodes or inside of a separator material. Some examples for Li anode degradation and Li dendrite formation will be shown. 2. X-ray absorption edge spectroscopic imaging at a synchrotron provides spatially resolved chemical information on the lithiation process even inside strong X-ray absorbers like NMC particles. The high spatial resolution also allows the analysis of individual battery particles. 3. Neutron imaging has a high sensitivity to lithium and allows studying in particular solid state electrolyte batteries during cycling. Some results will be presented and the use of Li isotopes for contrast enhancement will be discussed.
Finally, the talk will give some insights into the use of machine learning tools and the training of neural networks for optimized data segmentation and data analysis.

8:30 AM CH01.18.02
Operando Atomic Force Microscope-Scanning Electrochemical Microscopy (AFM-SECM) of pH Gradients at Gas Diffusion Electrodes Nathan T. Nesbitt[1,2], Thomas Burdyny[2], Divya Bohra[2], Recep Kas[3,2] and Wilson Smith[1,3,2]; [1]National Renewable Energy Laboratory, United States; [2]TU Delft, Netherlands; [3]University of Colorado Boulder, United States

Electrochemical carbon dioxide reduction (CO_2R) to renewable chemical feedstocks and fuels at high current density creates a high local concentration of hydroxide near the cathode. Due to diffusion limitations of hydroxide and homogeneous carbonate/bicarbonate reactions being out of equilibrium, this creates a pH gradient in the electrolyte between the cathode and the electrolyte bulk. Knowing this gradient is important for accurate analysis of CO_2R mechanisms, but it has yet to be measured in industrially relevant conditions. Using atomic force microscope-scanning electrochemical microscopy, we have measured this pH gradient above a gas diffusion electrode (GDE) and compared it with different transport models to determine the models' accuracy.

8:45 AM *CH01.18.03
Operando Kerr Gated Raman Spectroscopy to Investigate Ageing Processes on Lithium-Ion Electrode Interfaces Laurence J. Hardwick[1], Alex Neale[1], David Costa-Milan[1], Laura Cabo-Fernandez[1], Filipe Braga[1] and Igor Sazanovich[2]; [1]University of Liverpool, United Kingdom; [2]Central Laser Facility, United Kingdom

Ageing mechanisms have a great impact into batteries calendar life and performance. A better understanding of these complex processes is critical to improve the lifetime of the battery. Electrolyte ageing plays a key role in the decrease of capacity since insoluble species and gas by-products are formed during the electrochemical cycling of the battery. Fluorescent species are formed during cycling of lithium ion batteries as a result of electrolyte decomposition due to the instability of the non-aqueous electrolytes and side reactions that occur at the electrode surface. The increase in the background fluorescence due to the presence of these components makes it harder to analyse data due to the spectroscopic overlap of Raman scattering and fluorescence. Herein we will demonstrate both ex situ and operando Kerr gated Raman spectroscopy as an effective technique for the isolation of the scattering effect from the fluorescence. This enabled the collection of the Raman spectra of $LiPF_6$ salt and $LiPF_6$-based organic carbonate electrolyte, without the interference of the fluorescence component and the measurement of Raman bands of graphite carbon at high states of lithiation.

9:15 AM CH01.18.04
Improved *Operando* Raman Cell Configuration for Commercially-Sourced Li-Ion and Na-Ion Battery Electrodes Andy Wain[1], Tim Rosser[1], Edmund Dickinson[1], Rinaldo Raccichini[1], Katherine Hunter[2], Andrew Searle[2], Christopher Kavanagh[2], Peter Curran[2], Gareth Hinds[1] and Juyeon Park[1]; [1]National Physical Laboratory, United Kingdom; [2]Deregallera Ltd, United Kingdom

Operando Raman spectroscopy is a powerful analytical technique for observing real-time chemical changes in energy storage materials under electrochemical cycling conditions. However, the requirement for optical access to the sample surface of interest places constraints on cell geometry, leading to an unavoidable trade-off between electrochemical performance and spectral data quality. This issue is particularly prominent in the case of commercially-sourced electrode samples that have been densely processed onto metal foil current collectors, for which spectro-electrochemical cycling at industrially relevant current densities is highly challenging.

In this work we present an improved configuration for performing *operando* Raman spectroscopy on commercially-sourced alkali-ion battery electrodes, in which a spacer is used to alleviate electrolyte ion accessibility limitations and improve electrochemical cell performance compared to a previously established spectro-electrochemical cell configuration. Electrochemical simulation predicts an improvement in lithiation homogeneity and electrochemical cycling performance at higher specific currents, and this is corroborated experimentally for a foil-backed graphite Li-ion negative electrode. The wider applicability of this configuration is also demonstrated by way of a case study of hard carbon Na-ion negative electrodes measured over 50 cycles. We show that this approach enables reliable *operando* Raman spectroscopy on commercial battery electrodes under conditions of more practical relevance to industry than previous cell configurations.

Revisiting the Ethylene Carbonate–Propylene Carbonate Mystery with *Operando* Characterization Tim Melin and Erik Berg; Uppsala University, Sweden

The "EC-PC mystery" has puzzled electrochemists for decades. The historically persistent use of propylene carbonate (PC) rather than ethylene carbonate (EC) as electrolyte solvent in lithium based batteries significantly delayed their realization. The additional methyl group in PC is surprisingly the root cause of the failure of PC to form a stable solid electrolyte interphase (SEI) on the negative Li-ion electrode, but the underlying reason remains debated.[1] Several explanations have been hypothesized, mostly based on *ex situ* measurements of electrolytes and electrodes.[1,2] However, in order to obtain a detailed mechanistic understanding of the highly elusive interphase formation, *in situ* and *operando* techniques are needed.

In the presented study, electrode interphases formed as a result of EC and PC reduction are analyzed by two state-of-the-art *operando* techniques, Online Electrochemical Mass Spectroscopy (OEMS) and Electrochemical Quartz Crystal Microbalance with Dissipation monitoring (EQCM-D). OEMS and EQCM-D are techniques highly dedicated for analyzing volatile species[3] as well as viscoelastic properties of electrode interphases during their formation in operating Li-ion cells.[4] Both EC and PC based electrolytes show similar evolution profiles of H_2 and CO_2 while the extent of propylene (in the PC-based electrolyte) was significantly larger than the corresponding amount of ethylene (in the EC-based electrolyte). The findings correlate well with the EQCM measurements where a clear dissolution behavior of SEI in the PC-electrolyte was observed, while electrode mass deposition was irreversible when EC was present. Clearly, solubility of the various SEI components (primarily the dicarbonate) leads to dramatic differences in performance of PC as opposed to EC.[1] The presented study serves as a model for how *operando* techniques may provide deeper insights into well studied subjects, such as the EC-PC mystery.

Elucidating Performance-Limiting Side-Reactions in Large-Format Li-Ion Cells with *Operando* Electrochemical Mass Spectrometry Casimir Misiewicz; Uppsala University, Sweden

Advances in methodologies for real-time analysis of batteries have come an extraordinarily long way [1], especially with the development of *Operando* Electrochemical Mass Spectrometry (OEMS) . These approaches allow for the determination of side reactions during battery cycling with unprecedented selectivity and sensitivity, thus providing vital information necessary for determination of lifetime-limiting processes. However, the work thus far has primarily been carried out on model battery systems, where cell configurations and atmospheres are largely tampered with (through continuous flow [2] [3] in the *open* approach and purging [4] in the *semi-closed* approach [5]) and the operation conditions are therefore not comparable with real-life situations. Herein, the development and validation of an entirely *closed* OEMS system adapted for readily available commercial batteries is showcased. We provide a detailed description of two unique analysis designs with subsequent comparisons between them and other existing OEMS setups. Additionally, time-resolution modelling is applied to the data to determine precise gas onset points, ultimately eliminating diffusion related time delays. The prospects of utilizing OEMS for the study of commercially available rechargeable batteries after production or usage is evaluated.

Wednesday Morning, December 8, 2021
CH01-Virtual

10:30 AM *CH01.19.01
Effective Transport in Li-S Solid–State Batteries Wolfgang Zeier; University of Muenster, Germany

The advent of solid-state batteries has spawned a recent increase in interest in lithium conducting solid electrolytes, especially in the lithium thiophosphates. However, many open questions remain when trying to optimize electrolytes and understand solid state battery chemistries. Among the interesting solid-state battery systems, the conversion reaction of sulfur has been recently of interest.

In this presentation, we will show how an understanding of the chemomechanical changes as well as the interfacial decomposition reactions in Li-S solid state batteries help to better understand and design these systems.

Further, we will show that fast ionic conduction is paramount within solid state battery composites. Measuring the effective ionic transport in cathode composites provides an avenue to explore transport and stability limitations that in turn provide better criteria for solid state battery performance

11:00 AM CH01.19.02
***Operando* Surface Enhanced Raman Spectroscopy of the Stepwise Formation of Solid Electrolyte Interphases in Li-Ion Batteries** Neeha Gogoi and Erik Berg; Uppsala University, Sweden

Solid electrolyte interphase (SEI) formed due to the reductive decomposition of electrolytes on the graphite negative electrode is one of the most widely studied phenomenon in Li-ion batteries[1]. Yet, no real consensus of the governing processes has been established due to their inherent complexity and lack of dedicated characterisation techniques[2]. Herein we have employed *Operando* surface enhanced Raman spectroscopy (SERS) to investigate the SEI formation in a model electrolyte based on Lithium bis(trifluoromethanesulfonyl)imide (LiTFSI) in ethylene carbonate (EC). We observe a stepwise potential-dependent reaction process involving decomposition of both electrolyte impurities and the EC solvent. The SERS enhancement has enabled us to also identify several metastable intermediates. For instance, Li_2CO_3 is observed as an interphasial component formed primarily due to the electrochemical reduction of residual contaminants in the electrolyte. SERS provides a deeper understanding of the underlying processes during SEI formation and the dynamics of the interfacial composition during the battery cycling. Challenges when analysing the SEI and prospects for development of this approach will further be highlighted.

11:15 AM CH01.19.03
The Effects of Residual Water in Li-Ion Battery Model Systems Studied with Online Gas Analysis Robin Lundström and Erik Berg; Uppsala University, Sweden

The solid electrolyte interphase (SEI) is key to battery performance. The composition of the SEI is an assortment of decomposition products, mainly from reduced electrolyte species but also from residual contaminants, such as H_2O. The SEI both forms and changes during operation of a Li-ion battery. A full understanding of the SEI is challenging to attain with only post-mortem analysis. Therefore, analytical techniques monitoring the battery during operation, or *operando*, are needed to deconvolute the SEI formation in Li-ion batteries.
Many side-reactions, including SEI formation, in Li-ion batteries have volatile species forming as some of the decomposition products. Online Electrochemical Mass Spectrometry (OEMS) can sample the gas composition of a battery.[1] By sampling the volatile species from a battery cell during operation, a voltage-dependent gas evolution profile is gained. The result is a holistic overview of side-reactions in Li-ion batteries.

In this presentation, we deepen the study of the SEI formation on carbon electrodes and demonstrate how it is impacted by residual H_2O. Glassy carbon electrodes in carbonate-based electrolyte are studied using OEMS. More H_2O present in the battery cell has been linked to an increase[2] in CO_2 and decrease in C_2H_4 evolution[3]. We show that CO_2 and C_2H_4 evolution are connected with a linear relationship in relative amounts depending on H_2O content.
The thermal reaction between H_2O and electrolyte components can result in HF forming over time. A high HF concentration in the electrolyte breaks the linear relationship of CO_2 and C_2H_4 gas evolution, as a new major decomposition reaction affects the SEI formation. Different stages of CO_2 evolution and consumption during the formation cycle will be shown, where multiple processes are present. Unintended reactions taking place in the glassy carbon model system will be shown to have a significant impact on the SEI composition.[4] The influence of H_2O on the SEI formation in Li-ion battery systems and especially in model systems are highlighted.

11:30 AM *CH01.19.04
Using *In Situ* X-Ray Spectroscopy to Study Metal-Sulfur Batteries Lorenzo Stievano[1,2]; [1]Univ. Montpellier, France; [2]RS2E, France

Metal-sulfur batteries have been proposed in the last years as a promising energy storage technology for the future, due to the high theoretical capacity, remarkable energy density, and low cost. However, the major drawbacks of sulfur positive electrodes, such as the well known polysulfide shuttle effect and the low electrical conductivity of elemental sulfur, add to those specific of each negative electrode, such as the side reactions between metal anodes and electrolytes, are currently preventing their possible commercialization. All these effects are often interconnected, and strongly dependend upon the type and the amount of electrolyte used in the cells. Therefore a thorough understanding of the mechanisms of all these processes, both in the bulk and at the interfaces, during the lifetime of metal-sulfur batteries is necessary for mastering them and producing a viable metal-sulfur system.
Among the different technniques that have been developed for understanding these processes, in situ X-ray spectroscopies are among the most interesting ones. For instance, sulfur K-edge X-ray absorption and X-ray emission spectroscopies have been used to follow the evolution and the dynamics of the sulfur species in a working battery, while ex situ X-ray photoelectron spectroscopy was employed to study the evolution of the interfaces and the aging mechanisms of the metal-sulfur cells.
In this presentation, an overview of the application of X-ray spectroscopy methods to the study of metal-sulfur batteries is presented. It will be shown how these techniques together provide a unified view of metal-sulfur systems, suggesting possible strategies to circumvent their main drawbacks and thus enabling their practical applications.

12:00 PM CH01.19.06
***Operando* X-Ray Scattering with Stochastic Modelling to Quantify the Nanoscale Phase Evolution in Post-Lithium-Ion Batteries** Christian Prehal[1,2], Heinz Amenitsch[2], Stefan A. Freunberger[3,2] and Vanessa Wood[1]; [1]ETH Zurich, Switzerland; [2]Graz University of Technology, Austria; [3]IST Austria (Institute of Science and Technology Austria), Austria

Properties and function of beyond intercalation-type batteries are not only rooted in the chemistry but at least as much in the structure all the way from atomic to sub-micrometer length scales. This concerns specifically complex transformations such as the electrodeposition of insulating materials in conversion-type lithium-sulfur (Li-S) or lithium-air (Li-O_2) battery electrodes. Substantial performance improvements, therefore, rely on a quantitative physico-chemical understanding at all relevant length scales, which puts high demands on (*operando*) analytical techniques.
Here we present *operando* small and wide angle X-ray scattering (SAXS / WAXS) as a suitable method to study the nanoscale phase evolution of solid Li_2O_2 during charging and discharging a custom-built *operando* Li-O_2 cell. For data analysis, our recently developed method used for supercapacitors was adapted [1] and synergistically combined with modelling of Li_2O_2 nucleation and growth in a realistic 3D carbon pore model generated via stochastic modelling. This allows visualizing the nanoscale product formation in real-time and distinguishing between Li_2O_2 formed via disproportionation (solution mechanism) or direct electroreduction (surface mechanism). Contrary to what current knowledge predicts, we find that Li_2O_2 is formed to the widest extend via solution mediated disproportionation of LiO_2, even under conditions previously considered prototypical for Li_2O_2 surface growth [2]. Results were backed up by hydrodynamic voltammetry, electron microscopy and numerical modelling, and question significant parts of the currently accepted reaction model in Li-O_2 batteries [3].
Next to Li-O_2 batteries, the potential of the method is demonstrated by quantifying the reversible electrodeposition of solid reaction products during charging and discharging a custom-built *operando* Li-S cell. In situ SAXS / WAXS data analysis was combined with stochastic modelling of the three-phase nanostructure Li_2S / Li_2S_4 / electrolyte using the concept of PluriGaussian random fields [4]. The hierarchical Li_2S_4 – Li_2S composite nanostructures formed during Li-S discharge indicate that Li_2S forms via solid-state disproportionation of higher-order polysulfides rather than direct electroreduction at the carbon-electrolyte interface. Structural information derived from X-ray scattering was complemented by cryo (scanning and transmission) electron microscopy and small angle Neutron scattering. The found mechanism provides novel design criteria for improved capacities and improved cycle life in Li-S batteries.

Probing Interface Stability and Charge Distribution in Solid-State Batteries *via* STEM Miaofang Chi; Oak Ridge National Laboratory, United States

Solid-state batteries hold the promise of safer, cheaper, and longer-lasting batteries. Its largest bottleneck lies in their interfaces, including both interfaces with electrodes and internal grain boundaries. For example, many current solid electrolytes either involve concerning interfacial stability with electrodes and/or an unexpected dendrite growth along their grain boundaries. The associated underlying origins however remain unknown. To understand the interfacial mechanisms at play, the electrochemical stability, mechanical stability, and local potential variations, must be studied correlatively and ideally, under simulated operation. In this talk, I will show several examples of elucidating the interface stability, overpotential, and dendrite growth mechanism in model solid electrolytes, including lithium phosphorus oxynitride (LiPON), $Li_xLa_{2/3-x/3}TiO_3$ (LLTO) and Al- $Li_7La_3Zr_2O_{12}$ (LLZO). This presentation will also demonstrate the power of utilizing a suite of scanning transmission electron microscopy techniques, including cryogenic high-resolution imaging, in situ biasing microscopy, differential phase-contrast imaging, and low loss electron energy loss spectroscopy (EELS) to probe features defining the function of interfaces in solid-state batteries.

This research was supported by an Early Career project supported by the DOE Office of Science FWP #ERKCZ55. All microscopy technique development was performed and supported by Oak Ridge National Laboratory's (ORNL) Center for Nanophase Materials Sciences (CNMS), which is a DOE Office of Science User Facility.

Modelling X-Ray Absorption Spectra for Dynamic Interfaces in Multivalent Electrolytes Ana Sanz-Matias and David Prendergast; Lawrence Berkeley National Laboratory, United States

The increasing demand of large-scale energy storage with improved performance, safety and sustainability for renewable variable energy sources drives the search for post-Li-ion batteries based on multivalent cation chemistries (e.g., Mg, Zn and Ca). However, poor electrolyte stability against metal anodes and high voltage cathodes has been so far one of many barriers to the development of multivalent cation rechargeable batteries. (Electro)chemistry at the electrolyte-electrode interface is critical to battery performance. Multivalent cations are prone to complex formation with solvent molecules and anions, leading to different interfacial species with characteristic (electro)chemical properties. Although multivalent cation solvation/complexation structures have been investigated in the bulk, fundamental understanding of speciation at the interface is lacking.

Fluorinated anions are often used in multivalent and other post-Li-ion electrolytes. Fluorine K-edge X-ray Absorption Spectroscopy provides access to a surprising level of detailed electronic structure information about the anion coordination and decomposition process, despite the relatively predictable oxidation state and ionicity of the fluoride ion. In this work, we examine the sensitivity of the F K-edge to the fluorine bonding environment in solid, liquid and interfacial species relevant to energy applications. Utilizing a combination of Molecular Dynamics simulations and a recently developed many-body approach based on the ΔSCF method, we calculate the X-ray absorption spectra of multiple fluoride salts using density functional theory. Thin films and surfaces are also explored to establish whether they provide distinct spectral signatures that might be observable in the solid electrolyte interphase of working electrodes. At last, the solid-liquid interface of non-aqueous, Mg based electrolytes with fluorinated anions are examined.

Nucleation and Growth of Transition Metal Alloy Nanoparticles from Transition Metal Hydroxide Complexes Observed in Graphene Liquid Cells Azadeh Amiri, Abhijit H. Phakatkar and Reza Shahbazian-Yassar; University of Illinois Chicago, United States

The nucleation and growth of crystalline nanoparticles is an important fundamental process of synthesis in many applications to better control and engineer the properties of nanoparticles. In-situ studies of electron beam-induced formation of metal nanoparticles from the precursor solution in the liquid-cell transmission electron microscopy (LCTEM) is one of the helpful methods to reveal the nucleation and growth mechanism.[1,2] Especially, employing graphene liquid-cell (GLC) which encapsulates the liquid solution between thin graphene layers allows high-resolution imaging and better visualization of the important steps of nanocrystals nucleation and growth.[3,4] In this work, using the GLC microscopy technique, nucleation and growth of transition metal alloys in an equimolar aqueous mixture of Mn, Fe, Ni, and Zn chloride salt precursor solution under electron beam is studied.
The radio-chemistry formation of metallic particles commonly involves three major steps of (1) production of metal atoms in solution by electron beam-induced reduction of metal ions; (2) nucleation of solid-phase by atom clustering; and (3) growth of nucleated particles by monomer addition and particle coalescing. Solvated electron () produced by the radiolysis of water is a very strong reducing agent to reduce the transition metal ions with negative reduction potential to their zerovalent state. However, other ionic and radical species products of water radiolysis present in the solution can also react with metal atoms and oxidize them back to positive valence ionic states. Polyvinylpyrrolidone (PVP) is added to precursor solution can act as a strict stabilizer and a scavenger of OH radicals and minimize their oxidizing effect.
The transition metal salts dissolved in water were initially found as nanorod shape crystallin precipitates inside the GLC (Figure 1a). The analysis of the *fast Fourier transforms* (*FFT*) diffraction pattern matches the monoclinic crystalline structure of used transition metal hydroxide ($TM(OH)_2$). (Figure 1b). The direct transformation of metal hydroxide nanorods to metal nanoparticles was observed by focusing the electron beam on a smaller screening area. As a result of increasing the magnification, the electron dose increases, and metal ions are reduced to metal atoms. The nucleation of nanoparticles is detected in few seconds at two sides of the long rods and they grow to 2 nm size particles in 10 s. Then 3-4 adjacent small particles start to coalescence and make the bigger particles. The growth of particles is slowed down after reaching 5 nm in less than 60 s. (Figure 2). The in-situ formed nanoparticles have a FFC crystalline structure close to the FCC structure of transition metals used which shows a single-phase multi-metallic alloy is formed in the solution and at room temperature. (Figure 2c-d)

***In Situ* Transmission Electron Microscopy Studies of Multi-Elemental Nanoparticles Synthesis in Liquid Flow Cells** Azadeh Amiri, Abhijit H. Phakatkar and Reza Shahbazian-Yassar; University of Illinois Chicago, United States

Multi-element alloy nanoparticles are important materials for different catalysis and energy conversion applications due to the compositional complexity and lattice distortion.[1-2] Yet, fabrication of homogenous multi-metallic particles composed of miscible and immiscible elements is challenging and needs special kinetically controlled synthesis methods. [3-4]
In this work, we studied the in-situ colloidal synthesis of multi-element alloys through different equilibrium and non-equilibrium growth mechanisms. An equimolar aqueous mixture of Au, Pt, Ir, Cu and Ni chloride is used as the precursor solution and polyvinylpyrrolidone (PVP) is added as a stabilizer. A liquid flow holder integrated with microfluidic tubing is used to gradually inject the precursor solution into the liquid cell. The time-lapse series of TEM images show the fast formation of particles in solution entered into the liquid cell by electron beam reduction of metal ions, followed by nucleation of and growth id particle seeds. The crystalline phase structure, elemental composition and distribution of formed nanoparticles are identified by ex-situ aberration-corrected scanning transmission electron microscopy (STEM), energy-dispersive X-ray spectroscopy (EDS) and high angle annular dark field imaging (HAADF) characterization techniques.
Due to the difference in miscibility and reduction rate kinetics of metallic elements, particles formed in liquid cells have different sizes, morphologies, and compositions. Three different types of particles are detected as AuCu alloy, PtCuIrNi alloy and Ni@Cu core-shell nanoparticles. Larger particles with a size of 20-30 nm are gold-rich AuCu alloy with near hexagonal morphologies. The second type of detected particles are Ni@Cu core-shell 8-10 nm in size. Nickel has the lowest reduction potential and is more likely to be oxidized by oxidizing radicals and ions product of water radiolysis. The formation of Ni@Cu core-shell nanoparticles can be explained by the slower reduction rate of transition metal elements compare to noble metals used in the mixture. The third type of particle has the smallest size and most complex composition. The PtCuIrNi particle are 2-3 nm in size and have a single FCC crystal structure. The crystal of these multicomponent nanoparticles is composed of atoms with different size and binding energies which results in lattice distortion and complex surface energies of lattice planes. This complex structure and surface energies of crystal facets hinder the fast coalesce of nanoparticles and further growth of particles. This is n promising mechanism for the synthesis of small nanoparticles with increased surface area and highly active surface sites for many catalysis applications.

***Operando* XRD and Lattice Models as Tools to Determine Phase Diagrams—The Case of $LiNiO_2$** Matteo Bianchini[1,2], Markus Mock[1], Francois Fauth[3], Karsten Albe[4] and Sabrina Sicolo[1]; [1]BASF SE, Germany; [2]Karlsruhe Institute of Technology, Germany; [3]ALBA Synchrotron, Spain; [4]Technische Universität Darmstadt, Germany

Operando X-ray diffraction (XRD) is an established technique to observe cathode active materials (CAMs) and their crystallographic transformations upon Li (de)intercalation in Li-ion batteries.[1] With synchrotron radiation, high intensity and excellent temporal and angular resolution can be obtained, yielding accurate Rietveld refinement results.[2] This allows tracking unit cell symmetry and volume, atomic positions and even site occupancy factors; in other words it allows real-time investigations of compositional phase diagrams as a function of lithium content. In this respect, a complex and still debated CAM is $LiNiO_2$, which benefits nowadays of a wave of renewed interest fueled by the industry moving towards high-Ni layered CAMs.[3] In this respect, it also becomes important to study LNO with operando XRD in electrochemical setups resembling commercial applications, such as unmodified pouch cells.
In this presentation we will show that synchrotron XRD can indeed be used to measure pouch half cells in transmission mode to investigate CAMs, with a focus on $LiNiO_2$. Despite the fact that its phase diagram has been the object of numerous experimental and computational studies over the last two decades, even between recent experimental studies inconsistencies emerge on the position and width of single- and two-phase fields[4,5]. Modelling of the phase diagram has always been a daunting task and resulted in the prediction of several stable Li phases that were not observed experimentally. Aiming at resolving the sources of discrepancy among experiments and between experiments and theory, we combine operando synchrotron XRD and Rietveld refinement with Monte-Carlo Simulation using a modified cluster expansion formalism at the Density Functional Theory (DFT) level[6]. A surrogate lattice model pinpoints the influence of off-stoichiometry ($Li_{1-z}Ni_{1+z}O_2$) and elemental substitution on the phase diagram and yields an unprecedented match to experimental ones. The dominant effect of both off-stoichiometry and elemental substitution is to disrupt Li ordering, suppressing phase transitions and promoting solid-solution behavior and the corresponding smoothing of voltage curves. Our model is particularly effective at reproducing the monoclinic domain and allows to draw a correspondence between electrochemical features (dx/dV curve) and Li-vacancy orderings (including the first identification of a $Li_{5/8}NiO_2$ superstructure). Deviations from experiments at both ends of the phase diagram are resolved and attributed to faulting and sluggish kinetics at high and low state of charge, respectively. The formation of stacking faults, in particular, known from ex situ observations[7], is investigated for the first time under operando conditions.

2:10 PM CH01.03.03
Structural Evolution of All-Solid-State Li-Ion Battery Using *Operando* TEM and X-Ray Micro-CT Sorina Cretu[1,2,3], Martial Duchamp[2] and Arnaud Demortiere[1,3,4]; [1]Laboratoire de Réactivité et de Chimie des Solides, France; [2]Nanyang Technological University, Singapore; [3]RS2E-French Research Network on Electrochemical Energy Storage, France; [4]ALISTORE- European Research Institute, France

Conventional lithium-ion batteries (LiB)[1] are the most efficient energy storage devices that triggered the transformation of our lifestyle into a digital nomad with the revolution of portable electronics. Compare to conventional liquid electrolyte, inorganic solid-state electrolytes (SSE) represent a promising alternative due to their nonflammable nature, broader temperature operating range and larger electrochemical window. Therefore, all-solid-state-batteries (ASSB) made an important step toward new-generation in electrochemical energy storage systems[2]. However, several limitations still impact the performances of ASSBs such as SSE ionic conductivity, chemical evolution of SSE/active-materials interface, lithium dendrite growth, grain boundary conductivity and solid/solid interfacial resistance[3].
To get a better insight into the limiting parameters of the performances of the ASSBs, a better quantification of the relationship between the structural and electrochemical properties is strongly required. In this study, we propose an approach to carry out *Operando* Transmission Electron Microscopy (TEM) measurements[4] and X-ray micro computed tomography (XCT)[5] to study the chemical and morphological modifications while operating the ASSB focusing on the multiple solid/solid interfaces at a local scale using the TEM, but also having a general view using the XCT.
For this study ASSB using a oxide solid electrolyte, $Li_{1.5}Al_{0.5}Ge_{1.5}(PO_4)_3$ (LAGP)[6] was used due to their high stability in the air. Different batteries configuration was used for the *operando* TEM experiment and XCT. In the case of Operando TEM an $LiFePO_4$ (LFP)/LAGP/$Li_3V_2(PO_4)_3$ (LVP) battery was studied where LFP was choose as cathode material due to its safety and price attractions. One of the most difficult part in the realization process of the *operando* TEM experiment was represented by the production nanobattery process where the electrolyte layer must be thin enough (maximum 20 nm) to allow a full battery to be connected to the chip which allows applying bias. In the case of operando XCT NMC/LAGP/Li metal battery was studied where NMC and Li metal were chosen due to their high energy density.
A home-made electrochemical cell designed for tomography requirements has been used for monitoring Li dendrite, cracks formation, LAGP degradation in real-time during (de)lithiation process. The contact between lithium metal and solid electrolyte generated the formation of an instable interface where dendrites penetration in the solid electrolyte throw a delamination effect was spotted. Lithium exchange process produced extra stress and volume increase in the material which generated the production of the cracks in the battery. Once the irreversible process of the cracks started, lithium metal penetrated inside the cracks and slowly filled them, in the end producing the short-circuit the battery.
Operando TEM analysis allowed us a more local analysis where the solid/solid interface between cathode and solid electrolyte was studied at nanoscale. The appearance of cracks while cycling that was noticed using XCT was confirmed also with the TEM analysis. The migration of the cathode elements inside the solid electrolyte at the local scale upon cycling was noticed after the bias was applied offering us insights of the solid/solid interface in the ASSB at a local scale. The quantification of the dynamics of Li dendrite formation and the morphological changes within ASSB open new opportunities to attenuate failure processes occurring during the (de)lithiation mechanism.

Dynamically-Controlled Optoelectronic Behavior of Metal-Organic Materials Natalia Shustova; University of South Carolina, United States

Modulation of electronic properties as a function of external stimuli is driven by multifunctional device development. For instance, optical control over material electronic structures offers a powerful approach for optical switch integration, memory device evolution, and photocatalyst development. Tailoring electronic properties of metal-organic frameworks (MOFs) was previously achieved through metal node engineering, redox-active linker installation, or guest incorporation. We coupled previously applied synthetic strategies in this research area with the possibility of dynamically modulating electronic properties through integration of photoresponsive moieties within a framework.[1–3] In this presentation, a photophysics–electronics correlation will be discussed as a function of external stimuli. Optical cycling, modeling of density of states near the Fermi edge, conductivity measurements, and photoisomerization kinetics were employed to shed light on the process of tailoring MOF optoelectronic properties. This talk will also cover our recent efforts for engineering the first photochromic MOF-based field-effect transistor, in which the field-effect response could be changed through light exposure. As a demonstration, the change in current upon light exposure was sufficient to operate a two-LED fail-safe indicator circuit.[1]

2:00 PM CH02.01.02
Late News: Host-Guest Catalyst Systems for CO2 Conversion Using Transition Metal Complexes Encapsulated in Metal-Organic Frameworks Jeffery Byers[1], Chia-Kuang Tsung[1], Zhehui Li[1], Thomas Rayder[1,2], Enric Adillon[1,3], Banruo Li[1] and William Thompson[1]; [1]Boston College, United States; [2]The Ohio State University, United States; [3]California Institute of Technology, United States

The construction of host-guest catalyst systems for CO_2 hydrogenation reactions is described wherein molecular ruthenium-based complexes are encapsulated in the metal-organic framework (MOF) UiO-66. Encapsulation of the molecular complexes is made possible by utilizing an aperture-opening methodology that capitalizes on the dissociative ligand exchange process that occurs for the UiO-66 MOF. Through this method, host-guest catalyst constructs can be synthesized that decouple the synthesis of the transition metal complex, which serves as the catalytically active subunit, with the MOF host material. This advantage was used to develop a variety of catalysts used for the hydrogenation of carbon dioxide to useful fuels, such as formic acid and methanol. The method enables multicomponent catalytic systems that benefit from cascade catalysis. Additionally, the method is ammenable for installing functional groups that modulate catalytic function through second-sphere intereactions, which come about through modifications made to the MOF host material.

An Architectural Perspective on Heterogeneous Catalysis Debra R. Rolison, Paul A. DeSario, Catherine L. Pitman, Jeremy J. Pietron, Ashley M. Pennington, Todd Brintlinger, Evan R. Glaser, Travis G. Novak, Rhonda Stroud and Michelle D. Johannes; U.S. Naval Research Laboratory, United States

Our team investigates transport functionality—ion, electron, and mass—using aerogels as an ultraporous mesoscale platform that innately wires in three dimensions these three necessary mobilities for catalysis [1]. We track performance with a model bifunctional catalytic reaction: oxidation of carbon monoxide at metal nanoparticles (NPs) supported on reducing oxides. We can use the flexibility of sol–gel routes to prepare oxide aerogels as a means to site Au NPs either in the covalently bonded oxide network of TiO_2 or supported on the network using conventional routes to oxide-supported metals. We find that Au||TiO_2 interfacial design strongly impacts charge carrier (electron and proton) transport over mesoscale distances in the metal guest–oxide host architecture with implications for catalytic oxidations and controls the activity of CO oxidation under broadband illumination [2]. The intimacy of interfacial contact between Cu NPs supported on either TiO_2 or CeO_2 aerogels maintains the Cu NPs in a sufficiently metallic state to sustain a plasmonic response without ligand stabilization or during exposure to water/O_2 conditions or CO oxidation. The CeO_2 support also markedly increases activity for the thermal catalysis of CO oxidation over that obtained for Cu NPs supported on titania aerogels enabling Cu-based rather than Au-based oxidative catalysis [3].

2:30 PM *CH02.01.05
Enhancing MOF Performance Through the Introduction of Polymer Guests Shuliang Yang, Daniel T. Sun, Li Peng, Vikram V. Karve, Natalia Gasilova, Mehrdad Asgari, Emad Oveisi, Olga Trukhina and Wendy L. Queen; École Polytechnique Fédérale de Lausanne (EPFL), Switzerland

Abstract: Among several classes of porous materials, metal-organic frameworks (MOFs) are particularly attractive due to their unprecedented internal surface areas (up to 7800 m^2/g),[1] easy chemical tunability, and strong, selective binding of a host of guest species. Through judicious selection of MOF

building blocks, which include metal ions and organic ligands, one can readily modify their properties for a variety of potential applications. Despite these attractive features, there are still challenges in the field that limit our ability to use MOFs as a solution for a wide range of industrial problems. For instance, some MOFs have limited mechanical and chemical stability, particularly in highly humid, acidic or basic environments. Overcoming this problem could lead to extended lifetimes and hence increased feasibility for their use in areas where such conditions are required.
In response to these needs, we have recently begun to combine MOFs and polymers in an effort to boost MOF performance and extend their stability. Our recent work demonstrates that selected polymers can significantly enhance MOF performance in a number of important liquid and gas separations[2-4] as well as extend catalyst lifetimes in selected reactions.[5] In addition to this, controlled polymerization processes were employed to enhance the mechanical stability[6] of large pore frameworks and extend the chemical stability of a number structurally diverse MOFs not only in humid environments, but also in acidic and basic media.[7] We hope such work can help bring these frameworks a few steps closer to their deployment into a range of ecologically and economically important applications. In this presentation, our recent work, devoted to the development of novel MOF polymer composites, will be outlined.

3:30 PM CH02.01.06
Clathrate Behavior from a Molten Hydrogen-Bonded Organic Framework Adam H. Slavney and Jarad A. Mason; Harvard University, United States

Solid-state framework materials represent a unique class of solids in which chemists are able to exercise fine control of the crystalline structure through a carefully tuned combination of strong, directional bonding interactions and rigid organic struts. This level of control has enabled the design of highly effective materials for uses as varied as ion transport and gas capture and storage. However, despite these achievements, normal liquids remain the media of choice for many industrial adsorption applications as their fluidity greatly simplifies process design. As a means of bridging the liquid and solid adsorption paradigms we are interested in investigating the molten phases of framework materials. Due to their strong bonds, most framework materials decompose prior to melting. The few zeolitic imidazolate frameworks (ZIFs) which have been shown to melt do so at ~400 °C, temperatures too high to observe appreciable physisorptive interactions with guest molecules. We hypothesized that replacing the strong metal-ligand coordination bonds used in many frameworks with weaker hydrogen bonds would lead to significantly lowered melting points.

I will discuss our work on creating hydrogen-bonded frameworks (HOFs) with low melting points. By borrowing anti-crystal engineering strategies from the ionic liquid literature, we successfully lowered the melting point of a guanidinium sulfonate HOF from ~200 °C to as low as 70 °C. In fact, our molten HOF is itself an ionic liquid, albeit a very viscous one. The melting point of the framework is strongly dependent on its interactions with physisorbed guest species and can vary from 70 – 140 °C with different guests. In the absence of guests molecules, the HOF ionic liquid does not crystallize instead vitrifying into a glassy state at 45 °C. This phase behavior is strongly reminiscent of the clathrate hydrates; where water crystallizes into a network of hydrogen-bonded cages with encapsulated non-polar guests at low temperatures and high gas pressures. We demonstrate that the phase diagram of our HOF-guest system is isomorphic with that of a typical clathrate hydrate, emphasizing this connection. We suspect that the clathrate-like behavior we observe in our HOF may be a general phenomenon of molten frameworks at sufficiently low temperatures and this conceptual framework might be useful for future studies on molten framework materials.

Reactivity and Catalysis with Hydride Compounds Yoji Kobayashi; King Abdullah University of Science and Technology, Saudi Arabia

Hydrogenations are an integral part of many catalytic reactions. It is also natural to ask, then, whether this reaction can be catalyzed by hydride compounds. In solid state chemistry, the development of many new hydrides and related mixed-anion compounds has been reported; these advances form an excellent basis for developing new catalysts. We are interested in how these hydrides interact with small molecules, and whether they can lead to novel catalytic materials. Often, these are active as bulk materials, even without any supported metal. We will present how these materials can be used for ammonia synthesis/decomposition and CO_2 hydrogenation, while examining how the bulk structure/composition is involved.

SESSION CH02.02: Dielectric, Magnetic and Superconducting Materials I
Session Chairs: Brent Melot and Katharine Page
Tuesday Morning, November 30, 2021
Hynes, Level 3, Room 302

10:30 AM *CH02.02.01
Dielectric Behavior to Identify New Electronic Materials David J. Singh[1], Xin He[2], Patsorn Boon-on[3], Ming-Way Lee[3] and Lijun Zhang[2]; [1]University of Missouri, United States; [2]Jilin University, China; [3]National Chung Hsing University, Taiwan

Dielectric screening plays an important role in reducing the strength of carrier scattering and trapping by point defects for many semiconductors such as the halide perovskite solar materials. However, it was rarely considered as a screen to find new electronic semiconductors. We performed a material search study using the dielectric properties as a screen to identify potential electronic materials in the class of metal−pnictide ternary sulfosalts, containing Bi or Sb. These salts are basically ionic due to the electronegativity difference between the S and both the metal and pnictogen elements. However, we do find significant cross-gap hybridization between the S p-derived
valence bands and pnictogen p-derived conduction bands in many of the materials. This leads to enhanced Born effective charges and, in several cases, highly enhanced dielectric constants. We additionally find a series of compounds with low effective mass, high dielectric constant, and other properties that

suggest good performance as electronic materials and also several potential thermoelectric compounds.

11:00 AM CH02.02.02
Tuning La_2O_3-Type Structure Magnetic Topological Candidates Madalynn Marshall[1], Antonio Moreira dos Santos[2], Huibo Cao[2] and Weiwei Xie[1]; [1]Rutgers, The State University of New Jersey, United States; [2]Oak Ridge National Laboratory, United States

Within the condensed matter science community, interest in topological materials has grown rapidly. An exciting direction is the combination of topological electronic states with additional quantum phases including magnetic topological materials, which have a range of applications including spintronics, thermoelectric and photovoltaics. Previously, our group discovered the trigonal La_2O_3-type Mg_3Bi_2 material to be a type-II nodal-line semimetal. The strong spin orbit coupling (SOC) Bi layers in this structure create an ideal environment for the topological electronic states. To drive this material even further magnetic elements can be introduced, potentially leading to a coupling between the magnetism and topological quasiparticles that can be additionally enhanced through pressure techniques. Widely accepted as a beneficial clean tool, pressure has the ability to tune the electronic interactions in quantum materials through the atomic distances. In this work we explore various La_2O_3-type structure magnetic topological candidates consisting of either 3*d* or 4*f* magnetic elements. Various pressure techniques have been utilized to observe the intricate tuning of the magnetic and electronic properties in these materials including high-pressure neutron diffraction, revealing evident nuclear and magnetic structure transitions. Manipulating these materials will result in a further understanding of our ability to control the magnetic and topological properties.

11:15 AM CH02.02.03
Highly Improved Ferroelectricity and Reliability in $Hf_{0.5}Zr_{0.5}O_2$ Films Using a HfO_xN_y Interfacial Layer Beom Yong Kim[1], Hyeon Woo Park[1], Yong Bin Lee[1], Suk Hyun Lee[1], Minsik Oh[1], Seung Kyu Ryoo[1], In Soo Lee[1], Doosup Shim[1], Min Hyuk Park[2,1] and Cheol Seong Hwang[1]; [1]Seoul National University, Korea (the Republic of); [2]Pusan National University, Korea (the Republic of)

Since the ferroelectric (FE) property was first reported in the fluorite-structured Si-doped HfO_2 thin film in 2011, numerous researches on this emerging material have been conducted for memory and energy-related applications. The FE characteristic appears in the HfO_2 thin film because of the formation of the polar orthorhombic (o) phase. Although the non-polar monoclinic (m) phase is a thermodynamically stable phase in bulk HfO_2, it has been reported that the o-phase can be formed in HfO_2 thin films by controlling various factors such as dopants, surface energy, mechanical encapsulation, oxygen vacancies, and cooling rate. Meanwhile, the chemically reactive TiN bottom electrode (BE) has a tendency to induce a chemical reaction with the growing HfO_2 film, which can cause defects in the film and produce an unwanted interfacial dielectric layer. The former could significantly degrade the reliability through a leakage current flow and the eventual breakdown of the film during the endurance cycle tests, whereas the latter may degrade the remanent polarization (P_r) by inducing the depolarization effect. In this regard, the nitride interfacial layers, especially HfN_x (or HfO_xN_y) and ZrN_x (or ZrO_xN_y), are noteworthy. The inclusion of nitrogen may suppress the unwanted chemical between the (Hf, Zr)O_2 (HZO) film and the TiN BE, which could improve the reliability of the HZO film and suppress the depolarization effect. Among the HfN_x and ZrN_x, HfN_x could be more promising because it may suppress the in-situ crystallization of the HZO film during its atomic layer deposition (ALD), which adversely interfere with the o-phase formation.
In this study, the enhancements in the FE performance of the HZO-based TiN/HZO/TiN device with the insertion of $HfO_{0.61}N_{0.72}$ interfacial layer (IL) were examined in detail. After optimizing the growth condition of the HfO_xN_y layer by the reactive sputtering, a 2-nm-thick $HfO_{0.61}N_{0.72}$ IL was deposited on the TiN BE, which was oxidized in-situ to the $HfO_{1.62}N_{0.34}$ during the subsequent ALD of the HZO thin film. The adoption of the 2-nm-thick $HfO_{0.61}N_{0.72}$ IL suppressed the uncontrolled growth of larger HZO grains during the subsequent rapid thermal annealing process, which was accompanied by a more than 60% decrease in the inclusion of the undesirable m-phase compared to the structure without the IL. This improvement resulted in a ~30% increase in $2P_r$ without any change in the coercive field. Such improvement was maintained up to the HZO thickness of 20 nm. This could be ascribed to the formation of an amorphous $HfO_{1.62}N_{0.34}$ IL on the TiN BE, which suppressed the unwanted in-situ inclusion of the crystalline nuclei in the HZO film during the ALD of the HZO film. Also, the slight inclusion of the nitrogen atoms at the bottom interface enhanced the reaction barrier property against the adverse chemical reaction with the reactive TiN BE, which crucially improved the electrical reliability of the HZO film. As a result, the 10-nm-thick HZO film showed an endurance cycle of 1.5×10^{11} cycles with a $2P_r$ value of 23.3 μC cm^{-2} when the endurance cycle test was performed at 3.0 MV cm^{-1}. This is among the highest endurance performance levels even without cation doping. Therefore, $HfO_{0.61}N_{0.72}$ IL was highly promising in various FE HfO_2-based devices.

11:30 AM CH02.02.04
Low-Dimensional Magnetism with Triangular "CuV2" Motifs Yiran Wang[1], Masayuki Fukuda[2], Romain Gautier[1], Atsushi Miyake[3], Sergey Nikolaev[2], Hena Das[2], Masashi Tokunaga[3], Masaki Azuma[2] and Kenneth R. Poeppelmeier[1]; [1]Northwestern University, United States; [2]Tokyo Institute of Technology, Japan; [3]The University of Tokyo, Japan

Owing to the interesting spin gap behavior, low-dimensional magnetic systems attract considerable attention. Transition metals, such as Cu^{2+} and V^{4+} with spin $S = ½$, are often used to construct such systems. Recently, we synthesized two crystalline compounds which contain both Cu^{2+} and V^{4+} ions by the hydrothermal pouch method. Single crystal X-ray diffraction reveals that triangular "CuV2" motifs with different arrangements forms in the infinite one-dimensional chain compound $[H_3N(CH_2)_2NH_3]Cu(H_2O)_2[V_2O_2F_8]$ (**1**) and the molecular tetramer compound $[Cu(H_2O)$(4,4'-dimethyl-2,2′-bipyridyl)$]_2[V_2O_2F_8]$ (**2**). Magnetization measurement in a pulsed high-magnetic field suggests a presence of a spin gap of 48.6 and 57.6 K in compound **1** and compound **2**, respectively. First-principles calculations indicate the presence of strong and weak antiferromagnetic interactions between Cu^{2+} and V^{4+}, and weak ferromagnetic interactions between V^{4+} and V^{4+} in both systems. As a result, the quasi-one-dimensional chain compound **1** can be regarded as a chain of weakly coupled linear $S = ½$ spin trimers, and the molecular tetramer compound **2** can be decoupled into two weakly coupled $S = ½$ spin dimers.

SESSION CH02.04: Dielectric, Magnetic and Superconducting Materials II

4:00 PM *CH02.04.01
Tuning Chemical Short Range Order in High-Entropy Oxide Perovskite and Spinel Lattices Katharine Page[1,2], Xin Wang[1], Palani Raja Jothi[1] and Bo Jiang[2]; [1]The University of Tennessee, United States; [2]Oak Ridge National Laboratory, United States

Next generation materials of nearly every kind rely on chemical, electronic, and/or magnetic heterogeneity for creating, harnessing, and controlling functionality. High entropy oxides (HEOs), materials exhibiting a single-phase crystal structure containing five or more different cations on single

crystallographic lattice sites, have attracted great interest in diverse fields because of their inherent opportunities to tailor and combine materials functionalities. The control of local order/disorder in the class is by extension a grand challenge towards realizing their vast potential. We present detailed investigation of the cation site preferences, chemical short range order, and magnetic and thermal properties achieved in specific transition metal-based manganite perovskite and ferritic spinel HEO families through compositional tuning and variation in synthesis/processing conditions. A combination of local to long-range electron, X-ray and neutron scattering probes are employed to investigate their complex configurational diversity and associated structure-property trends. Experimentally derived models are supported by Density Functional Theory calculations and Metropolis Monte Carlo simulations. This work hints at the exquisite level of detail that may be required in computational and experimental approaches to guide structure-property tuning in emerging HEO materials.

4:30 PM CH02.04.02
Late News: Crystal Growth and Design of Defect Pyrochlores and Related High Entropy Oxides Lucas Pressley[1,1], Angela Torrejon[1], W A. Phelan[2] and Tyrel McQueen[1,1,1]; [1]Johns Hopkins University, United States; [2]Los Alamos National Laboratory, United States

A family of high entropy oxides with the formula $Mg_2Ta_3Ln_3O_{14}$ (*Ln* = La, Pr, Nd, Sm, Eu, Gd) has been discovered and synthesized. Single crystals, 5 mm OD × 2.5 cm, for *Ln* = Nd have been grown using the laser optical floating zone technique. Crystal orientations are confirmed by Laue diffraction, and structure solutions were obtained via single crystal X-ray diffraction. The structure is found to be a partially disordered pyrochlore, space group *Fd*-3*m*, fractional chemical formula $(Mg_{0.25}Nd_{0.75})_2(Mg_{0.25}Ta_{0.75})_2O_7$. Magnetization measurements indicate ordinary paramagnetic behavior in all compounds down to $T = 2$ K, except in the Eu variant which possesses Van Vleck paramagnetism. Specific heat measurements for *Ln* = Nd shows no phase transitions between $T = 300$ and 2 K. We demonstrate the ability to prepare magnetically disordered materials by substitution of Mg with Ni, Mn, and Co, demonstrating the flexibility of this family in accommodating defects. The stabilization of these compounds could be due to the entropy gain associated with defects, showcasing a "materials by design" approach by using disorder to stabilize novel magnetic and optical materials. Further work has been done targeting high entropy versions of other families of oxides, with particular focus on the perovskite structure.

4:45 PM CH02.04.04
Intermediate Twinning, Abnormal Grain Growth and Chemical Inhomogeneity—Challenges and Opportunities in Lead-Free Ferroelectrics Patricia Pop-Ghe[1], Monika Amundsen[2], Niklas Wolff[3], Amna Rubab[3], Lorenz Kienle[3], Anette Gunnæs[2], Eckhard Quandt[3] and Richard James[1]; [1]University of Minnesota, United States; [2]University of Oslo, Norway; [3]Kiel University, Germany

Recently, changing political and environmental demands are being met by an intense growth of research on efficient, environmentally friendly and ecological technologies. Among these technologies, lead-free ferroelectric ceramics have been widely studied, as possible applications range from the substitution of lead-based materials in piezoelectric devices and innovative cooling technologies to energy harvesting and conversion applications. However, their full potential remains unexploited for both bulk materials and thin films, the latter being a major driving force in today's key technology sectors. In this context, the ferroelectric potassium sodium niobate (KNN) ceramic is assumed to bear great potential ever since its discovery in the 1950's due to its combination of material properties i.e., its perovskite structure and correlated first-order phase transformations and ferroelectricity, as well as its high Curie temperature. However, composition and microstructure control are major challenges due the material's multi-scale chemical heterogeneity, including high volatility, as well as varying diffusion constants and leading to an insufficient electrical performance as compared to lead derivatives.

The focus of this work is on the analysis, optimization and theory-guided synthesis of KNN, based on the geometrically nonlinear theory of martensite (GNLTM). The latter gives precise rules for the minimization of structural fatigue, but its applicability to complex ceramic materials is unclear. For KNN a major goal is the suppression of abnormal grain growth and the bimodal grain size distribution that lead to degradation of thermal and electronic properties. We show that the GNLTM correctly predicts favorable lattice structures and thus improved material properties for the homogeneous ceramic in which abnormal grain growth has been successfully suppressed. We achieve excellent thermal stability and repeatability of the tuned ceramic as seen from temperature-dependent X-ray diffraction (XRD), temperature-dependent transmission electron microscopy (TEM), and energy dispersive X-ray spectroscopy (EDS). These investigations reveal that the GNLTM together with advanced synthesis and characterization techniques provides a useful strategy for the improvement of the reversibility and functionality of phase-change materials with complex chemistry and structure.

SESSION CH02.05: Poster Session I
Tuesday Afternoon, November 30, 2021
8:00 PM - 10:00 PM

CH02.05.01
Toward Durable Multimetal Oxyhalide Intergrowths for Solar Water Splitting Kaustav Chatterjee[1], Roberto dos Reis[2], Jaye K. Harada[2], Jette K. Mathiesen[3], Sandra L. Atehortua Bueno[1], Kirsten M. Jensen[3], James M. Rondinelli[2], Vinayak Dravid[2] and Sara E. Skrabalak[1]; [1]Indiana University, United States; [2]Northwestern University, United States; [3]University of Copenhagen, Denmark

Metal heteroanionic photocatalysts have gained attention for their visible-light absorption; however, they are also plagued by photocorrosion, which limits their long-term use. Such photocorrosion occurs from the photooxidation of the less electronegative non-oxide ions, leading to decomposition of the material's lattice. In this presentation, new intergrowth oxyhalide photocatalysts composed of tantalum and gadolinium will be shown to be stable materials under visible light for photocatalytic water splitting. These intergrowths were prepared using a halide flux method, with their crystal structures analyzed by Rietveld refinement of powder X-ray diffraction data and scanning transmission electron microscopy. These analyses support intergrowth formation. The Ta:Gd molar ratio was systematically varied in the intergrowths to rationalize the effect of charge separation and changes in band structure towards photocatalytic water splitting activity. Furthermore, these intergrowths are capable of sustained overall water splitting in a Z-scheme with $Ru/SrTiO_3$:Rh as a hydrogen evolution catalyst. The high stability of these intergrowth materials is attributed to O 2p orbitals at the valance band edge rather than Cl 3p orbitals, as discerned from electronic structure calculations. These results provide new strategies for designing durable artificial photosynthetic systems by rational modulation of crystal and electronic structure.

CH02.05.05
Stable Water-Soluble Complexes with Picolinamidine as a Solubilizing Ligand Raúl Castañeda, Tatiana Kornilova, Michael S. Petronis and Tatiana Timofeeva; New Mexico Highlands University, United States

In pursuit to obtain water-stable MRI contrast agents, the bidentate ligand picolinamidine (**PiAm**) was used to make complexes with copper, nickel, and zinc. The bidentate coordination of **PiAm** is analogous to that observed in 2,2′-bipyridine, but **PiAm** has an additional nitrogen atom which can act as both hydrogen bond donor, and acceptor, helping to improve the aqueous solubility of the target complexes. In this work seven different complexes with one, or two **PiAm** ligands, as well different geometries were obtained with $Cu^{II}Cl_2$, $Cu^{II}ClBr$, $Ni^{II}Cl_2$, $Ni^{II}2H_2O$ and $Zn^{II}Cl$. Interestingly these complexes are water-soluble, and they can be promising for some applications such as aqueous polymerization, hydrogen splitting, and MRI contrast agents. The stability of these complexes in water was tested using two different approaches: (i) using UV-vis, and (ii) by recovering the initial complex from an aqueous solution after the evaporation of water. Both approaches lead us to conclude that **PiAm** remains coordinated to the metal ion in an aqueous environment, although in some cases the chlorine ligands can be displaced. The geometry, chemistry, and similarities or differences in the crystal packing of these complexes will be discussed in detail in this work. Finally, the accurate measure of solubility and the EPR data of these complexes are underway and will be presented during the congress.

CH02.05.06

CeO_2 Aerogel-Supported Nickel for Highly Active and Stable Oxidation of Carbon Monoxide Travis G. Novak, Paul A. DeSario, Todd Brintlinger, Christopher N. Chervin, Rhonda Stroud and Debra R. Rolison; U.S. Naval Research Laboratory, United States

Nickel-based heterogeneous catalysts are widely researched as cost-effective alternatives to Pt or Au based materials for many reactions related to carbon chemistry, with ongoing efforts focused on improving stability and specific activity. Dispersing Ni on or within a highly porous oxide – such as Al_2O_3, TiO_2, or CeO_2 – can improve performance by both exposing more active sites and promoting metal-support interactions. However, the surface chemistry and stability of the active Ni phase is often unclear, as is the potential effect of the supporting oxide on the presence and persistence of certain phases. In this work, we photodeposit nickel nanoparticles (NPs) onto CeO_2 aerogels, an architecture that provides high surface area and a mesoporous structure allowing facile permeation of gas to interior active sites. Through *ex-situ* XPS analysis, we show that intimate contact between Ni and CeO_2 stabilizes Ni as $Ni(OH)_2$, the highly active phase for CO oxidation, Conversion to NiO that occurs in higher weight loading with aggregated Ni is prevented. Activity for Ni/CeO_2 aerogels is far greater than that of either unsupported Ni or Ni supported by structurally similar TiO_2 aerogels, indicating that this system benefits from a unique interaction between CeO_2 and Ni rather than simply the high surface area of the aerogel. CeO_2 aerogels with 2.5 wt.% Ni have both higher activity per mol of Ni and greater stability than higher weight loadings, with 95% CO conversion at 200 °C and no decline in activity after 12 h of continuous reaction. Our results reveal CeO_2 aerogels serve as an ideal supporting oxide for Ni catalysts and provide important insights regarding the effect of Ni phase for CO oxidation.

CH02.05.09

***In Situ* Synchrotron XRD Studies of Microstructure Evolution During the Salt-Mediated Coarsening of Nanoporous Metals** Adam A. Corrao[1,2], Gerard S. Mattei[1,2], Christopher M. Coaty[3], Victoria Petrova[3], Zhuo Li[1,2], Monty R. Cosby[1,2], Taewoo Kim[3], David P. Fenning[3,3,4], Ping Liu[3,3,4] and Peter G. Khalifah[1,2]; [1]Stony Brook University, United States; [2]Brookhaven National Laboratory, United States; [3]University of California, San Diego, United States; [4]University of California San Diego, United States

Conversion reaction synthesis (CRS) methods provide a scalable and versatile route to nanoporous metals (NPMs) of both noble and non-noble metals with a morphology that is highly desirable for catalysis and other applications that benefit from a high surface area. CRS-derived NPMs can exhibit enhancements in catalytic activity relative to conventional metal nanoparticles, though the optimal surface area will be system-specific and represents a compromise between the demands for activity (higher surface areas are better) and stability (which the highest surface area morphologies may lack). For this reason, it is important to gain both a fundamental understanding and practical control over processes that can be used to tune particle and pore sizes in NPMs.

While thermal annealing is generally suitable for tuning porosity, it has been observed that CRS-prepared NPMs often collapse during heating, resulting in the loss of surface area and particle interior accessibility. We have found that the collapse can be avoided by heating not the pure NPMs, but instead heating the NPMs when they are in the form of a CRS intermediate nanocomposite phase in which salt (typically LiCl) fills the NPM pores. *In situ* synchrotron X-ray diffraction studies with fine time resolution (~1 sec step size) have been used to quantitatively follow the rapid evolution in microstructure that occurs when Fe, Co, and Cu NPM-salt nanocomposites are heated. Intriguingly, the most rapid growth in the metal particle size occurs concurrently with a sharp reduction in lattice strain within the salt phase, indicating a non-innocent role of the solid salt in the coarsening process. This work provides the first quantitative mechanistic insights into the coarsening behavior of CRS-prepared NPMs.

Work has also been carried out to extend the CRS methodology from simple homogeneous metal systems to more complex heterogeneous systems that can have improved catalytic properties. One example of this is a ZnO-supported Co catalyst, which has an advantageous anisotropic morphology that provides better access to the interior porosity of the nanoporous Co metal than traditional isotropic NPM morphologies. It was found that the combination of the ZnO support and the anisotropic morphology led to a 3x improvement in H_2 production during the steam reformation of ethanol relative to chemically analogous isotropic nanoparticles.

CH02.05.10

Phase Transition Pathway by a Co-Operative Pseudo-Jahn Teller Effect Under Microwave Radiation Kelvin Dsouza and Daryoosh Vashaee; North Carolina State University, United States

Microwave interaction in materials has been studied, debated, and extensively used for its exciting effects in the last two decades. Applications for microwave processing have grown over the years, especially for material sintering, waste processing, organic and inorganic material synthesis, and the rate enhancement of chemical reactions.
The intrinsic dielectric loss in a material can be explained by lifetime broadened two-phonon difference processes. At temperatures near phase transition, this absorption due to phonon relaxation can result in different structural orientations of the crystal leading to order-disordered phases and phase retention in the crystal structure.
In this work, we investigate the effect of microwave radiation on structural phase transitions and present the results for the case of bismuth oxide. Bismuth oxide has numerous applications in solid oxide fuel cells, gas sensors, photocatalyst, and optoelectronics for its attractive properties of wide bandgap, ionic conductor, and high refractive index. There have been five polymorphs of Bi_2O_3 reported so far, including α, β, δ, γ, and ε, with α-Bi_2O_3 being the stable phase at room temperature. However, under microwave radiation, we were able to synthesize the metastable β phases at room temperature. The sample is characterized using X-ray diffraction, Raman spectroscopy, Differential Scanning Calorimetry, and UV-Vis spectroscopy to evaluate the structure and different phases in the sample. These metastable states are structurally related, and different phases can emerge depending on the temperature and intensity at which the sample is irradiated with the microwave. Lone pair activity plays a crucial role in the crystal structure, and the position and direction of these lone pairs explain the orientation of the crystal. The underlying electronic phenomena can be attributed to the co-operative pseudo-Jahn teller effect, which is the interaction of active pseudo-Jahn teller centers. By evaluating the symmetry descent in the crystal lattice for the phases adopted by bismuth oxide through heat treatment, one can justify the hypothesis of a co-operative effect. As phonons carry the interaction between these centers, we hypothesize that

the intrinsic microwave absorption leads to multi-phonon relaxation, disrupting the interaction between the centers. To calculate the intrinsic microwave absorption and support the hypothesis, we evaluate the phonon dispersion and the two phonon relaxation using first-principle calculations.

CH02.05.11
Tunable Novel Magnetic System in an Anti-$CeCoIn_5$ Structure Type Ranuri S. Dissanayaka Mudiyanselage[1], Chang-Jong Kang[1], Kaya Wei[2], Tai Kong[3], Gabriel Kotliar[1] and Weiwei Xie[1]; [1]Rutgers, The State University of New Jersey, United States; [2]National High Magnetic Field Laboratory, United States; [3]The University of Arizona, United States

The materials science community is constantly striving to discover new critical materials that meet future technological demands. Exploring rare-earth free magnetic materials is one direction, where Mn-based compounds have been identified as a promising candidate to replace the rare-earth elements. Here we have designed and synthesized Mn-based novel rare-earth free magnetic materials in the anti-$CeCoIn_5$ structure type by using chemical bonding concepts. Physical property measurements have confirmed that the magnetic behavior of these compounds range from room temperature ferromagnetic to an antiferromagnetic. Furthermore, theoretical assessments indicate that by including a strong spin orbit coupling and manipulating the lattice parameters, in particular the c/a ratio, a magnetic transformation from antiferromagnetic to ferromagnetic state or vice versa can be observed. Various pressure dependent techniques are being utilized to investigate this predicted behavior. Overall, these materials provide an ideal platform to enhance the understanding of intricate structure-magnetic relationships. Fundamental knowledge on the manipulation of magnetic properties will accelerate the discovery of new critical materials.

CH02.05.12
Structural Investigation of Cu-Pd, Cu-Pt, and Cu-Ru Nanoparticles Alexandre Foucher and Eric A. Stach; University of Pennsylvania, United States

Bimetallic structures are advantageous to reduce the use of precious metals and diminish the cost of catalysts for critical chemical reactions. For instance, Pd is used for alkyne hydrogenation, Ru for the Fischer-Tropsch process, and Pt is an excellent catalyst for CO or methanol oxidation. However, these metals are expensive, and monometallic particles are not always very stable. To this end, Pt, Pd, and Ru are often incorporated with Cu to create optimized intermetallic or core-shell structures. The combination of these three expensive metals and Cu also yield a unique electronic configuration at the surface of the particles. Alloying leads to increased stability, activity, and selectivity compared to monometallic compounds. However, dynamical restructuring effects during chemical reactions may alter the property of the bimetallic nanocatalysts. Change in valence states, composition, and crystallography will influence the physical properties of innovative alloys for catalysis.

In this study, three Cu-based alloys were synthesized and characterized. In-situ transmission electron microscopy (TEM) and electron energy-loss spectroscopy (EELS) were performed to understand structural and compositional changes upon exposure to elevated temperatures and O_2/H_2. Modification of the crystal structure at the surface of the nanoparticles and changes in the oxidation numbers can be correlated with increased or reduced chemical properties. Differences between alloyed and monometallic systems are investigated with EELS and electron pair-distribution function (ePDF) analysis. Results are also supported with density functional theory (DFT) calculations to understand the effect of crystallography, valence state, and composition on reactions.

Hence, bimetallic nanocatalysts' chemical and physical properties can be described by a combination of innovative characterization techniques supported by electronic structure calculation. This approach can be expanded to an extensive range of new materials to understand the origin of their properties.

CH02.05.13
Ternary Ti-Mo-Fe Nanotubes as Efficient Photoanodes for Solar-Assisted Water Splitting Nageh K. Allam; American University in Cairo, Egypt

Designing efficient and stable water splitting-photocatalysts is an intriguing challenge for energy conversion systems. We report on the optimal fabrication of perfectly aligned nanotubes on trimetallic Ti-Mo-Fe alloy with different compositions prepared via the combination of metallurgical control and facile electrochemical anodization in organic media. The X-ray diffraction (XRD) patterns revealed the presence of composite oxides of anatase TiO_2 and magnetite Fe_3O_4 with better stability and crystallinity. With the optimal alloy composition Ti- (5.0 at.%) Mo- (5.0 at.%) Fe anodized for 16 h, enhanced conductivity, improved photocatalytic performance, and remarkable stability were achieved in comparison with Ti- (3.0 at.%) Mo- (1.0 at.%) Fe samples. Such optimized nanotube films attained an enhanced photocatalytic activity of ~0.272 mA/cm^2 at 0.9 V_{SCE}, which is approximately four times compared to the bare TiO_2 nanotubes fabricated under the same conditions (~0.041 mA/cm^2 at 0.9 V_{SCE}). That was mainly correlated with the emergence of Mo and Fe impurities within the lattice, providing excess charge carriers. Meanwhile, the nanotubes showed outstanding stability with a longer electron lifetime. Moreover, carrier density variations, lower charge transfer resistance, and charge carriers dynamics features were demonstrated via the Mott-Schottky and electrochemical impedance analyses.

CH02.05.14
Engineering Random Dielectric Nanoscale Strains on Silicon Surface to Enhance Light Emission Sufian Abedrabbo[1], El Mostafa Benchafia[1], Ahmad Al-Qawasmeh[1], Nuggehalli M. Ravindra[2] and Anthony T. T. Fiory[3]; [1]Khalifa University of Science and Technology, United Arab Emirates; [2]New Jersey Institute of Technology, United States; [3]Integron Solutions, United States

Engineered materials and devices typically involve interfaces of various forms that introduce property modifications of interfaced materials by introduction of stresses and strains. In this study, we focus on interfaces created in silicon associated with inhomogeneous stresses and specifically address their strong effect on radiative properties of indirect bandgaps. In particular, attention is drawn to the sol-gel based dielectric coatings catalyzed by various acids on silicon that modulates the indirect bandgap of Si favorably towards radiative recombination of free-carriers. A hypothesis on the role of random nanoscale stresses is presented. Photoluminescence and strain levels properties of surface engineered interfaces via colloidal coatings is compared to those of thermal and chemical deposited coatings. Appreciable improvements of band edge light emission is revealed. Other techniques and structures that results also in inhomogeneous bulk strains and expected efficient radiative recombination properties will be presented. One of these include formation of ordered nanoscale dislocation loops below the silicon surface.

CH02.05.15
Na_2FePO_4F—A Computational Investigation into a Promising Cathode Material for Sodium-Ion Batteries Daniel N. Sykes[1,2], Yong-Seok Choi[1,2] and David O. Scanlon[1,2,3]; [1]University College London, United Kingdom; [2]Faraday Institution, United Kingdom; [3]Diamond Light Source, United Kingdom

Long-term viability of Li-ion battery energy storage may be limited by global lithium reserves. Recently, sodium-ion batteries (NIBs) have garnered a great deal of attention, partially because of sodium's natural abundance, its more even distribution across the earth and it costs less than lithium. NIBs are especially attractive for large-scale energy storage systems where cost and life cycle are essential. To this end, Na_2FePO_4F has been a material of interest as

a viable cathode material for sodium-ion storage due to the high discharge voltage and favourable theoretical capacity.[1] Recent work has shown the potential for doping in Na_2FePO_4F cathodes to increase average voltage, reduce band gap and Na-ion diffusion barrier.[2]
In this work we will present work completed on computationally investigating Na_2FePO_4F using Density Functional Theory (DFT) with the periodic code, VASP (Vienna Ab Initio Simulation Package), and the hybrid HSE06 [3] (Heyd-Scuseria-Ernzerhof) functional. Here we elucidated the bulk geometric structure of the material through relaxation as well as the most stable magnetic configuration. The electronic structure of the material has also been examined with a Density of States (DOS) and band structure being obtained. Furthermore, to examine the defect landscape of the material properly later, the different stable phases of Na_2FePO_4F have been investigated. Calculating the phase stability of Na_2FePO_4F builds a foundation for a detailed understanding of its defect chemistry at given chemical potentials.

Chemical Bonding Revisited—The Potential of Property Maps Carl-Friedrich Schön, Steffen van Bergerem, Christian Mattes, Leif Kobbelt, Martin Grohe and Matthias Wuttig; RWTH Aachen University, Germany

Physicists and chemists share a common belief. The properties of solids are determined by the arrangement of its constituting atoms, which is governed by the chemical bonding mechanism present in the material at hand. It should therefore be possible to revert this relation and infer from a material's properties which bonding mechanism is employed. This is no simple feat, as there is a multitude of physical properties which might be an indicator for the relevant bonding mechanism in the corresponding solid. We therefore utilize means of computer science by using classification algorithms to sort a database of materials to a priori arbitrary groups, which we aim to link to bonding mechanisms.
In our study, we have composed a database of elements and binary compounds, containing for example Aluminum, Gallium Arsenide, Diamond, Sodium Chloride, Germanium Telluride etc. For all compounds in the database, the corresponding values of a set of properties were included. This set contains the conductivity σ, the Born Effective Charge Z*, the Effective Coordination Number (ECoN) and the Bandgap EG, the melting point T_M, the density ρ and the atomic density ρ_A. To further increase the size of the dataset, miscible compounds were alloyed and the parameters interpolated accordingly, resulting in a total of about 330 compounds used for the classification.
A Gaussian mixture algorithm was utilized to separate the compounds in the database into *n* clusters, where each value from 2-6 was tested for the number of allowed clusters *n*. For three clusters, the traditional separation into covalent, ionic and metallic compounds could be reproduced, as no compounds with Hydrogen bonds or Van-der-Waals bonding were added to the database. Only few materials were wrongly classified, with the majority being mix-ups between covalent and ionic compounds. Interestingly, with the number of allowed clusters *n* set to 4, exactly those materials that have recently been proposed to utilize a novel chemical bond, named metavalent bond, are being assigned to the fourth cluster. We hence conclude, that our results support the concept of metavalent bonding by an a priori computational method. More importantly, this classification provides a close link between chemical bonding mechanisms and properties enabling novel routes to materials design.

CH02.05.17
Copper(II) Metal-Organic Framework (MOF) with Excellent Antifungal Activity So-Hyeon Yang[1], Mayura Veerana[2], Gyungsoon Park[2], Youngmee Kim[1] and Sung-Jin Kim[1]; [1]Ewha Womans University, Korea (the Republic of); [2]Kwangwoon University, Korea (the Republic of)

Metal-Organic Frameworks (MOFs) have been of great interest for decades due to their porosity and wide application possibilities, such as gas sorption, separation, catalysis, luminescence sensing, and biomedical applications. Among them, MOFs have been utilized as materials with antimicrobial properties against microorganisms. In this work, our group synthesized a Cu-MOF containing glutarate (Glu) and 4,4'-azopyridine (azpy) by solvothermal method. We tested its antifungal activity against two fungi, *C. albicans* and *A. niger*, and found that the Cu-MOF shows great antifungal properties for these two fungi. Based on this antifungal ability, it is expected that the material we synthesized can be used for purposes such as food storage and antifungal agents used for various contamination and infection. Detailed results and mechanisms will be discussed.

Barocaloric Effects in Metal–Organic Materials for Solid-State Cooling Jarad A. Mason, Jinyoung Seo, Jason Braun, Ryan McGillicuddy, Adam Slavney and Selena Zhang; Harvard University, United States

With more than 20% of the world's electricity currently used for cooling and a growing population demanding more comfortable living conditions amid an ever warming global climate, the need for sustainable cooling technologies is expected to increase dramatically over the next several decades. Most commercial cooling systems rely on vapor-compression cycles of environmentally harmful refrigerants that are prone to leakage. As an alternative, caloric effects can drive solid-state cooling cycles that feature a high energy efficiency and zero direct emissions, as well as faster start-up times, quieter operation, easier recyclability, and greater amenability to miniaturization than conventional vapor-compression technologies. Here, we will describe how pressure-induced thermal changes—barocaloric effects—mediated by order–disorder or spin-crossover phase transitions can be leveraged for solid-state cooling. In particular, we will discuss the structural and chemical factors that contribute to entropy changes, sensitivity to hydrostatic pressure, and thermal hysteresis in a series of metal–organic materials that exhibit large barocaloric effects.

11:00 AM *CH02.06.02
Design Strategies in Functional Porous Materials for Energy Storage Sara Thoi; Johns Hopkins Univ, United States

Despite their high theoretical specific energy of 2,600 Wh kg^{-1}, the commercialization of Li-S devices is hindered by irreversible capacity loss from the dissolution of polysulfide intermediates in the electrolyte solution. Inspired by the rich chemistry in solid-state materials, we integrate molecular units capable of tethering polysulfides into metal-organic frameworks (MOFs) to improve cycling stability and charge conductivity. Incorporation of redox-

active moieties in the framework further enable fast charge and discharge capabilities. Identification of structure-property-function relationships in tunable molecular platforms provide a pathway for translatable strategies across materials types and battery technologies.

11:30 AM CH02.06.04
Looking for Glazer Tilts in the Local Structure of Perovskites Sandra Skjaervoe and Simon J. Billinge; Columbia University, United States

Crystallographically determined long-range ordered structures of materials are often taken for granted when investigating properties and functionalities. Although this simplifies our lives, there is a growing awareness of the fact that short-range deviations from the long-range order is not only common but also determining for many of the properties, such as bandgap and magnetic order. As an example, many oxides with the perovskite structure, ABO_3, have well-defined crystalline order, but their properties can in some cases be explained better if one accounts for the local disorder.

To be able to understand how properties are affected by the short-range deviations, or local structure, we first have to properly describe what that local structure looks like. Just as with long-range ordered crystal structures, we can determine the local structure using scattering experiments and subsequently fitting the data to models. To obtain the local structure, however, we must also analyze the diffuse scattering in addition to the Bragg scattering, which is best done in real space as the pair distribution function (PDF). We build on the many already existing PDF studies on perovskites and constrain our structure model further by taking advantage of the knowledge that the structure tends to distort in ways that keep its BO_6 octahedra intact. The resulting distortions, collective or not, can therefore often be described by one of 23 unique tilting patterns of the rigid octahedra, identified by Glazer in the '70s [1]. In our implementation, fitting a model of any of the tilting patterns to scattering data requires refinement of no more than four variables at once – one lattice parameter and a maximum of three tilt amplitudes. Here we present our PDF analysis of a selection of perovskites and determine their degree and type of structural tilting disorder.

PDF analysis and modeling in the Billinge group was supported by the U.S. National Science Foundation through grant DMREF-1922234.

Rutile Rules—Lessons on the Mott-Peierls Transitions James M. Rondinelli; Northwestern University, United States

Transition metal compounds based on the structurally simple rutile structure exhibit a range of collective electronic phenomena, including metal-insulator transitions, superconductivity, and nontrivial fermions. The ability to manipulate such electronic states through structure is key to realizing new classes of adaptive and low-power microelectronics. Here I briefly overview our progress in understanding the structural contributions to driving metal-insulator transitions in binary and ternary rutile and trirutile compounds using electronic structure based methods. I will first describe our understanding of how geometric and bonding constraints determine the crystallization of compounds in the trirutile structure as opposed to other ternary structures in this space. Here, we predict several previously unreported candidate trirutile oxides, and one is successfully synthesized. I will then present results on vanadium-free rutile and trirutile phases, focusing on the stability and transformations in the electronic structure of 4d and 5d compounds where strong electron-electron interactions are expected to be weak. Our main finding is that one can control the conducting or insulating state by structural design through inductive control over metal-metal interactions with multiple cations or anions. Last, I will describe our recent progress in utilizing this structure-function understanding to automate the discovery process of electronic transitions with Bayesian optimization techniques.

This work was performed in collaboration with Ram Seshadri, Stephen Wilson, Emily Schueller, Kyle Miller, Jaye Harada, Lauren Walters, and Danilo Puggioni and financially supported by the National Science Foundation under awards DMR-1729489, DMR-1729303, and DMR-2011208.

Late News: Identifying New Inorganic Solar Absorbers with Long Carrier Lifetime Using High-Throughput Computational Screening Geoffroy Hautier[1,2], Diana Dahliah[2], Guillaume Brunin[2], Janine George[2], Viet-Anh Ha[2] and Gian-Marco Rignanese[2]; [1]Dartmouth College, United States; [2]University Catholique de Louvain, Belgium

Current solar absorbers for thin film technologies (e.g., CIGS or perovskites) can show good efficiencies above 20% but show limitations in terms of toxicity, earth-abundance or long-term stability. Finding new solar absorber is a cumbersome process involving complex synthesis and characterization steps. Computational modeling using density functional theory (DFT) on the other hand offers an attractive way to speed up this process. Here, we will report on a large scale high-throughput computational search for new solar absorbers among known inorganic materials. The originality of our approach lies in the consideration of intrinsic defects that are essential in controlling carrier lifetime.[1] More precisely, we searched among 7,000 copper-based known inorganic materials for materials presenting adequate band gap, transport (effective masses) and intrinsic defects (i.e., defects that will not act as important non-radiative recombination centers). We will report on a series of candidates and identify the copper phosphides and especially the alkali copper phosphides as very promising potential new solar absorbers. We will present the compounds of interest which have been synthesized before but have never been considered for solar applications and discuss the intrinsic chemical reasons for their adequate PV properties.

A Super Fast and Efficient High-Throughput Search Method for Near Room Temperature Superconductors Under High Pressure Tianran Chen[1,2] and Taner Yildirim[2]; [1]University of Maryland, United States; [2]National Institute of Standards and Technologies, United States

Due to the low atomic mass and high phonon frequencies of hydrogen, hydride compounds under extreme pressures are most promising in the search for near room temperature superconductors. First-principles based computational search has become extremely important not only predicting new materials but

also guiding high-pressure experimental measurements. However, the calculation of electron-phonon coupling and the corresponding T_c for a given system is usually computationally very expensive, limiting the application of computational search to a few numbers of candidate systems.

In this work, we have developed a super-efficient and fast high-throughput method for searching high-T_c hydride superconductors. We introduce new "metrics" that are strongly correlated to strong electron-phonon coupling and T_c but it is much faster to calculate them. Using our new method, we have searched more than 100,000 binary hydride superconductors and discovered many new high-T_c systems. Among them, we report our prediction of high-temperature superconductivity at relatively low pressure of 50 GPa in a novel binary metal hydride which may break the current record. A detailed mechanism of the superconductivity, phonons and electron-phonon coupling, anharmonicity, as well as the abnormal T_c-pressure dependence, will be also discussed. Our work will not only greatly accelerate the discovery of new hydride superconductors but also give a detailed understanding of important factors that yield superconductivity near room temperature at high pressures.

5:15 PM CH02.07.04
The Electronic Entropy Contribution to Some Congruent and Allotropic Phase Transitions Jonathan Paras and Antoine Allanore; Massachusetts Institute of Technology, United States

Knowledge of the entropy change at a phase transition remains critical for engineering materials. For allotropic phase transformations in transition metals and congruent transitions in intermetallic compounds, computation of the electronic structure, and by extension the entropy, has remained particularly difficult. We introduce a formalism that links electronic transport properties with the state electronic entropy to circumvent these difficulties in compounds like Cu_3Au and transition metals including Fe and Co. Our formalism connects materials chemistry and the partial molar entropy of electrons in solution, opening the door for quantitative engineering of the phase transition entropy via chemistry. Application to allotropic phase transitions in some transition metals at atmospheric pressure suggest a possible electron-driven origin of hexagonal close packed stability.

CH02.08.01
Development of Sodium Hybrid Quasi-Solid Electrolytes Based on Porous NASICON and Ionic Liquids C.S. Martínez-Cisneros[1], B. Pandit[1], B. Levenfeld[1], J.Y. Sanchez[1,2] and Alejandro Varez[1]; [1]University Carlos III of Madrid, Spain; [2]Univ. Grenoble Alpes, Univ. Savoie Mont Blanc, CNRS, Grenoble INP, France

Sodium batteries emerge as an alternative to produce the new, so called, post-lithium batteries (1). In this study, we explore (i) the effect of sodium content and sintering temperature in solid electrolytes based in NASICON-type compounds and (ii) the use of two methodologies to obtain porous NASICON samples: application of natural substances and organic materials as pore-formers and freeze casting. The main purpose is the attainment of hybrid quasi-solid state electrolytes (2), with enhanced room temperature conductivity, based on porous ceramic electrolyte layers infiltrated with ionic liquids. Using this approach, porous samples with different microstructure and porous morphology and distribution were achieved, providing an enhancement in conductivity (ranging from 0.45 to 0.96 mS cm-1 at 30°C) of one order of magnitude for infiltrated samples respect to pore-free samples. Preliminary electrochemical test on thick electrode showed a specific capacity higher than 80% respect to the theoretical one, which is quite promising considering the thickness of the electrolyte. According to these results the porous NASICON might be considered as a functional macroporous inorganic separator that can act as a Na+ reservoir.
The authors would like to thank the Agencia Española de Investigación /Fondo Europeo de Desarrollo Regional (FEDER/UE) for funding the projects PID2019-106662RBC43. This work has also been supported by Comunidad de Madrid (Spain) - multiannual agreement with UC3M (“Excelencia para el Profesorado Universitario” - EPUC3M04) - Fifth regional research plan 2016-2020.

As-Synthesized Alkyne-Coated CdSe Quantum Dots for Site-Directed Nanoparticle-Substrate Chemical Linkage Lucas Tortella and J. S. Niezgoda; Saint Joseph's University, United States

Site-directed and robust chemical binding of the nanocrystalline surface to a substrate is of utmost importance in the fields of printable electronics, fluorescence assays and catalysis, among others. Historically, nanocrystal preparation methods have involved chemically inert ligands than are post-synthetically exchanged from the surface of the crystal—whether in colloidal solution of in the solid film—to a more useful and/or fitting molecule for the given application. Here, in line with the overarching theme of the Niezgoda lab, we present our findings on the development of a preparation for CdSe quantum dots (QDs) prepared with a native terminal alkyne ligand, 10-undecynoic acid (UDYA), as the lone surface-bound molecule. Further, core/shell architectures of these particles have been prepared with decent quantum yields in the visible spectrum. High-resolution TEM images with elemental mapping show well-formed and monocrystalline particles, and the presence of the alkyne on the surface is verified with FTIR and NMR spectroscopies. These first-of-their kind native alkyne-coated fluorescent QDs are immediately useful in alkyne-azide click chemistry applications, wherein the QDs can be site-directed to any substrate decorated with azide moieties. Examples of colloidal, thin film and 3D-printed systems involving alkyne-azide click cyclization of the novel QDs to substrate are shown as proof-of-principle demonstrations of the wide applicability of these particles. We emphasize that the fundamental innovation of this project is that it effectively circumvents the need for a post-synthetic ligand exchange to accomplish robust QD-substrate chemical linkage, while still providing QDs with suitable quantum yield and stability.

CH02.08.04
High-Performance Supercapacitors by the Infiltration of Gel Polymer Electrolytes into Porous Electrodes Pado Kim, Min Guk Gu and Sung-Kon Kim; Jeonbuk National University, Korea (the Republic of)

The development of materials used for electrodes brings advances in energy storage technology. In addition, research on how to maximize the efficiency of electrodes with a combination with solid-state electrolytes, one of the key elements of energy storages. Polymer-based electrolytes such as solid polymer

electrolytes (SPEs) and gel polymer electrolytes (GPEs) are of great interest due to their flexibility in creating flexible energy storages. It also solves the weakness of liquid electrolytes: liquid leakage, volatility, flammability, weak chemistry properties, and electrochemical properties. Herein, we demonstrate a way to improve the electrochemical performances of the supercapacitor (SC) by infiltrating GPEs with high ion conductivity into electrode made of multi-walled carbon nanotube (MWCNT). GPEs are synthesized through polymerization of poly(ethylene glycol) methyl ether acrylate (PEGMA) in the presence of trimethylolpropane ethoxylate triacrylate (ETPTA) in $LiPF_6$ organic solution. By changing the chemical composition of PEGMA, ETPTA, and lithium solution we can adjust the mechanical properties and ionic conductivity of GPEs. Electrode-infilling gel polymer electrolyte (EI-GPE) with high ionic conductivity improves the characteristics of the electrode-electrolyte interface and creates a high-performance SCs. The SCs produced in this way exhibit excellent performance in capacitance and energy density, and exhibit a long cycle life even under mechanical deformation.

CH02.08.05
Insights to Electronic and Nanoscale Structure of Durable Multimetal Oxychloride Intergrowth Photocatalysts Kaustav Chatterjee[1], Roberto dos Reis[2], Jared Stanley[1], Vinayak Dravid[2] and Sara E. Skrabalak[1]; [1]Indiana University, United States; [2]Northwestern University, United States

Structure-property connections are a key theme in heterogeneous catalysis such as photocatalytic water splitting. Bismuth-based layered perovskite compounds such as Bi_4MO_8X (M=Nb, Ta; X=Cl, Br) have emerged as promising durable photocatalysts for visible-light driven water splitting. The unique electronic structure of these oxyhalides in the valence band suppresses the self-oxidation of non-oxide anions by photogenerated holes. The unique combination of electronic and optical properties in these oxyhalide perovskite materials lies in their rich structural complexity. In this study, the electronic and nanoscale structure of multimetal oxyhalide intergrowth oxychloride: Bi_4TaO_8Cl-Bi_2GdO_4Cl have been systematically investigated. We have varied the amount of Bi_4TaO_8Cl in the intergrowths to rationalize the effect changes in the local crystal and electronic structure. A combination of Ultraviolet Photoelectron Spectroscopy, UV-Visible Diffuse Reflectance Spectroscopy and Electron Energy Loss Spectroscopy techniques were used to determine and investigate the electronic structure of the oxyhalide intergrowths. The obtained conduction and valence band energy levels elucidate the possibility of photocatalytic water splitting as well as carbon dioxide reduction. By virtue of aberration-corrected scanning transmission electron microscopy and converged-beam electron diffraction (CBED), the nanoscale structure of the intergrowth materials was elucidated with atomic displacements at an accuracy of several picometers. Based on the high-order Laue zone reflections of CBED patterns, the local symmetry and tilting of TaO_6 octahedra in the intergrowth crystal structure were revealed. We believe our approach demonstrated here opens up opportunities for understanding the atomic-scale structure-property phenomena of novel photocatalytic systems.

CH02.08.06
High-Performance Microsupercapacitor Based on Laser-Induced Fluorinated Polyimide Films with Organic Gel Polymer Electrolytes Min Guk Gu[1], Pado Kim[1], Minsu Kim[2], Byoung Gak Kim[2] and Sung-Kon Kim[1]; [1]Jeonbuk National University, Korea (the Republic of); [2]Korea Research Institute of Chemical Technology, Korea (the Republic of)

Due to the need for small-scale electronic devices, many studies are in progress on energy storage devices. In particular, in the case of microsupercapacitors (MSCs), they can be embedded in small electronic devices and are being used as energy storage devices that can temporarily supply power to rechargeable batteries. For this reason, in this study, MSCs are fabricated by laser photothermal method of 3D porous laser-induced graphene (LIG) electrodes. A fluorine-based polyimide (fPI) film is used as substrates for LIG electrode (LIG-fPI). During the graphitization process caused by the laser, gaseous products including fluorine are released from fPI to form a microporous structure, which can overcome the disadvantage of a small electrode specific surface area seen in conventional LIGs, and increasing the specific surface area is a way to improve the energy density of MSCs. As the electrolyte used in this study, we choose an organic gel polymer electrolyte (o-GPE). MSCs with o-GPE are mechanically flexible and have excellent electrochemical performance. For o-GPE, poly(ethylene glycol) methyl ether methacrylate (PEGMA), trimethylol propane ethoxylate triacrylate (ETPTA) are used, and 2-hydroxyl-2-methyl-1-phenyl-1-propanone (HMPP) is used as a photo-initiator. UV-cured o-GPE impregnated with a liquid electrolyte containing lithium salt is made into a pouch cell with LIG-fPI, which is flexible and bendable. It exhibits very high energy and power densities of 0.58 mW cm^{-2} and 0.01 mWh cm^{-2}, respectively, at a high voltage window of 3 V. The resulting LIG-fPI-MSC is promising for use in rechargeable power supplies in various applications such as wearable microelectronics and the Internet of Things.

CH02.08.08
Late News: Generation of Zinc Oxide Nanoparticles in Presence of Ethylene Glycol Kerianys N. Torres[1], Veronica I. Nash-Montes[1], Josian Luciano Velazquez[2] and Sonia J. Bailón- Ruíz[1]; [1]University of Puerto Rico at Ponce, United States; [2]University of Puerto Rico at Mayagüez, United States

Nanomaterials as zinc oxide have potential applications in nanomedicine, biosensors, catalysts and biomedical bio-imaging because of their intrinsic optical properties. We report the synthesis and characterization of zinc oxide nanostructures in presence of ethylene glycol and the effect of the zinc precursor on the particle. Zinc oxide nanoparticles were produced in presence of ethylene glycol and zinc precursors at 197 °C by using a reflux system. The reaction time was ranged from two to six hours and the precursors evaluated were zinc sulphate heptahydrate (II) and zinc acetate dehydrated (II). As-synthesized nanostructures were characterized by Absorption and Photoluminescence spectroscopies. Besides, the presence of ethylene glycol on the ZnO was corroborated by Infrared Spectroscopy. Results evidenced that nanostructures exhibited strong emission peaks at 400 nm which comes from the recombination of their pars electron-hole. Whereas the absorption spectra exhibited shoulder peaks at approximately 360 nm which is attributed to the band gap. Also, preliminary studies evidenced that ZnO nanostructures have catalytic properties to destroy contaminants in aqueous matrices.

CH02.08.09
Late News: Antiferro- and Meta-Magnetism in the S=7/2 Hollandite Analog EuGa2Sb2 Tanya Berry[1], Sean R. Parkin[2] and Tyrel McQueen[1]; [1]Johns Hopkins University, United States; [2]University of Kentucky, United States

Recent work analyzing the impact of non-symmorphic symmetries on electronic states has given rise to the discovery of multiple types of topological matter. Here we report the single crystal synthesis and magnetic properties of EuGa2Sb2, an Eu-based antiferromagnet structurally consisting of pseudo-1D chains of Eu ions related by a non-symmorphic glide plane. We find the onset of antiferromagnetic order at TN = 8 K. Above TN; the magnetic susceptibility is isotropic. Curie-Weiss analysis suggests competing ferromagnetic and antiferromagnetic interactions, with peff = 8.1μB as expected for 4f7 J = S = 7/2 Eu2+ ions. Below TN and at low applied magnetic fields, an anisotropy develops linearly, reaching $\chi\perp/\chi\parallel$ =6 at T = 2 K. There is concomitant metamagnetic behavior along $\chi\parallel$, with a magnetic field of $\mu oH \approx 0.5T$ sufficient to suppress the anisotropy. Independent of crystal orientation, there is a continuous evolution to a field polarized paramagnetic state with M=7 μB/Eu2+ at μoH=2T as T→0 K. Specific heat measurements show a recovered magnetic entropy of $\Delta Smag \approx 16.4$ J.mol-1.K-1 from T ~ 0 K to T = TN, close to the expected value of Rln(8) for an S = 7/2 ion, indicating little low dimensional spin fluctuations above TN. We find no evidence of unusual behaviors arising either from the dimensionality or the presence of the non-symmorphic symmetries.

CH02.08.10
Late News: Effect of the Capping Agent on the Photocatalytic Performance of ZnS Nanostructures Veronica I. Nash-Montes[1], Kevin Correa[2],

Kerianys N. Torres[1], Josian Luciano Velazquez[2] and Sonia J. Bailón- Ruíz[1]; [1]University of Puerto Rico in Ponce, United States; [2]University of Puerto Rico at Mayagüez, United States

Tons of pollutants from textile industries are lost to effluents every year due to the inefficiency of dyeing processes. In this regard, conventional techniques as adsorption or coagulation have been used in water treatment to concentrate pollutants by transferring them to other phases. Alternative destructive techniques are needed to obtain a fast destruction of pollutants in wastewater treatment. In this way, photo-catalysis is an advanced oxidation process that includes a quick oxidation of the pollutant molecules, lack of production of polycyclic products, and final degradation of contaminants in the ppb range. This technology is based on the activation of nanomaterials (i.e. semiconductors) in presence of electromagnetic radiation and subsequent generation of radicals from water to directly oxidize many organic pollutants. Based on the above considerations, this research is an attempt at the use of Zn-based nanomaterials (i.e. as ZnS and ZnO NPs) for the degradation of environmental pollutants from aqueous matrices. The specific goals of this project are: i) Generate and characterize nanomaterials with photoactive properties, ii) Study the photochemical stability of photoactive nanomaterials, and iii) Demonstrate the degradation of environmental pollutants in presence of photoactive nanomaterials and the reuse of the nanostructures. Optical properties showed a luminescent peak at 420 nm and 442 nm and an absorption peak at 270 nm and 307 nm. Photodegrading capacities of quantum dots were evaluated in presence of Acid Red 14 at different concentrations (250 ppm and 500 ppm). Bare ZnS nanomaterials degraded Acid Red 14 successfully (75%) after 180 minutes.

CH02.08.11

Late News: Theoretical and Experimental Properties of Ag2SeO4 and Ag2SeO3 for Photoluminescent and Photocatalytic Applications Ivo M. Pinatti[1,2], Ana C. Tello[3], Marcio D. Teodoro[3], Ieda L. Rosa[3], Elson Longo[3], Juan Andres[2] and Alexandre Z. Simões[1]; [1]UNESP, Brazil; [2]UJI, Spain; [3]UFSCar, Brazil

Theoretical and experimental study of inorganic crystals is an interdisciplinary subject that is attracting intense research and development due to both fundamental and applied scientific value. Metallic selenites present different chemical structures and advanced physical properties such as pyroelectricity, ferroelectricity and piezoelectricity. Also, selenium-silver based matrices exhibit interesting structural, optical, and photoluminescent properties, which accounts for potential materials in many research fields like physics, chemistry and materials science. Moreover, the chemistry of selenium and silver is very prominent in biological systems, mainly because of their interactions with molecules like proteins. In this work, silver selenate (Ag_2SeO_4) and silver selenite (Ag_2SeO_3) microcrystals were prepared by the sonochemistry (SC), ultrasonic probe (UP), coprecipitation (CP), and microwave assisted hydrothermal (MH) methodologies. X-ray powder diffraction patterns results showed intense and sharp peaks related to the orthorhombic Ag_2SeO_4 and monoclinic Ag_2SeO_3 structures, attesting that materials are crystalline and present structural long-range order. It was also observed experimental Raman modes for both phase, which corroborated to the theoretical ones calculated indicating structural short-range order. The morphologies were confirmed by FE-SEM microscopy and Wulff construction, showing distinct shapes of different width and length due to the different methodologies of synthesis. Optical properties were attested by UV-vis spectroscopy which showed the characteristic semiconductor band gap value for both materials. Photoluminescence spectroscopy showed an intense band in the visible region with maximum at around 700 nm for all samples. Further trapping experiments prove that the holes and hydroxyl radical, in minor extent, are responsible for the photocatalytic degradation of dyes. The geometry, electronic properties of the bulk, and surface energies of these materials were evaluated using first-principles quantum mechanical calculations based on the density functional theory (DFT/B3LYP) to provide information at the atomic level. In this sense, experimental results were correlated to theoretical studies and enabled a deep understanding between structure and property. Inspired by the above considerations, these materials may present superior characteristics for new compounds with photoluminescent and photocatalytic applications.

CH02.08.12

Late News: Investigating Semiconductor Photocatalysts for C-C Bond Formation via First Principles Computations Arun Kumar Mannodi Kanakkithodi, Shukai Yao, Jiaqi Yang and Peilin Liao; Purdue University, United States

Semiconductor-based photocatalytic systems have been frequently used for small molecule activation and transformation reactions, such as water splitting for H_2 and O_2 evolution, CO_2 reduction, and N_2 reduction. During photocatalysis, light-irradiation on semiconductors leads to the generation of excited electrons which compete to recombine with co-generated excited holes, resulting in lower reaction yields. The simultaneous utilization of excited electrons and holes, for example via a cross-coupling mechanism, is thus of critical importance for useful organic transformations, such as C-C bond forming reactions. To realize cross-coupling for C-C bond formation, the redox potentials of carbonyls and alcohols must match the reduction (conduction band minimum) and oxidation (valence band maximum) power of the semiconductor, respectively.

In this work, we perform first principles-based density functional theory (DFT) computations to rationally design semiconductors with proper band-edge positions for photochemistry through varying facets and thicknesses, as well as introducing co-catalysts. We model surface slab structures with different facets for several important semiconductors of interest, such as CdS, $ZnIn_2S_4$, Cu_2ZnSnS_4 and Ag_2ZnSnS_4 (as well as related compounds with replacement or mixing at cation/anion sites), with different thicknesses of the bulk region. Relative electronic band edges are thus computed for multiple pseudo-2D semiconductors as a function of surface termination and thickness, and compared with redox potentials of relevant alcohols, carbonyls, amines and imines. We further study the formation energies of intrinsic point defects as a function of chemical potential conditions and charge states in selected compounds, namely Cu_2ZnSnS_4 and Ag_2ZnSnS_4, and suggest strategies to suppress the formation of harmful anti-site defects. Finally, we model the adsorption of organic molecules on selected semiconductor surfaces, and study photocatalytic coupling reaction mechanisms in the presence of H atoms or added electrons and determine energy barriers using nudged elastic band (NEB) calculations. Complementary experimental synthesis and characterization of ultrathin 2D semiconductor-based photocatalytic systems and the production of ketyl radicals from carbonyls are carried out by our collaborators. The computational screening undertaken in this work reveals novel ways of tuning the photocatalytic properties of semiconductors via modification of slab thickness and surface termination, composition engineering, and defect manipulation.

CH02.08.13

Late News: Enhancement of Thermoelectric Properties in CuCrSnS4/Cu2SnS3 Nanocomposite by Exchange Interaction of Itinerant Carrier and Superparamagnetism of CuCrSnS4 Precipitation Sujin Kim[1], Junphil Hwang[1], Tae Soo You[2], Mi-kyug Han[1], Minju Lee[1] and Sung-Jin Kim[1]; [1]Ewha Womans University, Korea (the Republic of); [2]Chungbuk National University, Korea (the Republic of)

Thermoelectric materials have attracted considerable research attention in recent decades due to their ability of reversible conversion between heat and electricity. The enhancement of thermoelectric performance is challenging due to the strong interrelation of Electrical conductivity and Seebeck coefficient. In this work, we studied eco-friendly Cr-doped Cu_2SnS_3 with $CuCrSnS_4$ nanoparticles. Our experiments and theoretical calculation(DFT) proved that doping Cr atom in Sn site of Cu_2SnS_3 enhanced electrical conductivity by modifying electron density of state. Moreover, by DFT calculation, it is found that doping Cr atom in Sn site makes chemical bonding soften resulting in lattice thermal conductivity decrease. Using XRD analysis, the solubility limit of Cr impurity in Cu_2SnS_3 is around 5 at%. Doping Cr atom above the solubility limit induced the spinel $CuCrSnS_4$ nanoprecipitations. The superparamagnetic fluctuation of spin angular momentum of spinel $CuCrSnS_4$ results in exchange interaction with itinerant carrier spin. The synergetic

effect of Cr doping made the power factor increase from 1.12 to 6.67 μW/cm/K^2. The $CuCrSnS_4$ were verified that second phase in Cu_2SnS_3 matrix by XRD and TEM analysis. The size of $CuCrSnS_4$ confirmed that 50 nm. Finally, Cr-doped-Cu_2SnS_3 with magnetic nanoparticles showed the highest zT value of 0.8 at 723 K comparing with pristine zT of 0.08 at 723 K.

CH02.08.14
Gas Solubility in Water Confined within Microporous Materials Malia Wenny and Jarad A. Mason; Harvard University, United States

The solubility of gases in water—despite being relatively low compared to other solvents—is key to many biological and industrial processes. Bulk water's highly structured hydrogen bonding arrangement is thought to impede the formation of transient voids large enough to accommodate gas molecules. However, when water is confined to the nanoscale, such as in a protein cavity, a carbon nanotube, or a microporous material, its structure and properties can differ dramatically from those observed in the bulk. In particular, the solubility of gases in confined water can be at least an order of magnitude higher than in bulk water, possibly due to differences in the density and hydrogen bonding arrangement of confined water. Understanding the origin and extent of this increase in gas solubility is important for biological and industrial gas-dependent processes that involve water, but experimental investigation of the structure of confined water within micropores and its impact on gas solubility is limited. Microporous materials such as metal–organic frameworks and zeolites provide excellent tools to study the structure and gas solubility of water confined to nanoscopic dimensions due to their chemical and structural tunability and well-studied gas adsorption behavior. This work examines the impact of pore size, shape, and chemistry on the structure and gas solubility of confined water, with particular emphasis on solid-state features such as the relative hydrophilicity of pore walls and the presence of open metal coordination sites capable of binding water molecules.

CH02.08.15
Simple Technique to Generate Small Cerium Oxide Nanoparticles Natalie M. Lopés Velasco[1], Eduardo Chaparro[2] and Sonia J. Bailón-Ruíz[1]; [1]University of Puerto Rico at Ponce, Puerto Rico; [2]University of Puerto Rico at Mayagüez, Puerto Rico

The generation of small Cerium Oxide Nanoparticles (CeO_2 NPs) was performed by a simple precipitation method in the presence of CETAB (hexadecyltrimethylammonium bromide), cerium nitrate hexahydrate ($(Ce(NO_3)_3.6H_2O)$) and ammonium hydroxide solution (NH_4OH). An amount of cerium precursor was added to CTAB and under constant agitation NH_4OH was added until the pH was at a basic of 10.0. The colloidal solution was heated in a reflux system at the range of 55 to 65 Celsius during 3 hours and 6 hours. The final solutions were purificated using the centrifugation system twice for 15 minutes on 7,000 rpm using deionized water. High resolution transmission electron microscopy (HRTEM) studies evidenced mainly spherical-shape and highly crystalline structures for both samples and average sizes of 6 nm and 8 nm for synthesis of 3 hours and 6 hours, respectively. The presence of CTAB as surfactant material would be controlling the growth and particle size of the material. Electron diffraction (ED) patterns evidenced cubic structures for both sizes in the (111), (200), (220), and (311) reflections which are indexes as face centered cubic (fcc) arrangements. Studies of Energy dispersive X-ray Spectroscopy (EDX) indicated Ce (25.6%) and O (74.4%) in the synthesis of 6 hours, and Ce (29.2%) and O (70.8%) at the synthesis of 3 hours. Generated nanoparticles because of their small sizes and high surface area will be evaluated in photodegradation studies to destroy organic pollutants in aqueous matrices.

CH02.08.16
Modeling Stabilization of Reactive Oxygen Species on Defect-Rich Ceria for Toxin Destruction Janna Domenico[1], Nam Q. Le[1], Travis G. Novak[2], Jeffrey Long[2] and Paul A. DeSario[2]; [1]Johns Hopkins University Applied Physics Laboratory, United States; [2]U.S. Naval Research Laboratory, United States

Materials based on ceria (CeO_2) show promising degradative activity towards a variety of pollutants and toxins including organophosphorus pesticides or chemical warfare agents. CeO_2 is highly reducible, leading to oxygen vacancy defects that assist in the formation and stabilization of reactive oxygen species (ROS). These persistent reactive species may later degrade toxic compounds over long timescales. We use density functional theory (DFT) to calculate the energies of binding and formation of ROS at multiple types of defect sites on low-index surfaces of CeO_2. Differences in the calculated energies, which should correlate with ROS lifetimes, originate in the geometry and electronic structure of these surfaces. We compare the predicted trends with the spectroscopic characterization of ROS at CeO_2 aerogels and defect-rich Gd-doped CeO_2 aerogels. The combined modeling and experimental results suggest strategies to engineer longer ROS lifetimes for enhanced toxin destruction through controlled nanoparticle morphology and doping.

CH02.08.17
The Coexistence or Absence of Magnetic Interactions and Superconductivity in Highly Doped $YSr_2Cu_3O_{7-d}$ Cuprates—The Fe and Mo Cases Miguel Angel Alario-Franco[1], Xabier Martinez de Irujo-Labalde[2], Sara A. López-Paz[1] and Susana García Martín[2]; [1]Universidad Complutense, Spain; [2]University of Oxford, United Kingdom

The total or even partial replacement of copper in the charge reservoir block in the well-known $YSr_2Cu_3O_{7-d}$ cuprate by other transition metals (TM) allows one to extend the hole doping range with respect to the conventional phase diagram (1). In particular, the introduction of highly valent cations such as TM= Fe^{3+}/Fe^{4+} or Mo^{5+} results in unusually high nominal hole concentrations at the CuO_2 planes (2,3).
Quite interestingly, despite the elevated doping levels, superconductivity with *relatively high* critical temperatures of Tc = 83 and 70 K are observed in the resulting $Mo_{0.3}Cu_{0.7}Sr_2TmCu_2O_{7+\delta}$ and $FeSr_2YCu_2O_{7+\delta}$ compounds, respectively. Besides the realization of unusually high hole doping levels, the chemical modification of the charge reservoir blocks allows one the study of the *effect of chemical disorder* in the superconducting properties, providing interesting structure-hole doping-Tc relations (4). Also, in the *case of the iron* by copper substitution, *additional complexity arises from the coexistence of magnetic and superconducting interactions* (5). Here we present a broad outlook on the unusual properties of these TM substituted cuprates.

CH02.08.18

Late News: TiO2/Ag Nanoparticles Synthesized by Self-Combustion Used as Alternatives for Postharvest Fruit Ripening Control Carlos Paucar, Paula Nevado and Claudia Garcia; National University of Colombia, Colombia

Fruits reach its maturity several days after its harvest, this process is highly complex since it is associated with biochemical changes that increase the levels of ethylene, which influences its maturation and quality parameters. Ethylene, in its role as an enzyme, is one of the variables with the greatest influence on the ripening and deterioration process in avocado. However, there are also other pathologies and to face pathologies of biotic origin, its management is made with products like imidazole which is toxic and is already banned in some countries. At present, materials such as TiO_2, ZnO, Ag and SiO_2 Nanoparticles could give them the ability to intervene in the amount of free ethylene, and on the other hand they have been found to have antimicrobial activity. TiO_2 nanoparticles are the most widely used at an industrial level due to their photocatalytic activity and properties such as biocompatibility, corrosion resistance and zero toxicity, and Ag nanoparticles due to their photoactivity are promoted as an antimicrobial agents. This work seeks to obtain TiO_2 / Ag nanoparticles by combustion synthesis to search for nanotechnology-based alternatives that can be used in the post-harvest process. Considering the photocatalytic properties of TiO_2 and its relationship with the absorption of ethylene and the antimicrobial properties of Ag, its potential for the postharvest process can be studied. TiO_2 nanoparticles with different concentrations of silver (0%, 0.75%, 1.5%, 3% and 4.5% mole percentage) were obtained by the burning combustion solution method using titanium isopropoxide and silver nitrate as precursors, nitric acid as oxidizing agent and glycine as fuel. Rhodamine-B dye degradation test was performed to verify its photocatalytic activity under visible light and it was observed that indeed the particles obtained have photocatalytic activity. An FTIR study has also been performed on each type of particle and it is observed that there are functional groups such as OH in a peak of 3452.5 cm^{-1}, which is vital for photocatalysis, there are peaks between 836.8 cm^{-1} and 530 , 2 cm^{-1} that corresponds to vibrations of Ti-O and there is a peak that can be associated with the interaction of OH with AgNO3 between 1669.3 cm^{-1} and 1313.4 cm^{-1} since it occurs only in the particles that were synthesized to obtain them with Ag . XRD has been performed to test anatase and rutile with Ag^+ inclusions in crystallographic phases present after combustion synthesis. As results of this studyAg-TiO_2 particles were obtained by the burning combustion solution method with photocatalytic activity under visible light and having ethylene absorption capacity . The presence of OH, Ti-O groups and the interaction of OH with Ag^+ can be observed, thereby the presence of silver in the sample and its photocatalytic activity is higher in samples with OH peak is more intense.

CH02.05.07
Mechanistic Investigation on the Solid-State Transformation of One-Dimensional Sb2Se3 Nanorods to SbSeI Nanorods Eran Edri and Subila Kurukkal Balakrishna; Ben-Gurion University of the Negev, Israel

Metal trichalcogenides and chalcohalides establishes a class of semiconducting materials with a quasi-one-dimensional crystal structure. These low-symmetry semiconductors have shown favorable optoelectronic properties for photovoltaic and photoelectrocatalysis: an optical bandgap in the visible-NIR region, and a relatively small electron affinity. However, there are limited synthetic strategies for nanostructured chalcohalides. Here we report a facile route for transformation of Sb2Se3 to SbSeI nanorods. The Sb2Se3 nanorods acted as templates to form small diameter SbSeI nanorods. The aspect ratio of SbSeI nanorods could be varied by changing the aspect ratio of the template. A detailed investigation of the transformation process reveals favorable thermodynamics and proceeds through a topotactic mechanism that may be suitable for other trichalcogenide-chalcohalide transformations. These ID materials show good charge transport and a bang gap (Eg) of 1.7 eV, which are suitable for photocathodes for hydrogen evolution reactions.

Chemistry of Chiral and Polar Transition Metal Silicon-Phosphides Kirill Kovnir[1,2]; [1]Iowa State University, United States; [2]US DOE Ames Laboratory, United States

Non-centrosymmetric intermetallic compounds with antisymmetric spin-orbit coupling exhibit a plethora of emergent properties, such as unconventional superconductivity, topologically non-trivial quantum properties, and quasiparticle behaviour. Chemical bonding preferences in the transition metal silicon-phosphides T-S-P create the asymmetric environment around metal atoms resulting in high abundance of non-centrosymmetric chiral and polar crystal structures. The synthesis of those phases is hampered by inertness of T and Si in contrast to high reactivity and vapor pressure of phosphorus. We developed a comprehensive synthetic strategy allowing to produce single crystals and phase-pure polycrystalline samples of metal tetrel-pnictides. The correlation between the crystal structure, chemical bonding, and optical and transport properties will be discussed.

11:00 AM CH02.09.02
Thermoelectric Transport and Crystal Morphology of the Quasi-1D Zintl $Ca_5M_2Sb_6$ Alexandra Zevalkink; Michigan State University, United States

Zintl phases, with their vast range of structural patterns in non-cubic space groups and their excellent high-temperature thermoelectric performance, stand out as an intriguing subject area for the study of transport anisotropy. The covalently-bonded polyanions exemplified by Zintl phases crystallize in a diverse range of highly anisotropic sub-structures, including isolated moieties, 1D chains, 2D sheets and 3D networks. Despite ample theoretical evidence of light band mass and enhanced thermoelectric efficiency in the covalently-bonded direction in Zintl phases, experimental confirmation is still largely lacking. This knowledge gap is exacerbated by the difficulty of growing single crystals large enough for complete characterization of transport properties. In the present study, we use a combination of theory and experiment to investigate the anisotropic electronic structure, transport properties, and growth habit of $Ca_5M_2Sb_6$ (M=Al, Ga, In), which is characterized by anionic sub-structures resembling infinite 1D chains of corner-linked MSb_4 tetrahedra. $Ca_5M_2Sb_6$ single crystals grown from an Sb-rich molten flux were found to form long, needle-like crystals oriented parallel to the polyanionic chains. Due to the small cross-section of the crystals, characterization of transport properties in the direction perpendicular to the chains is challenging. For this purpose, micro-ribbons were extracted from single crystals using focused ion beam milling, and laser photolithography was used to deposit contacts to measure electrical resistivity and Hall coefficients. The resistivity measured parallel to the growth direction was found to be nearly 20 times higher than the perpendicular direction, confirming predictions. In addition, to we investigated the surface energies of various terminations of $Ca_5Ga_2Sb_6$, revealing that the calcium content plays a central role in surface reconstruction, leading to the formation or breaking of surface covalent bonds. The relative surface energies are a strong function of growth conditions (either Ca rich or Ca poor), suggesting that the flux composition can be used to tune the growth habit, perhaps guiding future crystal growth of Zintl phases.

11:15 AM CH02.09.03
High-Pressure Structure and Bonding of AMg_2Pn_2 Thermoelectrics (*A*=Ca, Mg, Yb; *Pn*=Bi, Sb) Mario R. Calderon Cueva[1], Allison Pease[1], Wanyue Peng[1], Jingxuan Ding[2], Tyson Lanigan-Atkins[2], Olivier Delaire[2], Susannah Dorfman[1] and Alexandra Zevalkink[1]; [1]Michigan State University, United States; [2]Duke University, United States

Compounds in the structure type $CaAl_2Si_2$, in particular Mg_3Sb_2 and Mg_3Bi_2, have attracted great interest in recent years for their remarkable thermoelectric performance. Their impressive thermoelectric figure of merit (zT) stems, in part, from their anomalously low thermal conductivity. In the present study, in situ high-pressure synchrotron X-ray diffraction was used to investigate the structure and bonding of binary and ternary AM_2X_2 (*A*=Ca, Mg, Yb; *X*=Bi, Sb) compounds at pressures up to 50 GPa. These experiments allowed us to develop trends between bond compressibility and cation size and to study the stability of the $CaAl_2Si_2$ structure type. Our results for binary compounds confirm prior predictions of isotropic in-plane and out-of-plane compressibility but reveal large disparities between the bond strength of the two distinct Mg sites. We show that the octahedral Mg–Sb bonds are significantly more compressible than the tetrahedral Mg–Sb bonds. Conversely, the discrepancy in the polyhedral compressibility for the ternaries is not as pronounced as for the binaries. These results indicate that the bonds of the octahedrally-coordinated Mg are responsible for the ultralow Mg_3Sb_2 and Mg_3Bi_2. Further, we report the discovery of phases transitions above 4.0, 7.8, 11.3, and 18.0 GPa for Mg_3Sb_2, Mg_3Bi_2, $YbMg_2Bi_2$, and $CaMg_2Sb_2$, respectively.

11:30 AM CH02.09.04
Measurements of Thermal Conductivity of Materials at High Pressures and High Temperatures Using Flash Laser Heating Method with Pockels Cell Irina Chuvashova[1,2], Zachary Geballe[1], Sergey Lobanov[3], Lukas Schifferle[3] and Alexander Goncharov[1]; [1]Carnegie Science, United States; [2]Florida International University, United States; [3]Helmholtz Centre Potsdam, Germany

Thermal conductivity is the intrinsic property of a material that expresses its ability to conduct heat. The process of heat conduction depends on four basic factors: the temperature gradient, the cross section of the materials involved, their path length, and the properties of those materials. There are two categories of measurement techniques: steady-state and transient. Steady-state techniques infer the thermal conductivity from measurements on the state of a material once a steady-state temperature profile has been reached, whereas transient techniques operate on the instantaneous state of a system during the approach to steady state.
Thermal transport properties of minerals and melts at high pressures and temperatures is of central importance to the evolution and dynamics of planets. The pressure of the Earth's interior continuously increases with the depth from the surface of the Earth: several hundred MPa at the region of the crust, ~20 GPa at the upper mantle and ~130 GPa at the lower mantle. Precise data of thermal conductivity and/or thermal diffusivity for minerals at elevated pressure make it possible to estimate the heat budget in the Earth.
Direct measurements of thermal conductivity of Earth minerals at extreme pressures and temperatures are very challenging; the available experimental data are limited and inconclusive, causing geodynamical studies to rely on theoretical calculations and/or large extrapolations.
In the present work, we demonstrate the optimized technique to perform direct measurements of thermal conductivity of materials in diamond anvil cells at high pressures and high temperature. We used a continuous 100-Watt infrared laser for heating sample from both sides to a desired temperature and a pulsed 300-Watt infrared laser creating a microsecond long heat wave from one sample side. Thermal conductivity can be determined by measuring temperature of sample radiometrically using a streak camera coupled to a spectrograph from both sample sides as a function of time and fitting the results with FE calculations. KCl was used as PTM, Ir was used for absorption of the laser if the absorption of the sample was small. Pulse was shaped to a square shape by a Pockels cell, which simplified and improved the accuracy of FE calculations. Furthermore, we significantly improved FE analysis by introducing automatic procedures based on python codes enabling the fitting parameter optimization. Fast measurements of thermal emissions allowed us to resolve the heating response through the sample enabling direct measurements of thermal conductivity of Earth's lower mantle minerals and Fe alloys in the core.
This complex system can be used for pressures in the range of 5 to 150 GPa for materials with any laser absorption properties. We used this system to obtain the values of thermal conductivity of ferropericlase, bridgmanite, and iron-silicon alloys which correspond well with literature data albeit mainly measured at room temperature.

11:45 AM CH02.09.06
Exploring Ultralow Thermal Conductive Heteroanionic Materials Hydrothermal Synthesis Chi Zhang, Jiangang He, Rebecca McClain, Hongyao Xie, Songting Cai, Lauren Walters, Jiahong Shen, James M. Rondinelli, Mercouri G. Kanatzidis, Christopher Wolverton, Vinayak Dravid and Kenneth R. Poeppelmeier; Northwestern University, United States

Owing to large lattice anharmonicity from interface interactions between adjacent layers, layered heteroanionic materials have the potential to realize ultralow thermal conductivity[1-3]. As an analog of well-known ultralow thermal conductive phase BiCuOSe, BiAgOSe has been predicted to be a better ultralow thermal conductive material by DFT calculations[4,5]. Utilizing both DFT calculations and Pourbaix diagrams[6], we have optimized the hydrothermal reaction conditions and developed an efficient, high yield synthesis to obtain the BiAgOSe phase. Moreover, we have investigated the thermal transport behavior of BiAgOSe, and demonstrated that it has a lower lattice thermal conductivity compared to BiCuOSe. To study the origin of the ultralow thermal conductivity of BiAgOSe, we combined lattice dynamic calculations and synchrotron x-ray diffraction measurements and found that the low lattice thermal conductivity results from strong lattice anharmonicity and low phonon velocities which are associated with the vibrations of the silver ions.

Tetranuclear Copper(I) Clusters as Highly Efficient Blue Phosphors—Tunable Emissions via Remote Steric Effects Yuichiro Watanabe, Benjamin Washer, Matthias Zeller, Sergei Savikhin, Lyudmila Slipchenko and Alexander Wei; Purdue University, United States

Flexible and lightweight optoelectronic displays depend on luminophores that emit brightly at red, green, and blue wavelengths, but access to the latter is hindered by the limited availability or high cost of phosphors that can produce deep-blue emission. Here, we describe solid-state phosphorescence from a series of tetranuclear copper(I)-pyrazolate (Cu_4pz_4) clusters with high quantum yields and blue emission with color coordinates of [0.15, 0.11]. These emissions are remarkably sensitive to structural effects far from the Cu_4 core: When 3,5-di-*tert*-butylpyrazoles are used as bridging ligands, adding a C4 substituent can cause a blueshift in photoluminescence by over 100 nm. X-ray crystal structures of several Cu_4pz_4 clusters reveal C4 substitution (H, F, Cl, or Br) to have modest effects on solid-state geometries, yet structure-property trends and time-dependent density functional theory (TD-DFT) calculations show the impact of these remote substituents on phosphorescence to be entirely steric in nature. The size of the C4 unit controls the conformations of adjacent *tert*-butyl groups and can increase the rigidity of the Cu_4pz_4 metallacycle, which can diminish Jahn-Teller distortion and prevent the excited-state structure from adopting lower energy states prior to photoluminescence. Such remote steric effects on photophysical processes are unprecedented, and may offer a novel approach toward the design of molecular phosphors with tunable optoelectronic properties.

1:45 PM CH02.10.02
Systematic Bandgap Tuning of 2D Silver Phenylselenide Derivatives Through Organic Modification Tomoaki Sakurada, Watcharaphol Paritmongkol, Woo Seok Lee and William Tisdale; Massachusetts Institute of Technology, United States

Silver phenylselenide (AgSePh), a two-dimensional (2D) member of the broader class of hybrid organic-inorganic metal organochalcogenide (MOC) family, has gained a renewed interest as a novel class of hybrid organic-inorganic 2D semiconductors. AgSePh features multiple exciting properties such as narrow blue luminescence, in-plane anisotropy, large exciton binding energy, earth abundant elemental composition, and a scalable synthesis. In contrast to 2D layered perovskites and transition metal dichalcogenides, AgSePh has strong covalent bonding between organic and inorganic components. This unique covalent interaction makes AgSePh a *truly hybrid* organic-inorganic semiconductor and opens a new door to control the properties of 2D semiconductors through organic functionalization. In this presentation, we will show the unique bandgap tuning of AgSePh and its derivatives by systematically introduce para-substituted functional groups with varied electron-donating and electron-withdrawing capabilities. These newly synthesized derivatives adopt 2D layered structures and exhibit strong excitonic characteristics. We will discuss the effect of organic functionalization on the optical and electronic properties, and show the application of this knowledge on designing new MOC compounds with excellent optical properties.

2:00 PM CH02.10.03
Interaction Between 1D Defects and Dopants in La-Doped $BaSnO_3$ and Its Impact on Material Properties Hwanhui Yun and Andre Mkhoyan; University of Minnesota, United States

Interaction between lattice defects and dopants in crystalline materials has long been recognized, and its influence on the materials' properties has been evidenced in a wide range of materials(1). In thin-film semiconductors, significant density of 1D defects, from well-known dislocations to new types of line defect(2), are formed and interact with dopants, and it has received increasing research interest as the interplay of the crystalline defects and solute atoms can alter the electronic and optical properties of the thin films. Despite its significance, the study of the defect-dopant interaction has remained challenging due to the atomic-scale defect structures and low concentration of dopants. Here, analytical scanning transmission electron microscopy (STEM) and ab initio calculations are employed to directly examine the effects of dopants on 1D defects in promising perovskite La-doped $BaSnO_3$(3, 4).
The local atomic and chemical configurations of two representative dislocations, single (b=a<100>) and dissociated (b=a<110>) dislocations, in La-doped $BaSnO_3$ thin films are characterized via STEM imaging and energy dispersive X-ray (EDX) spectroscopy. In both single and dissociated dislocations, a substantial amount of dopant segregation inside and outside dislocation cores as well as dopant-driven atomic re-arrangement is observed. Core-loss electron energy-loss spectroscopy (EELS) analysis is used to probe the local chemical and electronic structure variation at the dislocations, and structural optimization and electronic ground state calculations provide insight into the origin of the dopant-induced atomic and electronic modifications. Finally, the dopant behavior at dislocations is compared with dopant segregation observed in unique Sn-core line defects in La-doped $BaSnO_3$(2), highlighting the complex but predictable nature of dopants at 1D defects and potential applications of these atomic-scale disorders(5).
La-doped $BaSnO_3$ films were grown on $SrTiO_3$ and $LaAlO_3$ substrates by hybrid molecular beam epitaxy method(6). Plan-view STEM samples were prepared by mechanical polishing, and STEM experiments were carried out using an FEI Titan G2 60-300 (S)TEM equipped with EDX and EELS detectors. Ab-initio calculations were performed using the Quantum Espresso package(7) for structural relaxation and WIEN2K code(8) for ground-state calculations.

Hidden Spontaneous Polarisation in the Chalcohalide Photovoltaic Absorber $Sn_2SbS_2I_3$ Seán R. Kavanagh[1], Christopher Savory[2], Aron Walsh[3] and David O. Scanlon[2]; [1]University College London & Imperial College London, United Kingdom; [2]University College London, United Kingdom; [3]Imperial College London, United Kingdom

Perovskite-inspired materials aim to replicate the optoelectronic performance of lead-halide perovskites, while eliminating issues with stability and toxicity.[1–3] Recently, chalcohalides of group IV/V elements have attracted attention, due to enhanced stability provided by stronger metal-chalcogen bonds, alongside compositional flexibility and ns^2 lone pair cations — a performance-defining feature of halide perovskites.[4] A rigorous description of their atomistic properties and performance potential is lacking, however.

Following the first experimental report of solution-grown tin-antimony sulfoiodide ($Sn_2SbS_2I_3$) solar cells,[5] with power conversion efficiencies above 4%

(exceeding the first reported solar efficiency of methylammonium lead-iodide (MAPI)),[6] we assess the structural and electronic properties of this emerging earth-abundant PV material.[7] We find that the experimentally reported centrosymmetric *Cmcm* crystal structure represents an average over multiple polar *Cmc2₁*configurations. The instability is confirmed through a combination of lattice dynamics and molecular dynamics simulations. We predict a large spontaneous polarisation of 37 μC/cm^2 that could be active for electron-hole separation in operating solar cells. The resemblance of this dynamic crystal structure and ferroelectric behavior to that of MAPI begs the question of its importance in high-performance defect-tolerant solar materials.

Moreover, using state-of-the-art *ab-initio* methods (hybrid Density Functional Theory including spin-orbit coupling effects), we rigorously assess the efficiency limits of this material on the basis of its electronic structure and predicted defect behaviour, calculating $\eta_{max} > 30$ % for film thicknesses t > 0.5 μm.

The results shine a spotlight on the largely-unexplored class of $A_2BCh_2X_3$ mixed-metal chalcohalides. These are candidates for solution-processed ferroelectric and optoelectronic devices, with the substitutional flexibility for engineering band gaps, band energies, and lattice polarisation. Our work provides insight regarding both the potential success of this emerging class of optoelectronic materials and structure-property relationships in perovskite-inspired materials, guiding design strategies and expanding the compositional space of candidate materials.

Organohalide Precursors for the Continuous Production of Photocatalytic Bismuth Oxyhalide Nanoplates Matthew N. Gordon, Kaustav Chatterjee, Alison L. Lambright, Sandra L. Atehortua Bueno and Sara E. Skrabalak; Indiana University, United States

Metal heteroanionic materials, such as oxyhalides, are promising photocatalysts in which band positions can be engineered for visible-light absorption by changing the halide identity. Advancing the synthetic routes towards these materials, bismuth oxyhalides of the form BiOX (X = Cl, Br) have been prepared using rapid and scalable ultrasonic spray synthesis (USS). Central to this advance was the identification of small organohalide molecules as halide sources. When these precursors are spatially and temporally confined in the aerosol phase with molten salt fluxes, powders composed of single-crystalline BiOX nanoplates can be produced continuously. A mechanism highlighting the in situ generation of halide ions is detailed. These materials can be used as photocatalysts and provide proof-of-concept of USS as a route to more complex bismuth oxyhalide materials.

An Insight into the Phase Dependent Photocatalytic Activity of Bulk and Exfoliated Defect-Controlled 2D Flakes of Copper Sulfide System Under Simulated Solar Light Madina Telkhozhayeva, Rajashree Konar, Eti Teblum and Gilbert D. Nessim; Bar-Ilan University, Israel

Sunlight-driven photocatalysis is an environmentally friendly approach to solve ecological issues and energy crisis. The development of simple, yet sufficiently stable, photocatalytic materials responsible for harvesting full-spectrum light remains a significant challenge so far. With regard to the design of advanced photocatalysts, low-dimensional materials show tremendous prospects due to their unique surface and electronic properties, which are not seen in their bulk counterparts. Among the various inorganic semiconductors, copper sulfides ($Cu_{2-x}S$, $0 \leq x \leq 1$) have attracted great interest in applications linked to photovoltaic devices and photocatalysis due to their low cost, high element abundance, non-toxic nature, structural and compositional versatility.[1] However, the properties of copper sulfides are sensitive to the Cu-S stoichiometry, which determines the density of copper vacancies, thus the hole concentration; therefore it is critical to finely tune their phases for use in applications.
Herein, we first demonstrate the phase transformations of bulk copper sulfides from digenite (Cu_9S_5) to djurleite ($Cu_{1.97}S$) and low-chalcocite (Cu_2S) by the continuous reactive thermal annealing in ambient pressure chemical vapor deposition (CVD), followed by their top-down exfoliation. XRD, HRTEM, and XPS analyses confirm that monoclinic Cu_2S is primarily formed at higher temperatures or greater reaction times and using reducing atmosphere owing to its lower free energy of formation and greater symmetry in its crystal structure. Although copper sulfide does not have a typical MX_2 structure common for transition metal chalcogenides (TMCs), we successfully exfoliated it into 2D flakes using high-frequency liquid-phase exfoliation (LPE) due to its layered morphology.[2] From AFM, we measured the average thickness of approximately 4 nm of the exfoliated flakes with relatively large lateral size up to 10 μm. We tested the three phases of bulk copper sulfides and their exfoliated forms as photocatalysts for dye degradation under simulated solar light irradiation. Exfoliated Cu_2S flakes exhibited superior photocatalytic activity with a rate constant roughly twice higher than that of bulk chalcocite, which could be predominantly attributed to their unique 2D structure and layered morphology, where the exfoliated flakes can provide an ultrahigh fraction of surface atoms, which could serve as the active sites for dye photodegradation. In addition, the enhanced photocatalytic activity could be attributed to the 2D planar defects such as stacking faults in different portions of exfoliated Cu_2S that were introduced during the annealing in reducing atmosphere without altering its structure and crystallinity. Furthermore, optical spectroscopy results demonstrate that the 2D Cu_2S has sufficient bandgap energy for simultaneously absorbing across the whole solar spectrum. Photocatalytic mechanism experiments and electron-spin resonance (ESR) data indicate that both superoxide radicals and holes served as dominant active species during the photocatalytic reaction. Our study provides a better understanding of possible phase transformations in the copper sulfide system and paves the way for developing next-generation 2D copper sulfide photocatalysts to capture a broad range of the solar spectrum for environmental decontamination.

Novel Metal–Organic Glasses and Liquids from Metal–Bis(acetamide) Frameworks with Low Melting Temperatures Mandy Liu[1], Ryan McGillicuddy[1], Hung Vuong[2], Songsheng Tao[2], Adam Slavney[1], Miguel I. Gonzalez[1], Simon J. Billinge[2] and Jarad A. Mason[1]; [1]Harvard University, United States; [2]Columbia University, United States

Molten phases of metal–organic networks offer exciting opportunities for using coordination chemistry principles and reticular synthesis to access liquids and glasses with unique and tunable structures and properties. Here, we discuss general thermodynamics strategies to design extended coordination solid structures with an increased enthalpic and entropic driving force for reversible, low-temperature melting transitions and illustrate this approach through a systematic study of novel bis(acetamide)-based networks with record-low melting temperatures. The low melting temperatures of these compounds are the result of weak coordination bonds, conformationally flexible bridging ligands, and weak electrostatic interactions between spatially separated cations and anions, which collectively reduce the enthalpy and increase the entropy of fusion.
Through a combination of crystallography, spectroscopy, and calorimetry, we demonstrate that trends in enthalpy of fusion are dictated by the strength of coordination bonds and hydrogen bonds within each extended coordination solid, while trends in entropy of fusion are strongly influenced by the degree to which residual motion and positional disorder are restricted in the crystalline state. Pair distribution function (PDF) and extended X-ray absorption fine structure (EXAFS) analysis of $Co(bba)_3[CoCl_4]$ [bba = *N*,*N*′-1,4-butylenebis(acetamide)], which features a record-low melting temperature for a three-dimensional metal–organic network of 124 °C, provide evidence of metal–ligand coordination in the liquid phase, as well as intermediate- and extended-range order that support its network-forming nature. Glass formation is observed from the metal–organic liquids with various chemical compositions, and rheological measurements are used to rationalize differences in glass-forming ability and relaxation dynamics. These findings reveal exciting potential of manipulating melting thermodynamics of extended coordination solids by controlling structural and chemical factors in their crystalline state, as well as accessing metal–organic glass and liquid phases with unique structures and properties.

Chiral Organic Semiconductors—Predicting Molecules and Motifs Kim E. Jelfs; Imperial College London, United Kingdom

Recent years have seen a surge in interest throughout the materials science community in the rational design of crystal structures that maximise a material's suitability as an organic semiconductor. Predicting the spatial arrangement of molecules in the solid state and, therefore being able to compute the resulting electronic properties, provides insights into structure-property relationships to guide the material design process. We have been predicting polymorphs and charge mobilities for a myriad of [6]helicenes. Helicenes are a class of axially chiral twisted graphene-like molecules, with potential applications as organic semiconductors. Due to their discernible molecular geometry, helicenes tend to pack in recurring structural motifs. The ubiquity of certain motifs across polymorphs can be exploited to screen a vast pool of helicenes for the best charge transport material along a specific motif. We generated approximately 1400 different [6]helicene molecules, packing in the most frequently encountered translational dimer motif. We computed the transfer integral and inner reorganisation energy to screen for good semiconductors. For the most promising [6]helicene molecules, a CSP search was performed and the lowest energy polymorphs' charge carrier mobility was computed. We observed very low inner reorganisation energies for symmetrically disubstituted [6]helicenes containing side groups with a triple bond. The most promising candidates have been selected for full crystal structure prediction and are being synthesised by our experimental collaborators. More recent work analysing the packing of helicenes on surfaces using coarse-graining methods will also be discussed.

8:30 AM CH02.11.07
Lone-Pair-Induced Structural Ordering in the Mixed-Valent 0D Metal-Halides $Rb_{23}Bi^{III}_xSb^{III}_{7-x}Sb^{V}_2Cl_{54}$ ($0 \le x \le 7$) Kyle M. McCall[1,2], Bogdan M. Benin[1,2], Michael Woerle[1], Dominique Borgeaud dit Advocat[1], Thomas Vonderach[1], Kostiantyn Sakhatskyi[1,2], Sergii Yakunin[1,2], Detlef Guenther[1,2] and Maksym V. Kovalenko[1,2]; [1]ETH Zurich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Mixed-valent solid-state compounds have long been known for their vibrant colors, and the pnictogen-halide semiconductors containing ns^2 lone pairs are no exception, exhibiting intense absorption bands with unusual colors. In contrast, zero-dimensional (0D) ns^2-based metal-chlorides without mixed-valency are generally colorless but have recently demonstrated unique properties that are promising for optoelectronic applications such as broadband lighting, thermometry, and radiation detection.
Here, a new family of mixed-valent alkali pnictogen halides with composition $Rb_{23}Bi^{III}_xSb^{III}_{7-x}Sb^{V}_2Cl_{54}$ ($0 \le x \le 7$) is discovered through solvothermal synthesis. Single-crystal X-ray diffraction reveals that the deep red $Rb_{23}Sb^{III}_7Sb^{V}_2Cl_{54}$ crystallizes in an orthorhombic space group (*Cmcm*) with a unique, layered 0D structure driven by the repulsion of the $5s^2$ lone pairs of the $Sb^{III}Cl_6$ octahedra. In contrast to the prototypical $Cs_4Sb^{III}Sb^{V}Cl_{12}$ tetragonal structure with highly symmetric octahedral environments, here the $Sb^{III}Cl_6$ octahedra exhibit trigonal or disphenoidal distortion from the lone pair, yielding layers with distinct orientations of the octahedra as these asymmetric units pack around the $Sb^{V}Cl_6$ octahedra. Partially or fully substituting Sb^{III} with isoelectronic Bi^{III} yields the series $Rb_{23}Bi^{III}_xSb^{III}_{7-x}Sb^{V}_2Cl_{54}$ ($0 < x \le 7$), with a similar layered 0D structure but exhibiting rotational disorder that yields a trigonal crystal system with a polar space group (*R*32). Second harmonic generation of 532 nm light from a 1064 nm laser using $Rb_{23}Bi^{III}_7Sb^{V}_2Cl_{54}$ powder confirms the non-centrosymmetry of this compound. As with the prototypical mixed-valent pnictogen halides, the visible absorption bands of the $Rb_{23}Bi^{III}_xSb^{III}_{7-x}Sb^{V}_2Cl_{54}$ family are the result of intervalent Sb^{III}-Sb^{V} and mixed-valent Bi^{III}-Sb^{V} charge transfer bands, with a blueshift of the absorption edge as Bi^{III} substitution increases. No PL is observed from this family of semiconductors, but a crystal of $Rb_{23}Bi^{III}_7Sb^{V}_2Cl_{54}$ exhibits a high resistivity of 1.0×10^{10} Ωcm and weak X-ray photoconductivity with a μτ product of 8.0×10^{-5} cm^2 s^{-1} V^{-1}. Beyond simply adding a new entry to the growing library of 0D metal halides, the unique 0D layered structures of the $Rb_{23}Bi^{III}_xSb^{III}_{7-x}Sb^{V}_2Cl_{54}$ family highlight the versatility of the ns^2 lone pair and offer ripe opportunities for tuning and improving these materials; namely, the ability to tune both lone-pair expression as well as the charge transfer absorption band characteristic of mixed-valent materials within the same structure.

8:35 AM CH02.11.02
Reversible Phase Transformations in Novel Dual-Phase Ce-Substituted Perovskite Oxide Composites for Solar Thermochemical CO_2 Redox Splitting J. Madhusudhan Naik[1], Clemens Ritter[2], Brendan Bulfin[3], Aldo Steinfeld[3], Rolf Erni[4] and Greta R. Patzke[1]; [1]University of Zurich,

Switzerland; [2]Institut Laue-Langevin, France; [3]ETH Zurich, Switzerland; [4]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Solar thermochemical (STC) splitting of CO_2 and/or H_2O via two-step metal oxide redox cycles is a promising approach to generate large-scale quantities of synthetic liquid hydrocarbon fuels. STC pathway utilizes the enitre spectrum of solar radiation as a source of high-temperature process heat to split CO_2 and/or H_2O into CO and/or H_2.[1] The CO and H_2 (*syngas*) produced may be directly used as a fuel or furthur processed into synthetic liquid hydrocarbon fuels by the Fischer-Tropsch process. The two-step thermochemical temperature-swing cycle involves an endothermic reduction step of a redox metal oxide at high temperatures (1300–1500 °C), generating lattice oxygen vacancies, followed by an exothermic re-oxidation step with CO_2 and H_2O at low temperatures (800–1000 °C).[2] Perovskite-type ($ABO_{3-\delta}$) oxides are being considered as an attractive redox material class alternative to the state-of-the-art material ceria ($CeO_{2-\delta}$), due to their high structural and thermodynamic tunability. However, these advantages are offset by the unfavorable re-oxidation equilibria due to their low entropy change compared to pure ceria, leading to lower mass specific fuel productivity under most conditions relevant for STC cycles. This work reports a novel dual-phase Ce-substituted Mn-deficient perovskite oxide (LSC25M75), $La^{3+}_{0.48}Sr^{2+}_{0.52}(Ce^{4+}_{0.06}Mn^{3+}_{0.79})O_{2.55}$ (*R-3c*, 70 %) and pyrochlore $Ce^{4+}_{2.6}La^{3+}_{1.4}O_{6.28}$ (*Fd-3m*, 30 %) composite material, aiming to overcome individual thermodynamic limitations of perovskite oxide and ceria based redox materials. Thermochemical CO_2 redox splitting and long-term cyclability of LSC25M75 evaluated with a thermogravimetric analyzer and an IR furnace reactor over 100 consecutive redox cycles demonstrated a two-fold higher CO_2 conversion extent than the current state-of-the-art perovskite oxide, $La_{0.60}Sr_{0.40}MnO_{3-\delta}$ (LSM).
Improved understanding of the true phases and the structure-property relationship of materials under operational conditions is necessary for developing high performance STC redox materials. The underlying reaction mechanism for the obtained high performance were elucidated for the first time using complementary diffraction techniques. Based on in situ high temperature neutron, ex situ synchrotron X-ray and electron diffraction experiments, we obtained an unprecedented structural insight into thermochemical perovskite oxide materials. We propose a novel CO_2 splitting reaction mechanism involving a reversible temperature induced phase transition from the n = 1 Ruddlesden-Popper phase ($Sr_{1.10}La_{0.64}Ce_{0.26})MnO_{3.88}$ (*I4/mmm*, K_2NiF_4-type) at reduction temperature (1350 °C) to the n = 2 Ruddlesden-Popper phase ($Sr_{2.60}La_{0.22}Ce_{0.18})Mn_2O_{6.6}$ (*I4/mmm*, $Sr_3Ti_2O_7$-type) at re-oxidation temperature (1000 °C) after the CO_2 splitting step. [3]

8:40 AM CH02.11.03
Local Order—A New Control Parameter for Optimizing Material Properties Arkadiy Simonov and Yevheniia Kholina; ETH Zurich, Switzerland

Disorder is commonly used in chemistry for designing functional materials. For instance, preparation of solid solutions is nothing else than the introduction of a controlled number of point defects in a crystal. Disordered systems, though, provide more degrees of freedom: not only the number of defects, but also their distribution can be used to optimise the functional properties of materials, however up until now, defect distribution was hard to control and thus was rarely used in practice.

In this talk we will show how to precisely tune distribution of point defects by changing various chemical parameters during crystal growth, and characterise it with the single crystal diffuse scattering.

We will use Prussian Blue Analogues (PBAs) as our model system. PBAs is a class of cyanide materials with the general formula $M[M'(CN)_6]_{1-\delta} * xH_2O$ where M and M' are transition metals. Depending on the nature of transition metals, PBAs can accommodate a large number of vacancies on the $M'(CN)_6$ site (for instance δ=0.33 for M=Mn and M'=Co) which makes them highly porous and, as a result, attractive for hydrogen storage applications. Distribution of $M'(CN)_6$ vacancies is important for the performance of this material, since more disordered vacancy configurations provide more diffusion pathways through the structure, larger accessible volume, and easier transport.

8:45 AM CH02.11.05
Rare Earth Doped Nanoscale Upconverting Fluorides $Na_{1.5}Yb_{1..5}F_6$ and SrF_2 and Their Application for Dosimetry and Thermal Supervision Michael Arnold, Julia Katzmann, Christiane Schuster and Thomas Härtling; Fraunhofer IKTS, Germany

A recent approach to measure electron radiation doses in the kGy range is the use of phosphors with an irradiation dose-dependent luminescence decay time. $NaYF_4$:Yb^{3+},Er^{3+} is limited as it shows pronounced fading. Therefore, in this work a modified synthesis of three fluorides is presented that the results in nanoparticles co-doped Yb and Er, Ho or Tm that is shown to be a promising dosimeter material. Upon excitation with a 980 nm laser a typical upconversion luminescence is observed. For all these materials a dose dependency of the luminescence decay time is observed. However, of the most importance is the very low fading effect of the luminescence decay time. In the case of SrF_2 that is as low as 5 % in the 30 days after irradiation and beyond. This makes this type of materials attractive for electron beam dosimetry in spite of lower upconversion intensity compared to $NaYF_4$ or $BaYbF_5$. In addition all two materials show $Na_{1.5}Yb_{1..5}F_6$ and SrF_2 shows thermoluminescent properties.

Experimental: The precipitation (SrF2) [1] is done with an ammonium fluoride solution (all Sigma Aldrich) in distilled water. The hydrothermal syntheses of $Na_{1.5}Yb_{1.5}F_6$:RE run in a PTFE autoclave with a stainless steel envelop. All compounds were characterized by x-ray powder diffractometry and micro structure photography. The samples were irradiated in an EBLab 200 electron irradiator (Comet) using 200 KV acceleration voltage. Doses of 5 kGy up to 50 kGy were applied to the samples. To measure luminescence decay curves, the phosphor samples were excited by a 1 ms light pulse from a 980 nm laser diode (max. 80 mW, Roithner SPL980-100-105M-PD) and the temporal upconversion luminescence decay was recorded by a silicon photodiode (Osram SFH2200). Ten consecutive curves were averaged and then exponentially fitted to obtain the decay time.
Results: After electron beam irradiation (200 keV) of a thin immobilized phosphor layer the luminescence decay time of the SrF_2: 2%Er, 2…20%Yb phosphor decreases from 1520 µs to values between 1250 µs and 1020 µs, depending on the irradiation dose as shown in Figure 1a. For samples irradiated with 5, 10 and 20 kGy, respectively, the luminescence decay times were repeatedly measured until 50 days after irradiation (Figure 1b). The material $Na_{1.5}Yb_{1.5}F_6$:Ho,Yb shows a decay time dependence of the temperature (Figures 2a and 2b) in case of the radiated materials. The altered decay time after electron beam radiation is similar low fading in 30 days than SrF_2;Er,Yb.
Conclusion: In this work, a series of fluoride sub-micron powders co-doped with different amounts of Yb^{3+} sensitizer and trivalent Er, Ho Tm activator ions were synthesized. For SrF_2:Er,Yb(2%/20%), a dose-dependent reduction of the material's luminescence decay time after electron irradiation is observed. This allows the use of the powder as a dosimeter material. Encouragingly, SrF_2:Er,Yb(2%/20%) shows reduced fading of the luminescence decay time compared to the previously studied $NaYF_4$:Yb^{3+}, Er^{3+}. The thermal response of the radiated $Na_{1.5}Yb_{1.5}F_6$:Ho,Yb make this material suitable for temperature supervision [2] on electronic boards e.g.

Figure 1: a) end point of the decay time (TCSPC) after different electron beam doses, b) fading of different radiated SrF_2:Er Yb samples (a fifty days storage shows the same)

Figure 2: thermal response of the decay time with radiated SrF_2:Er Yb (a) and $Na_{1.5}Yb_{1.5}F_6$:Ho,Yb (b) by the same dose

Doping by Design—Enhanced Thermoelectric Performance of GeSe-Based Alloys Through Metavalent Bonding Yuan Yu, Carl-Friedrich Schön, Oana Cojocaru-Mirédin and Matthias Wuttig; RWTH Aachen University, Germany

For thermoelectrics doping is usually the first step to tailor the charge carrier concentration and concomitant properties. Doping should also turn GeSe, which features intrinsically a low concentration, into a competitive thermoelectric. Yet, elemental doping fails to adjust the charge carrier concentration. Doping with $AgSbSe_2$, on the contrary, works and causes a remarkable enhancement of thermoelectric performance. This improvement is closely related to a change of bonding mechanism, as evidenced by sudden alterations of the optical dielectric constant ε_∞, the Born effective charge Z* and the bond breaking mechanism. These property changes signal the formation of metavalent bonds. These bonds lead to an octahedral-like atomic arrangement and a favorable band structure featuring small effective masses. A quantum-mechanical map distinguishes the different types of chemical bonding. It reveals that orthorhombic GeSe is located in a map region where covalent bonding prevails, while cubic and rhombohedral GeSe are located in the region characterized by metavalent bonding. These assignments are in line with the measured properties and thermoelectric performance of the different phases. Our work thus redefines doping rules and provides a 'treasure map' to tailor thermoelectric properties of chalcogenides and related p-bonded materials.

8:55 AM *CH02.11.08
Towards Reversible High-Voltage Multi-Electron Reactions in Alkali-Ion Batteries Using Vanadium Phosphate Positive Electrode Materials Laurence Croguennec[1], Edouard Boivin[2,1], Long H.B. Nguyen[1,2], Jacob Olchowka[1], Dany Carlier[1], Jean-Noel Chotard[2] and Christian Masquelier[2]; [1]ICMCB, CNRS, Bordeaux Univ., Bordeaux INP, France; [2]LRCS, Picardie Jules Verne Univ., France

Vanadium phosphate positive electrode materials attract great interest in the field of Alkali-ion (Li, Na and K-ion) batteries due to their ability to store several electrons per transition metal. These multi-electron reactions (from V^{2+} to V^{5+}) combined with the high voltage of corresponding redox couples (e.g., 4.0 V vs. Na^+/Na for V^{3+}/V^{4+} in $Na_3V_2(PO_4)_2F_3$) could allow the achievement of the 1 kWh/kg milestone at the positive electrode level in Alkali-ion batteries. However, a massive divergence in the voltage reported for the V^{3+}/V^{4+} and V^{4+}/V^{5+} redox couples as a function of crystal structure is noticed. Moreover, vanadium phosphates that operate at high V^{3+}/V^{4+} voltages are usually unable to reversibly exchange several electrons in a narrow enough voltage range. During this talk, through the review of redox mechanisms and structural evolutions occuring upon electrochemical operation of selected widely studied materials, we will identify the crystallographic origin of this trend: the distribution of PO_4 groups around vanadium octahedra, that allows or prevents the formation of the vanadyl distortion (O . . . V^{4+}=O or O . . . V^{5+}=O).[1-4] While the vanadyl entity massively lowers the voltage of the V^{3+}/V^{4+} and V^{4+}/V^{5+} couples, it considerably improves the reversibility of these redox reactions. Therefore, anionic substitutions, mainly O^{2-} by F^- , have been identified as a strategy allowing for combining the beneficial effect of the vanadyl distortion on the reversibility with the high voltage of vanadium redox couples in fluorine rich environments.

Understanding the Short-Range Order Preference in the Antiperovskite Cathode Material Li_2FeSO Samuel W. Coles[1,2], Kit McColl[1,2], Alexander Squires[1,2], Conn O'Rourke[1,2], Saiful Islam[1,2] and Benjamin J. Morgan[1,2]; [1]University of Bath, United Kingdom; [2]Faraday Institution, United Kingdom

In cation disordered cathode materials the presence of any short-range ordering of cations can have a strong influence on their function, in particular their electrochemical behaviour on cycling[1]. The recently discovered anti-perovskite cathode material Li_2FeSO has a promising theoretical capacity[2], but still encounters issues with capacity fade and long-term structural degradation[3].

This theoretical study seeks to explore the short range ordering of cations in Li_2FeSO by using a DFT+U based cluster expansion. It will be shown that there is a strong preference for the formation of OLi_4Fe_2 of oxygen octahedra, which we postulate is due to equidistribution of charge. More curiously we find that the asymmetric arrangement of lithium and iron ions around the sulfur and oxygen anions is favoured versus symmetric arrangements. Subsequent Wannier analysis of DFT calculations shows that this stabilisation has its origins in the generation of dipoles on the anions. We conclude that these anion dipoles are not only the origins of the short-range order in Li_2FeSO but also induce disorder in this material.

Tunable Phase Transitions in a Two-Dimensional Superionic Conductor Alex Rettie; University College London, United Kingdom

Superionic conductors (SICs) possess liquid-like ionic diffusivity in the solid state, finding wide applicability from electrolytes in energy storage to

materials for thermoelectric energy conversion. Type I SICs, where high ionic diffusivity is linked to the crystal structure *via* a first-order transition and is therefore either on or off, are attractive for energy storage and conversion applications providing the transition temperature can be controlled. However, such SICs (e.g., AgI, Ag_2Se, etc.) have been found exclusively in 3D crystal structures so far, limiting existing approaches to applied pressure and nanoscale size effects – which affect the transition temperature in one direction – while the effects of chemical substitution cannot be easily decoupled from 3D ion-conducting pathways. Layered materials have spatially separated mobile and immobile sublattices, potentially facilitating wide tunability and functioning as platforms to study two-dimensional superionic conduction.
We previously identified a first-order, order-disorder phase transition in 2D KAg_3Se_2 – a dimensionally-reduced derivative of 3D Ag_2Se – at ~695 K using in-situ XRD and DSC [1]. Here, we use quasi-elastic neutron scattering and AIMD simulations reveal that a-KAg_3Se_2 is a type I SIC with a highly disordered Ag sublattice restricted to 4 Å thick layers [2]. The superionic local structure was probed by in-situ XPDF analysis, confirming the defect dynamics from AIMD simulations . Thermal analyses of cation-substituted AAg_3Se_2 (*A* = Li-Cs) compounds indicate that the superionic transition temperature can be tuned by the composition of the immobile charge-balancing layers. Future directions to design materials with tailored ionic conductivities and phase transitions will be discussed.

SESSION CH02.12: Physical Properties of Inorganic Solids II
Session Chairs: Amparo Fuertes and Hiroshi Kageyama
Monday Afternoon, December 6, 2021
CH02-Virtual

1:00 PM *CH02.12.01
Complex Halide Perovskites Kurt Lindquist[1], Bridget Connor[1], Michael Boles[1], Stephanie Mack[2,3], Jeffrey Neaton[2,3] and Hemamala Karunadasa[1,4]; [1]Stanford University, United States; [2]UC Berkeley, United States; [3]LBNL, United States; [4]SLAC National Accelerator Laboratory, United States

I will present our recent studies on further increasing the accessible electronic structures of the versatile family of halide perovskites by synthesizing mixed-metal compositions. Our work on halide double perovskites has prompted us to explore still more complex perovskites. In particular, I will discuss unusual new architectures that combine sublattices of different dimensionality and the consequences of incorporating three distinct stoichiometric metals in the octahedral sites.

Atomistic Investigation of Uranium Oxycarbide (UCO) Phase Stability, Point Defects and Fission Products Properties Ibrahim Cheik Njifon and Edmanuel Torres; Canadian Nuclear Laboratories, Canada

We present atomistic modelling of uranium oxycarbide (UCO), a candidate fuel kernel for TRISO particles in the high temperature gas reactors (HTGRs). The use of UCO aims at mitigating the formation and release of CO gas [1] which is associated with the TRISO particle failure. Under operation, UCO microstructure evolves to form the high atomic mass UC(O) phase with rocksalt structure and the low atomic mass UO2(C) phase with fluorite structure [2, 3]. This study sheds light on phase stability, structural and thermodynamic quantities of both UCO phases. Defects stability, atomic self-diffusion and fission products incorporation are also investigated in the UO2(C) phase. Our results demonstrate a strong dependence on carbon content, which may have a significant impact on the fuel chemistry under operation, thereby playing an important role in the fuel performance properties such as fission products retention and release in UCO fuel kernel of TRISO particles.

Development of Noble Metal Free Bi-Functional Electrocatalysts for Hydrogen Evolution Reaction on Porous Carbon Support and Performance Study Sanju Gupta; University of Central Florida, United States

Developing bi-functional electrocatalysts for both oxygen reduction reaction (ORR) and hydrogen evolution reaction (HER) is crucial for enhancing the energy transfer efficiency of metal-air batteries and fuel cells, as well as producing hydrogen with high purity. Herein, a series of Ni-Co alloyed nanoparticles encapsulated in or decorated on activated charcoal and porous carbon support (BAX) synthesized using electrodeposition and employed as a bifunctional electrocatalyst for both ORR and HER. The scanning electron microscopy measurements showed optimal loading of Ni-Co nanoparticles, with a size of approximately 5–10 nm, which were uniformly dispersed on the nanoporous carbons support, with occasional aggregated of nanoparticles. The as-prepared samples exhibited effective ORR activity in alkaline media and excellent HER activity in both alkaline and acid solutions. While the cobalt nanoparticles showed an overpotential of 54 mV dec^{-1}, Ni–$Co_{3:1}$ showed higher current density and higher overpotential of 130 mV dec^{-1} at 10 mA cm^{-2} in 1 M KOH, respectively suggesting Volmer-Tafel and Volmer-Herovsky mechanism, respectively, for HER. Overall, Ni: Ni:$Co_{3:1}$/BAX on graphite rod samples displayed the best activity and stability among the series, which is comparable and superior to that of commercial 10% Pd/C. The strategy for encapsulating bimetallic alloys within porous carbon materials is promising for fabricating sustainable energy toward electrocatalysts with multiple electrocatalytic activities for alternative energy-related applications.

1:40 PM CH02.12.04
Multimodal Structure Solution with ^{19}F NMR Crystallography of Spin Singlet Molybdenum Oxyfluorides Fenghua Ding, Kent J. Griffith and Kenneth R. Poeppelmeier; Northwestern University, United States

Complex crystal structures with subtle atomic scale details are now routinely solved using complementary tools such as X-ray and/or neutron scattering combined with electron diffraction and imaging. Identifying unambiguous atomic models for oxyfluorides, needed for materials design and structure–property control, is often still a considerable challenge. In this work, NMR crystallography and single-crystal X-ray diffraction are combined for the

complete structure solution of three new compounds featuring a rare triangular early transition metal oxyfluoride cluster $[Mo_3O_4F_9]^{5-}$. After framework identification by single-crystal X-ray diffraction, 1D and 2D solid-state ^{19}F NMR spectroscopy supported by *ab initio* calculations are used to solve the structures of **(1)** $K_5[Mo_3O_4F_9]\bullet 3H_2O$, **(2)** $K_5[Mo_3O_4F_9]\bullet 2H_2O$, and **(3)** $K_{16}[Mo_3O_4F_9]_2[TiF_6]_3\bullet 2H_2O$ and to assign the nine distinct fluorine sites in the oxyfluoride clusters. Furthermore, ^{19}F NMR identifies selective fluorine dynamics in $K_{16}[Mo_3O_4F_9]_2[TiF_6]_3\bullet 2H_2O$. These dual scattering and spectroscopy methods are used to demonstrate the generality and sensitivity of ^{19}F shielding to small changes in bond length—on the order of 0.01 Å or less—even in the presence of hydrogen-bonding, metal–metal bonding, and electrostatic interactions. Starting from the structure models, the nature of chemical bonding in the molybdates is explained from molecular orbital theory and electronic structure calculations. The average Mo–Mo distance of 2.505 Å and diamagnetism in **(1)**, **(2)** and **(3)** are attributed to a metal–metal bond order of unity along with a $1a^21e^4$ electronic ground state configuration for the $[Mo_3O_4F_9]$ cluster, leading to a rare trimeric spin singlet involving d^2 Mo^{4+} ions. The approach to structure solution and bonding analysis is a powerful strategy to understand the structures and chemical properties of complex fluorides and oxyfluorides.

1:45 PM CH02.12.05
New Atomistic Framework for Identifying, Optimizing and Extrapolating Structure-Property Relationships in Inorganic Solids Olivier C. Gagné[1] and Frank Hawthorne[2]; [1]Carnegie Institution for Science, United States; [2]University of Manitoba, Canada

Growing interest in the design of functional materials with increasingly complex crystal structures calls for a more detailed understanding of structure-property relationships in inorganic solids. Whereby functional material properties are often linked to irregular bond distances, deciphering the causal mechanisms underlying bond-length variation, and the *extent* to which bond lengths vary in solids, has important implications in the design of new materials and the optimization of their functional properties.

Investigation of the relation between bond-length variation and the expression of functional material properties begins with systematization of chemical-bonding behavior via large-scale bond-length dispersion analysis. Completion of the largest bond-length dispersion analysis to date for inorganic solids (177,446 bond lengths hand-picked from 9210 crystal-structure refinements for oxides; 6,770 bond lengths from 720 crystal-structure refinements for nitrides ; 33,626 bond lengths from 1832 crystal-structure refinements for chalcogenides) recently enabled straightforward identification of anomalous (i.e. irregular) bonding behavior for all ions of the periodic table observed bonding to O^{2-}, N^{3-}, and S^{2-}/Se^{2-}/Te^{2-}. In addition to comprehensive description of bond-length variations in inorganic solids, the large amount of data on anomalous coordination environments provided by this undertaking allows (1) conclusive resolution of the causal mechanisms underlying bond-length variation in inorganic solids, and (2) quantification of the extent to which these causal mechanisms result in bond-length variation.

In a sample of 266 highly irregular coordination polyhedra covering 85 transition-metal ion configurations bonded to O^{2-}, the most common cause of bond-length variation is observed to be *non-local bond-topological asymmetry* — a widely overlooked phenomenon whose associated bond-length variation results from asymmetric patterns of *a priori* bond valences — followed closely by the pseudo Jahn-Teller effect (PJTE). Two new indices, Δ_{topol} and Δ_{cryst}, calculated on the basis of crystallographic site, are proposed to quantify bond-length variation arising from bond-topological and crystallographic mechanisms in extended solids; Δ_{topol} is defined as the mean weighted deviation between the bond valences of a given polyhedron and that of its regular variant with equal bond lengths, while Δ_{cryst} similarly quantifies the difference between *a priori* and observed bond valences. Bond-topological mechanisms of bond-length variation are (1) non-local bond-topological asymmetry and (2) multiple-bond formation, while crystallographic mechanisms are (3) electronic effects (e.g. vibronic mixing, lone-pair stereoactivity), and (4) crystal-structure effects (e.g. structural strain).

Comprehensive bond-length dispersion analyses for inorganic nitrides and chalcogenides reveal several “phenomenological gaps” compared to their oxide counterparts, thus providing synthetic opportunities via the transposing of anomalously bonded coordination units bearing functional properties into new compositional and/or structural spaces. Resolving the contribution of (static) bond-topological *vs* (tunable) crystallographic mechanisms of bond-length variation via the Δ_{topol} and Δ_{cryst} indices, combined with their spatial resolution within the coordination polyhedron and unit cell, is proposed to quantify the *effective* tunable extent of a functional property for a given crystal structure, e.g. via alteration of the responsible coordination unit(s). The known extent for which bond-topological and crystallographic mechanisms materialize into bond-length variations, provided by large-scale bond-length dispersion analyses, guides optimization of these properties within the constraints of physically realistic crystal structures. Such information is essential to the design of new materials with (1) increasingly complex crystal structures, and (2) superior functional properties.

1:50 PM CH02.12.06
Photocatalytic Degradation of Lignin Using Gold Nanorod Immobilized TiO_2 Photoanode Under Mild Conditions Hai Nguyen[1], Shuya Li[1], Saerona Kim[1], Gyu Leem[1], Benjamin Sherman[2], Chang G. Yoo[1] and Jingshun Zhuang[3]; [1]SUNY College of Environmental Science and Forestry, United States; [2]Texas Christian University, United States; [3]The Michael M. Szwarc Polymer Research Institute, United States

Lignin is an alternative source of petroleum production, which consists of useful aromatic functional groups in lignocellulosic biomass. The aromatic-rich fraction in lignin is converted to biofuel through fermentation. Past studies have focused on lignin valorization under harsh conditions such as high temperature, pressure and/or additional oxidants. However, our research group has developed the dye-sensitized photoelectrochemical cells (DPECs) system for visible light induced lignin degradation at room temperature. Here, we introduce DSPECs incorporated with gold nanorods (Au NRs) for the application of lignin depolymerization. The Au NRs can be a promising candidate to increase the performance of the photocatalytic system and enhance light-harvesting efficiency. The Au NRs are immobilized to TiO_2 electrodes by using bifunctional L-glutathione (GSH) featuring dicarboxylic acid and thiol moieties. These moieties allow to anchor Au NRs to the surface of TiO_2. The TiO_2-based photoanode incorporates a surface-bound Au NRs-based photocatalyst and solution-dissolved nitroxyl mediators (e.g., 4-acetamido 2,2,6,6-tetramethylpiperidine-1-oxy) to perform solar-driven photocatalytic oxidation of the lignin model compounds under aerobic conditions with simulated solar illumination.

1:55 PM CH02.12.08
Phase Analysis of Titanium Oxide Nanoparticles by the Application of Attenuated Crystal Models on X-Ray Pair Distribution Functions Songsheng Tao[1], Jonas Billet[2], Jonathan De Roo[3] and Simon J. Billinge[1,4]; [1]Columbia University, United States; [2]University of Ghent, Belgium; [3]University of Basel, Switzerland; [4]Brookhaven National Laboratory, United States

Metal oxide nanoparticles have a number of important technological applications in electronic devices. In particular, titanium(IV) oxide nanoparticles have potential applications in lithium ion batteries. A particular synthesis challenge with titanium(IV) oxide nanoparticles is that it has multiple possible structural phases. Differentiating between the various phases is particularly challenging when they are nanoparticles and it is crucial to be able to identify the structural phases of synthesized nanoparticles. Beyond knowing the phase distribution in the sample, it is also important to study crystallite sizes and shapes, as well as the presence of common defects, since these factors have an important impact on the functionalities. X-ray atomic pair distribution function (PDF) analysis is an important and powerful tool to use for this purpose because it reveals the local structure on nanometer length-scales, revealing quantitative information about the structural phase, particle morphology and defects in nanoparticulate materials, which is beyond the capability of traditional x-ray diffraction methods when the nanoparticles are small (< 10nm in diameter). One of the common methods for studying nanoparticles

using PDF analysis is to use attenuated crystal model (ACM) to test candidate structures and extract quantitative information about them. Given the growing importance of the PDF approach in nano-materials science and chemistry, we feel that it is helpful to the community to discuss the approach in a pedagogical way. Here we address a gap in the literature and present a detailed workflow for applying ACM in a robust and accurate way, using titanium(IV) oxide nanoparticles as an example. Using this approach we find that the nanoparticles contain the bronze phase as the major phase and the anatase phase as the minor phase, obtain the structural parameters of both phases, and that the particle sizes of the major phase are probably following a lognormal distribution. This work was supported by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences (DOE-BES) under contract No. DE-SC0012704.

2:00 PM CH02.12.09
Strength and Toughness Variation in Transition Metal Carbides Due to Electronic Structure and Hybridization Jenny G. Ziegler, Katelyn Young and Zubaer M. Hossain; University of Delaware, United States

Ultra high temperature ceramics, or uthc have various applications, especially in aircrafts and spacecrafts. They must have outstanding refractory properties at elevated temperatures. However a key limitation is in the toughness of these materials, which severely limits its applications. This is why they are used to make rocket engine nozzles and thermal barrier coatings. The most common example of a uhtc is silicon carbide, SiC. SiC is an important uhtc since it has a high melting temperature, high strength and is very lightweight. Yet it is still not perfect since it has low toughness like uhtcs. On the other hand many transition metal carbides have very low melting temperatures, but they are extremely tough. One of the key differences between transition metal carbides and SiC is the hybridization of the molecule. Using a combination of density function simulations and analytical analysis we examine the toughness, strength,Young's modulus of SiC with diamond-crystal structure and HfC, ZrC, TaC, TiC, VC, and NbC with rock-salt crystal structures under symmetry-preserving and symmetry-breaking deformations. In this presentation we will discuss how certain electronic structures and hybridizations create materials with variable toughness, young's modulus, and strength. By examining the patterns in electron redistribution we will see how the type of orbital (p,d,s) and hybridization (sp3, spd) affect the mechanical properties. By examining how mechanical properties are developed due to the electronic structure we can find alternatives or supplements to SiC. This new understanding will help us create better materials for nozzles of rockets and other elements of rockets.

2:05 PM *CH02.12.10
Reversible Sulfide Oxidation in Alkali-Rich Li-Ion Battery Cathodes Kimberly A. See; California Institute of Technology, United States

Current Li-ion batteries store charge by intercalation and deintercalation of Li^+ into a host material such as a transition metal oxide. Capacities are typically limited to less than one equivalent of Li^+ per transition metal and the charge compensation is largely localized on the transition metal. Utilizing the electronic states of the anions represents an interesting way to increase the Li^+ that can be stored to reach so-called "Li-rich" regimes in which greater than one equivalent of Li^+ is stored per transition metal. We will discuss a family of Li-rich sulfides that undergo reversible multi-electron redox involving both the transition metal (*M*) and the sulfide. Anion subsitution allows us to tune the covalency of the M-anion bond, systematically control the voltage of anion oxidation, and control the distribution of eletroactive atoms in the material during the charge. Anion oxidation causes interesting strutural changes that will be discussed, along with the structure-property relationships that control anion oxidation reversibility.

2:35 PM CH02.12.11
Electronic Phase Segregation in the Hexagonal Perovskite $Ba_3SrMo_2O_9$ Struan Simpson and Abbie Mclaughlin; University of Aberdeen, United Kingdom

Strongly correlated transition metal oxides are renowned for their ability to phase-segregate into multiple competing states with distinct electronic properties. Prominent examples include colossal magnetoresistant (CMR) manganites, where chemical disorder mediates segregation into ferromagnetic metallic and antiferromagnetic charge/orbital-ordered states[1]. This phenomenon has drawn considerable attention in oxides containing 3*d* transition metals, yet reports are comparatively scarce for their 4*d*/5*d* counterparts.

In recent years, 6H-perovskites of the form $Ba_3B'M_2O_9$ (*B*' = rare earth, *M* = 4*d*/5*d* transition metal) have been investigated for their potential to exhibit spin-liquid ground states[2]. This structure type is distinguished by bioctahedral M_2O_9 dimers; short distances between the *M* cations, combined with spatially diffuse 4*d*/5*d* orbitals, can facilitate the formation of quasi-molecular M_2O_9 clusters with spin-gapped excitations[3]. However, most $Ba_3B'M_2O_9$ compositions feature magnetic moments localised on the *M* cations so that the formation of quasi-molecular clusters is suppressed.

We have observed an unprecedented electronic phase segregation (EPS) in the new 6H-perovskite $Ba_3SrMo_2O_9$. This is the first report of a $Ba_3B'M_2O_9$ composition where *M* = Mo. Below 230 K, $Ba_3SrMo_2O_9$ segregates into two electronically distinct phases: a hexagonal $P6_3/m$ phase consisting of weakly interacting $Mo^{5+}{}_2O_9$ spin dimers, and a monoclinic $P2_1/m$ phase containing a 50:50 mixture of quasi-molecular $Mo^{5+}{}_2O_9$ clusters and localised Mo^{5+} spins. We propose this segregation has a unique origin related to competition between direct Mo–Mo bonding and Mo–O–Mo superexchange. In contrast to established electronic materials like CMR manganites, EPS appears to manifest without the aid of charge order or chemical disorder. Accordingly, $Ba_3SrMo_2O_9$ comprises a seemingly unique electronic material.

Unravelling the Effect of Superficial Rh Depletion on Shallow d-States of Gallium-Rhodium Liquid Metal Alloys Tzung-En Hsieh[1], Haiko Wittkämper[2], Johannes Frisch[1,3], Mihaela Gorgoi[1,3], Regan Wilks[1,3], Christian Papp[2] and Marcus Baer[1,2,4]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (HZB), Germany; [2]Friedrich-Alexander Universität Erlangen-Nürnberg (FAU), Germany; [3]Helmholtz-Zentrum Berlin für Materialien und Energie GmbH, Germany; [4]Helmholtz Institute for Renewable Energy (HI ERN), Germany

In this study, we report on the investigation of the electronic and chemical structure of supported GaRh alloys as model systems for the active phase in Supported Catalytically Active Liquid Metal Solutions (SCALMS). SCALMS is a novel class of single atom catalysts comprised of a liquid metal matrix and a diluted catalytically active transition metal. We prepared a series of gallium-rhodium samples with different Ga/Rh molar ratios and tracked the evolution of the surface electronic structure decreasing Rh concentration (from 100 % to 1 %). We employed Photoemission Spectroscopy (PES) to probe the shallow core levels of the top layers of the GaRh alloys. Our results reveal a narrowing of the rhodium 4d-band and the formation of Ga-Rh intermetallic compounds (IMCs). Furthermore, we discuss annealing and surface oxidation effects. We observe the dissolution of GaRh IMCs during

annealing and the incorporation of Rh into the formed gallium oxide (GaO_x) layers as a result of surface oxidation. These results contribute to a more fundamental understanding of the valence band structure of GaRh SCALMS and its relation to the catalytic reactivity.

9:00 PM *CH02.13.01
Cyanide-Anion Based Dynamic Solid-State Materials Ryo Ohtani; Kyushu university, Japan

Our group investigates new materials synthesized by the anionic four-coordinate/penta-coordinate molecules with cyanides as building units, combined with various metal ions or organic cations. They often exhibit interesting dynamic structural characteristics such as thermal expansion and melting. Recently, we synthesized a cyanide-bridged three-dimensional framework $FePd(CN)_4$ incorporating four-coordinate iron(II) ions. $FePd(CN)_4$ was synthesized by a thermal treatment to remove waters from a two-dimensional six-coordinate iron(II) coordination polymer $Fe(H_2O)_2Pd(CN)_4.4H_2O$. $FePd(CN)_4$ consists of a two-fold interpenetrated PtS topology three-dimensional structure where four-coordinate iron(II) ions has intermediate geometry between tetrahedral and square planar geometries. $FePd(CN)_4$ exhibits large anisotropic thermal expansion behavior including uniaxial colossal TE and negative 2D-TE. Moreover, we are also focusing on the penta-coordinate mixed-anion units to construct polar skeletons. Such compounds achieved a characteristic polarity switching via anion manipulation along polar axis in crystals.

9:30 PM *CH02.13.02
New Mixed-Anion Semiconductor Photocatalysts for Visible-Light-Induced Water Splitting Ryu Abe; Kyoto University, Japan

Photo-induced water splitting using semiconductor photocatalysts has attracted considerable attention for producing H2 as a clean energy carrier, while the effective utilization of visible light is imperative to achieve the desired efficiency for practical applications.[1] Various mixed-anion compounds such as oxynitrides, oxysulfides, and oxyhalides have been extensively studied as promising photocatalysts for visible light-induced water splitting, because their valence band maximum (VBM) values are generally more negative than those of conventional oxides, due to the significant contribution of high-energy p orbitals of the non-oxide anions (e.g., N-2p, S-3p, Br-4p, and I-5p) mixed with O-2p. Some tantalum oxynitrides (TaON and BaTaO2N) have been successfully employed as a H2-evolving photocatalyst in Z-scheme water splitting systems, combined with another O2-evolving photocatalyst such as WO3.[2] However, most of mixed-anion compounds suffer from facile self-oxidative deactivation of non-oxide anions by photogenerated holes, thereby imposing surface modifications such as loading some cocatalysts to circumvent the oxidative deactivation. For example, we have demonstrated that the loading of IrO2 or CoOx nanoparticles as a cocatalyst for water oxidation on such oxynitrides suppress the self-oxidative deactivation to some extent, and thus enable us to employ such surface modified (oxy)nitrides (TaON and Ta3N5) as O2-evolving photocatalysts in Z-scheme systems with (IO3–/I–) redox.[2] Such surface modification has been proven effective for the fabrication of (oxy)nitride-based photoanode. The porous tantalum oxynitrides (TaON or BaTaO2N) electrode prepared on conducting substrates showed relatively stable O2 evolution with significantly high quantum efficiency in an aqueous solution, after loading of effective cocatalyst nanoparticles for water oxidation.[3,4]

We have recently demonstrated that Sillén–Aurivillius type perovskite oxyhalides such as Bi4NbO8Cl can stably and efficiently oxidize water to O2 under visible light without any surface modifications, and also exhibits a stable Z-scheme water splitting[5] when coupled with a H2-evolving photocatalyst.[4] It was revealed that the VBMs of these materials consist mainly of O-2p orbitals, instead of Cl-3p (or Br-4p), but their positions are much more negative than those of conventional oxides. Thus, they possess narrow bandgaps for visible light absorption as well as sufficiently negative CBMs for water reduction. DFT calculation visualized a fairly strong hybridization between the Bi-6s and O-2p orbitals, which can explain why the O-2p orbitals are elevated in energy, combined with the result on Madelung site potential analysis that can rationalize the origin of high energy of O-2p orbital in these materials.[6, 7] Since O– anions are known to be relatively stable, photogenerated holes populated at the O-2p orbitals will not lead to self-decomposition but to oxidize water. These results could provide new strategies for developing durable materials for water splitting under visible light, by manipulating the interaction between post-transition metal s orbitals and O-2p orbitals.

Crystal Structure and Electronic Properties of Cation-Ordered Non-Cubic Pentavalent Fullerides Keisuke Matsui and Kosmas Prassides; Osaka Prefecture University, Japan

Metal fullerides are molecule-based strongly correlated electron systems, whose properties can be tuned by both changes in bandfilling and bandwidth (or equivalently interfullerene separation). The electronic properties of trivalent cubic fullerides, A_3C_{60} (A = alkali metal) vary with lattice volume, resulting in a dome-shaped superconducting transition temperature (T_c) dependence adjacent to an antiferromagnetic (AFM) insulating phase - fingerprint of strong electron correlations. As evidenced by the maximum $T_c \sim 38$ K (highest among molecular superconductors) and upper critical magnetic field $H_{c2} \sim 90$ T (highest among isotropic superconductors), fullerene is a unique materials platform in condensed matter physics. The flexible volume tunability of fullerides by chemical/physical means has inspired the search for possible emergence of superconductivity at other bandfillings. Indeed, there are superconducting fullerides in octavalent (Ba_4C_{60}, $T_c \sim 7.7$ K) and nonavalent ($A_3Ba_3C_{60}$, $T_c \leq 6$ K) materials in which the Fermi level lies in the t_{1g} (LUMO+1)-derived band.
The properties of pentavalent fullerides M_2AC_{60} (M = divalent cation) have not been explored systematically although some theories do suggest the emergence of superconductivity. Two decades ago, studies showed that non-superconducting Ba_2AC_{60} (A = K, Rb, Cs) [1, 2] form a cation-ordered face-centered-cubic (*fcc*) structure, in which Ba^{2+} and A^+ ions occupy small tetrahedral and large octahedral holes, respectively. In particular, there was little change in the lattice volume with changing the A^+ ion (= K, Rb, Cs) size in Ba_2AC_{60} because the octahedral holes are of a much larger size (~ 2.06 Å) than

that of the A^+ ions (e.g. Cs^+ ~ 1.67 Å). Therefore, substituting the tightly-packed Ba^{2+} ion in the small tetrahedral hole (~ 1.14 Å) with other divalent cations may allow access to unexplored regions in the pentavalent fulleride phase field.
Here we present our recent work on the families of ternary fullerides, M_2AC_{60} (M = alkaline-earth or rare-earth metal). We have successfully prepared cation-ordered M_2AC_{60} phases via solid-state synthesis, systematically varying both M^{2+} and A^+ ions. Interestingly, X-ray diffraction profiles show that smaller M^{2+} ions lead to non-cubic crystal structures (orthorhombic) in which the M^{2+} ions are shifted to off-centered positions, in contrast to isoelectronic *fcc*-Ba_2AC_{60}. Both the reduction in symmetry and the pentavalent character of the fulleride units are confirmed by Raman spectroscopy. The electronic properties of the materials have been studied by SQUID magnetometry, and EPR and NMR spectroscopy. Complementary synchrotron X-ray absorprion studies reveal intriguing mixed valence behavior in the rare-earth fulleride systems.

First-Principles Analysis on Electronic Structure of 10H Long-Period Stacking Ordered Phases in Mg-Zn-Y Alloys Riku Sato[1], Shinya Ogane[1], Kazumasa Tsutsui[2], Yuta Tanaka[2] and Koji Moriguchi[1,2]; [1]Tohoku University, Japan; [2]Nippon Steel Corporation, Japan

Since the functionalities of materials usually originate from the spatial inhomogeneity in the associated systems, the local inhomogeneities such as defect, surface, interface, and nanostructure often play an important role for developing sophisticated materials. In this paper, among the many phenomena related to inhomogeneity in materials, we will report our computational research on the modulation of electronic structure by the solute elements for the long period stacking ordered (LPSO) phases.
In 2001, Kawamura et al. have developed a novel $Mg_{97}Zn_1Y_2$ (at. %) alloy using rapidly solidified powder metallurgy processing [1]. It has extremely high tensile yield strength of 610 MPa and elongation of 5% mechanical strength at room temperature. After that, other high-strength Mg alloys have been reported one after another [2-5] which alloys are usually composed of Mg, transition metal (TM) elements, and rare earth (RE) ones. It has also been reported that the reinforced phases in these Mg alloys contain stacking faults (SF) with long periodicity along the c-axis, and solute elements of TM and RE segregate into these SF regions [1-5]. Since the structural modulation and the chemical modulation are experimentally confirmed to be synchronized in the reinforced phases, the associated phases in these Mg alloys are called the synchronized long period stacking ordered (LPSO) phases.
Some investigations on the thermodynamic stability for LPSO phases have also been reported so far [6-8]. Egami et al. have recently examined the thermodynamic behaviors of dilute Mg-Zn-Y ternary alloys to form a unique solute-enriched stacking-fault based on the calculation of phase diagrams (CALPHAD) method along with the first-principles analyses [8]. They have found that the co-segregations of Zn and Y solute elements at the stacking faults make the fault layers more stable than the hcp-Mg matrix-base configuration. Furthermore, within the stacking faults, spinodal-like decomposition into the Mg-rich solid-solution and the Zn/Y-rich L12-type order phase is also reported to cause a significant reduction of the total Gibbs energy of the system. These results based on the CALPHAD method stimulate our curiosity as to how alloying elements associated bring about the changes of atomistic interactions in the LPSO structures.
We have presented the theoretical studies on the energetics of metallic polytypes including the LPSO structures from the viewpoint of interlayer interactions [9, 10]. Our theoretical analyses have suggested that the relatively long-distance interatomic interaction is a significant factor for the energetic stabilization of the LPSO composed of the close-packed structures [10]. Since the phase stability is generally determined by the electronic states, the associated electronic structure can provide a more basic knowledge on the thermodynamic phase stability for the LPSO phases. In the present work, comparative studies are carried out on the electronic structure of $Mg_{92}Zn_{12}Y_{16}$, $Mg_{108}Zn_{12}$, $Mg_{104}Y_{16}$, and Mg_{120} with two and/or ten stacking layers based on first-principles calculations within the density functional theory. In our presentation, we will discuss the correlation between the modulation of electronic structure by Zn and Y solute elements and the phase stability of the LPSO-Mg structures.

Development of an EAM Type Potential with a Long-Range Cutoff Radius for Describing Metallic Polytype Energetics Shinya Ogane[1], Riku Sato[1], Yuta Tanaka[2], Kazumasa Tsutsui[2] and Koji Moriguchi[1]; [1]Tohoku University, Japan; [2]Nippon Steel Corporation, Japan

The Kepler conjecture in 1611 states that no arrangement of equally sized spheres filling space has a greater average density than that of the face-centered cubic and/or hexagonal close packing arrangements [1]. This conjecture has been only recently proved by the Flyspeck project team [2]. The polytypes are characterized by a stacking order with a given repeating unit along a directional axis and are theoretically possible to have endless permutations of the sequences. The close-packed (CP) polytypes in which the associated stacking is composed of the CP planes are, therefore, considered to be the crystalline systems realizing the Kepler conjecture. Significant changes in physical properties due to the intentional polytype formation have also been reported in various fields of metallic and semiconductive systems [3-5].
Predicting polytype phase stability for a material has still been a long-standing issue in condensed matter physics and/or materials science [6, 7]. This situation stems from the fact that the atomistic interactions on polytype energetics might be quite complex and delicate despite the simplicity of their geometrical structure. We have recently presented a theoretical consideration on the CP polytype total energetics using the geometrical analysis for the correlation between interlayer interactions and interatomic ones [8]. These results suggest that short-range interactions are not enough to describe the CP polytype energetics and provide significant insights for creating interatomic models successfully showing the polytypes other than 3C and 2H structures as a ground state, those have never yet been implemented as far as the authors know.
Since the ground state for metallic lanthanum (La) is the double hexagonal CP structure (DHCP), the La can be an important reference system for studying polytype formation mechanism. It is, therefore, possible to investigate the essential factors determining the polytype selection rule through the dynamical analyses for metallic La. In the present work, we report on the process of constructing an interatomic potential for metallic La, that can be used for molecular dynamics (MD) simulations. The Embedded Atom Method (EAM) type functions reported by Mishin et al. [9] are adopted for constructing the numerical potential model in this study. Since our previous theoretical studies have shown that the long-range nature of interactions is an important facter for determining the ground state of polytype [7, 8], the cutoff radius has been carefully selected considering the computational cost.
Our interatomic potential can well describe the total energy vs. volume curves for various crystal structures and the Bain path energetics along the fcc-bcc

structures deduced by the first-principles calculations. This potential is, therefore, an interaction model for metallic polytypes that can describe not only the energetics but also the lattice dynamics such as lattice dynamical instability, which is generally significant for the phase transition phenomena [10, 11]. Our research is at the stage of working on MD analyses for the polytype formation mechanism using this potential. In the presentation, other basic properties, transferability of the potential constructed, and some results of the MD analyses will be also discussed.

Atomic-Scale Observation of Electrostatic Origin Octahedral Distortion in Ruddlesden-Popper Phases Youngjae Hong and Sung-Yoon Chung; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Precise identification of the distortion, tilt, and rotation of octahedra is an essential step toward understanding the structure-property correlation in view of the fact that the physical properties of ABX_3 perovskite-based oxides strongly depend on the geometry of oxygen octahedra containing B site cations. In this work, we find out an crucial electrostatic origin responsible for Jahn-Teller-type tetragonal elongation of oxygen octahedra during atomic-level direct observation of two-dimensional [AX] interleaved shear faults in five different perovskite-type materials. When the [AX] sublayer has a net charge, for instance $[LaO]^+$ in LaNiO3, significant tetragonal elongation of oxygen octahedra at the fault plane is observed and it blocks the strong repulsion between the consecutive $[LaO]^+$ layers. Moreover, our findings on the distortion induced by local charge are identified to be a striking common feature in $A_{n+1}B_nX_{3n+1}$-type Ruddlesden-Popper structure with charged [AX] sublayers. This study thus demonstrates that electrostatic origin local charge is a crucial factor significantly affecting the crystal structure of complex oxides.

Late News: Gap-State Engineering for Enhanced Ferroelectric Photovoltaic Effect Under Visible Light Irradiation Hiroki Matsuo and Yuji Noguchi; Kumamoto University, Japan

Ferroelectric materials exhibit the characteristic photovoltaic (PV) effect that can generate photovoltage far exceeding their bandgap energy (E_g)[1]. The ferroelectric photovoltaic (FPV) effect arises from polarization-driven carrier separation under light irradiation and the absence of limitation in the photovoltage by the bandgap is a great advantage of the FPV effect over the conventional PV effect in *p-n* junctions of semiconductors. Since typical ferroelectric oxides have wide bandgap, a vanishingly small photoresponse under visible light has been an issue to be overcome. Though bandgap tuning can partly improve the photoresponse, narrowing of the bandgap is, in principle, accompanied by a substantial loss of ferroelectric polarization. In this study, to enhance the visible-light activity of the ferroelectric materials without sacrificing the ferroelectric polarization, we propose an approach, 'gap-state' engineering, in which defect states within the bandgap act as a stepping stone for photocarrier generation[2,3]. We investigate the FPV effect in ferroelectric $BiFeO_3$ (BFO) epitaxial thin films doped with various transition metals (TMs). Impact of the TM doping on electronic structures and the PV response were investigated by combined analysis using the density functional theory (DFT) calculations and experimental measurements for the TM-doped BFO epitaxial thin films.
The DFT calculations revealed that substitution of Mn^{3+} for Fe^{3+} generates doubly degenerated half occupied defect level derived from Mn-3*d* orbitals within the bandgap of BFO. The defect level i.e., gap states, locates at 0.8 eV above the valence band maximum, which corresponds to 1.9 eV below the conduction band minimum. Experimental analyses of the PV properties were performed for epitaxial thin films of undoped BFO and 5% Mn-doped BFO (BFMO) with a single domain structure prepared by the pulsed-laser deposition (PLD). We found that both the photocurrent density and the photovoltage were markedly enhanced by the introduction of small amount of Mn especially under illumination with photon energy lower than E_g.
These results present that the gap states formed within the bandgap enables two-photon excitation and provides the enhanced PV response over a broad spectral range. This approach utilizing the gap states will be promising route to the development of visible-light-active ferroelectrics without sacrificing the ferroelectric polarization.

Atomic-Scale Direct Observation of Pre-Melting of RP Faults in Perovskite Oxide System Ji-Sang An and Sung-Yoon Chung; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Melting is a common phenomenon in our daily life and it is fundamental to daily life, basic science and technology. Therefore, understanding and controlling the melting phenomenon becomes important in various disciplines. In particular, pre-melting which occurs below the melting temperature has been studied for in-depth understanding of melting and numerous studies have shown that pre-melting usually occurs in 2-dimensional defects like surface, grain boundaries and dislocations. In this study, using atomic-scale direct observation of scanning transmission electron microscopy (STEM) and acceptor doepd $BaCeO_3$ as model system, pre-melting phenomena also can occur in Ruddlesden Popper(RP) faults in ABO_3 type perovskite oxide. Chemical composition analysis and STEM images demonstrate that the amorphous phase is the RP-mediated liquid phase and as sintering temperature goes up, the thickness of amorphous phase in RP faults getting thick. And with electron beam irradiation, re-crystallization of the amorphous layer can occur. To the best of our knowledge, the present study demonstrates for the first time ever observation of pre-melting in RP faults providing a broader academic depth to pre-melting or melting.

Discovery of Two-Dimensional van der Waals Materials and Topological Dirac Semimetal in the Class of ABC Zintl Phases Sung Wng Kim; Sungkyunkwan university, Korea (the Republic of)

The discovery of new families of two-dimensional (2D) van der Waals (vdW) layered materials has always attracted great attention to pursue beyond

graphene. It has been challenging to artificially develop the van der Waals bonded layer structure that is constructed by the stacking of honeycomb atomic lattice composed of two elements as in hexagonal boron nitride. In this talk, a new class of 2D vdW materials, layered Zintl phases will be introduced. These new 2D layered Zintl phases can allow unlimited extent of 2D science in terms of the diversity of materials and their physical properties. A new class of 2D materials was developed from a 3D structured material that has (1) a multicomponent system, (2) primary atomic bonds in three-dimensionality, (3) thermodynamic and chemical stability, and (4) diversity in chemical compositions. Through the dimensional manipulation of crystal structure, we create an unprecedented 2D vdW zinc antimonide (2D-ZnSb), which is the layered Zintl phase with sp^2-hybridized bonding characters in Zn-Sb honeycomb atomic layers [1]. The vdw layered structure of 2D-ZnSb is evolved by selectively etching the lithium cations from the layered LiZnSb Zintl phase that is formulated by alloying the lithium atoms into sp^3-hybridized bonded three-dimensional ZnSb (3D-ZnSb), demonstrating the bidimensional polymorphism of 3D- and 2D-ZnSb. Finally, the recent experimental and theoretical studies on diverse physical properties obtained in the new 2D materials will be discussed with the focus on the three-dimensional topological Dirac semimetal of KZnBi compound [2].

Design and Topochemical Synthesis of Metastable (oxy-)Chalcogenide Materials Laurent Cario, Shunsuke Sasaki, Louis Béni Mvélé, Catherine Guillot-Deudon, Maria Teresa Caldes, Isabelle Braems, Benoit Corraze, Etienne Janod and Stephane Jobic; CNRS, Université de Nantes, France

Layered transition metal compounds have been extensively investigated due to their unconventional electronic/magnetic properties. Topochemical reactions, which introduce/withdraw ions into/from host materials retaining their lamellar structures, serve as one of the most effective tools to design such low-dimensional materials. Despite their huge advances during the recent decade, most of topochemical reactions rely on redox activities of transition metal cations in host lattices so that their charge balance are respected throughout the process. Conversely the redox activity of molecular anions for topochemical syntheses remains almost unexplored. This study demonstrates the topochemical reaction of layered polychalcogenides or oxychalcogenides containing pre-formed (Sn)2- (n=2,3) oligomers with transition metals or alkali metals to form (metastable) layered compounds at low temperature [1,2,3]. Structure prediction calculations and advanced electron microscopy techniques confirms that depending on the metal nature the reaction with the oligomers lead either to the intercalation of the metallic species [1,2], or to the deintercalation of part of the chalcogen atoms [3]. This study paves therefore the way to the design of (oxy-)chalcogenide compounds with interesting potential applications.

8:30 AM *CH02.14.02
Divalent Magnetic Cations to Generate Magnetoelectric Properties in Corundum-Derived Structures Antoine Maignan[1,2], Christine Martin[1,2] and Françoise Damay[1,3]; [1]CNRS, France; [2]crismat, France; [3]CEA, France

Several ways can be used to achieve magnetoelectric (ME) effects [1 and references herein] such as strain-mediated coupling between ferroelectric and (anti)ferromagnetic composites, compounds hosting both d^0 ferroelectricity and 4f or d^n magnetism and lone-pair cation (such as $BiFeO_3$ [2]). In general, for the latter, the electric polarization is large but the ME coupling weak. Another class of multiferroics (MF), also called spin-induced MF, gathers the $3d^n$ magnetic compounds whose magnetic symmetry breaks both space-inversion and time-reversal. These type-II MFs are very often compounds exhibiting large ME coupling. Searching for large ME coupling, the linear ME (LME) compounds are also attracting as a third class of ME. Though these centrosymmetric compounds are not MF, a magnetic field application induces a polarization, with P proportional to H, as the prototype α-Cr_2O_3 corundum [3,4].
For solid state chemists, this structural type forms a very broad field to play with, as illustrated for instance by the numerous isomorphic transition metal niobates and tantalates of composition $M_4A_2O_9$ (429), with M a divalent cation (M = Co, Fe, Mn) [5]. Recent re-investigations of $Co_4Nb_2O_9$ magnetic structure [6-8], a LME exhibiting one of the largest ME coefficient (≈ 30 ps/m [6]), triggered a surge of interest for these $M_4A_2O_9$ crystallizing in a trigonal structure (SG: *P*-3*c*1) and which magnetic structure is still a matter of debate [5-8].
Among the 429, solely cobalt and manganese niobates and tantalates were known to be LME till 2018 [9-12], after which the $Fe_4Nb_2O_9$ [13] and $Fe_4Ta_2O_9$ [14-15] ME were reported. From the synthesis side, these oxides containing divalent iron are difficult to prepare as pure phases.
Interestingly, there exist $M_{4-x}M'_xA_2O_9$ solubility ranges, involving a careful control of the (PO_2,T) synthesis conditions depending on M and M' and on x, which open the route to produce new LME and ME behaviours. In particular, to exacerbate the P response to H, the M/M' magnetic cations disorder can be exploited to modify the magnetization H dependence. The preliminary results obtained by mixing divalent Fe and Co have allowed us to produce a much steeper P(H) dependence, the $Fe_2Co_2Nb_2O_9$ compound exhibiting ME properties overpassing those of the $Co_4Nb_2O_9$ and $Fe_4Nb_2O_9$ end members.
On the opposite, considering that $Ni_4Nb_2O_9$ is orthorhombic, ferrimagnetic and not ME [16], the Ni solubility in $M_{4-x}Ni_xNb_2O_9$ with M=Co or Fe has been investigated. These magnetic substitutions by Co or Ni are now compared to those by diamagnetic ones.
The synthesis, characterizations of the crystal/magnetic structures and magneto(di)electric properties of several such corundum - derived compounds, including Mn_3WO_6 [17], will be presented to illustrate the richness of these systems to generate new (L)ME candidates.

9:00 AM CH02.14.03
Spectroscopic and First Principles Characterization of Electronic, Optical and Defect Properties of P-Type $CuBi_2O_4$ Sebastian E. Reyes-Lillo[1], Zemin Zhang[2] and Jason K. Cooper[3]; [1]Universidad Andres Bello, Chile; [2]Lanzhou University, China; [3]Lawrence Berkeley National Laboratory, United States

$CuBi_2O_4$ is an emerging p-type semiconductor for applications as a photocathode in photoelectrochemical (PEC) solar fuel production. Recently, we have examined p-$CuBi_2O_4$ thin films with a comprehensive spectroscopic and first principles characterization methodology to describe its fundamental electronic and optical properties while addressing intrinsic limitations in the observed PEC performance [1]. In this talk, connections will be established between electronic structure, optical properties, and PEC performance through a combination of X-ray spectroscopies (X-ray absorption spectroscopy, X-ray emission spectroscopy, and resonant inelastic X-ray scattering) and density functional theory (DFT) based modeling. The results provide the basis for the understanding of the observed polaron limitations in $CuBi_2O_4$. In addition, we investigate the presence and working mechanism of natural defects, through experimental and first principles approaches. Two main types of defects, oxygen vacancies and hydrogen impurities, are found in $CuBi_2O_4$ thin films with a high level. Our DFT results show that oxygen and hydrogen defects act as donor impurities, and therefore, their suppression increases the carrier density and enhance the performance of $CuBi_2O_4$. Our work aims at broadening the understanding of materials governed by polaronic limitations as well as the investigation of defects in p-type metal oxide semiconductors to further advance their application in solar-fuels generating systems.

Impact of Surface Area on Capacity Retention in the $LiNi_{0.5}Mn_{0.5-x}Co_xO_2$ (x = 0.1 - 0.3) Series—Tradeoffs from the Ni^{2+}/Ni^{3+} Ratio Rajalakshmi Senthil Arumugam, Ramesh Shunmugasundaram and Vanessa Wood; ETH Zürich, Switzerland

The most commonly used cathode materials in Li-ion batteries are layered lithium metal oxides ($LiTMO_2$, TM = transition metal ion) due to their large theoretical capacities (~280 mAh/g).[1] Among the layered cathode materials, lithium nickel manganese cobalt oxides ($Li(Ni_xMn_yCo_{1-x-y})O_2$ or NMC) exhibit promising electrochemical properties, which primarily depends on the atomic composition of Ni, Mn and Co in the structure.[2] Several NMC compositions such as NMC 111, 442, 532, 622 and 811 (the three numbers denote the ratio of Ni to Mn to Co) have been studied extensively. This study systematically studies the effect of TM ratio on the electrochemical behavior of cathode materials and why these particular TM ratios have emerged to be of highest commercial interest.
To do so, this study focuses on cathode material compositions in the series $LiNi_{0.5}Mn_{0.5-x}Co_xO_2$ ($0 \leq x \leq 0.3$) that includes $LiNi_{0.5}Mn_{0.3}Co_{0.2}O_2$ or NMC 532. Three cathode materials NMC 541, NMC 532 and NMC 523 were synthesized by systematically varying the concentrations of Mn and Co but keeping the Ni content constant. This systematic variation in atomic percentages of Mn and Co leads to different Ni^{2+} to Ni^{3+} ratios (4:1 for NMC 541, 3:2 for NMC 532, and 2:3 for NMC 523). For each composition, two morphological variants with different surface areas were made. The compounds were structurally and electrochemically characterized. The results of this study show that NMC 532 achieves a balance between a larger number of antisite defects with increasing Ni^{2+} (e.g. NMC 541) and the higher surface reactivity found with increasing Ni^{3+} (e.g., NMC 523), both of which lead to capacity fade. This explains why NMC 532 is the highest performing material in the $LiNi_{0.5}Mn_{0.5-x}Co_xO_2$ series.

Functional Materials by Design—Developing Treasure Maps with Quantum Chemistry Matthias Wuttig[1], Carl-Friedrich Schön[1] and Jean-Yves Raty[2]; [1]RWTH Aachen University, Germany; [2]Universite de Liege, Belgium

Scientists and practitioners have long dreamt of designing materials with novel properties. Yet, a hundred years after quantum mechanics lay the foundations for a systematic description of the properties of solids, it is still not possible to predict the best material in applications such as photovoltaics, superconductivity or thermoelectric energy conversion. This is a sign of the complexity of the problem, which is often exacerbated by the need to optimize conflicting material properties. Hence, one can ponder if design routes for materials can be devised.
In recent years, the focus of our work has been on designing advanced functional materials with attractive opto-electronic properties, including phase change materials, thermoelectrics, photonic switches and materials for photovoltaics. To reach this goal, one can try to establish close links between material properties and chemical bonding. However, until recently it was quite difficult to adequately quantify chemical bonds. Some developments in the last decades, such as the quantum theory of atoms in molecules [1] have provided the necessary tools to describe bonds in solids quantitatively. Using these tools, it has been possible to devise a map which separates different bonding mechanisms [2]. This map can now be employed to correlate chemical bonding with material properties [3]. Machine learning and property classification demonstrate the potential of this approach. These insights are subsequently employed to design phase change as well as thermoelectric materials [4,5]. Yet, the discoveries presented here also force us to revisit the concept of chemical bonds and bring back a history of vivid scientific disputes about ‘the nature of the chemical bond’.

Structure/Function Relationship in Luminescent Pure and Ti-Doped HfO_2 Nanocrystals Alessandro Lauria; ETH Zürich, Switzerland

Intense recent research efforts are directed toward the development of novel materials morphologies, such as nanoparticles, able to efficiently convert ionizing radiation into light. Fluorescent or scintillating materials attract great interest in lighting technology, solar applications, theranostics and self-lighting photodynamic therapy. Moreover, additive manufacturing advancements suggest the possibility to fabricate nanoparticle-based materials applicable in several fields. Therefore, novel luminescent nanomaterials free from toxic or expensive elements, such as rare earths, are desirable building blocks for promoting future developments in all these fields.
In this work, the structural and morphological properties of pure and Ti-doped HfO2 nanoparticles are studied in dependence of calcination temperatures leading to a fine tuning of either morphology and functional defect configuration. Indeed, tuneable optical features are observed in undoped monoclinic HfO2 nanocrystals and their dependence on the structural properties of the material at the nanoscale are disclosed. TEM, XRD, XPS, and surface area data combined with the analysis of the luminescence allowed us to identify the dual nature of the broad emission at 2.5 eV, where an ultrafast defect-related intrinsic luminescence overlaps with a slower emission ascribed to extrinsic Ti impurities.[1]
When titanium is employed as luminescence activator, a bright emission is observed under excitation with both UVC radiation and X-rays. [2] These results represent useful insights toward the design of novel promising nanomaterials suitable for rare-earth-free UV pumped white LEDs based on intrinsic defect engineering, and for X-ray triggered oncological therapies by using the Ti (IV)-related bright radioluminescence to excite photosensitizer molecules for singlet oxygen generation.

Growth of Branched Nanowires via Solution Based Au Particle Deposition for Charge Carrier Diffusion Induced Nanowire Light Emitting Diodes Kristi Adham, Lukas Hrachowina, David Alcer and Magnus T. Borgström; Lund University, Sweden

Conventional LEDs consist of heterojunction structures in which the active region (usually a multi quantum well stack (MQW)) is embedded in-between the layers in a p-n junction. Recent developments have made it possible to decouple the active region from the p-n junction and demonstrate a working LED where electron and holes are injected by carrier diffusion into the MQW. [1] In order to improve this architecture further we propose to implement it in nanowire (NW) structures. From theoretical simulations it has been shown that NWs with diameter below a threshold value, trap light very poorly because the electric field is not kept inside the NW [2]. To make use of this property and to separate the active region from the p-n junction we aim to make heterostructures with branched nanowires, where core p-i-n NWs with a high bandgap are grown, followed by a subsequent growth of NW branches with lower bandgap. The difference in bandgap would induce carrier diffusion towards the branches, which have a small diameter (~25-50 nm), where the carriers can recombine, and as a consequence light is emitted. The benefits of using nano scale building blocks in this architecture is not only that lattice matching requirements are relieved, but opens up to completely avoid the challenge of total internal reflection as the light emitted has much longer wavelength than the nanowire diameter.

We have developed a cost beneficial method to deposit Au particles along the entire length of the core nanowires which act as catalyst for the growth of the branches. A stock solution of $HAuCl_4 3H_2O$ (10 mM) was prepared, in order to deposit Au particles on the sidewalls of the cores by submerging the substrates inside the solution. To study the deposition of the Au particles, core p-i-n InP NWs in a hexagonal pattern with a pitch of 1 m and a length of approximately 2 m were grown on InP(111):Zn substrates by Metal Organic Vapor Phase Epitaxy. For our study we have varied the concentration of the solution by diluting the stock solution into concentrations of 0.25, 0.5, 1, 2 and 4 mM and we have varied the temperature of the solution during deposition and the time which we submerge the substrates to find the optimal deposition parameters. To study the nucleation and growth of the branches we have grown InP branches by varying the trimethylindium (TMIn) flow and keeping growth time constant at 1 minute. By changing the concentration of the solution, we can control the growth direction of the branches to (111B) or the (110) direction.

In conclusion, we have deposited Au catalyst particles on the sidewalls of core NWs. We have studied the parameters for the deposition such as the solution concentration and temperature and the time of deposition. We have successfully grown InP branches on p-i-n InP cores and aim to develop heterostructures as the next step with InGaP p-i-n cores and InP branches leading to the intended charge carrier diffusion needed for these type of light emitting diodes with promise to high efficiency at low cost.

Microwave-Assisted Routes for Rapid and Efficient Topochemical Modification of Layered Perovskites John B. Wiley; The University of New Orleans, United States

Microwave processing methods have greatly decreased the times needed to topochemically modify layered perovskites. Reactions involving ion exchange, intercalation, grafting, and exfoliation have all been impacted. Here we find that quality products can often be obtained in hours instead of days. In this presentation, methods and products will be highlighted in terms of the utility of this approach, not only in the formation of bulk materials, but also in the production and modification of exfoliated nanosheets.

The Role of Dimensionality on the Spin and Charge Transport Properties of Metal Halide Semiconductors Luisa L. Whittaker-Brooks; University of Utah, United States

Metal halide semiconductors while highly desirable for a host of applications, present several challenges that remain unresolved, including the ability to control their dimensionality at the molecular level (orientation and mode of attachment), matching of phonon band structure in inorganics with discrete vibrations within the molecule, and tuning energetic offsets for effective charge and spin transfer. Each of these parameters ultimately governs charge transport, the preservation of coherence, and energy transfer.
In this talk, I will discuss fundamental guidelines for the design of dimensionally stable metal halide heterostructures with controlled morphology and interfaces that serve as conduits for deterministic and coherent spin and charge transfer. I will divide my talk into two different sub-topics, i.e., (1) how matching phonon structure across interfaces through control of mode and site of attachment of molecules to surfaces allow for efficient coherent charge transfer and (2) how topologically protected electronic states can be defined by 2D assembly of pi-conjugated molecules and layered metal halide materials on surfaces for spin-coherent electronic transport. Here, I will emphasize the role that dimensionality plays in modulating the spin and charge properties of metal halide heterostructures.

1:30 PM CH02.15.03
Tailoring the Structure and Morphology of Mesoporous High Entropy MCo_2O_4 Spinel Oxide Nanoparticles Xin Wang[1], Palani Raja Jothi[1] and Katharine Page[1,2,2]; [1]The University of Tennessee, Knoxville, United States; [2]Oak Ridge National Laboratory, United States

The unique structure diversity, tunable compositions, and physical-chemical properties of high entropy oxides (HEOs) attract wide research interests. At the same time, there are vast economic and environmental needs for obtaining stable, high-capacity, and low-cost catalysts for automotive and industrial exhaust applications; in particular, high surface areas and high thermal stability of oxygen storage capacity catalysts are often incompatible. Here, an eco-friendly soft-templating route is applied to form mesoporous HEO spinel nanostructures (MCo_2O_4, M= Mn^{2+}, Fe^{2+}, Ni^{2+}, Mg^{2+}, Zn^{2+}, etc.), in which high surface area, thermal stability, and compositionally tuned catalysis behavior can be simultaneously achieved. The structural order/disorder in the HEO spinel lattice can be achieved through M cation selection and the morphology (ranging from highly faceted octahedron to highly mesoporous nanocrystalline agglomerates) can be tuned through the selection of templates and reaction conditions. We apply a wide array of characterization techniques, including electron microscopy, and neutron and X-ray total scattering probes, to correlate these characteristics with thermal and catalytic properties. Identifying the role of specific lattice defects, chemical short-range order, and nanoscale heterogeneity in this MCo_2O_4 spinel family will promote design principles and strategies for HEO nanostructured catalysts.

1:35 PM CH02.15.04
Bulk Synthesis of Ternary Metal Nitrides Through Low-Temperature Ion Exchange Reactions Paul K. Todd; National Renewable Energy Lab, United States

Ternary nitrides are an emerging class of inorganic materials for use in a variety of optical, electronic, and refractory applications. In preparing inorganic nitrides, selection of precursors and reaction conditions is dependent on controlling the reactivity of the nitride anion, as decomposition to yield N_2 is thermodynamically favorable at high temperatures used in traditional ceramic processes. While high pressures or reactive environments like ammonia can change the chemical potential of nitrogen to favor a nitride product, reactions that occur under low-temperatures and mild reaction conditions are desired. Here we present on low-temperature ion-exchange reactions that yield magnesium metal nitrides and zinc metal nitrides at low-temperatures and pressures. First, we report on the synthesis of rocksalt $MgZrN_2$, rocksalt Mg_2NbN_3, and hexagonal $MgMoN_2$ using magnesium nitrochloride and the corresponding transition metal halides as precursors. Key to these preparations is a low-temperature anneal (300-450 °C), which calorimetry experiments show results in Mg-M-N product formation. Then, we present on additional experiments using these magnesium metal nitrides as a structural template to perform selective ion-exchange reactions with zinc halide precursors to yield metastable zince metal nitrides: rockalt $Zn_xMg_{1-x}ZrN_2$, rocksalt $Zn_xMg_{2-x}NbN_3$, and layered $Zn_xMg_{1-x}MoN_2$. Overall, these low-temperature ion exchange reactions hold promise to increased discovery of new ternary metal nitrides.

1:40 PM CH02.15.05
Thermodynamic Investigation of $LiFePO_4$ in Triphylite, Heterosite and Solid Solution Phases Hillary Smith, Alexandra Specht and Aleah Wilson; Swarthmore College, United States

The electrochemical properties of a battery cathode material depend on the structural and associated thermodynamic changes that are induced by ion intercalation and deintercalation. Despite the prevalence of $LiMPO_4$ cathodes (M represents Mn, Fe, Co, Ni, or a mixture of multiple of these elements), some aspects of local structural characteristics and thermodynamics are not thoroughly understood in these materials. Li_xFePO_4 undergoes a transformation from a two-phase mixture of triphylite and heterosite to a distinct solid solution phase at elevated temperatures. In this work, the phase transformation in Li_xFePO_4 x=0.6 is investigated using neutron powder diffraction, inelastic neutron scattering, and calorimetry. We report contributions to the vibrational and configurational entropy as a function of temperature, both above and below the phase transformation. Results are compared to first-principles calculations of phonon spectra. New insights into the how the electronic and ionic conductivity differs in each phase will be discussed.

1:55 PM CH02.15.06
Nanofluids' Evaluation for Enhanced Recovery in the Oil Industry Ana Paulina Gomora Figueroa; Universidad Nacional Autónoma de México, Mexico

Nanotechnology has the potential to upgrade the oil and gas industry within different areas such as exploration, drilling, production, and enhanced oil recovery (EOR). For instance, the use of nanoparticles as an EOR method exhibit many advantages since:
The size and shape of nanoparticles can be easily modified during fabrication.
Nanoparticles' surface chemical properties can be easily adapted to turn them hydrophobic or hydrophilic and modify the chemical interaction with specific types of surfaces.
Nanoparticles may resist more complex conditions in comparison with conventional EOR chemical methods.
During the last decade, numerous studies have been conducted employing nanoparticles for EOR purposes. Although different types of nanoparticles, both organic and inorganic, show a significant increase in the additional recovery factor (RF) of crude oil, these results are encouraging, specifically for mature fields.

This work presents the synthesis of inorganic nanoparticles and their performance evaluation in oil displacement tests under different conditions: water-oil ratios, the concentration of nanoparticles, temperature, and salinity of various synthetic brines. Tests were carried out with sandstone to evaluate the interactions between rock-nanoparticles and brine-nanoparticles. During these tests, the nanoparticles displaced up to 50 % of the oil, compared to 26 % of oil displaced by synthetic brines. Additionally, we demonstrated that nanoparticles are helpful to reduce the water-oil interfacial tension, resulting in the formation and stabilization of Pickering-type emulsions, which have shown the ability to be formed in-situ and improve oil recovery in crude oil reservoirs. The results opened the door to future experiments for assessing the wettability alteration promoted by nanofluids and the efficiency of displacement of oil contained in a porous media.

2:00 PM CH02.15.07
Late News: Growth and Structure of the Topological Semimetal Candidate SmMnBi2 Tiglet Besara and Sudha Krishnan; Missouri State University, United States

The *M*Mn(Bi,Sb)$_2$ (*M*=rare earth or alkaline earth) family has emerged as a fertile ground for exploration of topological semimetals. Topological semimetals are charge-balanced compounds that host Dirac or Weyl fermions and with electronic excitations protected by topology. Several members of this family have been explored, such as (Ca,Sr,Ba,Eu,Yb)Mn(Sb,Bi)$_2$, all with divalent oxidation state of the rare earth or alkaline earth metal. Here, we report on the discovery of a new member of the family, $SmMnBi_2$, and compare its structure to other compounds in the family. Surprisingly, despite the near-identical ionic sizes of Eu^{2+} and Sm^{2+}, the structural layers in $SmMnBi_2$ differ from that of $EuMnBi_2$.

2:05 PM CH02.15.09
Structure-Property Relationships in Na-Si Clathrates—Old and New Questions from a (Deceptively) Simple Binary Phase Matt Beekman[1], Antti J. Karttunen[2], Winnie Wong-Ng[3], James A. Kaduk[4,5], Ethan Cruse[1], Christian Posadas[1] and George Nolas[6]; [1]California Polytechnic State University, United States; [2]Aalto University, Finland; [3]National Institute of Standards and Technology (NIST), United States; [4]Illinois Institute of Technology, United States; [5]North Central College, United States; [6]University of South Florida, United States

Na_xSi_{136} ($0 \leq x \leq 24$) materials with the clathrate-II crystal structure provide a unique opportunity to investigate the direct effect of guest content on physical properties of intermetallic clathrates in a chemically simple system with only two elements. The preferential filling of two framework cages with very different sizes is accompanied by very different guest-framework interactions, resulting in a non-monotonic structural response to cage filling that is correlated with a metal-insulator transition near $x = 8$. Temperature-dependent single-crystal and powder X-ray diffraction experiments show that the room temperature linear coefficient of thermal expansion increases by nearly a factor of 3 upon filling, attributed to an increase in the anharmonicity in the interatomic interactions. Furthermore, negative thermal expansion, present at low temperature ($T < 150$ K) in Si_{136} and Na_xSi_{136} at lower Na contents, disappears for $x > 16$. Extremely large atomic displacement parameters obtained from structure refinements, as well as dynamic instability observed in first principles calculation of phonon dispersion, suggest the Na guest in the larger cage is displaced off-center, but the exact nature of the off-centering and dynamical behavior remains difficult to elucidate. Thus, modeling and understanding the physical mechanisms underlying the effects of guest content on electrical, thermal, and mechanical properties of these silicon clathrates is non-trivial.

2:10 PM *CH02.14.09
Oxychalcogenide Building Blocks Toward Nonlinear Optical Properties Houria Kabbour[1], Batoul Almoussawi[1], Hiroshi Kageyama[2], Mike Whangbo[3,4] and Shuiquan Deng[4]; [1]Univ. Lille, CNRS, Centrale Lille, ENSCL, Univ. Artois, UMR 8181 – UCCS – Unité de Catalyse et Chimie du Solide, France; [2]Kyoto University, Japan; [3]North Carolina State University, United States; [4]Chinese Academy of Sciences, China

Among the versatile mixed anion compounds [1], oxychalcogenides are emerging as promising alternative candidates for a variety of applications including for energy. Recently, they have been pointed as interesting systems for mid IR nonlinear optical (NLO) properties [2]. In particular, strong second harmonic generation (SHG) responses are found for NLO compounds with functional groups composed of mixed anions such as in $BaGeSe_2O$ with GeO_2Se_2 tetrahedra [3] (compared to its oxide analogue with GeO_4 tetrahedra). Here we will discuss, through several structure types based on thiovanadates $V(O,S)_4$ building blocks, the possibility to tune the symmetry and engineer the band gap. $Ba_5(VO_2S_2)_2(S_2)_2$ [4] with third-harmonic generation properties and $Ba_7S(VOS_3)_2(S_2)_3$ and its selenide-derivatives [5] will be discussed with support of density functional theory (DFT). We will see that the presence of Q–Q bonds (Q= chalcogenide) lead to original lattices with multiple anionic species and add greater structure and electronic structure versatility to design functional materials. On another hand, we will present unprecedented oxysulfide building block for SHG active materials and give a comprehension of the SHG response mechanism with support of DFT calculations [6].

4:00 PM *CH02.16.01
Towards Solid–State Electroytes—Complex Halides and Hydrides as New Fast Li-Ion Conductors Duncan Gregory; Univ of Glasgow, United Kingdom

Many of the most widespread and commercially successful materials in Li-ion batteries are oxides. Nevertheless, some of the best performing materials contain elements from elsewhere in the periodic table (e.g. chalcogenides, pnictides). Although halide salts have long been employed as electrolytes in solution or in the molten state, there are few examples of halides as solid-state cationic conductors and until recently, still fewer in terms of hydrides.

This contribution focuses principally on the possibilities for designing fast Li-ion conducting (pseudo-)halides as potential electrolytes in all-solid-state batteries. In switching the materials design emphasis from cations to anions, it will be shown how both static and dynamic disorder might be exploited to enhance Li-ion transport and how diffusion pathways might be modified in terms of anion geometry and electronegativity (polarizability). Concepts of lattice “softness” and complex anion dynamics become crucial components of such a design strategy. Synthesis (often of metastable solids) can be challenging, but mechanochemistry and other “soft” chemical approaches, can provide a means to access such materials, while facilitating nanostructuring and generating defects.

This contribution covers several exemplar systems of promising complex hydride and halide Li fast-ion conductors, including $Li(BH_4)_{1-y}X_y$, $LiAlX_4$ and $LiCe(BH_4)_3X$; X = Cl, Br, I, among others. In each case a raft of techniques including neutron diffraction and muon spin relaxation spectroscopy have been fundamental in elucidating the structure-property relationships in these systems. A synergic combination of experiment and computational calculations are

beginning to shed light on the mechanisms for Li-ion conduction in these families of non-oxide materials and their prospects as solid state electrolytes will be evaluated.

4:30 PM CH02.16.02
Group VI Metalates as Thermosensitive Phosphors Federico A. Rabuffetti; Wayne State University, United States

Group VI metal oxides featuring MoO_4^{-2} and WO_4^{-2} anions are ideal semiconducting host materials for thermosensitive phosphors activated by Mn^{4+} and/or rare-earth metals. A distinct feature of these materials is their structural diversity in terms of metal coordination and connectivity, which makes them an ideal platform to exercise compositional control over their temperature-dependent luminescence response. In this talk, I will highlight the potential of molybdate and tungstate phosphors as luminescent thermometers. I will show that selected Mn^{4+}-activated metalates serve as bandshift thermometers with a temperature sensitivity comparable to that of quantum dots but with a much broader usable temperature range. Further, I will show how the crystal-chemistry of group VI metalates may be exploited to generate thermochromic phosphors via codoping Mn^{4+}–Tb^{3+} pairs. Findings presented in this talk expand the scope of applicability of Mn^{4+}-activated thermosensitive phosphors beyond ratiometric bandshape and lifetime thermometry. They also provide structural guidelines for discovering and screening novel oxide hosts for dual-activator luminescent thermometers.

4:45 PM CH02.16.03
A General Method for Reconstructing the Orientation Ordering of Materials Constituents from Their Scattering Anisotropy Guan-Rong Huang[1], Jan-Michael Carrillo[1], Yangyang Wang[1], Changwoo Do[1], Yuya Shinohara[1], Takeshi Egami[1,2], Lionel Porcar[3], Yun Liu[4], Bobby Sumpter[1] and Wei-Ren Chen[1]; [1]Oak Ridge National Laboratory, United States; [2]The University of Tennessee, Knoxville, United States; [3]Institut Laue-Langevin, France; [4]National Institute of Standards and Technology, United States

We outline a state-of-the-art approach for reconstructing the orientation distribution function (ODF) of materials from their scattering anisotropy using real spherical harmonics (RSH) expansion. Without assuming the functional form of ODF, we perform the reconstruction through the RSH decomposition of their scattering intensity and ODF subject to certain constraints from symmetries and orientation order parameters. We demonstrated its validity by the quantitative agreement between case studies of molecular dynamics simulations and numerical computations. Our proposed method is applicable for general materials subject to various external conditions. Material's properties usually reflect on the coarse-grained averages of the relative orientation and separation at molecular levels over a characteristic length scale. One of the well-known examples is the magnetic response of materials is the ensemble average of magnetic moments over all the possible configuration distributions in phase space. Knowing how the molecular orientation distributes enables us to investigate the fundamental mechanism between the microscopic variables and macroscopic properties of interest in response to the applied fields. It can facilitate us with materials design and characterization for its practical use under different conditions. These can be exemplified by the magnetization alignment induced by the applied magnetic field or the orientational ordering of anisotropic nanoparticles in composites undergoing mechanical deformation. Typically, the microscopic information of material's orientation is conceived in its corresponding scattering spectra, which is an ensemble average in momentum space. Under the external fields without rotational symmetry, the constituent of materials would possess a preferred orientation, which will reflect on the anisotropy of their scattering signature. Therefore, how to reconstruct the ODF of materials from their scattering anisotropy is inevitably important.

5:00 PM DISCUSSION TIME

5:15 PM CH02.04.03
Multipolar Hidden Orders in $5d^1$ Double Perovskites Aria Mansouri Tehrani and Nicola Spaldin; ETH Zurich, Switzerland

We present a density functional theory study of the interplay between multiple hidden and established charge, magnetic and structural orders in $5d^1$ double perovskites. The ordering of structural distortions, magnetic dipole moments, atomic orbital occupancies, and electronic charges is widespread in materials and leads to well-known behaviors such as changes in the crystal structure, the onset of ferromagnetism, or metal-insulator transitions. While such orderings have been extensively investigated, there remain many materials that show intriguing changes in behavior indicating the onset of order, but for which the nature of the order is not yet known. Double perovskite oxides (halides) with 5d1 transition magnetic ion have been of particular interest recently to explore these multipolar hidden orders which stem from their unique crystal chemistry and the interplay of spin-orbit coupling, crystal-field splitting, and electron-electron repulsion. Here, we present a density functional theory study of multipolar ordering (e.g. charge quadrupoles and magnetic octupoles) and their coupling with the dipolar magnetic and the crystal structure of two $5d^1$ double perovskites, Ba_2MgReO_6 and Cs_2TaCl_6. Both of these compounds are spin-orbit-driven Mott insulators with a symmetry-lowering structural phase transition at low temperatures driven by the ordering of charge quadrupoles. Our primary goal is to provide an understanding of the interplay between the structural distortions, the charge quadrupole ordering, and the magnetic dipole ordering in these compounds. In addition to shedding light on the detailed behavior of Ba_2MgReO_6 and Cs_2TaCl_6, our analysis provides a novel insight into the crystal structure-multipolar order relationship of $5d^1$ double perovskites.

9:00 PM *CH02.17.02
Porous Ionic Crystals Based on Polyoxometalates as a Tunable Platform for Functional Materials Sayaka Uchida; The University of Tokyo, Japan

Porous crystalline materials such as zeolites and metal-organic frameworks (MOFs) have attracted wide attention due to their well-defined porous structures and high surface area, which are useful in gas storage and separation, ion exchange and conduction, and heterogeneous catalysis. Polyoxometalates (POMs) are nano-sized metal-oxide molecular anions with unique catalytic, electrochemical, magnetic, and luminescent properties and have stimulated research in broad fields of science. Recently, the incorporation of POMs in nano-sized cavities of MOFs has been reported; these POM-MOFs show unique functions such as oxidative removal of hydrogen sulfide, selective adsorption of cationic dyes, and visible-light-driven hydrogen production. In contrast, we have reported that the complexation of POMs with molecular cations with appropriate elements, charges, sizes, symmetry, ligands, etc., results in the formation of voids and channels in the crystal lattice. The properties of porous ionic crystals (PICs) based on POMs can be

summarized as follows. (a) POMs show reversible redox properties, which can lead to the formation of “redox-active” PICs. (b) Guest binding and catalytically active sites can be incorporated beforehand into the ionic components. These functions can be maintained and utilized in the PICs since the ionic components still exist as discrete molecules in the crystal lattice. (c) The ionic components create strong electrostatic fields at the internal surfaces of PICs, which are suitable for accommodating and stabilizing polar guests and reaction intermediates. (d) POMs can transport protons as counter cations efficiently because the negative charge of POMs is smeared over the external oxygen atoms decreasing the effective surface charge density. These properties lead to interesting functions in selective ion-uptake/exchange, proton conduction, heterogeneous catalysis, formation of luminescent mixed-valence metal clusters, etc., which are unique to PICs.[1-12]

Tri-Phase Photocatalysis for CO_2 Reduction and N_2 Fixation with Efficient Electron Transfer on a Hydrophilic Surface of Transition-Metal-Doped MIL-88A (Fe) Niwesh Ojha; IIT Patna, India

Efficient transfer of charges at the interface of transition-metal and semiconductor can improve efficiency of photocatalyst. Herein, we examined the photoactivity of Mn and Zn-doped MIL-88A for CO_2 reduction and N_2 fixation by water under UV-visible irradiation and ambient conditions. Gaseous-phase photo-reduction of CO_2 generated CO, H_2, and CH_4. Apparent quantum yield of Zn-MIL-88A was found to be 2.16-folds higher than that of pristine MIL-88A catalyst. Also, the highest NH_4^+ generation rate was for Zn-MIL-88A catalyst. Dissecting the underlying mechanism discloses that electrons efficiently transferred from doped transition-metals to the Fe-O cluster of MIL-88A. The hydrophilic surface of the tested catalysts in a tri-phase photocatalyst system led the process to be controlled by mass-transport; which governed the product distribution and limited the kinetics of the process. Experimental results also unveil that the addition of transition metals improved stability, charge-separation, and efficiency of the resulting photocatalysts.

Analysis of Chemical and Electronic States Related to Hydration Reactivity of Lime Phase Coexisting with Other Oxides to Utilize Steelmaking Slag Hiromi Eba, Ryosuke Serigano, Kousuke Yonemoto and Yuuki Suzuki; Tokyo City University, Japan

In steelmaking processes that refine pig iron into tough steel, calcined lime (CaO) is added to remove unwanted components, such as Si, P, and S, and steelmaking slag is produced as a by-product. This slag consists primarily of CaO and SiO_2 and is effectively used as recycled materials for construction and civil engineering. However, part of the CaO in the slag remains in the unreacted form, *i.e.* as free lime, which expands to about double volume by hydration. Therefore, fresh slags that contain free lime must undergo aging. In general, slags containing high amounts of free lime have higher expansibility than their counterparts, which have lower CaO contents. The expansibility, however, varies with the particle size, physical state of the free lime, and the corresponding chemical composition. Therefore, estimating the expansibility solely as a function of the free lime content is difficult. In this study, to promote the utilization of steelmaking slag, the hydration reactivity and electronic state of free lime were observed. It was confirmed by X-ray diffraction (XRD) and thermal analysis that the hydration reactivity decreases when CaO forms a lime-phase solid solution with FeO, and it was revealed by X-ray photoelectron spectroscopy (XPS) observations and DV-Xα calculation that the decrease in reactivity occurs due to deepening of the energy levels of the electron orbitals. The morphology and hydration reactivity of the free lime contained in a synthesized slag were observed by XRD and electron probe microanalysis. Fe-containing phases and double oxides were found to be adjacent to free lime; the former is considered to be related to the formation of a solid solution with FeO, and the latter closely surrounds the free lime and shields it from the outside; thus, both contribute to suppressing the hydration reaction. Furthermore, it was found that simply mixing lime with double oxides suppressed the hydration reaction. XPS and thermal analysis confirmed that a chemical change occurred on the surface of the free lime; that is, the energy levels of the electron orbitals are deepened and the hydration reaction is suppressed due to chemical interactions with the double oxides to stabilize the lime surface. It was clarified that in order to effectively promote the hydration of free lime, it must be exposed by breaking the structure of the slag that protects the free lime and suppresses hydration.

9:40 PM CH02.17.05
Tuning of Mixed Valency in Rare-Earth Fullerides at Ambient and Elevated Pressures Naoya Yoshikane[1], Keisuke Matsui[1], Hitoshi Yamaoka[2], John Arvanitidis[3] and Kosmas Prassides[1]; [1]Osaka Prefecture University, Japan; [2]RIKEN, Japan; [3]Aristotle University of Thessaloniki, Greece

The electronic properties of rare-earth elements, RE are dominated by the 3+ oxidation state, but 2+ can be also stabilized for Sm, Eu, and Yb due to their comparable energy [1]. As a result, mixed valency phenomena are encountered in compounds of these rare-earths (Kondo insulators, heavy fermions) with the average RE valence strongly affected by changes in external stimuli (temperature, pressure). Research in elastic, conducting, optical, and magnetic properties triggered by such valence changes remains at the frontier of solid-state chemistry.
The RE fullerides with stoichiometry, $RE_{2.75}C_{60}$ (RE=Sm, Yb) constitute an intriguing class of electronic systems due to the strong electronic coupling between the highly-correlated mixed-valence RE cation and C_{60} anion sublattices. Past work pointed towards strong coupling of lattice and electronic degrees of freedom with the occurrence of pressure-induced lattice collapse and concomitant insulator-metal transition around 4 GPa [2,3]. However, to-date there has been no direct study of the RE electronic states – all information about valence changes has come indirectly from diffraction and Raman spectroscopic measurements.
Here we report the results of element-specific synchrotron X-ray absorption spectroscopic (XAS) measurements of the average Sm valence in binary and ternary Sm fullerides, authenticating the mixed valence character of the materials for the first time. In addition, we directly address the evolution of the Sm electronic states both by chemical pressure induced by progressive introduction of smaller-in-size valence-precise Ca^{2+} ions and by external physical pressure [4,5]. Following this spectroscopic work, we address the structural behavior of this family of materials by high-resolution synchrotron X-ray powder diffraction measurements at elevated pressures – the observed lattice collapse with increasing pressure sensitively depends on the level of Ca^{2+} substitution and perfectly mirrors the Sm valency transition authenticated by synchrotron XAS. The pressure-induced phase transition is isostructural but is accompanied by well-defined renormalization of the rare-earth metal positions and their shift towards high-symmetry positions. The results provide a rationalization of the pressure-induced drastic changes in structural, conducting and optical properties of RE fullerides that are coupled with the extreme fragility of the rare-earth valence.

High Pressure Synthesis of Novel Perovskite-Related Cuprates Shintaro Ishiwata; Osaka University, Japan

The discovery of high temperature superconductivity in cuprates has spurred the search for novel low dimensional cuprates such as spin ladder compounds. On the other hand, less attention has been paid for the three dimensional counterpart, the perovskitetype cuprates ACuO3, presumably because of the difficulty in high pressure synthesis. In this talk, a novel orthorhombic perovskite PrCuO3 obtained by high pressure synthesis will be introduced[1]. Synchrotron x-ray diffraction and x-ray absorption spectroscopy reveal that PrCuO3 consists of quasi-one-dimensional chains of Cu-O with square-planar coordination, and the oxidation state of Cu ions is about 2.2+. The formation of the Cu-O chain reflects the cooperative Jahn-Teller distortion of nearly divalent Cu ions. Upon the La substitution for Pr, we found the abrupt change in structure and electrical conductivity, from the orthorhombic semimetal to rhombohedral metal, which is accompanied by the AB site charge transfer. This system offers a unique opportunity to explore novel quantum phases of correlated electrons as the simplest one-dimensional counterpart of the high temperature superconducting cuprates. In addition, we will introduce a computational structure prediction for novel oxygen-deficient perovskite-type cuprates on the basis of the density functional theory and Bayesian optimization[2].

Why Lattices and High Valence States are Stabilized in Perovskite-Type Oxides by Madelung Lattice Site Potentials Masahiro Yoshimura[1,2] and Kripasindhu Sardar[1]; [1]National Cheng Kung University, Japan; [2]Tokyo Institute of Technology, Japan

Perovskite-type oxides(ABO3) are quite common for various Ferroelectric, Piezoelectric, Conducting Electrode and/or even Superconducting oxides. However, it has not been clear why they will take perovskite-type structure(s) . For the stability of Perovskite Lattices, classic Tolerance Factors based upon ion packing model have been considered even now. One of the present authors proposed another concept: Madelung lattice energy should be the key factor of the Lattice and Valence Stability.[1,2)] The total Madelung Lattice energy(U) could be considered by the summation of Sub-Lattices Energies of A, B and O sites. Since they are given each lattice site potential (Φ) and its valence(q): that is, U = ΦA x qA + ΦB x qB + 3ΦO x qO. Using a recent Program:VESTA[3)],we have confirmed 1) U_{ABO3} is always larger than the summation of U_{AO} + U_{BO2} or $U_{AO1.5}$ + $U_{BO1.5}$. 2) U_{ABO3} become larger when valence pairs are shifted from 3+ and 3+ to, 4+ and 2+ then 1+ and 5+ or 0+ and 6+. 3) Furthermore, those large B Sublattice potential can be strongly related to high valence state of B ions in Perovskite ABO3. Since the ionization potential [loss] can be compensated by high lattice site potential [gain], high valence ion(s) can be stabilized in B site with high lattice-site potential. For example, Ce4+, Pr4+, and Tb4+ can be stabilized in a Fluorite lattice, and more stabilized in the B site of Perovskite ABO3 lattice. Un-common high-valence ions like Co3+, Ni3+, Fe4+ in the B-sites of the Perovskite ABO3 lattices can be explained similarly. On the other hand, those high-valence ions cannot be stabilized in the A site of Perovskites nor various A2O3, like A-type and C-type M2O3,or corundum, lattices thus they take rather common valence states in those cases. The Madelung Lattice energy(U) is Enthalpy at 0 K,thus it consists of ca. 90% of total free energy(G) of the compound. Therefore the valence stability of certain ions in particular lattices is directly related to the Madelung self-site potential(Φ) of the lattice site. The entropy term by Temperature and P_{O2} can contribute < 10% of U at 1000K. Therefore it might be rather minor effects for those internal lattice potential energy. Vacancy formation energies can also be estimated by Madelung Lattice Site Potentials. More precise data can be calculated by recent First Principle Calculation using several additional parameters, but they should include several hypothetical parameters and much longer times for calculation.

Quantifying Nano-Electromechanical and Nano-Mechanical Measurements with a Metrological Atomic Force Microscope Roger Proksch; Asylum Research and Oxford Instruments, United States

Voltage modulation (VM) of atomic force microscopy (AFM) has been used to quantify a host of electronic, electrochemical and electromechanical functionalities across nanometer length scales. The critical importance of such information has resulted in the development of a plethora of VM-AFM techniques for exploration of either long or short-range forces. Of relevance for ferroelectrics, piezoresponse force microscopy (PFM) imaging and associated spectroscopies have effectively opened the door to the exploration of nanoscale ferroelectric properties. The rise of PFM, however, has also brought about claims of ferroelectricity in materials which were subsequently thought to be not ferroelectric,[1] even unlikely materials such as soda-lime glass. Explanations for the origins of these unexpected nanoscale phenomena have not been in short supply, including new material properties, surface-mediated polarization changes and/or spatially resolved behavior that is not present in bulk measurements. At the same time, it is well known that VM-AFM measurements are susceptible to numerous forms of crosstalk and despite efforts within the AFM community, a global approach for quantitative, crosstalk-free techniques remains elusive. In an effort to understand the true origins of the measured VM-AFM signals we demonstrate the presence of hysteretic ("false ferroelectric") long-range interactions between the sample and cantilever body and show that these are intrinsic to traditional VM-AFM detection methods. However, we show that with interferometric displacement sensor (IDS) [2] it is possible to separate the true tip motion from the cantilever dynamics. Using the IDS we have established a rapid and simple flagging routine of false piezo and ferroelectric responses and are able to demonstrate fully quantitative and repeatable nanoelectromechanical characterization. These quantitative measurements are critical for a wide range of new devices ranging from mems actuators, memristor devices, energy storage and dynamic computer memory. While our initial work was focused on electromechanical measurements, we have extended this microscope to improved quantification of force-based mechanical measurements. Quantifying the force and displacement with this metrological AFM has enabled improved quantitative and high speed modulus mapping in a variety of environments. [3, 4]

11:00 AM CH03.01.02
Controlled Manipulation of Benzene and Phenyl Groups Across Different Energy Landscapes Chao Zhou[1], Omur E. Dagdeviren[1,2], Milica Todorović[3], Eric Altman[1] and Udo Schwarz[1]; [1]Yale University, United States; [2]University of Quebec, Canada; [3]Aalto University, Finland

With the continued development of scanning probe microscopy techniques, manipulation of single molecules has become possible. Thereby, the manipulation path can be chosen at will and the energy landscape around the molecule can be quantified before and after manipulation. This not only allows to extract the energy barriers between potential minima along the manipulation pathway but may more generally provide unprecedented insight into the chemical interaction of individual molecules with their surroundings. To further explore the approach's potential, we conducted controlled manipulation experiments with benzene on a Cu (100) surface as a model system using a novel manipulation protocol that despite not requiring any active feedback during execution provides the normal and lateral forces at the instance of the jump with piconewton accuracy, which leads to very robust operation. The results indicate that the molecules were either pushed, pulled, jumped to the tip, or did not move depending on the chemical surroundings of the molecules and the chemical identity of the tip. We then compared the experimentally obtained energy landscapes and barrier heights with computational results obtained by combining density functional theory with machine learning approaches. The Bayesian Optimization Structure Search (BOSS) protocol suggests that the presence of the tip lowers the energy barrier the molecule has to overcome during its motion, which evolves with the chemical identity of the tip. In addition, phenyl groups were produced from iodobenzene precursors, from which the iodine atom was split off by applying a controlled bias voltage. We then manipulated the phenyl group away from the iodine atom and measured the required energy barrier, which was found to decrease with increasing distance from the iodine atom. Calculations indicate that there are different ways the molecules can move that have different barriers, so the finding of different barrier heights may simply reflect different processes. Overall, our results indicate that a reliable methodology where surface reactions can be induced by the tip of a scanning probe microscope and the reaction pathway is chosen at will could be in reach, which would

ultimately enable an individualized, site-specific understanding of single-molecule surface chemistry.

11:15 AM CH03.01.03
Theoretical Models for KPFM with Flexible Tip Apices Ondrej Krejci[1] and Adam Foster[1,2,3]; [1]Aalto University, Finland; [2]Kanazawa University, Japan; [3]Graduate School Materials Science in Mainz,, Germany

More than 10 years ago two types of Scanning Probe Microscopy (SPM) – Scanning Tunneling Microscopy (STM) [1] and non-contact Atomic Force Microscopy (nc-AFM) [2] – showed a possibility to reveal positions of atoms on small flat organic molecules in real space without any damage to the sample. These two works noticeably enhanced the field of molecular, 1 and 2D material studies in surface science (i.e. [3]). The sub-molecular resolution was achieved by usage of non-reactive and flexible tip-apices like CO-molecule [4]. Kelvin Probe Force Microscopy (KPFM)[5] is a technique proceeded with combined nc-AFM/STM instrument, which basically measures the effect of applied voltage between the microscope tip and sample on the measured force. It has possibility to measure the changes of work-function on the microscale and electric field above the sample on the nanoscale. However, the physics behind KPFM signal with flexible-tip apices showing the sub-molecular resolution, which could help with elemental recognition, remain unknown. In this work, we will summarize up-to-date knowledge about KPFM [5,6] focusing mainly on measurements with simultaneous frequency modulation - Atomic Force Microscopy / Scanning Tunneling Microcopy instruments. Based upon this, we will present a new model for electrostatic field, which is describing the experiments with CO-metal tips [7] and metal substrates. This new electrostatic model is applied in a Density Functional Theory (DFT) calculations simulating the full tip-sample system. The results of the DFT calculations will be compared with simple mechanistic models capturing various sources of achieved signal. All these models and simulations have aim to recover the physics behind KPFM with flexible tip apices. This knowledge can help to get more information about the sample with SPM and is possibly a further step towards reliable chemical resolution in SPM.

11:30 AM CH03.01.04
Imaging Ballistic and Viscous Flow of Carriers in Graphene Using Scanning Tunneling Potentiometry Zachary Krebs, Wyatt Behn and Victor Brar; University of Wisconsin - Madison, United States

The flow of electrical current through a material can, in special circumstances, mimic the flow of a viscous fluid. This so-called 'hydrodynamic' regime occurs when the rate of momentum-conserving collisions between charge carriers is larger than the momentum-relaxing rate due to other scattering sources. Until very recently this condition has been difficult to satisfy in real materials, hampering experimental studies of electronic transport in this unique regime. Ultraclean graphene has emerged as an ideal platform for studying hydrodynamic flow, opening up the possibility of directly imaging fluid-like behavior such as vortex formation. In this talk, I will show scanning tunneling potentiometry (STP) measurements of quasiparticle flow around tunable electrostatic barriers in graphene on a hexagonal boron nitride substrate. Measurements are performed as carriers pass through μm-scale channels that are continuously narrowed until they are blocked entirely, forming 'electrostatic dams'. Local STP measurements of the electrochemical potential allow for direct characterization of the evolving flow profile near the channels, which is observed to be non-Ohmic, and highly dependent on the sample temperature and the channel width. Under all flow conditions, we observe the formation of Landauer resistivity dipoles across the barriers due to scattering. However, at low temperatures (4.5 K) the channel conductance is observed to be consistent with ballistic transport, while at elevated temperatures (77 K) the conductance is observed to increase. We attribute this 'superballistic' transport to a viscous enhancement of the conductance originally predicted by Gurzhi, a hallmark of hydrodynamic flow. We further use these measurements to extract the electron-electron scattering length at a range of carrier densities. We compare our measurements to finite-element simulations of a Stokesian fluid with different parameters, finding good agreement at 77 K for a fluid with a kinematic viscosity of 0.7 m^2/s. Our results demonstrate the incredible utility of STP in distinguishing between different electronic transport regimes, and quantifying the interaction length scales that lead to a distinct flow profiles.

11:45 AM CH03.01.05
Sub-Molecular Resolution nc-AFM and KPFM Imaging of Dipolar Molecule Assemblies on Si(111):B Natalia Turek[1], Sylvie Godey[1], Dominique Deresmes[1], Christophe Krzeminski[1], Judicael Jeannoutot[2], Younes Makoudi[2], Frank Palmino[2], Frederic Cherioux[2], David Gao[3] and Thierry Melin[1]; [1]IEMN-CNRS, France; [2]FEMTO ST-CNRS, France; [3]NANOLAYERS, United Kingdom

We studied by non-contact AFM (nc-AFM) the formation of molecular self-assemblies on the pas-sivated surface of boron doped silicon B-Si(111)-($\sqrt{3}\times\sqrt{3}$)R30°. The investigated molecules (1-(4'cyanophenyl)-2,5-bis(decyloxy)-4-(4'-iodophenyl)benzene) possesses aliphatic chains attached to a triphenyl core ended with two possible different terminations (either iodine or cyano group). The use of a passivated semiconductor substrate enables creating regular and extended structures without significant change in electronic properties of molecules [1]. Scanning tunneling microscopy and nc-AFM imaging have been performed using a low-temperature (AFM/STM (JT AFM/STM,SPECS) operated at T=4K with high stiffness Kolibri sensors (k=540 kN/m, f_0=1 MHz). The growth of a periodic molecular network is observed, formed by parallel lines made by molecule aromatic cores and interdigitated aliphatic chains placed between adjacent rows. We obtain submolecular resolution in the constant height δf images without intentional tip functionalization, but only by conditioning the tip on the silicon surface [2]. We will discuss the high-resolution AFM imaging, as well as the conformation of the molecules in the observed assemblies (e.g. changes in the interdigitated aliphatic chains ordering). Kelvin Probe Force Microscopy (KPFM) images of single molecules and molecular assemblies with sub-elementary charge sensitivity [3] and submolecular resolution will be provided and discussed, in particular with respect to the choice of the molecular terminations. They reveal the dipolar character of asymmetric molecules and are consistent with the formation of dipole-driven molecular arrays, in the case of self-assemblies. Density functional theory calculations as well as molecular dynamics simulations will be compared with experimental results.

12:00 PM CH03.01.06
Late News: Anomalous Tip-Sample Interaction on Soft 2D Materials Revealing Inter-Layer van der Waals (VDW) Strength by Scanning Tunneling Microscopy (STM) Nirjhar Sarkar, Prab Bandaru and Robert C. Dynes; UC San Diego, United States

A new solution is offered to understand an instrumental artifact which is the anomalously high atomic amplitudes on graphite surface measured by Scanning Tunneling Microscopy (STM) using the local elastic deformation theory. This is demonstrated by a series of simple experiments done to measure atomic topography of various 2D surfaces like Niobium diselenide, monolayer graphene and graphite across their monatomic step heights to show how tip-sample interaction causing the anomalous atomic amplitudes is of purely mechanical nature and not electronic. The underlying physics of Van der Waal bonding playing a major role in these interactions with 'soft' 2D surfaces will be uncovered.

12:15 PM CH03.01.07
A Graphene-Based Platform for Investigation of Protein Assembly by Infrared Nanospectroscopy Xiao Zhao[1,2], Dong Li[1], Yi-Hsien Lu[1], Paul Ashby[1] and Miquel Salmeron[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

The nanoscale structures and dynamical processes of proteins have been extensively studied by various imaging techniques such as electron microscopy and atomic force microscopy (AFM) in liquid. However, these imaging techniques can damage or perturbate the samples and do not provide chemical identification. This prevents a direct monitoring of structural and chemical evolution under physiological conditions. Herein, we demonstrate a new nondestructive platform that enables nanoscale Infrared (IR) spectroscopy for protein at graphene-aqueous solution interface by combining graphene liquid cell and Fourier Transform Infrared Nanospectroscopy (nano-FTIR). Single layer graphene separating the assembly solution and the tip minimize the sample damage and tip contamination. The S-layer protein structural evolution during and after assembling process is monitored by recording the amide I and II vibration bands, which provides unique and complimentary information to the AFM morphology in liquid. Our platform opens up broad opportunities for *operando* study of soft materials or nanostructures (enzyme, other membrane protein, virus, and plastic material) in their realistic condition and under external stimuli.

SESSION CH03.02: New Developments I

2:00 PM CH03.02.02
Using High-Speed, Molecularly Resolved AFM to Investigate Nucleation from Solution James J. De Yoreo[1,2], Benjamin A. Legg[1], Marcel D. Baer[1], Christopher J. Mundy[1,2], Jaehun Chun[1,3] and Kislon Voitchovsky[4]; [1]Pacific Northwest National Laboratory, United States; [2]University of Washington, United States; [3]City University of New York, United States; [4]University of Durham, United Kingdom

Investigating nucleation from solutions is challenging, because it is a consequence of unstable density fluctuations, making the structures and events that must be probed both transient in nature and small in spatial extent. Thus high-speed, molecularly resolved AFM provides a powerful and unrivalled method to investigate nucleation from solution by choosing systems that nucleate onto surfaces. Here we illustrate the deep level of fundamental insight into the pathways and energetics of nucleation made possible by this method by using it to investigate epitaxial nucleation of gibbsite ($Al(OH)_3$) on muscovite mica (001). AFM results combined with streaming potential measurements reveal a surface population of ions that is dominated by hydrolyzed species ($Al(OH)_2^+$ and $Al(OH)^{2+}$) even though Al^{3+} vastly dominates the bulk solution. These adsorbed ions evolve into subcritical clusters with increasing saturation state and temperature, constituting a population whose size distribution and fluctuations exhibit many similarities to the predictions of classical nucleation theory (CNT). However, severe discrepancies with CNT emerge when the values of key thermodynamic parameters are extracted from the AFM data. Moreover, the resulting gibbsite film forms simultaneously across the surface, rather than through the appearance of rare critical-size nuclei. Using kinetic Monte-Carlo (KMC) simulations, we demonstrate how this behavior can arise from electrostatic interactions between positively charged aluminum clusters and the negatively charged mica surface. Our results indicate that surface charging can dynamically modify both the chemical potential for accumulating ions on the surface, and the edge tension of the clusters. As the film grows, these interactions stabilize a nanostructured surface mesophase, which evolves gradually via a process of cluster growth and coalescence and is not limited by the classical formation of a critically sized nucleus. Our results show that high speed AFM provides a direct molecular view of nucleation at surfaces that reveals both consistencies and deviations from the simple classical picture and highlights the inherent role of surface charge in determining pathways and outcomes of nucleation.

Enhancing the Force Stability, Force Precision and Time Resolution of BioAFM with Focused-Ion-Beam Modified Cantilevers Thomas Perkins[1,2]; [1]University of Colorado Boulder, United States; [2]National Institute of Standards and Technology, United States

Atomic force microscopy (AFM)-based single-molecule force spectroscopy enables a wide array of studies, from measuring the strength of a ligand-receptor bond to elucidating the complex unfolding pathway of individual membrane proteins. Such studies and, more generally, the diverse applications of AFM across biophysics and nanotechnology are improved by enhancing the force stability, force precision, and time resolution of bioAFM. For an advanced, small-format commercial AFM, we uncovered how these three metrics were limited by the cantilever itself rather than the larger microscope structure, and then describe three increasingly sophisticated cantilever modifications using a focused ion beam that yielded enhanced data quality. For example, our most recent cantilever design, a "Warhammer," achieved a sub-pN force precision and stability over 5 decades of time (1 ms – 100 s) coupled with 8-µs time resolution in liquid when positioned just above a surface. High-precision single-molecule studies of membrane proteins—the target for over 50% of current and future drugs—have lagged analogous studies of globular proteins due to instrumental limitations. We revisited the unfolding of the canonical membrane protein bacteriorhodopsin with a 100-fold improvement in time resolution and a 10-fold improvement in force precision. The resulting data revealed the unfolding pathway in unprecedented detail. I will conclude by discussing extensions of this capability to other diverse biomolecules, including nucleic-acid structures and globular proteins involved in hereditary heart disease. The metrological enhancements enabled by modified AFM cantilevers are not limited to single-molecule force spectroscopy but are broadly applicable across diverse AFM studies. Importantly, these modified cantilevers are robust, reusable over multiple days and, in our lab, typically modified by undergraduates. Thus, they are neither too costly nor too challenging to modify for routine use.

Direct Probing of the Interfacial Hydrogen Bonding and Dynamics of PMMA Confined in Porous Organosilicate Using Correlative Scanning Probe Microscopy David W. Collinson and Reinhold H. Dauskardt; Stanford University, United States

Understanding the chemistry and dynamics of polymers at the nanoscale and under confinement is of utmost importance for high performance and emerging materials and composites. Scanning probe microscopy (SPM) techniques promise extremely high resolution and direct, sensitive measurement of

polymer chemical and mechanical properties down to 1-10 nm. However, collection and interpretation of SPM data remains complicated due to the difficulty in interpreting measured properties at such fine scales. Correlative approaches using both mechanical and chemical SPM techniques, in conjunction with modelling of tip-surface interactions, can enable discovery even at the limits of SPM resolution and performance.

Here, we demonstrate the ability to directly measure the loss tangent of poly(methyl methacrylate) (PMMA) confined to 7 nm diameter pores in an organosilicate (OCS) matrix utilizing dynamic atomic force microscopy (AFM) and modelling of the tip-sample interactions. Further, we identify a decrease in the loss tangent of PMMA when confined to an OCS matrix treated to increase silanol density on the pore surfaces. At the nanoscale, X-ray photoelectron spectroscopy as well as other optical spectroscopy techniques demonstrate that the increased silanol density leads to an increase in hydrogen bonding between the carbonyl groups in the PMMA chains and the surface silanols. The increased bonding reduces chain mobility and consequentially decreases the observed loss tangent as the surface interaction strength increases. The correlative microscopy approach enables a direct link between the observed decrease in the loss tangent of PMMA as measured by AFM and the underlying change in polymer chemistry responsible.

The highly sensitive measurements and findings described above are enabled by a technique known as gas cluster ion beam (GCIB) etching. Previously, it has been challenging to prepare composite surfaces that consist of soft polymers and hard ceramic components that are sufficiently smooth to enable high resolution mechanical property measurements. To overcome these challenges a GCIB procedure is presented that allows for damage free removal of the PMMA and OCS to produce a surface with an R_a of approximately 0.3 nm. GCIB is a promising sample preparation method that has not been extensively used in the preparation of polymer composite samples for SPM. Expanded use of GCIB should enable a broader range of samples, particularly in-situ samples, to be probed with SPM techniques.

CH03.03.03
Using Electrostatic Force Microscopy to Investigate Localized Charges on Single-Walled Carbon Nanotubes Erin E. Christensen, Trevor M. Tumiel, Mitesh Amin and Todd D. Krauss; University of Rochester, United States

Electrostatic force microscopy (EFM) is a modification of atomic force microscopy (AFM) which allows for a quantitative determination of localized charges and dielectric constants at the nanometer scale. In our implementation of EFM, the tip is lifted off the surface and scanned at a constant height under an applied AC and DC voltage, thereby providing sensitivity to extremely small capacitive and coulombic forces. By modeling the surface charge-cantilever force through a coulombic interaction, quantitative determinations of surface charge magnitude and location are possible down to less than 0.1 *e* at room temperature. In this presentation we have used EFM to study the spatial distribution and magnitude of charged regions along individual single-walled carbon nanotubes (SWCNTs). For dozens of long NTs dispersed with ionic surfactant we found surprisingly large charge density variations all along the NT with magnitudes on the order of 1 *e* to 15 *e* per 25 nm^2, which is roughly the EFM spatial resolution. Also, the charges had both positive and negative signs. Acquiring EFM data from before and after photoexcitation suggests that the ionic surfactant actually creates local electrostatic perturbations that act as barriers for exciton transport, which leads to distinct localized regions of charge. Additionally, we have been able to correlate single molecule photoluminescence (PL) spectroscopy and AFM microscopy images of the same individual SWCNTs. We found a highly unexpected localization of PL at sites of significant surfactant coverage. From our EFM measurements, we know these sites routinely display greater static charge accumulation, which suggests a connection between the electrostatic and optical characteristics of SWCNTs. Current efforts in our laboratory aim to provide a more detailed comparison of the charge and emissive profiles of individual NTs by correlating single molecule spectroscopy with EFM.

SESSION CH03.04: Technical Developments

Late News: Magnetic Mapping of Iron Using Magnetic Force Microscopy Kevin J. Walsh[1], Stavan Shah[1], Angie Blissett[1], Binbin Deng[1], Ping Wei[1], Josh Sifford[1], Sheng Tong[2], Samuel Oberdick[3], Doug Scharre[1], Gang Bao[2], David McComb[1], Dana McTigue[1] and Gunjan Agarwal[1]; [1]The Ohio State University, United States; [2]Rice Univeristy, United States; [3]University of Colorado Boulder, United States

Iron (Fe) is an essential metal involved in a wide spectrum of physiological functions in the body, including oxygen transport, enzymatic reactions and amino acid synthesis. Ferritin, the major iron storage protein in the mammalian body, consists of ~8 nm iron cores in the form of the iron-oxide crystal ferrihydrite. The size, distribution and oxidation state of ferritin(iron) has been shown to play an important role in health and disease. Histochemical staining, the routinely used approach to characterize iron distribution, offers limited insight into the chemical environment and composition of tissue iron. One of the properties of ferritin(iron) which has not been adequately exploited in histology is the magnetic behavior of tissue iron.
In this study we elucidate, how magnetic force microscopy (MFM), an atomic force microscopy (AFM)-based technique, can be used to map (magnetic) iron deposits in histological sections. MFM analysis was conducted on physiologically present ferritin(iron) deposits in naïve rodent spleen. To examine ferritin(iron) deposits in pathological tissues, an acutely injured rodent tissue (spinal cord) as well as tissues from chronic injury as present in brain tissue (hippocampus) from patients with Alzheimer's disease (AD) were used. Perl's histochemical staining was used to confirm the presence of ferric iron (Fe^{3+}) and analytical transmission electron microscopy was used to verify ferritin(iron) deposits at the ultrastructural level. MFM images were analyzed to ascertain the size of magnetic deposits, the strength of the magnetic signal (phase), and fluctuations (roughness) of the MFM signal.
Our results show that while Perl's histological staining is sensitive to the use of chemical fixatives, MFM analysis is not affected between fixed and unfixed tissues. Further, the size(s) of the magnetic deposits ascertained using MFM corresponded to that of ferritin(iron) rich lysosomal iron ascertained using electron microscopy. The size of these iron-rich deposits was significantly smaller in the diseased tissues (injured spinal cord and AD brain tissue) as compared to naïve spleen. Further naïve spleen exhibited significantly higher strength of the MFM signal when compared to injured spinal cord and brain

tissue. Interestingly, the roughness of MFM signal was similar across all tissues. TEM analysis indicated that the density of lysosomal ferritin(iron) deposits, was the major factor accounting for variances in MFM phase differences in mice tissue. Thus, rich and physiologically relevant information can be obtained through MFM mapping of histological iron.
To enable a multimodal analysis of iron we further developed an indirect MFM technique where TEM, MFM and fluorescence microscopy could be performed on the very same sample. In indirect MFM the sample is physically separated from the MFM probe by an ultrathin membrane. Further studies along these directions can allow for a high throughput and multimodal analysis of the quantity and quality of iron in AD. This can be of special relevance in neurodegenerative diseases where a transition of ferrihydrite into magnetite/maghemite is reported as the two minerals differ in their magnetic properties. Finally, the high sensitivity and spatial resolution offered by MFM makes it an attractive technique for a label free mapping of iron deposits in histology.

Time-Resolved Scanning Ion Conductance Microscopy for Three-Dimensional Tracking of Nanoscale Cell Surface Dynamics Samuel Leitao[1], Barney Drake[1], Katarina Pinjusic[1], Xavier Pierrat[1], Vytautas Navikas[1], Adrian Nievergelt[1], Charlène Brillard[1], Denis Djekic[2], Aleksandra Radenovic[1], Alex Persat[1], Daniel Constam[1], Jens Anders[2] and Georg Fantner[1]; [1]EPFL, Switzerland; [2]Universität Stuttgart, Germany

Dynamic nanoscale information of cell structures and organelles plays a vital role in understanding cellular function. Nanocharacterization techniques, such as super-resolution optical microscopy, electron microscopy, and atomic force microscopy (AFM), have been applied to image the structure of cells in great detail. The major challenge is to obtain three-dimensional (3D) information at nanometer resolution without affecting the viability of the cells and avoiding interference with the process. Scanning probe microscopy methods such as AFM can generate high-resolution characterization of stiff cell surfaces, such as bacteria [1]. However, the mechanical contact between the tip and the sample deforms soft membranes, disturbing the native state of eukaryotic cells and prevents long time-lapse imaging. Here, we show a scanning ion conductance microscope (SICM) for high-speed and long-term nanoscale imaging of soft cells [2]. By implementing advances in nanopositioning, nanopore fabrication, microelectronics, and controls engineering we developed a microscopy method that can resolve spatiotemporally diverse 3D processes on the cell membrane at sub-5nm axial resolution. Moreover, we combine 3D surface data from SICM with volumetric super-resolution optical fluctuation imaging (SOFI), to generate correlative high-resolution information of live cell morphology [3]. This true non-contact technique enables a detailed look at long-period membrane events with sub-second resolution and may offer insights into cell-cell interactions for infection, immunology, and cancer research.

Fully Motorized, Tip-Scanning AFM with Photothermal Excitation for Improved Imaging and Cell Measurement Methods Jonathan Adams[1], Christian Bippes[1], Lukas Howald[1], Simon Fricker[1], Patrick Frederix[1], Pieter van Schendel[1], Hans Gunstheimer[1], Laura Gonzalez[1], Gabriel König[1], Gotthold Fläschner[1,2] and Dominik Ziegler[1]; [1]Nanosurf AG, Switzerland; [2]ETH Zürich, Switzerland

Since its invention, atomic force microscopy (AFM) has become a widely used technique in many different research disciplines from physics, through materials science to life sciences. Instruments and measurement methods alike have been developed that allow for imaging surface structures and probing the mechanical and electrical properties of samples at high spatial resolution. Along with new methods, a major aim in recent AFM development is towards improved ease of use, reliability, and integration with complimentary techniques. Our newly developed DriveAFM addresses these topics by including several technological features that improve the ease of use and extend the capabilities of the instrument. It features a fully-motorized, tip-scanning design that allows for integration with optical microscopy, flexibility regarding sample size and weight, and the possibility for automated system operation from laser adjustment to sample translation. Most importantly, we implemented photothermal cantilever excitation in this tip-scanning AFM and used this feature in several new imaging and measurement methods.

Photothermal excitation directly excites the cantilever by locally heating it at its base, and thus allows stable and clean excitation in almost any environment [1]. Here, we will show the technical difficulties and concepts implemented to include photothermal excitation in a fully motorized tip scanning AFM employing a new optomechanical design [2] as well as measurement data enabled by this implementation. The clean and unambiguous photothermal excitation of the cantilever and its textbook-like response, especially liquids, allows new kinds of measurements, e.g. time-resolved measurement of mass changes [3] or probing the nanomechanical properties of cells over a wide range of frequencies [4]. The ability to effectively drive small, fast cantilevers with photothermal excitation also below their resonance frequency allows off-resonance imaging modes being operated at higher actuation frequencies compared to typically used piezo-based actuation schemes [5].

Massively Parallel, Cantilever-free Atomic Force Microscopy Wenhan Cao[1], Nourin Alsharif[1], Zhongjie Huang[2], Alice White[1], YuHuang Wang[2] and Keith A. Brown[1]; [1]Boston University, United States; [2]University of Maryland, United States

Resolution and field-of-view present a challenging tradeoff in microscopy. Atomic force microscopy (AFM), in which a cantilevered probe deflects under the influence of local forces as it scans across a substrate, is a key example of this tradeoff with high resolution imaging being largely limited to small areas. Here, we show that nanoscale motion of cantilever-free probes can be imaged using conventional optical microscopy to enable massively parallel AFM. Specifically, we realize optically reflective rigid probes on a compliant film that comprises a distributed optical lever that reports local deformation.

By observing the optical contrast on each probe in an array as it is raster scanned across a sample, we demonstrate parallel imaging of surface topography with 1,088 probes with 100 nm lateral resolution and sub 10-nm vertical precision across 0.5 mm. The scalability of this approach makes it well suited for imaging applications that require high resolution over large areas such as integrated circuit quality control, optical metasurface inspection, and multi-scale characterization of biological tissue.

11:30 AM CH03.04.05
A Novel Scheme to Interpret Linear and Non-Linear Interactions in Dynamic Atomic Force Microscopy Jaime Colchero[1], Pablo Contreras Vélez[1], Jesus Sanchez Lacasa[2,1] and Juan Francisco Gonzalez Martinez[3,1]; [1]University de Murcia, Spain; [2]Weizmann Institute of Science, Israel; [3]University of Malmo, Sweden

In practical applications Dynamic Atomic Force Microscopy (DAFM) a (highly) non-linear oscillator, since the oscillation amplitude is (much) larger than the typical length scale of tip-sample interactions. However, it is mostly modelled as a (multifrequency) harmonic oscillator. This very simple approximation works surprisingly well, also for cases where the DAFM system is clearly operated in a large oscillation regime, and therefore non-linearity should be important. In this work, we will discuss why this apparent contradiction is in fact possible. For this, a new scheme to interpret and unify linear and nonlinear interactions is proposed. Using the classical model for the driven damped harmonic oscillator, its response is described by means of a complex number. We explicitly calculate how the time dependence of the deflection is processed by a typical Lock-In setup to obtain a point in the complex plane representing the oscillation state.

Using the Virial Theorem and work of San Paulo et al. [1] as starting point, we show how a linear DSFM system can be easily interpreted in terms of “Circles”. Essentially, as the drive frequency is tuned through the resonance frequency the outputs of a typical DSFM electronics describe to a very good approximation a “Circle” when visualized in xy-mode on an oscilloscope. Interestingly, our model shows that this “Circle” remains essentially invariant when including the non-linearity of typical tip-sample interactions. These “Circles” are distorted only by dissipation which varies with tip-sample distance. We therefore propose that this representation scheme allows a very sensitive method to separate the effect of conservative interactions (linear as well as non-linear) from the effect of dissipative interactions.

The Impact of Nanostructure on Viscoelastic Properties of Polymer Composites Bede Pittenger, Sergey Osechinskiy, John Thornton, Sophie Loire and Thomas Mueller; Bruker, United States

The mechanical behavior of polymer composites is controlled by the properties of the components as well as the microstructure of the material. Because confinement effects and interphase formation can alter properties of the microphases, only measurements performed directly on the composite can provide a complete picture of this local property distribution.
In contrast, the bulk viscoelastic properties of these materials targeted during material development are usually measured using dynamic mechanical analysis, DMA (also known as dynamic mechanical spectroscopy, DMS). This measurement involves application of an oscillating stress or strain to a macroscopic sample, with the response of the sample measured as a function of oscillation frequency). When heterogeneous samples are measured using this macroscopic technique, no information about the properties of the microstructure is available – only the spatially averaged properties of the whole sample.
Atomic Force Microscopy (AFM) has the resolution and mechanical sensitivity to provide the needed local mechanical property information. However, previous AFM measurements of viscoelastic properties [1,2] have suffered from several drawbacks, making it impossible to compare directly with DMA. To address this issue, we have developed a mode combining the benefits of AFM and DMA [3]. Like bulk DMA, AFM-nDMA provides spectra of storage and loss modulus at low frequencies. Unlike bulk DMA, it can localize the measurements and generate maps with resolution of a few nanometers.
In this presentation we will demonstrate how AFM-nDMA spectra can be compared directly to bulk DMA spectra. We will review insights gained when time-temperature superposition [4] is applied to AFM-nDMA data to generate master curves, including for materials that only exist in microscopic domains within the sample. Finally, we will discuss how comparing this nanoscale viscoelastic data with that of the bulk can clarify structure-property relationships in polymer composites.

2:00 PM *CH03.05.02
Physical Interpretations of Multimodal AFM Contrast on Soft Materials Greg D. Haugstad[1], Andrew Avery[2], Brad Hauser[3], Stephen Hubig[4], Rachel Rahn[4] and Melinda Shearer[5]; [1]University of Minnesota, United States; [2]Unilever Research, United Kingdom; [3]Donaldson, United States; [4]Ecolab, United States; [5]PPG Industries, United States

In this work we quantitatively analyze up to eight AFM measurables that can generate materials contrast on soft matter, including (i) sliding friction force in contact mode; (ii, iii) adhesion and contact stiffness in force-distance curve mapping (both slow and fast variants, e.g. "force volume" and "peakforce" modes), (iv, v) phase imaging in net attractive- and net repulsive-regime dynamic/AC mode (aka traditional amplitude-modulation "tapping mode"); (vi, vii) contact resonance amplitude and frequency under pulsed-IR excitation (aka resonance-enhanced mode on a Bruker NanoIR3 AFM-IR system); (viii) Fourier-reconstructed conservative and dissipative force versus distance relationships analyzed and mapped using machine learning in intermodulation mode (i.e., IntermodulationProducts AB Multi Lockin Analyzer / software system).

We apply select combinations of these methods to polymer blends, nanostructured single-layer and multi-layer coatings, two-surfactant and surfactant/nanoparticle ultrathin films, and polymer/small-molecule (e.g., drug) mixtures, all being systems of interest to our industrial as well as academic collaborators. We seek improved understandings of (i) complementary information obtained (mechanical, tribological, surface energy, chemical) as well as (ii) methodological limitations and optimizations.

2:30 PM CH03.05.03
Multidimensional Tomography of Soft Materials by Atomic Force Microscopy and Dynamic Mechanical Spectroscopy Renato C. Aguilera[1], Maxim Dokukin[1,2], Nadia Makarova[1] and Igor Sokolov[1,1,1]; [1]Tufts University, United States; [2]NanoScience solutions, Inc., United States

Material fate and degradation *in situ* is regulated not only by chemical interactions but also the stress and strain from coupled mechanical systems. Strain defects and breakage of nanoscale soft materials such as tissue scaffolds, biopolymers, and cells are elusive to characterize due to their subtle and slow viscoelastic response. Here, we present the application of our new technique, FT-NanoDMA, to create a multidimensional tomography of the dynamical mechanical properties of such soft materials. FT-NanoDMA stands for Fourier transformed nano dynamical mechanical analysis, which is implemented in conjunction with atomic force microscopy (AFM). It allows for simultaneous recordings at different frequencies of multiple dynamical mechanical properties of soft materials, such as the storage and loss moduli, loss tangent, etc. The FT-nanoDMA is a modality that allows for mechanical analysis of nanointerfaces and single cells with a nanoscale spatial resolution (up to 10-70 nm when recorded on fixed cells) and spans the entire biological spectroscopic range (up to 300 Hz). The images of the distribution of these parameters can be recorded at each particular depth, thereby creating a stack of images suitable to create a multidimensional tomography of single cells. We demonstrate examples, which show that the tomographic images show unique features not present in the complementary fluorescent/optical images of cells.

3:45 PM CH03.05.05
AFM Based Nanomechanical Experiments to Capture Interphasial Property Gradients in Poly(methyl methacrylate)–Polyrotaxane Blends Suzanne Peterson, Glendimar Molero, Zewen Zhu, Hung Jue Sue and Pavan Kolluru; Texas A&M University, United States

Poly (methyl methacrylate) (PMMA) is often used as a lightweight, shatter resistant alternative to glass, but exhibits low scratch resistance and poor ductility. It was recently shown that blending PMMA with a very low concentrations (1 wt%) of two different polyrotaxanes (PR) - unmodified PR (uPR) and modified PR (mPR) improves these properties. uPR was created by grating cyclodextrin (CD) rings onto a polycaprolactone (PCL) backbone, while the mPR had methacrylate functional groups at the end of the PCL to facilitate miscibility with PMMA. Although bulk scale dynamic mechanical analysis (DMA) and dielectric spectroscopy on these PMMA-PR blends have indicated that significant PMMA-PR interactions in these systems lead to different molecular mobility changes, which eventually contribute to the observed mechanical property changes at the bulk scale, a direct understanding of the local interfacial interactions is missing. This presentation will discuss the use of Atomic Force Microscope (AFM) based nanomechanical spectroscopic methods to directly map the local time-dependent mechanical property gradients at the interphase regions in PMMA-uPR and PMMA-mPR blends, which in turn will provide direct insights into how PMMA-PR interactions affect their mechanical behavior.

3:00 PM BREAK

4:00 PM CH03.05.06
Direct Evidence for the Polymeric Nature of Polydopamine Katerina Malollari, Peyman Delparastan and Phillip Messersmith; University of California, Berkeley, United States

Inspired by the adhesive proteins of mussels, polydopamine (PDA) has emerged as one of the most widely employed materials for surface functionalization. Despite numerous attempts at characterization, little consensus has emerged regarding whether PDA is a covalent polymer or a noncovalent aggregate of low molecular weight species. Here, we employed single-molecule force spectroscopy (SMFS) to characterize PDA films. Retraction of a PDA-coated cantilever from an oxide surface shows the characteristic features of a polymer with contour lengths of up to 200 nm. PDA polymers are generally weakly bound to the surface through much of their contour length, with occasional “sticky” points. Our findings represent the first direct evidence for the polymeric nature of PDA and provide a foundation upon which to better understand and tailor its physicochemical properties.

SESSION CH03.06: Cells and Biological Samples I
Session Chairs: Keith Brown and Igor Sokolov
Thursday Morning, December 2, 2021
Hynes, Level 3, Room 301

10:30 AM CH03.06.01
How to Combine AFM with Machine Learning Analysis Igor Sokolov and Siona Prasad; Tufts University, United States

Recent large interest in machine learning (ML) analysis has been extended to atomic force microscopy (AFM). In this talk, I will address three questions which typically arise when AFMers start applying ML to classify the AFM images:
1. What mode is the best to use?
2. How many images is sufficient to run machine learning classifiers and believe the results?
3. How do I know that the obtained classification is not an artifact of some fine-tuning?
I this talk, I will suggest answers to the questions. In short, the mode of operation should be robust, repeatable. This is the key. The number of images required for classification can be roughly estimated using “the rule of 10”. A more precise algorithm to identify the required number of images will be described. To be confident that one doesn’t deal with an artifact of fine-tuning or overtraining a classifier, we suggest a rather simple yet powerful method of estimating the exact amount of overtraining by using randomization of the initial classification. Examples will be given.

10:45 AM CH03.06.02
Carbon Nanotube Penetration of Cell Membranes Fabio Priante[1], Ygor Jaques[1], Takeshi Fukuma[2] and Adam Foster[1,2]; [1]Aalto University, Finland; [2]Nano Life Science Institute (WPI-NanoLSI), Kanazawa University, Japan

The possibility of non-destructively measuring living cells and their internal structures with nanoscale resolution would allow for a much greater understanding of numerous biological phenomena. To realize this goal, the use of carbon nanotube (CNT)-terminated tips in atomic force microscopy

(AFM) has been shown to hold promise [1].
However, even in the very first step of the proposed “nanoendoscopic” process, consisting in the penetration of the plasma membrane, it is not always easy to give a precise interpretation of the experimental signal, which is a convolution of cell dynamics, tip shape and buffer solution.
Here, we use coarse-grained (CG) molecular dynamics simulations to investigate the effect that different widths, thicknesses and functionalization of the CNT tip can have in the penetration process. To simulate the membrane and the solvent dynamics we use the Martini 2 Force Field [2], while the CNT is simulated with a Martini-compatible force-field [3] which is more accurate in reproducing multi-layer graphene mechanical properties.
We carry out the membrane penetration by steering the CNTs downwards with constant velocity, then extracting the system's free energy using umbrella sampling, finally obtaining simulated force profiles. Additionally, we probe the possible role of the membrane skeleton mesh size [4] by emulating its effect as a position restraint on the lipids at the membrane’s edge. We directly compare our results to experimental measurements using an equivalent setup and outline the successes and limitations of the model.

11:00 AM CH03.06.03
Mechanobiology of Cancer Metastasis to Bone Using Direct Nanoindentation Dinesh R. Katti, Kalpana Katti, Sumanta Kar, MD Shahjahan Molla and Sharad V. Jaswandkar; North Dakota State University, United States

According to the World Cancer Research Fund, Breast cancer and Prostate cancer are among the most prevalent cancers in women and men, respectively. World Health Organization estimates that about 3.4 million breast and prostate cancer cases are reported each year, and about a million deaths occur worldwide due to these cancers. These cancers are almost entirely curable if detected in the early stage at the primary sites. However, most deaths occur due to metastasis when the cancer cells from the primary site migrate to a distant organ. Bone appears to be a niche for both cancers. We have developed a novel testbed using a bone mimetic nanoclay based scaffold to regenerate human bone using human mesenchymal stem cells followed by seeding prostate and breast cancer cells to generate tumors. Extensive analysis of the tumors using gene and protein expression assays and imaging confirm that the testbeds can replicate tumors during mesenchymal to epithelial transition (MET) for both cancers. Mechanical properties of cells have been used to describe the disease state for a variety of diseases. The confocal imaging of the cells from tumors shows significant changes to the cytoskeleton in terms of the quantity and organization within the cells as cancer progresses at the bone metastasis site. In the present work, for the first time, we have used mechanical response from cells from direct nanoindentation experiments on cancer cells from tumors generated on the testbeds to describe the evolution of cell properties during cancer progression at the bone metastasis sites. The nanoindentation experiments are conducted in static and dynamic modes to evaluate elastic moduli, hardness, and viscoelastic properties of cancer tumor cells. We report the evaluation of mechanical properties of cells from tumors grown on the testbed, over time, with two breast cancer cell lines (MCF-7 and MDA-MB231) at the bone metastases site using static and dynamic nanoindentation modes. A new fixture was designed and fabricated to conduct live-cell nanoindentation experiments. The force-displacement response, elastic moduli, hardness, plastic deformation, viscoelastic properties, and other mechanics characteristics were captured, along with confocal imaging of the cytoskeleton and gene and protein expressions at the same time points. Our results indicated a significant reduction in elastic modulus and increased fluid-like behavior of bone metastasized MCF-7 cells caused by depolymerization and reorganization of F-actin. On the other hand, bone metastasized MDA-MB-231 cells showed insignificant changes in elastic modulus and F-actin reorganization over time. We also measured changes to nanomechanical properties of MDA PCa2b prostate cancer cells during the MET and cancer bone metastasis progression over time. The stiffness of PCa cells decreases with metastasis; however, the mechanical plasticity increases during the same time, suggesting that PCa cells become softer on undergoing MET and softer with metastasis progression. In all cases, the imaging and gene, protein expression studies, and computational modeling point towards the depolymerization of actin and reorganization of the cytoskeleton as key factors in the evolution of cell mechanics. These studies present the use of direct nanoindentation as a potential new biomarker for metastasis progression.

Effect of Rapid-Solidification Induced Cellular Structures on the Corrosion Behavior of an Additively Manufactured 316L Stainless Steel Investigated by High-Speed AFM Yuliang Zhang, Thomas Voisin, Zhen Qi, Rongpei Shi, Tuan Anh Pham, Nathan Keilbart, Yu-Ting Hsu, Xiao Chen, Roger Qiu and Brandon Wood; Lawrence Livermore National Laboratory, United States

Additively manufactured 316L stainless steels (AM 316L SS) using laser powder bed fusion exhibit outstanding mechanical properties such as high strength and high ductility. The rapid-solidification induced sub-grain cellular structures, a dominant microstructural feature present in the as-built material, are largely responsible. However, in term of corrosion properties, the effect of these cellular structures has yet to be confirmed. A difference in metal dissolution rate between cell walls and cell interior has been reported but the underlaying mechanisms remain unclear. To certify the use of AM 316L SS in corrosive environment, it is necessary to observe, understand, and predict the local effect of the microstructure on the resistance to corrosion, notably the initiation mechanisms. Here, we combine in-situ high-speed AFM (HS-AFM) during corrosion in HCl and NaCl solution, TEM, and SEM/EBSD to try and capture the native oxide breakdown, re-passivation, pit nucleation, and metal dissolution. We quantitively measure and map, in-situ, the metal dissolution rates in the cellular structure for different grain orientations and compare to the conventional, well annealed material.

11:30 AM CH03.06.05
Robustness of AFM-based Method to Identify Mechanical Properties of the Cell Body and Pericellular Coat Nadia Makarova and Igor Sokolov; Tufts University, United States

The atomic force microscopy (AFM) combined with the force volume mode allows measurement of both indentation force curves and sample topography and is used to study cell mechanics. As was demonstrated in multiple publications, the Hertz mechanical model is not sufficient to describe cell mechanical properties in a self-consistent way. Self-consistency can be attained when using a relatively dull AFM probe and processing the data through the brush model. The brush model allows determination of both the mechanical properties of the cell body and the physical properties of the pericellular (glycocalyx) layer. Separation of the mechanical response of the pericellular layer from deformation of the cell body has demonstrated its utility in multiple studies, such as mechanics of cancerous and aging cells, and endothelial cells associated with various cardiovascular diseases. Despite its utility, the brush model has not yet been tested for its robustness with respect to the uncertainties within the model and experimental data. In other words, there is a need to demonstrate how unambiguous and precise the parameters extracted with the brush model are, when considering the uncertainty within the model and possible ambiguities of the collected force curves.
Here we address this need. We present the calculation of the elastic modulus of the cell and characteristics of the pericellular layer for a diverse set of cells:

fibroblasts of zebrafish, mouse neuroblastoma cells, and human cervical epithelial cells. We perform the analysis and demonstrate that the brush model is robust. Errors in defining the modulus, which come from both model and experimental uncertainties, are within 3%, which is substantially smaller than a typical uncertainty in the spring constant of the AFM cantilever. To quantify the uncertainties in the extracted force due to the brush layer, we characterize the brush with Alexander de Gennes model, which is described by the equilibrium size of the brush layer and grafting density of the brush molecules. Although it is an obviously oversimplified approximation, we see the uncertainty in those parameters is not larger than 25%. It is worth noting that the brush parameters calculated in this way is completely independent of the calculation of the modulus.

Measuring Mechanical Properties Of Developing Embryo with AFM Takaharu Okajima; Hokkaido University, Japan

It is widely recognized that embryogenesis is strongly associated with cell mechanical properties [1]. However, little is known about how embryonic single cells change their mechanical properties during their developing process due to a lack of technique. I will present our recent studies regarding the stiffness of cells in developing ascidian embryos with AFM [2] and the rheological measurements. The results showed that the force-distance curves measured in upper regions of embryonic cell surfaces were well fitted to the conventional Hertzian contact model, and the apparent Young's modulus was calibrated using a modified Hertzian contact model [3] considering the tilt angle of the sample surface. The cell shapes in the height and the Young's modulus images were almost identical, and the cell locations were in good agreement with the 3D virtual embryo model determined from confocal microscopic images, indicating that the embryonic cell stiffness measured by AFM mainly reflected the mechanical properties of cells that directly contacted the AFM probe. Furthermore, the cell stiffness exhibited a remarkable increase at the onset of cell division and then decreased after cell division, which is reminiscent of changes in an *in vitro* dividing single cell forming cortical actin filaments [4]. The results indicate that AFM is useful for measuring the embryonic cell stiffness in the developing process and can facilitate a better understanding of how embryonic single cells in animals are spatiotemporally regulated via mechanical cues.

Viscoelasticity of Single Polymer Chains Investigated by Single-Molecule Force Spectroscopy Xiaobin Liang[1] and Ken Nakajima[1,2]; [1]Tokyo Institute of Technology, Japan; [2]The University of Tokyo, Japan

In single-molecule force spectroscopy (SMFS), many studies have focused on the elasticity and conformation of polymer chains, but little attention has been devoted to the dynamic properties of single polymer chains. In this study, we measured the energy dissipation and elastic properties of single polystyrene (PS) and poly(N-isopropylacrylamide) (PNIPAM) chains in different solvents using a homemade piezo-control and data acquisition system, which provided more accurate information regarding the dynamic properties of the polymer chains. We quantitatively measured the chain length-dependent changes in the stiffness and viscosity of a single chain using a phenomenological model consistent with the theory of viscoelasticity for polymer chains in dilute solution. The effective viscosity of a polymer chain can be determined using the Kirkwood model, which is independent of the intrinsic viscosity of the solvent and dependent on the interaction between the polymer and solvent.

1:45 PM CH03.07.03
EUV Photoresist Dissolution Using Microperfusion Stage for High-Speed AFM Jiajun Chen[1], Luke Long[2], Andrew Neureuther[2], Patrick Naulleau[1] and Paul Ashby[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

The push towards high-resolution lithography in the semiconductor industry has yielded the introduction of extreme ultraviolet (EUV) into high-volume manufacturing. However, looking forward to future technology nodes, further improvements are required in photoresist materials to keep pace with and fully utilize improvements in the EUV source and scanner. One of the critical steps is to understand the role of the dissolution process, which converts latent exposure chemistry in the photoresist into a developed pattern. This process is particularly challenging to follow due to the requirement of nanometer spatial and sub-second temporal resolution simultaneously. Most metrology of the patterning process thus ignores either the temporal component of the dissolution process by measuring just the final developed structure or the spatial component as is done in most dissolution rate monitoring techniques. In our study, a microfluidic sample stage is designed to enable the delivery of full-strength developer within fractions of a second with better concentration control and smaller dead volume for less lag and more accurate time zero determination. Moreover, our microfluidic design minimizes the mixing problem of the full-strength developer and water, which usually disrupts laser-based detection mechanism, allowing us to monitor the development process with high-speed atomic force microscopy (AFM) at the nanoscale. Thus, our system offers the ability to probe the spatially-dependent nature of the dissolution process in a fab-like environment, providing insight into exposure-dependent dissolution rate gradient, material swelling, and polymer entanglement.

2:00 PM CH03.07.04
High Contrast Atomic Force Microscopy for Additive Filled Through-Thickness Vertical Block Copolymer Morphologies for High Permeability Oil-Water Separation Membranes Kshitij Sharma[1], Khadar B. Shaik[1], Ali Ammar[1], Mohammad K. Hassan[2], Samer Adham[3], Mariam Al Ali Al-Maadeed[2] and Alamgir Karim[1]; [1]University of Houston, United States; [2]Qatar University, Qatar; [3]Qatar Science and Technology Park, Qatar

Block copolymers with mechanically identical blocks having identical glass transitions such as Polystyrene-b-Poly(methyl methacrylate) (PS-b-PMMA) show poor contrast between domains, especially in vertically ordered microstructure. Addition of plasticizers that segregate into selective domains and significantly reduce the glass transition temperature of that block also increase its contrast for detection through atomic force microscopy. These additives also enhance the chemical incompatibility between blocks producing sharp interfaces that can be easily detected for the additive swollen domains. In this study, we demonstrate producing vertical domain assembly in as-cast block copolymer (BCP) thin films by controlling the casting environment using solvent mixtures and plasticizing additives. The combined interaction between the plasticizer segregated into selective domains and the solvent mixture drives the ordering front to produce through film vertical assembly in PS-b-PMMA films with cylindrical and lamellar volume fractions. The morphology

is probed with atomic force microscopy to analyze the effect of additive volume fraction on domain sizes and film morphologies. Ultrafiltration membranes are an energy-efficient alternative to overcome the environmental challenges occurring from the rising amounts of mixed oil and water through oil-spills and industrial wastewater etc. Ultrafiltration membranes were fabricated from these vertically oriented structures and are promising candidates for oil-water separation applications. In addition to the uniform pore size of the membranes, the membranes have been designed to function as highly permeable as well as selective active layers on top of the polyethersulfone (PES) support membranes. This has been accomplished during the membrane preparation stage by the addition of varying amounts of plasticizing and homopolymer additives to further modify the membranes. The influence of these additives on the pore characteristics and membrane performance have accordingly been analyzed as a function of their mass ratio with respect to BCP. The created asymmetric membranes were demonstrated to be effective for oil/water separation when plasticizing additives were added in the 50%-60% mass ratio.

2:15 PM CH03.07.05
Amplitude Nanofriction Spectroscopy Antoine Lainé[1], Andrea Vanossi[2], Antoine Nigues[3], Erio Tosatti[2] and Alessandro Siria[3]; [1]Lawrence Berkeley National Laboratory, United States; [2]SISSA, Italy; [3]ENS - PSL, France

Macroscopic friction behaviors originate from the mechanical and tribological response of asperities at the microscopic and nanometric level. As a consequence atomic scale friction stands as a cornerstone for the field of tribology. At such small scale, materials exhibit mechanical properties reminiscent of soft materials, such as adhesion and high deformability, thus making similar experimental challenges arise. From a sliding friction perspective, the dynamics undergo different successive steps from elastic pinning to large velocity kinetic friction. Atomic force microscopy usually only probes the steady state response leaving the early sliding response unexplored. Here, we unveil a combined experimental and simulation framework based on a high-frequency oscillatory strained interface to resolve the onset of sliding aa well as the large velocity steady-state at once. A model contact of a few atoms formed between a gold tip and graphite is used to demonstrate our experimental ability to explore the different sliding regimes. We uncover peculiar behaviors, from thermolubricity for the smaller contact, to superlubricity as the contact gets larger than the unit cell of graphite. This new experimental methodology paves the way for a better understanding of sliding friction and its different dynamic stages.

2:30 PM CH03.07.06
Developing a Framework for the Forward Prediction of the Mechanical Properties of Polymer Nanocomposites Heer Majithia, Boran Ma and L. Catherine Brinson; Duke University, United States

To enable the forward prediction of mechanical properties of polymer nanocomposites, we have developed a novel framework that uses experimental methods and finite element analysis and we demonstrate it for a nanocomposite made of a polydimethylsiloxane (PDMS) matrix and silica particles (SiO_2). We have experimentally determined the microstructure distribution and the local mechanical properties of the extent of the interphase between the silica particles and the PDMS matrix via atomic force microscopy (AFM), and the macroscale properties of the PDMS matrix via dynamic mechanical analysis (DMA). We hypothesize that by accurately determining the local properties in the interphase we can predict the behavior of the macroscale nanocomposite as the interphase between the polymer matrix and filler has altered properties that are thought to be responsible for the enhanced properties observed in thin films and polymer nanocomposites. A key challenge in accurately determining the extent of the interphase around a nanoparticle via AFM occurs as a result of the complex contact conditions between the AFM tip and the polymer near an interphase. To address this we have developed a method similar to one used in nanoindentation experiments to eliminate the indentation depth dependence of the local property measurements and calculating depth independent properties that are not convoluted by extraneous influences. Consequently, we have performed finite element analysis (FEA) simulations to predict the macroscale properties of PDMS-SiO_2 nanocomposites and validated them against experimental data for PDMS-SiO_2 nanocomposites. This framework provides a method to achieve the forward prediction of mechanical properties of polymer nanocomposites with limited experimental work, optimizing the process to discover and develop materials with desired properties.

Quantifying Nanoscale Electromechanical Properties of Polymeric and Soft Materials via Advanced Modes of Piezoresponse Force Microscopy Liam Collins; Oak Ridge National Laboratory, United States

Electromechanical coupling underlies a broad range of diverse applications from energy harvesting to biotechnology. Voltage modulated (VM) AFM techniques including piezoresponse force microscopy (PFM) are uniquely positioned to probe electromechanical properties with spatial resolution from micrometers to nanometers. As with all AFM techniques, the goal of any PFM measurement should be towards quantification of the local material properties. Unfortunately, quantification of PFM signals remains a significant challenge. Indeed, with the growing popularity of PFM there has been a congruent rise in reports of nanoscale electromechanical functionality, including ferroelectric hysteresis, in materials that should be incapable of exhibiting piezo- or ferroelectric response. This presentation will evaluate the appropriateness of advanced modes of PFM, including interferometric and multifrequency methods, for quantification of soft and hybrid materials. A particular focus will be overcoming the susceptibility of PFM measurements to crosstalk, a pre-requisite for quantification of piezoelectric coupling coefficients. Throughout the presentation examples of quantitative measurements on soft and polymeric materials including PVDF-TrFE and hybrid organic inorganic perovskites will be described. *This work was conducted at the Center for Nanophase Materials Sciences, which is a DOE Office of Science User Facility.*

8:30 AM *CH03.08.02
Multimodal Chemical and Surface Potential Nano-Imaging Through Peak Force Infrared–Kelvin Probe Force Microscopy Xiaoji Xu; Lehigh University, United States

Multimodal measurements of chemical composition, electrical properties, mechanical properties, and topography by scanning probe microscopy (SPM) deliver correlations across properties at the nanoscale and provide clues to the structure-function relationship of materials. In the past, measurements with these modalities are operated separately with different operational modes of SPM. Not only do the sequential measurements require additional operation time, subject to scanner/sample drift, but also, different modalities of SPM have different spatial resolutions, which undermine correlative analysis. For

example, the popular frequency-modulated Kelvin Probe Force Microscopy measures the surface potential with 30~50 nm spatial resolution under the ambient conditions, whereas the SPM measurements of chemical composition, mechanical properties, and topography can routinely achieve < 10 nm spatial resolution.

At the MRS conference, we will present our invention of an integrated SPM mode that can simultaneously provide chemical, surface potential, mechanical, and topographic imaging at < 10 nm spatial resolution under ambient conditions. First, we will present our development of pulsed force Kelvin probe force microscopy (PF-KPFM) that delivers 10 nm spatial resolution from surface potential measurement under ambient conditions. Second, we will briefly describe the peak force infrared (PFIR) microscopy on infrared nano-imaging and spectroscopy. Finally, we will introduce our invention of peak force infrared-Kelvin probe force microscopy (PFIR-KPFM) that combines PFIR and PF-KPFM in one unified SPM mode. In a single scan, the integrated PFIR-KPFM delivers simultaneous multimodal measurement at a comparable and high spatial resolution of < 10 nm. We demonstrated the PFIR-KPFM on a range of samples, from perovskite photovoltaics to protein aggregates, and revealed correlations among modalities.

9:00 AM CH03.08.03
Scanning Probe Microscopy—Are There Even Best Practices? Richard J. Sheridan[1], David W. Collinson[2], Marc Palmeri[1] and L. Catherine Brinson[1]; [1]Duke University, United States; [2]Stanford University, United States

Scanning probe microscopy encompasses techniques that span length scales, time scales, and operational complexity scales. Because of the existence and value of these complex measurements, it is typical for an eager, new user to require extended training together with an expert to reliably acquire the advanced, precise data they hope to collect.

In our new review in Progress in Polymer Science [1], we attempt to address the nuances of extended training by providing a resource in the form of a collection of recommendations and best practices in the nanomechanical characterization of polymers and other soft/heterogeneous materials. The review discusses and compares the variety of nanomechanical techniques available, provides details and practical considerations for real nanonomechanical experiments, and summarizes notable published works as case studies for the application of available modes for nanoscale property mapping. This presentation selects a very small subset of the content to demonstrate the utility of the review as a guide, but also to draw attention to some unanswered questions that were raised as this domain continues to mature.

Our review is concentrated on nanomechanical AFM of polymers, both because that system is one of our group's competencies, and also because it prevented the scope of the review from growing without limit. But already the narrow scope raises questions: Are these recommendations applicable to other materials, like hydrogels or metals? Can they be applied to other scanning probe microscopy techniques, like scanning tunneling microscopy or single molecule force spectroscopy? To what extent? In this presentation, we seek to lay a foundation for a greater discussion and collaboration between groups and sub-fields regarding best practices, training, and converting individual or even institutional knowledge into common knowledge.

Automated Scanning Probe Microscopy Based on Deep Kernel Learning Yongtao Liu[1], Stephen Jesse[1], Susan E. Trolier-McKinstry[2,2], Maxim A. Ziatdinov[1,1] and Sergei V. Kalinin[1]; [1]Oak Ridge National Laboratory, United States; [2]The Pennsylvania State University, United States

Ferroelectric materials remain a source of physical discovery through the long history of the field. On-going development has pointed to the crucial role of domains and domain walls in ferroelectric materials. The development of scanning probe microscopy (SPM) allows visualization of domain structure and its evolution under external fields, such as electric bias applied through tip and electrodes, strain, light illumination, and heating. However, the behaviors of interest mostly are related to domain structures and concentrated in specific locations. This initializes the opportunities of automated microscopy with an automatically defined workflow for scanning sequence and data acquisition. Here, we used a Deep Kernel Learning (DKL) framework to explore the domain structure and physical properties of ferroelectric materials. We further developed a workflow based on the DKL for Piezoresponse Force Microscopy (PFM) that allows problem-specific tuning of workflow and operation in real-time, which allows exploring polarization switching and domain structure in ferroelectric materials. The structure of the DKL kernel provides insight into the physics of the process. We further build the relationship between domain wall geometry and presence of ferroelastic domain walls, as well as topography, and hysteresis loop shape. Previously in the post-experiment approach, this was accomplished via im2spec and rotational variational autoencoder (rVAE) approaches. The DKL allows to learn these relationships during the experiment. This workflow can also be adapted to other microscopy systems, such as electron microscopy and optical microscopy.

Acknowledgments: This work is supported by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences Energy Frontier Research Centers program under Award Number DE-SC0021118. 9:30 AM CH03.08.05
Conductive Hotspots in Hf0.5Zr0.5O2—An Automated Experiment Investigation Yongtao Liu[1], Shelby S. Fields[2], Kyle P. Kelley[1], Stephen Jesse[1], Susan E. Trolier-McKinstry[3,3], Maxim A. Ziatdinov[1,1], Jon Ihlefeld[2,2] and Sergei V. Kalinin[1]; [1]Oak Ridge National Laboratory, United States; [2]University of Virginia, United States; [3]The Pennsylvania State University, United States

HfO_2-based materials have attracted a great deal of interest because they exhibit robust ferroelectricity at extremely thin thickness and are thermodynamically compatible with conventional semiconductors, leading to a wide range of applications in ferroelectric-based devices, such as field-effect transistors, random-access memory, and tunnel junctions. However, the local uniformity of HfO_2-based materials is rarely investigated, which is important for their application. In this work, we developed an automated experiment (AE) workflow in scanning probe microscopy (SPM) to investigate the local conductivity of a Hf0.5Zr0.5O2 (HZO) thin film. This AE workflow maps a large field of view of material first and automatically locates the regions of interest (ROI); then, detailed zoom-in measurements are automatically performed in the ROIs to systematically understand the material under study. Further, to solve a universal problem—measurement drift—in microscopes, we embedded a drift correction algorithm to maintain the in-situ measurement. This drift correction method is based on a recently developed shift-invariant variational autoencoder (shift-VAE). Finally, we investigated the heterogeneous conductivity of the HZO thin films by this AE workflow, revealing the evolution of conductive hotspots around several tens of nanometers in HZO with bias voltage and time. The hotspots show complex spatiotemporal dynamics as a function of time and bias during the scanning, suggesting the presence of complex conduction mechanisms. These results underpin a wide range of HZO-based applications. We believe that the AE approach developed in this work will be universally useful for microscopy measurements.
Acknowledgments: This work is supported by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences Energy Frontier Research Centers program under Award Number DE-SC0021118. This work is conducted at the Center for Nanophase Materials Sciences, a US

1:00 PM *CH03.09.01
Infrared Nanospectroscopy at the Single Molecule Scale for Bio- and Materials Science Francesco Simone Ruggeri; Wageningen University, Netherlands

Biological processes at the base of life rely on a wide class of biomolecular machines that have characteristic nanoscale physical dimensions and whose function emerges from a correlation between their chemical and structural properties. Therefore, a fundamental objective of modern analytical methods in Physics and Chemistry is to unravel the heterogeneous chemical and physical properties of single biomolecules and relevant bio-surfaces at the nanoscale. While innovative imaging methods have been developed to characterise biomolecular processes at the nanoscale, imaging microscopies are to the most part chemically blind; thus hampering the characterisation of inhomogeneous and complex systems.
Here, we first demonstrate that Atomic Force Microscopy (AFM) provides detailed information not only on the morphological, but also on the mechanical properties of biomolecular processes and functional materials at the nanoscale [1,2]. Then, to overcome the limitations of conventional imaging microscopies, we show a real breakthrough with the development and application of Infrared Nanospectroscopy (AFM-IR) in bio- and materials science. AFM-IR combines the high spatial resolution of AFM (~1 nm) with the chemical analysis power of infrared (IR) spectroscopy to retrieve unprecedented correlative information at the nanoscale on the structural, mechanical and chemical properties of heterogeneous bio-molecular processes and functional biomaterials.[3] As most recent advances in the field, we demonstrate the achievement of single protein molecule chemical identification and structural determination.[4] Then, we show the application of this single molecule sensitivity to unravel the molecular interaction fingerprint between a small molecule and its target [3], the surface properties of artificial model membranes [6] and the structure of functional protein self-assemblies to be exploited as a novel class of biomaterials in bioscience [7-8].
Overall, the aim of our present and future research is to expand the capabilities of nanoscience for chemistry and biology to open a new window of observation on the fundamental biomolecular processes at the core of life and ageing, to shed light on the structure-activity relationship of biomolecules, and characterises functional surfaces and materials for nano- and bio- science applications.

1:30 PM CH03.09.02
Deciphering the Effect of Matrix Stiffness on Mechanical Properties of Human Umbilical Vein Endothelial Cells Quynh T. Tran, Abir Kazan, Sylvain Gabriele and Philippe E. Leclere; University of Mons, Belgium

In the field of cell mechanics, a change in physicochemical properties of the extracellular matrix (ECM) can cause profound functional modifications, such as differentiation, replication, migration, and apoptosis. Thus the physicochemical properties of culture substrates were modulated in order to mimic in vitro the complexity of physiological environments. In this work, polydimethylsiloxane and hydroxy-polyacrylamide hydrogel (hydroxy-PAAm) were used to study the impact of matrix stiffness on endothelial cell mechanics. Firstly, the viscoelastic properties were estimated in physiological conditions by nano Dynamic Mechanical Analysis, based on single force curves, while the probe is indenting the surface with nano-Newton forces. Our findings show a linear stiffness gradient while the bis-acrylamide/acrylamide ratio increases. In addition, we show that the adhesion from PeakForce Quantitative NanoMechanics (PF QNM) is higher significantly than the value obtained in Force Volume. Then we quantitatively mapped the nanomechanical properties of human umbilical vein endothelial cells (HUVECs) plated on polydimethylsiloxane and hydrogels. We found that the elastic modulus of the cell body is about 12-18 kPa which is higher than the cell lamellipodia (5-10 kPa) with Tan δ approximately 0.5 for cell body.

1:45 PM *CH03.09.03
Understanding Biomechanics of Bladder Cancer Cells Malgorzata Lekka[1], Nadia Makarova[2], Joanna Pabijan[1], Kajangi Gnanachandran[1] and Igor Sokolov[2,2,2]; [1]Institute of Nuclear Physics PAN, Poland; [2]Tufts University, United States

The bladder is a highly variable mechanical microenvironment expanding from a few to hundreds of kPa due to functional reasons. Interestingly, such a large range of functional stiffness seems not to influence the mechanical properties of urothelial cancer cells as they become more deformable already at the early stages of cancer progression as measured by atomic force microscopy (AFM). Several structural components contribute to the mechanical properties of bladder cancer cells. Primarily, they are related to the organization of polymerized actin form (actin filaments) and the overall actin content. Cell mechanics alter dynamically in response to external or internal stimuli, including the organization of cells (single cells, monolayers or more complex structures) and the interplay of cellular deformability with the surrounding microenvironment (i.e., extracellular matrix, ECM). All steps of cancer progression involve specific interactions between cell surface receptors and multiple components of the ECM, including basement membranes (BMs), mainly composed of laminins or type IV collagen. This structural scaffold, making a physical barrier, contributes to such phenomena as cell adhesion, proliferation, and migration. Laminin binding to receptors present on a cell surface initiates cell invasion through BMs. The actin cytoskeleton is linked with the focal adhesion molecules, thus altered expressions of related molecules will affect cell deformability. This leads to glycocalyx as the other component contributing to bladder cancer mechanics at the cellular level. By applying the brush model, the mechanical properties of the cells studied under specific cleavage conditions were correlated with the presence of the particular type of the pericellular glycocalyx layer. Distinct contributions of cell structural elements to cell biomechanics form a question of the leading cause of the alterations in mechanical properties of cells. The working hypothesis can be summarized as follows: mechanical properties of local cellular microenvironment define the invasive and migratory phenotype of cancerous cells

through irreversible changes in composition and structure of both proteoglycan's component of the glycocalyx and expression of the adhesive molecules leading to cytoskeleton reorganization. Cells leaving the primary tumour site carry this information and use it to form a secondary, metastatic site.

2:15 PM *CH03.09.04
Verification of Microscale Modulus Control in Photopolymer 3D Printing Jason Killgore; National Institute of Standards and Technology, United States

Atomic force microscopy (AFM) is uniquely capable of characterizing the 3-dimensional modulus variations that arise in vat photopolymerization additive manufacturing processes such as stereolithography, digital light processing and inkjet. 3D control of part shape and properties is essential to realize additive manufacturing opportunities in critical applications such as organ printing and dentistry. We will discuss how AFM can be used both ex-situ and in-situ to the printing process to inform where heterogeneity and shape deviation arise in printed parts. We will then employ and verify various models to correct and control for such variations, yielding geometrically and mechanically precise parts. Ex site characterization of as-printed parts, both pristine and cryo-ultramicrotomed reveals true process control of properties based on light exposure and feature size. In-situ characterization complements ex-situ by revealing differences between resin, green-state and final part properties. Overall, the interplay between characterization and control enables new freedoms in 3D printed part design, particularly at the smallest length scales.

Customized MFM Probes Based on Magnetic Nanorods Miriam Jaafar[1], Javier Pablo Navarro[2], Eider Berganza[3], Pablo Ares[1], Cesar Magen[4], Julio Gómez- Herrero[1], Jose De Teresa[4] and Agustina Asenjo[5]; [1]Autonomous University of Madrid and Condensed Matter Physics Center, Spain; [2]Helmholtz-Zentrum Dresden Rossendorf, Germany; [3]Karlsruhe Institute of Technology, Germany; [4]Instituto de Nanociencia y Materiales de Aragón (INMA), Universidad de Zaragoza-CSIC, Spain; [5]Instituto de Ciencia de Materiales de Madrid, Spain

Atomic Force Microscopy (AFM) is a powerful technique in biophysics and nanomedicine, since it allows imaging and manipulating nanostructures in physiological conditions on a single molecule level [1]. Magnetic Force Microscopy (MFM) is an AFM-based technique where a nanometric magnetic probe is scanned in close proximity to a surface detecting the local magnetic fields gradients near it. MFM has been applied to the study of a variety of magnetic systems, including magnetic nanoparticles. Despite the importance of studying magnetic nanostructures with biological applications in physiological conditions, the applicability of MFM to these systems was limited up to now because of the difficulty in developing MFM for detecting magnetic interactions in liquids. This is a consequence of the higher damping forces acting on the cantilever when working in liquid environment, as compared to air, which results in a significant loss of sensitivity of the MFM signal. In the work presented here, we start by introducing the necessary development for MFM imaging in liquid media [2] and discussing the influence of the chosen cantilever on the obtained MFM signal-to-noise ratio. Then, we present the development of new magnetic probes fabricated by Focused Electron Beam Induced Deposition (FEBID) using specially designed cantilevers for liquid medium and demonstrating that further improvement on the performance can be gained [3].

8:15 AM CH03.10.03
Three-Dimensional Fast Force Mapping as a Means for Understanding Interfacial Solution Structure and Its Impact on Interparticle Forces Sakshi Yadav[1], Elias Nakouzi[1], Jaehun Chun[1,2] and James DeYoreo[1,3]; [1]Pacific Northwest National Laboratory, United States; [2]The City University of New York, United States; [3]University of Washington, United States

Many of the processes occurring at electrolyte-solid interfaces, such as corrosion, catalysis and heterogeneous nucleation, as well as the interactions and response dynamics of colloidal systems, are mediated by the solution near the interface. However, our knowledge of interfacial solution structure (ISS) has been limited by a dearth of experimental techniques that can visualize ISS at the atomic scale. AFM-based three-dimensional fast force mapping (3D FFM) is a recently developed method that provides this ability. During FFM, changes in phase and amplitude (or frequency) of an oscillating AFM tip due to interactions with its surroundings is recorded as the tip approaches and retreats from the surface. By collecting these 1D force curves over a 2D area, a 3D map of solution structure is created. As part of an effort to understand the interactions and dynamics leading to growth of nanomaterials through the process of oriented attachment (OA), we are using 3D FFM to visualize solution structure at a variety of crystal interfaces. Here we report on studies of the Zn (0001) interface in which we pursue three novel directions. First, we attempt to understand how the ISS depends on the nature of the solvent by examining both water and ethanol. Second, we utilize the polar nature of ZnO to investigate how differences in surface termination — O vs Zn — impact the ISS. Third, we introduce custom-made nanocrystal AFM probes fabricated by depositing ZnO onto commercial silicon probes to understand the structure seen by ZnO particles as they approach one another during OA. Our results to date demonstrate distinct differences between 3D FFM data collected in water and ethanol. In particular, a strong attractive force at a tip-sample separation of ~1nm is measured in water, yet absent in ethanol. Measurements on Zn- and O-terminated surfaces reveal differences in both the surface morphology and the interfacial structure. We successfully used the ZnO tips to execute FFM; the initial data show that the tip chemistry strongly influences the solution structure confined between the two surfaces. In summary, our findings reveal a complex dependence of ISS on surface termination, solvent composition and tip chemistry. By resolving the key limitation of conventional 3D FFM – namely the discrepancy between the tip and sample materials – we provide a more straightforward basis for predicting long-range interactions between ZnO particles, delineating the solution structure, and advancing the quantitative interpretation of 3D FFM data.

Single-Molecule Conductance of Discrete, π-Stacked Pyridinium Dimers Hao Yu, Jialing Li, Songsong Li, Charles Schroeder and Jeff Moore; University of Illinois at Urbana-Champaign, United States

Charge transport in π-stacked aromatic rings is central to biological processes and organic electronics. However, direct experimental investigation of

intermolecular charge transport between aromatics at molecular level is challenging. In this work, we use a supramolecular self-assembly approach to control the stacking geometry of two pyridinium molecules, thereby providing a promising model system to investigate intermolecular charge transport behaviors in discrete pyridinium dimers. The charge transport properties of free and dimerized pyridiniums were characterized using a scanning tunneling microscope-break junction (STM-BJ) technique, thereby enabling direct measurement of single-molecule conductance. Our results show that π-stacked pyridinium dimers exhibit up to 10-fold enhanced molecular conductance compared to single pyridinium. The experimental results were further analyzed with insights from density function theory (DFT) calculations. From a broad perspective, we anticipate that merging supramolecular chemistry and single-molecule conductance experiments will afford new functional molecular electronics.

8:45 AM CH03.10.05
Hydrogen Depassivation Lithography with a MEMS-Based Scanning Tunneling Microscope Afshin Alipour[1], Emma L. Fowler[1], S. O. Reza Moheimani[1], James H. Owen[2], Ehud Fuchs[2] and John Randall[2]; [1]The University of Texas at Dallas, United States; [2]Zyvex Labs, United States

About ten years after invention of Scanning Tunneling Microscope (STM), scientists found that STM can be used to modify sample surfaces at atomic scale. This led to the invention of STM-based lithography in which the STM tip is used as a source of a very fine and low energy electron beam to pattern a monolayer resist adsorbed on the sample surface with ultimate atomic resolution and precision. As a result, STM has been proposed as a viable alternative to conventional e-beam lithography whose resolution and precision is fundamentally limited to a few nanometers.
Despite this superiority in resolution, slow speed and low throughput have been major downsides of the STM which hinder its widespread use. A key contributor to these limitations is its relatively large nanopositioner, i.e. the piezotube. For this drawback, miniaturization stands out as a practical solution for the bulkiness of the STM piezotube. A Microelectromechanical-System (MEMS) STM nanopositioner can offer higher bandwidth and an opportunity for parallel operation of a multi-tip STM due to its small footprint.
In our previous work [1], we presented a MEMS-based STM system. There, we integrated a one-degree-of-freedom MEMS STM nanopositioner into a commercial Ultrahigh-Vacuum (UHV) STM system to replace the Z axis of its piezotube. As a result, a hybrid system is achieved in which the MEMS device provides the Z-axis motion which requires higher sensitivity, while the XY-plane motions are still delivered by the piezotube during the scan. Compared to the Z-axis of the piezotube, the MEMS device features tenfold higher bandwidth (i.e. 10 kHz) with the same range of motion (1-2 µm).
In this work, we further examine the practical benefits of this hybrid system over a conventional piezo-based STM. Thanks to the MEMS nanopositioner, higher scan speeds are achieved during both imaging and lithography compared to the original UHV STM system. Dimer row resolution images of Si(001):H were obtained at scan speeds over 2 µm/s with the hybrid STM in conjunction with the improved control loop [2].
STM-based lithography was also tested with the proposed hybrid system. With the greater sensitivity of the MEMS Z-actuator and the improved control loop, it is expected that lithography can operate at much higher tunnel current setpoints, allowing for much faster lithography. In our experiments, the sample used was a H-terminated Si(100)-2×1 surface. First, the sample surface was imaged, and its lattice was detected based on the image. Then, H atoms were selectively desorbed by moving the tip along a predefined trajectory over the sample surface using an appropriate bias voltage (+4 V) and tunnel currents up to 40 nA, providing write speeds up to 100 nm/s. The results obtained in this work demonstrate that the proposed MEMS-based STM system is conducive to high-speed atomic-scale lithography.

Dynamic Ferroelectric Domain Manipulation via Automated Experimentation in Piezoresponse Force Microscopy Kyle P. Kelley, Stephen Jesse, Rama K. Vasudevan and Sergei V. Kalinin; Oak Ridge National Laboratory, United States

Domain structures and topological defects in ferroelectric materials underpin a broad range of applications ranging from materials with giant electromechanical responses to domain wall electronics. Correspondingly, exploring the functionalities of domain walls and controlled modifications of domain structures is of interest for a broad spectrum of applications. However, the dynamic nature of these objects severely constrains piezoresponse force microscopy approaches to explore their functionality. Here, to overcome this challenge, a real space image-based feedback approach is utilized to control the atomic force microscope tip bias during ferroelectric switching allowing for modification routes triggered by domain states under the tip. Specifically, the complex trigger system (*i.e.*, "FerroBot") is to used study frustrated and metastable domain and domain-wall dynamics in a $Pb_xSr_{(1-x)}TiO_3$ system. We have demonstrated that microscopic mechanisms of the domain-wall dynamics can be identified, *i.e.*, domain-wall bending can be separated from irreversible domain reconfiguration regimes. In conjunction, phase-field modeling was used to corroborate the observed mechanisms. This study highlights a new pathway toward discovery and control of metastable states in ferroelectrics, and more generally paves way for automated systems for controlled modification of domain walls and defects to improve material properties. This work was supported by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, Materials Sciences and Engineering Division at Oak Ridge National Laboratory's Center for Nanophase Materials Science, which is a U.S. DOE Office of Science User Facility.

Determination of Doping Profiles in Semiconductor Nanowires by Electrical Modes from Scanning Probe Microscopy Georges E. Bremond[1,2]; [1]INSA de Lyon, France; [2]Université de Lyon, France

Recently, semiconductor nanowires (NW) have gained more and more attention, as they are the building blocks of various future functional devices at the nanoscale. The measurement and quantitative determination of doping and doping profile within semiconductor nanowires (NW) are crucial in order to develop the technology using them. Specific methods and techniques are in high demand to understand the incorporation of doping into such one-dimensional structures. In the last two decades, scanning capacitance microscopy (SCM) and scanning spreading resistance microscopy (SSRM) based on atomic force microscopy, has emerged as promising tools for two-dimensional high resolution carrier/dopant profiling. In SCM, the capacitance change providing by an alternating bias applied between the tip/sample system under a DC bias to alternately accumulate and deplete carriers within the semiconductor underneath the local tip is dependent on the local carrier concentration of the semiconductor. In SSRM, the local resistivity, allowing the determination of the doping concentration, is determined via the spreading resistance measurement at the tip/sample system, applying an additional DC bias on the sample and using a logarithmic current amplifier. As multi-parameter experiments, these two techniques need of an accurate calibration method

for a quantitative doping analysis.
In this study we present first a doping calibration method based on cross-sectional scanning of multilayers samples ,with , for pedagogic demonstration, different Ga doping concentration in n-type ZnO allowing the quantitative measurement by SCM and SSRM. Then, to study NWs, we have developed a methodology of sample preparation, based on dip-coating filling of NWs field. The dip-coating parameters as coating solution, removal rate and NW field morphology have been controlled by SEM, ellipsometry and atomic force microscopy topography in order to optimize the filling and polishing process. As examples, some results are presented on ZnO and GaN NW: One important results has been to be able to measure using SCM and SSRM, the non-intentionally n-type doping (nid) of ZnO nanowires, well estimated at $210^{18}cm^{-3}$, explaining the difficulty to turn these NWs into p-type during p-type doping experiments, a crucial problematic in ZnO. Using antimony (Sb) doping in nid ZnO core/ Sb ZnO shell NW structures, we have successfully determined the decrease of carrier concentration with respect to the nid ZnO core, which can be ascribed to the formation of Sb-related acceptors compensating the native donors. The understanding of this electric compensation mechanism is the clear signature of a p-type Sb doping feasibility in ZnO NW. This important result opens the way to succeed in the p-type doping in ZnO.
The generalization of this doping profiling methodology to other NW semiconductors is also pointed out for instance to study the non homogeneity of Si and Mg doping in GaN NWs.

Direct Observation of the Double-Layering Quantized Growth of Mica-Confined Ionic Liquids Bingchen Wang[1,2] and Lei Li[1]; [1]University of Pittsburgh, United States; [2]University of Wisconsin–Madison, United States

Since the interface between ionic liquids (ILs) and solids always plays a critical role in important applications such as coating, lubrication, energy storage, and catalysis, it is essential to uncover the molecular structure and dynamics of ILs confined to solid surfaces. Here, we present our direct observation of a unique double-layering quantized growth of three IL (i.e., [Emim][FAP], [Bmim][FAP] and [Hmim][FAP]) nanofilms on mica. AFM results show that the IL nanofilms initially grow only by covering more surface areas at the constant film thickness of 2 monolayers (ML) until a quantized increase in the film thickness by another 2 ML. Based on the AFM results, we propose a double-layering model describing the molecular structure of IL cations and anions on the mica surface. The interesting double-layering structure can be explained as the result of several competing interactions at the IL-mica interface. Meanwhile, the time-dependent AFM results indicate that the topography of IL nanofilms could change with time, and the mobility of the nanofilm is lower for ILs with longer alkyl chains, which can be attributed to the more ordered packing between longer alkyl chains. Our findings have important implications on the molecular structure and dynamics of ILs confined to solid surfaces.

Nanoscale Viscoelasticity of Living Tissues with AFM—Physics of Biological Growth and Shape Across Temporal and Spatial Scales Sonia Contera, Jacob Seifert, Alba Rosa Piacenti and Casey Adam; University of Oxford, United Kingdom

The dynamic shapes of biologial tissues emerge from a complex interplay of physics, chemistry and genetics, which determines--at each temporal and spatial scale--the mechanical properties that eventually form the adaptive structures of living organisms. Shape and mechanical stability of living organisms rely on precise control in time and space of growth, which is achieved by dynamically tuning the mechanical (viscous and elastic) properties of their hierarchically built structures from the nanometer up. It is now well-established that cellular behaviour (including stem cell differentiation) crucially depends on the mechanical properties of the cells' environment. Attention has been directed towards the importance of the *stiffness* of the natural (extracellular matrix, ECM) or artificial matrices where cells grow, with the purpose of either understanding mechanotransduction, or controlling the behaviour of cells in tissue engineering. While stiffness (i.e. the capacity of a material to elastically store mechanical energy) has been the focus of most experimental research, neither cells or matrices are elastic. Biological systems dissipate energy (i.e. they are viscous) and hence they do not respond to mechanical deformations instantaneously (like an ideal Hookean spring), but present different time responses at different spatial scales that characterise their responses to external stimuli. Measuring viscoelasticity (especially at the nanoscale) has remained experimentally challenging [1,2]. I will present atomic force microscopy (AFM)- based techniques developed in my lab to measure and map the nano-viscoelasticity of living organisms, cells, membranes, collagen, ECMs, and tissue engineering matrices across the spatial and temporal (from Hz to 100s of kHz) scales, and chirp-based spectroscopic techniques to assess viscoelasticity from Hz to 100s kHz at the nano and micro scale developed in my lab. I will also present tests for assessing which viscoelasic model better fits the experimental AFM results. Our results have uncovered that extracellular matrices of both plants [3] and tumours present an almost perfect linear viscoelastic behaviour.

Nanocorresopy—Unravelling Multifactorial Properties of Biomaterials at Nanoscale Wojciech Chrzanowski; The University of Sydney, Australia

Nanoimaging and probing of physical-chemical characteristics is central to the development of new nanomaterials for energy and environment, communication, computing and security as well as for health and medicine. While all these areas are of significant importance, health and medical applications remain the most challenging because they involve interactions with living organisms. Inherently, such interactions are less predictable and directly linked to human health, which highlights their societal impact. Therefore, resolving the principles that govern biological behaviours and developing modern technologies that exploit new capabilities offered by nanomaterials to control multicellular environment is likely to result in significant advances in a quest for innovative therapies for major health threats including multi drug resistance, cancer and diabetes.
We know that biological responses are not controlled by a single material parameter. It is rather an interplay of many parameters such as size, shape, surface charge, chemistry and mechanical properties that defines the biological outcome. Therefore, correlative characterisation of structural, physical and

biological interactions at the nanoscale is paramount in order to correlate nanomaterials to their biological modulatory capabilities. Precise knowledge of key characteristics of nanomaterials will ultimately allow us to predict their safety and fate in biological systems and in the environment. It will unlock new opportunities to create safe-by-design systems for various biomedical applications.
To overcome limitations of current methods we proposed a correlative approach that uses nanoscale infrared spectroscopy, Lorentz contact resonance spectroscopy and Molecular force probe spectroscopy to interrogate nanoscale mechanical properties and map chemical structure of nanoparticles. To demonstrate strength of the nanocorrescopy in nanomaterials characterisation we used a copolymer composite mPEG-PLGA (methoxy-poly (ethylene glycol)-b-poly (lactic-co-glycolic) acid) nanorods. We demonstrated that the nanocorresocpy is capable of characterising precisely distribution of viscoelastic and chemical properties with the spatial resolution of <150 nm and <20 nm respectively. We further showed that this methodology enable characterisation of the corona formation on nanoparticles and for the first time assess its evolution in real time. We believe that the nanocorrescopy provides new opportunities to characterise variety of biomaterials used in biomedicine to ensure their safety, reliability, and sustainability.

11:30 AM CH03.11.03
Late News: *Ex Situ* AFM–Molecule Chip Technique for Single-Molecule Detection of Antibody–Antigen Bindings on a Semiconductor Chip Surface Ming-Pei Lu[1], Ying-Ya Weng[2] and Yuh-Shyong Yang[3]; [1]Taiwan Semiconductor Research Institute, National Applied Research Laboratories, Taiwan; [2]Institute of Biomedical Engineering, National Yang Ming Chiao Tung University, Taiwan; [3]Department of Biological Science and Technology, National Yang Ming Chiao Tung University, Taiwan

In-situ AFM typically possesses the single-molecule detection sensitivity of the antibody-antigen binding, however, yielding inevitably great limitations due to operational issues from a practical application viewpoint. Here, we propose a method of an ex-situ AFM-molecule chip technique with the feature of graphically superimposed alignment that enables ex-situ AFM analysis of an immobilized antibody at the same location on a semiconductor chip surface before and after incubation with its antigen, which makes all required chemical/biological treatments feasibly executed in the standard laboratory manner, allowing the single-molecule ex-situ AFM detection in a way with more practicality, flexibility, and versatility. Accordingly, by taking the hepatitis B virus X protein (HBx) for instance, the individual information of the topographical characteristics for the immobilized IgG antibodies/aggregates on the chip surface can be extracted using this ex-situ AFM analysis method, and further analyzed statistically. Experimental observations revealed that individual IgG antibodies covalently immobilized on the aldehyde-terminated chip surface, presumably featuring a predominately head-on orientation, possessed an AFM height of approximately 5.416 nm in statistical analysis. Furthermore, information regarding the AFM height change of individual IgG antibody/aggregate arising from the conformational change in the IgG-HBx complex formation was investigated in a statistical manner as well, leading to an increased height of approximately 1 nm. To broaden the application spectrum of the ex-situ AFM-molecule chip technique, we attempted to apply this technique to identify the locations and spatial distributions of the immobilized molecules on the bioFET surfaces. The surface topographical measurements at the same location on the nanowire bioFET surface were recorded after the chip cleaning, antibody modification, and antigen incubation steps, respectively. As a result, information regarding the correlation between the spatial distributions of the biological molecules on the bioFET surface and the corresponding electrical characteristics of the nanowire bioFETs can be obtained, highlighting that the single-molecule ex-situ analysis method can be beneficial to the development of bioFET applications. More importantly, other analysis modules in the SPM family can also be employed to simultaneously record various fundamental characteristics of the molecules on the chip surface at the single-molecule level while recording the topographical information of the chip surface using an AFM module, significantly revealing versatile applications of the ex-situ SPM-molecule chip technique (here using the SPM to replace the AFM for highlighting the potentials of multi-functional applications) in multidisciplinary areas across materials, chemistry, physics, and biology.

Predicting Hydration Layers over Surfaces Yashasvi S. Ranawat[1], Ygor Jaques[1] and Adam Foster[1,2]; [1]Aalto University, Finland; [2]Kanazawa University, Japan

Several technological and natural processes are dominated by the mineral-water interactions, for example biominerelisation, corrosion etc, and hence, characterization of such interfaces is vital. Atomic Force Microscopy (AFM) has gained prominence in characterizing such surfaces.
However, the complex interplay of the tip with the hydration layers over the surface govern the AFM tip's interaction with the hydration layers, and impede high resolution requirements needed for characterization. The theoretical molecular dynamics (MD) approaches have helped with the surface characterization. Given a hydration layer image, the search space is wide and the MD approach becomes prohibitively expensive. Here we introduce deep learning methods to reliably predict the hydration layer over a given surface.

Linking Text Extracted Data and Existing Resources Towards Predictive Models Elsa Olivetti; Massachusetts Institute of Technology, United States

Data continues to be a fundamental ingredient for accelerating and optimizing materials design and synthesis. Advances in applying natural language processing (NLP) to material science text has greatly increased the size and acquisition speed of materials science data from the published literature. This presentation will describe work to extract information from peer reviewed academic literature across a range of materials and explicit links between text-derived data and physics-based simulation data to inform materials discovery. We will present cases from microelectronics, catalysis and solid-state electrolytes.

11:00 AM CH04.01.03
Simultaneous Electrochemical Analysis of Material Libraries with Real Combinatorial High-Throughput Characterization Hannah N. Barad, Björn Miksch and Peer Fischer; Max Planck Institute for Intelligent Systems, Germany

Fabrication of CMLs with variations in deposition parameters, composition, thickness, oxidation state, and even nanostructure morphology have been demonstrated, but measuring and analyzing their properties is not straightforward. Typically, the measurements entail serial methods that measure samples point-by-point on pre-determined positions on the CMLs. While these measurements are often termed ‘high-throughput’ they are only so in the sense of processing large amounts of data. Especially, in the case of electrochemical measurements, the analysis can take a very long time, even days, to complete for one CML.

Here, we present a real high-throughput parallel method for determination of electrochemical properties. We do this using an array of ion-sensing field effect transistors (ISFETs) that was specifically designed for high-throughput measurements. ISFET sensors are used to detect changes in concentrations of specific ions in a solution, and as such can follow changes in electrochemical reactions. For this work we chose to examine CMLs of electrolyzers for oxygen evolution reaction (OER), which may form OH^- or H^+ intermediates during the reaction. In our setup, the sensor array is placed in solution directly above the studied CML, and we examine the changes in H^+ concentration as a result of the OER. The ISFET array allows us to quickly screen for material combinations of interest for OER, and generate large amounts of data in a short period of time, enabling parallel high-throughput CML characterization. We will share our most recent results in the generation of high-throughput CMLs [1] and analyzing these with similarly high-throughput parallel electrochemical measurements.

Machine Learning Assisted Metal-Insulator Compound Transition Discovery and Understanding—Database, New Features and Online Classifier Tool Alexandru Georgescu[1], Peiwen Ren[1], Aubrey R. Toland[2], Shengtong Zhang[1], Kyle Miller[1], Daniel Apley[1], Elsa Olivetti[3], Nicholas Wagner[1] and James M. Rondinelli[1]; [1]Northwestern University, United States; [2]Georgia Institute of Technology, Georgia; [3]Massachusetts Institute of Technology, United States

Understanding, and predicting new materials with relevant electronic properties is a key task in materials science. This task is complicated in the case of materials with complex electronic interactions, particularly in the case of materials with an open d-shell of a transition metal ion known as correlated materials. This is due to the limitations of current theoretical methods, as well as the scarcity and heterogeneity of known materials. Of these materials, materials that exhibit a thermally driven metal-insulator transition (MIT) are particularly important for technological applications, yet only around 60 are known. To accelerate materials discovery and understanding, we have built, with the assistance of natural language processing techniques, the first materials database of MIT and related compounds which is now available for scientists' use (1,2). We have trained a machine learning model on this database, allowing us to extract new relevant features for this class of materials, including generalized tolerance factors, the Ewald energy, as well as confirmed the importance of well-known ones such as the Hubbard U (1). Finally, we provide this model in a user-friendly binder format that scientists can run in their browser and obtain new predictions on whether a material is a metal, insulator, or MIT in seconds based on .cif structure files - without installing any software on their machine (1,3). Our work shows how machine learning can be used to accelerate materials discovery and understanding at every step of the research process. If time permits, I will present results on newly identified metal-insulator transition compounds.

Stach[4], Jason Weaver[6], Philippe Sautet[3,3], Boris Kozinsky[2,7] and Anatoly Frenkel[1,8]; [1]Stony Brook University, The State University of New York, United States; [2]Harvard University, United States; [3]University of California, Los Angeles, United States; [4]University of Pennsylvania, United States; [5]Columbia University, United States; [6]University of Florida, United States; [7]Robert Bosch LLC, Research and Technology Center, United States; [8]Brookhaven National Laboratory, United States

Fundamental atomic-level understanding of the active site structure is a central requirement of rational catalyst design. Due to the large configurational space inherent to many catalytic systems, it is very challenging to resolve the active sites directly. Moreover, these structures often exhibit dynamical behavior in response to the reactive environment. Here, we propose a multipronged strategy of decoding reactive structures at the atomic level, combining catalysis, characterization, machine learning, and first-principles based kinetic modeling. We unambiguously demonstrate the effect of catalyst treatment on its nanostructure and reactivity toward the prototypical hydrogen-deuterium (HD) exchange reaction, using a dilute alloy Pd_8Au_{92} supported on highly stable raspberry colloid template SiO_2. Remarkably, the Sabatier optimum is established with small Pd_n ensembles, where the reactivity is tuned by modulating the active site on the order of only a few atoms (n = 1-3) through catalyst pretreatment.

The catalyst is activated by O_2 treatment and decreases in activity upon H_2 treatment. These observations are explained in terms of catalyst restructuring induced by the treatments, as evidenced by X-ray absorption spectroscopy and coordination numbers extracted from neural network inversion of the spectra. A quasi-random alloy is revealed: the majority of Pd remains dispersed inside Au, with a small amount of Pd segregating toward the surface upon O_2 treatment and dissolving into the bulk upon H_2 treatment. Extensive theoretical modeling of the HD exchange reaction network on several model surfaces establishes Pd monomers, dimers, and trimers as decisive candidate structures for the active site. Very good agreement is found between theory and experiment in terms of the apparent activation energy: O_2-treated samples are dominated by desorption-limited Pd trimers, whereas H_2-treated samples are characterized by dissociation-limited Pd dimers & monomers. These dilute Pd ensembles numerically satisfy the observed coordination numbers for all of our samples, thereby fulfilling both the kinetic and structural criteria of the active site. Our multidisciplinary approach enables precise identification of the active site at atomic resolution with fully consistent structure-activity relationship.

Encoding Dynamical Information in Graph Representation Learning for Large-Scale Protein Function Prediction Yuan Chiang and Shu-Wei Chang; National Taiwan University, Taiwan

Understanding the protein structure-function relationship is essential for broad biological fields, with important applications in the design of new functional biomaterials, drugs, and antibiotics for biotechnology and pharmaceutical industries. Recent advances in protein function prediction take advantage of graph-based deep learning approaches to correlate protein 3D structure and topological features with molecular functions. The latest end-to-end model PersGNN had achieved a boost in Gene Ontology classification compared with baseline graph neural networks (GNNs). However, proteins in nature are not static but dynamic molecules interacting with the environment, constantly alternating conformation, and even forming assemblies of quaternary complexes. This talk will present the expressiveness and robustness of GNNs to encode information from spatial proximity, persistence homology, together

with normal mode analysis across protein residues. The learned representation aggregates node-level features from local to global hierarchy and provides graph-level embedding with inter-residue dynamical couplings for downstream function prediction. High throughput classification tasks for over 100,000 proteins and 1,000 function tags from Protein Data Bank and Gene Ontology demonstrate remarkable performance gain in the discriminatory power based on such dynamics-informed representation. The proposed method can be readily extended to wide crystalline and amorphous materials that can be represented as graph-structured data and be incorporated with particle-based dynamics.

***Ab Initio* Modeling of Configurational Disorder in Complex Systems by Combining Machine Learning and Cluster Expansions** Julia Yang[1] and Gerbrand Ceder[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Disordered multicomponent systems have immense engineering design flexibility and a subsequently rich space of properties. A lattice cluster expansion is one powerful computational tool to obtain precise, detailed configurational and energetic resolution, but in practice has primarily been used in binary systems or ternary alloys. In this presentation we will discuss approaches to significantly increase the complexity of systems to which the cluster expansion can be applied, including a high number of species, different valence states of ions, complex underlying lattices, and large off-lattice relaxations. We demonstrate this approach to a multicomponent, multi-sublattice lithium manganese oxyfluoride electrode system, setting up the largest cluster expansion ever attempted to our knowledge. In order to bridge the vastly under-determined configurational space observed by neutron diffraction with computation, we apply the sparse group lasso statistical method to reduce model complexity from over 4500 features to fewer than 200. We also use Bayesian optimization via Gaussian Processes in oxidation state assignments during data cleaning, demonstrating its success in high dimensional spaces with limited training data. Lastly, we extend existing theoretical cluster expansion methods and derive how to analytically calculate and characterize local structural and chemical orderings in any state of disorder. Our developments make the fitting and analysis of complex systems tractable and provide guidance for thorough, high-throughput computational studies of multi-component, disordered systems.

2:15 PM CH04.02.03
Topology-Informed Machine Learning for Predicting Glasses' Properties Mathieu Bauchy; University of California, Los Angeles, United States

Although machine learning offers a unique, largely untapped opportunity to accelerate the discovery of novel glasses with exotic functionalities, it faces several challenges. Since they are usually only driven by data and do not embed any mechanistic knowledge, machine learning models can sometimes violate physical and chemical laws. For these reasons, machine learning techniques are usually good at "interpolating" data but have thus far a limited potential for "extrapolating" predictions far from their initial training set, which prevents the efficient exploration of new unknown compositional domains. Here, we present a new machine learning framework aiming to predict the properties of oxide glasses. As expected, we show that "blind machine learning" (i.e., which does not embed any physical or chemical knowledge) can successfully interpolate data but fails at extrapolating predictions far from its training set. As an alternative route, we report a new "topology-informed machine learning" framework that addresses this limitation. This framework relies on artificial neural networks and embeds a topological description of the connectivity of the atomic network. We show that our "topology-informed machine learning" model allows us to extrapolate predictions far from the training set. More generally, topology-informed machine learning offers a promising route to overcome the tradeoff between accuracy, simplicity, and interpretability—which are otherwise often mutually exclusive in traditional "blind machine learning" models.

2:30 PM CH04.02.06
Identifying High-Stability Motifs of Structural Patterns in Molecular Crystals Rose K. Cersonsky[1], Maria Pahknova[1], Edgar A. Engel[2] and Michele Ceriotti[1]; [1]École Polytechnique Fédérale de Lausanne, Switzerland; [2]University of Cambridge, United Kingdom

Molecular crystals play an important role in various fields of science and industry, with applications in the pharmaceutical, electronics, and food industries. Predicting the stability of crystal structures formed from molecular components is non-trivial, given the complexity inherent to the multiscale nature of their structure and the subtle balance of weak intermolecular interactions governing the structure-property relations. We have curated a dataset containing over 3'000 molecular crystals, their constituent molecules, and their related properties. We use it to demonstrate the use of machine-learning techniques to estimate the stability of the crystalline structures. We use general-purpose descriptors of atomic structure and modify them to explicitly incorporate information on the molecular nature and thermodynamics of the material. In combination with a principal covariates regression analysis that explicitly determines the best low-dimensional representation of structure-property relations, we demonstrate how to identify the atomic motifs associated with a strong stabilizing effect on molecular packing.

2:45 PM CH04.02.07
Spanning the 5D Space of Grain Boundaries—A Comprehensive Database of Grain Boundary Structures and Their Interface Energy Eric R. Homer, Gus L. Hart, Derek Hensley, Jay Spendlove, Braxton Owens and Lydia Serafin; Brigham Young Univ, United States

The space of possible grain boundary structures is vast, with 5 macroscopic, crystallographic degrees of freedom that define the character of a grain boundary. While numerous datasets of grain boundaries have been created to examine this space, none has systematically examined the full range of possibilities. We will present a dataset of more than 4200 unique grain boundaries in the 5D crystallographic space. Our sampling includes a range of possible microscopic, atomic configurations for each unique 5D crystallographic structure, which we refer to as metastable grain boundary structures. In all, the number of metastable structures associated with the 4200 unique grain boundaries is over 31 million. We will present an overview of the methods used to generate this dataset, an initial examination of the raw data, as well as methods and insights gained in machine learning of grain boundary energy structure-property relationships.

3:00 PM CH04.02.08
Learning with Delayed Rewards—A Case Study on Inverse Defect Design in 2D Materials Suvo Banik[1], Troy Loeffler[2], Rohit Batra[2], Harpal Singh[3], Mathew J. Cherukara[2] and Subramanian Sankaranarayanan[2]; [1]University of Illinois at Chicago, United States; [2]Argonne National Laboratory, United States; [3]Sentient Science Corporation, United States

Defect dynamics in materials are of central importance to a broad range of technologies from catalysis to energy storage systems to microelectronics. Material functionality depends strongly on the nature and organization of defects – their arrangements often involve intermediate or transient states that present a high barrier for transformation. The lack of knowledge of these intermediate states and the presence of this energy barrier presents a serious challenge for inverse defect design, especially for gradient-based approaches. Here, we present a reinforcement learning (Monte Carlo Tree Search) based on delayed rewards that allow for efficient search of the defect configurational space and allows us to identify optimal defect arrangements in low dimensional materials. Using a representative case of 2D MoS_2, we demonstrate that the use of delayed rewards allows us to efficiently sample the defect configurational space and overcome the energy barrier for a wide range of defect concentrations (from 1.5% to 8% S vacancies) – the system evolves from an initial randomly distributed S vacancies to one with extended S line defects consistent with previous experimental studies. Detailed analysis in the

feature space allows us to identify the optimal pathways for this defect transformation and arrangement. Comparison with other global optimization schemes like genetic algorithms suggests that the MCTS with delayed rewards takes fewer evaluations and arrives at a better quality of the solution. The implications of the various sampled defect configurations on the 2H to 1T phase transitions in MoS_2 are discussed. Overall, we introduce a Reinforcement Learning (RL) strategy employing delayed rewards that can accelerate the inverse design of defects in materials for achieving targeted functionality.

3:15 PM CH04.02.09
Predictive Computational Frameworks to Guide the Solid-State Synthesis of Novel Materials Wenhao Sun; University of Michigan, United States

Solid-state synthesis from powder precursors is the primary processing route to multicomponent ceramic materials. The black-box nature of the reaction vessel typically precludes an understanding of the solid-state reaction mechanisms that govern phase evolution, leading to trial-and-error approaches to synthesis. In the age of autonomous laboratories, better theories of materials synthesis are needed to predict and guide robotic synthesis approaches to novel materials. Here, we combine *ab initio* thermodynamics with *in situ* synchrotron X-ray scattering and TEM to build predictive theories for which non-equilibrium phases form during solid-state ceramic synthesis, and why. I will present examples from the ceramic synthesis of NaxMO2 (M = Co, Mn) layered oxides [1] and also the classic high-temperature superconductor YBa2Cu3O6+x (YBCO) [2]. We derive an interfacial reaction model to predict the first-phase-to-form between two powder precursors, which can consume a large fraction of the reaction energy and can topotactically template structural transformations to other non-equilibrium intermediates. Our insights can help guide the choice of precursors and parameters employed in the solid-state synthesis of ceramic materials, and constitutes a step forward in building predictive thermodynamics and kinetics-informed machine-learning strategies for the autonomous synthesis of novel materials.

3:30 PM CH04.02.10
Late News: Parsimonious Neural Networks Learn Interpretable Physical Laws Alejandro Strachan; Purdue University, United States

Machine learning is playing an increasing role in the physical sciences and significant progress has been made towards embedding domain knowledge into models. Less explored is its use to discover interpretable physical laws from data. We propose parsimonious neural networks (PNNs) that combine neural networks with evolutionary optimization to find models that balance accuracy with parsimony. The power and versatility of the approach is demonstrated by developing models for classical mechanics and to predict melting temperature of materials, and performance of energetic materials from fundamental properties. In the first example, the resulting PNNs are easily interpretable as Newton's second law, expressed as a non-trivial time integrator that exhibits time-reversibility and conserves energy, where the parsimony is critical to extract underlying symmetries from the data. In the case of melting, the PNNs not only find the celebrated Lindemann melting law, but also new relationships that outperform it in the pareto sense of parsimony vs. accuracy.

SESSION CH04.03: Image and Spectral Analysis by Computer Vision and Related Methods I
Session Chair: Suvo Banik
Wednesday Morning, December 1, 2021

10:30 AM CH04.03.01
Reconstructing the Exit Wave in High-Resolution Transmission Electron Microscopy Using Machine Learning Jakob Schiotz[1], Frederik Dahl[1], Matthew Helmi Leth Larsen[1], Christian Kisielowski[2], Stig Helveg[1], Ole Winther[1] and Thomas W. Hansen[1]; [1]Technical University of Denmark, Denmark; [2]Lawrence Berkeley National Laboratory, United States

High-resolution Transmission Electron Microscopy (HRTEM) is a powerful technique for examining matter at the atomic scale. In particular, the ability to acquire single projection images of the sample volume in a parallel fashion employing low electron doses and dose-rates makes HRTEM attractive to detect the atomic-scale realm of matter [1]. However, interpreting the image is not always straightforward, as images are formed by phase contrast.

A focal series of HRTEM images enables reconstruction of the exit wave function, which provides the most informative measure of the sample. A series of typically 20-50 images acquired with varying defocus is used to numerically reconstruct the most likely exit wave, which is then interpreted as it corresponds closely to the structure of the sample [2,3].

Here we show that a convolutional neural network is able to reconstruct the exit wave function from a focal series of only two or three images – but not from a single image. The convolutional neural network is based on the U-Net architecture [4] and is almost the same as the one we have previously used to identify the positions of atomic columns in single images of metallic nanoparticles [5].

We train the neural networks on simulated images. The simulated images are produced with the multislice algorithm, using pyqstem [6], both the exit wave function and images produced with three different values of the defocus are saved. The exit waves are then blurred slightly by folding with a gaussian, and a neural network is trained to reconstruct the exit wave from the images. The network is validated on a different set of simulated images.

In all cases we work with thin flakes of 2D materials, although the methods should generalize to other classes of materials. We train and validate networks based on three different types of samples of increasing difficulty. The first two are unsupported nanoflakes of molybdenum disulphide (MoS_2), and molybdenum disulphide supported on a graphene substrate. MoS_2 is an active catalyst for photooxidation, hydrogen evolution and hydrodesulphurization reactions. The third type is a diverse collection of existing and proposed quasi-two-dimensional materials, taken from the Computational 2D Materials Database (C2DB) [7]. In all cases the neural network is able to learn to reconstruct the exit wave function of the vast majority of the samples in the validation sets.

Finally, we demonstrate that the network trained on simulated data for graphene-supported molybdenum disulphide can also be used to analyze images

from an experimental focus series taken on a sample of a realistic model of an industrial MoS_2 based hydrodesulphurization catalyst. The neural network is able to reconstruct the exit wave with such fidelity that the atomic structure of both the MoS_2 nanoparticle and the supporting graphene is clearly recovered.

Machine Learning for Information Extraction from Transmission Electron Microscopy Data Xingzhi Wang[1,2], Jie Li[1,1], Chang Yan[2], Justin C. Ondry[3], Jakob Dahl[1,2], Teresa Head-Gordon[1,1,2], Peter Ercius[2] and A. Paul Alivisatos[1,3]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]The University of Chicago, United States

Recent advancements in transmission electron microscopy (TEM) have significantly improved the information-richness and efficiency of acquisition of TEM data. Traditional methods for TEM data analysis based on manual interpretations of TEM images are often found insufficient to take full advantages of the richness of information contained in these data. Here, we will demonstrate how machine learning can be used to provide potential solutions for this problem. First, we will demonstrate an unsupervised machine learning algorithm for classifying the shapes of gold nanoparticles from TEM images. The algorithm is capable of extracting shape parameters of nanoparticles from TEM images, and classify the particles based on their shapes, requiring minimum human input in the process. The algorithm's performance will be tested on two datasets of gold nanoparticles with different morphologies, and compared to human analysis of the same datasets to validate its accuracy and efficiency. We will show that the algorithm provides a method for efficient extraction and interpretation of statistical morphological information of metal nanoparticles, while introducing minimum human biases into the results. We will then demonstrate the use of machine learning to identify and track atomic movements during the oriented attachment and annealing processes of semiconductor nanocrystals observed by *in-situ* TEM. We will show how advancements in the automation of electron microscope imaging has allowed the acquisition of this dataset in high-throughput, and how machine learning can provide an efficient method to extract information from such a highly complex dataset. We hope that the two applications we show here will serve as examples of how machine learning can be incorporated into the analysis of large and/or complex TEM datasets, enabling the extraction of information that may not be obtainable otherwise.

11:00 AM CH04.03.04
Convolutional Neural Networks for Recognizing Superconducting Phases in Powder X-Ray Diffraction Nam Q. Le[1], Janna Domenico[1], Eddie Gienger[1], Timothy Montalbano[1], Ian McCue[1], Alexander New[1], Christine Chung[1], Elizabeth Pogue,[2], Tyrel McQueen[2] and Christopher Stiles[1]; [1]Johns Hopkins University Applied Physics Laboratory, United States; [2]Johns Hopkins University, United States

X-ray diffraction (XRD) is indispensable in high-throughput materials screening, both for confirming the synthesis of expected phases and for revealing new structures in unexplored material systems. As a case study, samples synthesized from binary and ternary intermetallic systems were screened for A15-type phases based on XRD measurements. These compositions span both known and unknown phase diagram compositions. Many A15 phases are Type-II superconductors at comparatively high temperatures relative to other metallic alloys, motivating a hypothesis that screening novel A15 phases will lead to a high proportion of novel superconductors. A bottleneck in this approach is identification of relevant phases from the XRD patterns, which, even using current software, requires human intervention and is thus not suitable for fully automated workflows. We report results of a convolutional neural network (CNN) trained to classify A15-like phases based on a large database of synthetic data with simulated noise, and show strategies needed to address class imbalance challenges intrinsic to identification of single classes of phases. This enables high-throughput sample screening and allows focusing of human time only on the most interesting materials. These approaches can extend readily to other materials discovery settings where properties are strongly tied to particular phases that are distinguishable based on XRD patterns.

SESSION CH04.04: AI for Materials Design I

Materials Project and Data-Driven Materials Design Kristin A. Persson[1,2]; [1]UC Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

The powerful combination of supercomputing resources, robust algorithms for solving the laws of physics and state-of-the-art software infrastructure are enabling rapid, systematic calculations of real materials properties from quantum mechanics across chemistry and structure. A result of this paradigm change are databases like the *Materials Project* (www.materialsproject.org) which is charting the properties of all known inorganic materials and beyond, designing novel materials and offering the data free of charge to the community together with online analysis and design algorithms. The growing body of available, reliable data has reached the stage where automated learning algorithms can be effectively trained and utilized to accelerate all aspects of the materials design cycle: from property prediction to materials synthesis and characterization. In 2021, the Materials Project has rolled out a completely revamped infrastructure to meet growing demands on data accessibility and user experience. A stand-alone data portal has been launched for community data contributions, which is designed to automatically connect contributed materials data with the organization and users of the Materials Project. We will present the new infrastructure and exemplify the approach of data-driven materials design using in-house case studies as well as community-driven research. The data spans design, characterization and synthesis - closing the loop and showcasing rapid iteration between ideas, computations, insight and new materials development.

2:00 PM CH04.04.03
Enhancing Discovery and Characterization of Materials Far From Equilibrium with ML Duncan Sutherland[1], R. Van Dover[1], Carla Gomes[1], Michael O. Thompson[1], Maximilian Amsler[1], Aine Connolly[1], Sebastian Ament[1], John M. Gregoire[2] and Ming-Chiang Chang[1]; [1]Cornell University,

United States; [2]California Institute of Technology, United States

Materials processed under conditions that are far from equilibrium can yield new metastable materials with uncommon and valuable properties. Exhaustive exploration of the material space is often intractable due to the many synthesis degrees of freedom, e.g., processing time, temperature, and multiple composition variables. To explore this complex space most efficiently, our workflow employs high-throughput experimentation along with powerful machine learning algorithms. Our experiments consist of lateral gradient laser spike annealing of thin films characterized by micron scale analytics. To rapidly interpret these data, we use a combination of complementary active learning schemes: Gaussian process regression to map out phase boundaries and NMF/compressive sensing to label phases where possible. For a wide range of material systems (oxides, nitrides, and chalcogenides), we demonstrate the richness of the processing phase diagrams and identify methods to address the challenges that arise when executing completely autonomous interpretation.

2:15 PM CH04.04.04
CASTING—A Continuous Action Space Tree search for INverse desiGn Suvo Banik[1], Srilok Srinivasan[2], Troy Loeffler[2], Sukriti Manna[1], Rohit Batra[2], Henry Chan[2], Pierre Darancet[2] and Subramanian Sankaranarayanan[2,1]; [1]University of Illinois at Chicago, United States; [2]Argonne National Laboratory, United States

The most common and popular methods for structure search and optimization are based on evolutionary design. This can often be cumbersome, limited to few tens of parameters, and fails for large structural configurations or design problems with high degrees of freedom. Reinforcement learning approaches mostly operate in discrete action space such as in Go game but the applications of that to inverse problems is limited since most inverse problems deal with continuous action space. There are a large number of inverse structural search problems ranging from crystal structure search in material sciences to topology design in Quantum information, where it is highly desirable to optimize structure/configuration to target desired properties or functionalities. This talk will provide an overview of our current efforts to perform scalable crystal structure search to discover and design metastable or non-equilibrium phases with desired functionality. We will demonstrate select use cases that highlight the efficacy of CASTING for molecular, crystal structure, defects, topology, device, and component design.

2:30 PM CH04.04.05
Discovery of Novel Inorganic Crystal Structures via Generative Adversarial Networks. Taylor D. Sparks, Michael Alverson and Ryan Murdock; Univ of Utah, United States

The idea of material discovery has excited and perplexed scientists for centuries. Several methods have been employed to find new types of materials, ranging from replacement of atoms in a crystal structure to advanced machine learning methods for predicting entirely new crystal structures. In this work, we investigate the performance of various Generative Adversarial Network (GAN) architectures to find innovativee ways of generating theoretical crystal structures that are synthesizable and stable. Over 300,000 entries from Pearson's Crystal Database are used for the training of each GAN. The space group number, atomic positions, and lattice parameters are parsed and used to construct an input tensor for each of the network architectures. Several different GAN layer configurations are designed and analyzed, including Wasserstein GANs with weight clipping and gradient penalty, in order to identify a model that can adequately discern symmetry patterns that are present in known material crystal structures.

SESSION CH04.05: Poster Session: Accelerating Materials Characterization, Modeling and Discovery by Physics-Informed Machine Learning
Wednesday Afternoon, December 1, 2021

Hynes, Level 1, Hall B

CH04.05.02
Understanding Gold Nanorod Synthesis from Experiments and Literature Using Quantitative Analysis of Plasmonic Absorption Spectra Samuel P. Gleason[1], Jakob Dahl[1], Mahmoud Elzouka[2], Xingzhi Wang[1], Sean Lubner[2], Ravi Prasher[2] and A. Paul Alivisatos[1]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Gold nanorods (AuNRs) have found applications in cancer imaging and treatment, catalysis, and solar technology due to their size dependent and highly tunable optical properties. The utilization of these applications requires the synthesis of AuNRs of specific sizes and shapes. The determination of the sizes and shapes of AuNRs produced by a colloidal synthesis is commonly achieved using TEM analysis. This procedure requires a significant time investment and expensive instrumentation to attain the volume and quality of images necessary to produce statistically significant distributions. Our method extracts quantitative information about AuNR size distributions from absorption spectra. We treat an absorption spectrum as a linear combination of single particle spectra, and use numerically simulated spectra to determine the length, diameter, and aspect ratio distributions of simulated AuNRs which reproduce the experimental spectrum. This model has been used as an automated tool on AuNRs synthesized using robotic high throughput synthesis, which utilizes a modified one step seedless AuNR synthesis procedure. The accuracy of this model is verified using TEM analysis of samples of this dataset and by the extraction of well labeled spectra from the AuNR synthesis literature. This project demonstrates an effective method to extract population level size distribution information from a colloidal nanocrystal sample. Through using this model on high throughput samples and literature spectra where quantitative information about the size distributions is unknown, the quantitative impact of synthetic procedure on the size distributions of AuNRs can be determined, further developing the fundamental knowledge of AuNR synthesis. In principle, this approach can be extended to any other nanocrystal system where the absorption spectra are size dependent and accurate numerical simulation of the absorption spectra is possible.

CH04.05.04
Real-Time 3D Analysis During Tomographic Experiments on tomviz Jonathan Schwartz[1], Chris Harris[2], Jacob Pietryga[1], Huihuo Zheng[3], Prashant Kumar[4], Anastasiia Visheratina[4], Nicholas Kotov[1,4], Yi Jiang[3], Marcus D. Hanwell[5] and Robert Hovden[1,1]; [1]University of Michigan, United States; [2]Kitware, United States; [3]Argonne National Laboratory, United States; [4]University of Michigan–Ann Arbor, United States; [5]Brookhaven National Laboratory, United States

Three-dimensional (3D) characterization across the nanoscale is now possible using scanning / transmission electron microscopes (S/TEM). Unfortunately, tomographic reconstructions can take one to several days to complete depending upon the dataset size or algorithm(s) employed. Even worse, the reconstruction occurs offline, long after all the data has been collected, preventing immediate interpretation during an ongoing experiment. While

advancements in detector hardware have boosted throughput with digital data collection, substantial human effort and computational resources are still required to process the deluge of raw data. Thus, it has been a longstanding goal to begin 3D analysis of specimens in real-time allowing immediate assessment of nanoscale structure. Continuous 3D feedback provides early diagnosis of specimens to bridge material synthesis with accelerated characterization. Achieving high-throughput electron tomography requires an integrated pipeline that links the microscope hardware to optimized reconstruction algorithms and efficient 3D volumetric visualization. Moreover, this pipeline should be multi-threaded to run dynamic visualizations that updates as new data is collected or reconstruction algorithms proceed.

Here we present interactive 3D visualization that seamlessly runs while experimental projections are collected in an electron microscope using the tomviz platform (www.tomviz.org). Tomviz presents 3D materials structure to scientists in real-time enabling high-throughput specimen interpretation with immediate tomogram visualization. During the experimental acquisition, tomviz monitors for new projections which are continuously appended into the reconstruction process. After a reconstruction updates, tomviz immediately renders the 3D volume. We demonstrate real-time tomography on a helical nanoparticle comprised of a Cysteine amino-acid coordinated with Cadmium (Cys/Cd). The specimen's left-handed chirality is discerned in the first twenty minutes and a high-resolution volume is available within 50% of the experiment (20-30 minutes). Real-time tomography demands maximally efficient computational speed to ensure the optimization runs faster than the experimental data acquisition rate. Tomograms are reconstructed in parallel with data acquisition and a high-quality 3D reconstruction is available before the experiment ends. Tomviz contains novel real-time algorithms that are compatible with high-performance computing clusters to produce and visualize large 3D volumes (>1024 voxels).

The multithreaded pipeline in tomviz enables interactive 3D analysis of the current reconstruction state with minimal impact on performance. A robust graphical interface allows for 3D objects to be rendered as shaded contours or volumetric projections and these objects can be rotated, cropped, or sliced as the reconstruction evolves. Thus, scientists can go beyond superficial inspection to quantify specimen features or internal structure while simultaneously operating the microscope. This immediate feedback can save researchers days of effort as reconstructions are no longer processed offline.

Tomviz offers unparalleled electron tomography throughput with real-time 3D analysis — it is an open-source repository that is available to all institutions for download at www.tomviz.org

CH04.05.05
Identifying Unknown Organic Molecules in Atomic Force Microscopy Images Through Deep Generative Models Fabio Priante[1], Niko Oinonen[1], Fedor Urtev[1] and Adam Foster[1,2]; [1]Aalto University, Finland; [2]Nano Life Science Institute (WPI-NanoLSI), Kanazawa University, Japan

The use of functionalized tips in Atomic Force Microscopy (AFM) has enabled the investigation of organic molecules with atomic resolution [1]. To more easily interpret the resulting images - which is often a non-trivial task, even for experts - a machine-learned approach based on Convolutional Neural Networks (CNN) has been recently proposed [2]. This method associates unique descriptors to a high-resolution AFM image, allowing automatic extraction of the spatial configuration of the molecule being probed, even for highly three-dimensional cases.
However, if no previous knowledge is available about the identity of the molecule in question, it is very difficult to draw meaningful conclusions.
Here, we approach the problem of recognizing both the identity and the configuration of unknown molecules in high-resolution AFM by using the CNN-extracted descriptors to guide the latent space optimization of a deep generative model for molecular graphs.
These models have seen a rapid development over the past few years, as a way to generate plausible small-molecule drug candidates [3]. Usually, once a generative architecture has been trained to reproduce sufficiently well the distribution of the training data (e.g. the QM9 dataset), optimization of the model's latent space can then be carried out to maximize a property of interest, such as drug-likeness, obtaining a list of best candidates.
In the context of AFM, we optimize the latent space of a state of the art generative model using a score which gives the alignment of each generated molecule with the original CNN-extracted descriptors. As a result, a ranked list of best-fit, chemically valid molecules is proposed as possibly underlying the starting AFM image.

SESSION CH04.06: Machine Learning for Material Processing and Synthesis
Session Chair: Jakob Dahl
Thursday Morning, December 2, 2021
Hynes, Level 3, Room 303

10:30 AM CH04.06.01
Elucidating the Weakly Reversible Cs–Pb–Br Perovskite Nanocrystal Reaction Network with High-Throughput Maps and Transformations Jakob Dahl[1,2,2], Xingzhi Wang[1,2], Xiao Huang[1], Emory Chan[2] and A. Paul Alivisatos[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Advances in automation and data analytics can aid exploration of the complex chemistry of nanoparticles. Lead halide perovskite colloidal nanocrystals provide an interesting proving ground: there are reports of many different phases and transformations, which has made it hard to form a coherent conceptual framework for their controlled formation through traditional methods. In this work, we systematically explore the portion of Cs–Pb–Br synthesis space in which many optically distinguishable species are formed using high-throughput robotic synthesis to understand their formation reactions. We deploy an automated method that allows us to determine the relative amount of absorbance that can be attributed to each species in order to create maps of the synthetic space. These in turn facilitate improved understanding of the interplay between kinetic and thermodynamic factors that underlie which combination of species are likely to be prevalent under a given set of conditions. Based on these maps, we test potential transformation routes between perovskite nanocrystals of different shapes and phases. We find that shape is determined kinetically, but many reactions between different phases show equilibrium behavior. We demonstrate a dynamic equilibrium between complexes, monolayers, and nanocrystals of lead bromide, with substantial impact on the reaction outcomes. This allows us to construct a chemical reaction network that qualitatively explains our results as well as previous reports and can serve as a guide for those seeking to prepare a particular composition and shape. The dataset shown here is openly accessible, has already resulted in several-follow on publications and has been used in a classroom setting to help undergraduate students learn how to explore questions at the intersection of materials chemistry and data analytics.

Predicting Synthesizability of Double Perovskite Halide via Machine Learning Joonchul Kim; Soongsil University, Korea (the Republic of)

Double perovskite structure has brought significant attention due to its great potentials for applications of rechargeable batteries, lighting-devices, and energy harvesting materials. Despite of its importance, it is difficult to find the thermodynamically stable structure satisfying target properties due to its enormous chemical space. Conventionally, the tolerance factor is used to predict the stability of the perovskite materials, but its usage has not been fully validated for the double perovskite structures. For example, the halide-type double perovskite structures have demonstrated exceptional physicochemical properties, but its search space is enormous; the chemical formula of the halide-type of double perovskite is $ABB'X_3$ and the number of atomic elements, which can locate at A and B site, reaches 70 and 4 elements to X site, leading to 1,400,000 structures. In this regard, applying the high-throughput materials screening to this type of material cannot be performed with the conventional method such as experiments or *ab initio* calculations.
In this study, to overcome above-mentioned issues, machine learning algorithm is employed to search for new stable double perovskite halide materials. First, the inorganic materials properties are adopted from well-established Materials Project database and double perovskite oxide database that we constructed in our previous work and they are used as a training set (around 120,000 structures and 11,000 double perovskite oxide). Then, the chemical features are constructed to describe given materials. We used the regression as well as the classification method for optimizing the surrogate model. Finally, trained machine learning model is applied to the whole chemical space of the double perovskite halide material (13,542 structures; they are chosen based on previous tolerance factor for validation of the current model). Initially, the prediction accuracy for the formation energy was obtained to be r-squared score of 0.77 and RMSE of 0.399 (eV/atom) when trained only with previous data sets. Finally, to further improve the prediction accuracy more efficiently, we employed the optimization method; exploration by quantifying the prediction uncertainty. This method clearly validated that the r-squared value is increased to 0.90, only by adding 6.5% of selected halide data to the training data.
In this study, the actual formation energy and convex hull energy of the Double perovskite candidate material were calculated using DFT. Machine learning models performed using DFT computational results were successfully able to predict formation energy and convex hull energy of double perovskite halide.

"Big Data" Characterization of Material Properties and High Temperature Kinetics James Horwath[1], Peter Voorhees[2] and Eric A. Stach[1]; [1]University of Pennsylvania, United States; [2]Northwestern University, United States

Deactivation of supported metal nanocatalysts under harsh reaction conditions limits the feasibility and efficiency of important industrial reactions. High reaction temperatures and reactive environments enable nanoparticle evolution to reduce the particles' high surface energy, while simultaneously reducing the number of available reaction sites and catalytic activity overall. While research aimed to describe coarsening and degradation processes in nanoscale systems has been undertaken for decades, the difficulty of *in situ* observation and the analysis of *in situ* experimental data has inhibited the development of a theory which comprehensively describes the evolution of supported nanoparticles.

With the goal of understanding coarsening and degradation kinetics in model catalyst systems, we used *in situ* Transmission Electron Microscopy (TEM) to track the evolution of supported gold nanoparticles heated to 900C under vacuum. Using unsupervised machine learning to automatically process TEM images, nanoparticles sizes and positions as a function of time were extracted from experimental images. Using detailed characterization from both ensemble- and particle-scale measurements, we present an analytical model describing nanoparticle degradation as a competition between evaporation into the surrounding vacuum and diffusion between particles along the support. Moreover, we can fit our model to the evolution trajectories of hundreds of individual nanoparticles to determine statistically validated values for fundamental physical properties such as the diffusion coefficient, solid-vapor surface energy, and the equilibrium vapor pressure for gold nanoparticles at high temperature. By comparing these values with literature references, and thereby affirming the validity our model, we can investigate the physical meaning of the remaining parameters which are not measurable by traditional experimental methods. As an example, we are able to use our rich dataset describing nanoparticle evolution to characterize mean diffusion distances for gold adatoms on the silicon nitride support to show that, while nearest neighbor interactions dominate the role of diffusion in nanoparticle growth, there is a measurable contribution for long range interactions across the system of supported particles. This finding demonstrates how a traditional mean-field kinetic model paired with novel data analysis methods can yield results which could not be obtained by either method alone and motivates further study into new physical models which can describe coarsening and evaporation without relying on mean field assumptions.

Reconstruction of Low-Index Au Surfaces Using Large-Scale Machine Learning Molecular Dynamics with Many-Body Bayesian Force Fields Cameron J. Owen, Lixin Sun, Yu Xie and Boris Kozinsky; Harvard University, United States

Gold surfaces have a long history of microscopic studies due to their propensity to reconstruct in complex patterns depending on the terminating surface facet and the environment (temperatures and atmosphere). However, the details of restructuring processes and metastable intermediate structures, which could be critical for catalytic reactions, remain unknown due to the limits of microscopy time resolution and accuracy of classical force field simulations.

This work demonstrates a robust many-body Bayesian potential trained with an on-the-fly active learning framework implemented using Gaussian process regression in the FLARE code [1]. The active learning module uses molecular dynamics (MD) simulations of low-index surfaces to sample important configurations and runs density functional theory (DFT) calculations when the prediction Bayesian uncertainty exceeds a threshold. The trained Bayesian force field is then used to perform a large-scale MD to study surface diffusion and reconstructions of various surface facets, e.g., semi-hexagonal reconstruction on (100), Herringbone reconstruction on (111), and missing-row reconstruction on (110).

Structure Discovery in Atomic Force Microscopy Adam Foster[1,2]; [1]Aalto University, Finland; [2]Kanazawa University, Japan

Atomic force microscopy (AFM) with molecule-functionalized tips has emerged as the primary experimental technique for probing the atomic structure of organic molecules on surfaces [1]. Most experiments have been limited to nearly planar aromatic molecules, due to difficulties with interpretation of highly distorted AFM images originating from non-planar molecules [2]. Here we develop a deep learning infrastructure that matches a set of AFM images with a unique descriptor characterizing the molecular configuration, allowing us to predict the molecular structure directly in a few seconds on a laptop [3]. We apply this methodology to resolve several distinct adsorption configurations and conformations of molecules based on low-temperature AFM measurements. In general, we find high success rates in predicting the atomic and chemical structure of molecules. This approach opens the door to apply high-resolution AFM to a large variety of systems for which routine atomic and chemical structural resolution on the level of individual objects/molecules would be a major breakthrough. We also look at applications of similar approaches to the imaging of biomaterials and AFM imaging in liquids.

2:00 PM CH04.07.03
Autonomous Identification of X-Ray Diffraction Spectra Using Probabilistic Deep Learning Nathan Szymanski[1,2], Christopher Bartel[1,2], Yan Zeng[2], Qingsong Tu[2] and Gerbrand Ceder[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

To enable the development of self-driving laboratories and their application to the synthesis of inorganic materials, we designed a deep learning approach that automates the analysis of diffraction spectra and identifies chemical reaction products. Using a convolutional neural network, our model was trained on simulated spectra that were augmented with physics-informed perturbations to account for possible experiments artifacts left over from sample preparation and synthesis. These diffraction spectra were derived from experimentally reported phases as well as hypothetical solid solutions with off-stoichiometric compositions. For the analysis of spectra obtained from mixtures of materials, we developed a branching algorithm to evaluate suspected mixtures and identify the set of phases that maximize the probabilities given by the neural network. Our model was tested on simulated and experimental data from materials in a five-component system, achieving accuracies up to 92% and 87% for the identification of single- and multi-phase spectra, respectively. These results show an improvement greater than 10% when compared to previously reported methods based on profile matching and deep learning. To extend the application of our approach to arbitrary sets of materials, we provide a software suite that facilitates the training of new models, which we hope may be used to automate the characterization step in high-throughput and autonomous experimental workflows.

2:15 PM CH04.07.04
High-Fidelity Retrieval of Nanoscale Short-Range Order Distribution in GeSn Alloys Guided by Statistical Methods in Atom Probe Tomography Shang Liu, Alejandra V. Covian, Cory T. Cline and Jifeng Liu; Dartmouth College, United States

GeSn alloys on Si have been an attractive research area given their capability to engineer the bandgap for mid-infrared applications and compatibility with Si-based integrated circuits. Recently, short-range order (SRO) in GeSn alloys has been theoretically predicted [1] especially for >15 at.% Sn composition, which profoundly impacts the band structure of GeSn alloys. In principle, atom probe tomography (APT) is a powerful experimental technique to study SRO (e.g., via radial distribution function, RDF) by offering 3D atomic reconstruction of the alloy. In reality, however, high-fidelity retrieval of lattice information and accurate RDF has been limited to metals [2,3]. Deriving SRO of semiconductors alloys from APT has been a significant challenge due to larger measurement error in atomic positions as well as lower detection efficiency compared to elemental metals. In fact, the APT data of semiconductor alloys resembles a significantly perturbed lattice, and ~50% of the atomic sites are empty due to the limited detection efficiency. Therefore, one can no longer identify the lattice from the raw APT data. Currently, SRO analyses in alloys are limited to relatively crude methods such as artificially cutting a line midway between the theoretical distances of the k th and (k+1) th nearest neighbor shells to accommodate the perturbed atomic positions [4]. To overcome this limit and retrieve SRO at high fidelity, here we demonstrate a new method that only requires the input of crystal structure to derive SRO in GeSn alloys from the nonideal APT data by combining Poisson distribution and k-nearest neighbors (KNN) analysis. This approach establishes a statistical correlation between the nominal KNN directly obtained from the nonideal APT data to the *true* KNN shell for diamond cubic structure, thereby regrouping the former to reconstruct the latter at high fidelity. Lattice constants can also be derived using an iterative approach given the crystal structure. We demonstrate that our method can retrieve lattice constants with ~1.5% accuracy from the APT data of Ge and GeSn alloys. For GeSn alloys, we define SRO parameter $\alpha^{KNN}_{Sn\text{-}Sn}$ as the probability for a Sn atom to have another Sn atom in the *true* KNN shell divided by the Sn at.% in the same region. For example, $\alpha^{KNN}_{Sn\text{-}Sn}>1$ indicates more Sn-Sn clustering than a random alloy. This way, we were able to study nanoscale SRO distribution along the depth of the GeSn thin films. Our study shows that $\alpha^{KNN}_{Sn\text{-}Sn}$ decreases from 1.052±0.051 to 1.026±0.045 as the depth increase from 150 to 800 nm under the surface, with 18 10 nm×10 nm×10 nm blocks examined at each depth. These results indicate more preference towards Sn-Sn clustering near the surface where the Sn composition is higher due to strain relaxation [5]. The discovery of a relatively large fluctuation in SRO in GeSn, together with the theoretical prediction of large band structure variation with SRO, explains why the photoluminescence (PL) peaks are broad even at low T for GeSn (i.e., width $>>k_bT$). Furthermore, we propose an algorism based on least square fit to rearrange atoms to nearby perfect lattice sites, which show a very good consistency with the aforementioned results before rearrangement. A great advantage of APT-based SRO analyses is that we can map the SRO at nanoscale in a relatively large region with millions of atoms (e.g., 30x30x800 nm^3), while other methods either give an average (EXAFS) or only analyze a very small region (STEM). Our method can be extended to other material systems such as high-entropy alloys.

2:30 PM CH04.07.05
Machine-Learning Prediction of Structural Transition Temperature in Multicaloric MTX Alloys with Model Interpretability Analysis Timothy Hartnett[1], Vaibhav Sharma[2], Radhika Barua[2] and Prasanna Balachandran[1,1]; [1]University of Virginia, United States; [2]Virginia Commonwealth University, United States

The global rise of environmental concern has highlighted the need to switch from harmful vapor-compression-based cooling technologies to more friendly options. Solid-state cooling devices based on multicaloric materials are one promising option. Multicaloric materials undergo a reversible thermal change driven by more than one external energy source. One promising multicaloric materials family of interest is the intermetallic MTX compounds.

The MTX materials [where M = transition metal (Mn, Fe, Ni, Co); T = transition metal (Mn, Fe, Ni, Co); X = main group p-block element (Si, Ge, Sn, Al, Ga)] undergo a martensitic phase transition from the low temperature, martensitic Pnma (TiNiSi-type) phase to the high temperature, austenitic $P6_3/mmc$ (Ni_2In-type) phase. Nominally, in the stoichiometric parent compound, MnNiSi, the martensitic phase transition (T_m) occurs at 1200 K. The Pnma phase is

also ferromagnetic and has a Curie temperature (T_c) of 662 K. Through alloying with other transition metals and p-block elements, T_m and T_c can be tuned to coincide resulting in a hysteretic magnetostructural phase transformation that is first-order in thermodynamic character There is significant interest in identifying alloy compositions where the magnetostructural transition temperature (T_t) is observed near room temperature with minimal hysteresis so that devices can be built with maximum cooling efficiency.

Here, we develop a data-driven machine learning (ML) approach to predict the T_t and hysteresis of solid solutions of MTX alloys. We compiled a dataset of experimentally synthesized and characterized MTX solid solutions from surveying the published literature. We represented each composition using three sets of features: (1) compositions, (2) elemental descriptors, and (3) those generated from density functional theory calculations. Four separate ML methods were considered for regression (1 linear, 3 non-linear), and the best method was selected based on test set performance quantified by R^2 goodness-of-fit. The top-performing model was then validated experimentally on new solid solutions.

In addition to prediction, we also implemented a novel post hoc interpretability technique to understand model behavior. Typically, many ML algorithms are treated as black-box models. While ML-based approaches have been demonstrated to optimize materials design and discovery, the lack of model interpretability means that it is very difficult to extract valuable scientific insights from the trained models. To address this problem, we implement a common model interpretability technique, global feature importance, along with less common, local instance-level variable attribution techniques. The results show that the model prioritizes features that are known to impact the T_t in the system. The results of the local analysis also show that the variable attribution varies significantly for different compositions highlighting the limitations of global feature importance.

2:45 PM CH04.07.06
Time-Resolved Phase Formation Studies Inform Machine Learning Algorithms During Autonomous Materials Discovery Aine Connolly, Ming-Chiang Chang, Katie Gann, Maximilian Amsler, Duncan Sutherland, Michael O. Thompson and R. Van Dover; Cornell University, United States

High-throughput experimentation today explores not only compositional space, but also process space. In our work, we use micro- to milli-second thermal processing to synthesize metastable phases in binary and ternary systems, and a combination of optical spectroscopy and synchrotron x-ray diffraction (XRD) to characterize them. However, post-processing analysis constrains understanding to the terminal structures only, without identifying transient structures that may develop during synthesis. The search for autonomous materials using ML and AI algorithms would be enhanced by incorporating time-resolved information regarding the phase evolution alongside the characterization of the final phases.

The unique experimental characteristics of the lateral-gradient Laser Spike Annealing technique allows this temporal structural evolution to be mapped onto a spatial dimension, enabling a wide range of characterization techniques. For initial studies, optical imaging has been used to track the phase formation sequence as a function of both time and temperature during lgLSA in materials such as Bi_2O_3 and Ga_2O_3. In single-composition Bi_2O_3, for example, initial nucleation of the δ phase occurs early during heating with transformation to the β phase also observed during the temperature ramp; in this system, no subsequent transformations have been identified during cooling to ambient conditions. Behaviors across a number of binary systems will also be discussed. Ultimately, these data can be integrated into closed-loop experiments to inform the autonomous search for new materials.

3:00 PM CH04.07.07
Late News: Analytical Methods to Characterize Dynamics of Individual Dislocations with DFXM Leora E. Dresselhaus-Marais; Stanford University, United States

Dislocation boundaries dominate the multiscale structure and properties of metals, setting the complex dynamics that determine how they respond to external stresses or heating. Characterization of these intricate multiscale dynamics is extremely difficult at the single-dislocation level, due to experimental and analytical challenges. Dark-field X-ray microscopy (DFXM) was recently demonstrated to resolve the dynamics of populations of deep subsurface dislocations at the single-dislocation level, but challenges persist in assigning the positions and character. We have developed a suite of computer-vision methods to identify and track dislocations in DFXM movies collected on single-crystal aluminum during annealing. This talk will present our new methods and the opportunities they hold to quantify statistically significant defect dynamics in crystalline materials at the mesoscale.

3:15 PM CH04.03.03
Deep Learning-Based Analysis of Optical and Morphological Properties of Chiral Micron-Scale Helices Anastasiia Visheratina[1], Alexander Visheratin[2], Prashant Kumar[1] and Nicholas Kotov[1]; [1]University of Michigan–Ann Arbor, United States; [2]Beehive AI, United States

Chiral nano- and micron-scale inorganic structures have potential in many technological fields, including biosensing, chiral catalysis, enantioselective separation, and quantum computing. While they have numerous unique physico-chemical properties, their ability to exhibit high chiroptical activity is the key characteristic that spurs research in this area. To date, many researchers are focused on the development of materials with hierarchical chirality since the combination of nano-, meso-, and micron-scale chiral elements in one structure can allow to rotate light polarization in a wide spectral range. However, top-down approaches, such as ion-beam lithography, extensively used for growing such helices, are limited for the fabrication of nanoscale elements and have a low mass production efficiency. Also, there is a need for novel methods for the structural characterization of chiral nano- and micron-scale inorganic structures.
Here we developed a facile bottom-up approach for the formation of microscale helices of bowtie shape. Depending on the enantiomer of chiral molecules used, bowties have a right- or left-handed twist with 100% enantiomeric excess. Transmission electron microscopy of bowties allowed to establish that bowties are self-assembled from nanoparticles with 3.4 nm diameter that are then arranged into stacked twisted nanosheets. The latter have a thickness of about 100 nm and a 50 nm separation between each other. Careful adjustment of synthesis conditions allows growing bowties with desired length, width, thickness, and twist, which, in turn, lead to the strong chiroptical activity that could be carefully tuned in a from UV-Vis to NIR spectral range. Computations of bowties chiroptical activity have shown that the circular dichroism and g-factor spectra blue-shift as the pitch of bowties decreases. Varying synthesis conditions, we synthesized more than 600 different samples and obtained more than 1200 scanning electron microscopy (SEM) images to study their nucleation, growth, and final morphology. Analysis and characterization of SEM images can be significantly improved and fastened by using artificial intelligence approaches. We developed a convolutional neural network model for the recognition of bowties on SEM images and the determination of their handedness (right-handed, left-handed). Our next step is to advance the model and make it able to calculate the enantiomeric excess of bowties and their dimensions.
Also, to predict the optical properties based on the concentrations of chemicals used, we developed a multi-layer fully connected neural network. The approach that was chosen is to model target parameters independently to get better accuracy. The model has four hidden layers with the following number of neurons in each - 400, 2000, 1000, 400. The developed neural network allows to predict bowties parameters (length, width, thickness, and twist angle) and their optical properties (circular dichroism peak wavelength and g-factors) with good accuracy.

We believe that these results open new horizons for designing, characterization, and engineering of chiroptical materials and metamaterials with a strong and tunable polarization rotation essential for multiple emerging technologies.

Low-Uncertainty Condensation Heat Transfer Characterization Using Intelligent Vision Siavash Khodakarami and Nenad Miljkovic; University of Illinois at Urbana-Champaign, United States

Vapor condensation is of great significance to a plethora of applications such as power generation, thermal management, and water desalination. Over the past century, many hydrophobic coatings have been developed to promote dropwise condensation (DWC) on surfaces of interest. DWC on hydrophobic coatings is preferred as it has heat transfer coefficients (HTC) one order of magnitude higher than filmwise condensation (FWC) on an uncoated surface. Quantification of the heat transfer performance during condensation is normally done in vacuum systems to limit the presence of the non-condensable gases (NCG), and to enable high-fidelity temperature measurements for heat transfer quantification. Numerous difficulties exist with these classical techniques mainly related to the high uncertainties in the measured heat flux and calculated HTC when proper experimental conditions are not used. Here, we demonstrate a visualization-based method for rigorous and high-fidelity heat transfer characterization during DWC. State-of-the-art computer vision techniques are used to extract physical features which are used to predict the heat transfer performance of hydrophobic tubes undergoing DWC. We demonstrate the utility of our visual approach by using it to estimate the local axially-varying heat flux on a tube with spatially varying wettability without using any temperature measurement. Unlike classical methods, we demonstrate that our method has a fixed heat flux estimation uncertainty of 13% of the measured value. In contrast, we show that the measurement uncertainty of classical techniques is a function of sensor uncertainty, geometrical parameters such as length and diameter of the sample, and the heat flux itself, and is generally several times higher than the uncertainty associated with our vision-based method. Our visualization-based method does not require high-speed imaging and can be applied with regular 30 FPS imaging. Our computer-vision method demonstrates significant utility for conditions where conventional temperature-based methods fail such as DWC with short or small diameter tubing, experiments with laminar cooling flows, small heat flux condensation, or obtaining local heat flux measurements.

8:15 AM CH04.08.02
Towards Automation of Particle Size Distribution Analysis of Catalyst Layers for Polymer Electrolyte Fuel Cells André Colliard Granero[1,2], Mohammad Javad Eslamibidgoli[1], Mariah Batool[3], Jasna Jankovic[3], Michael Eikerling[1] and Kourosh Malek[1]; [1]Forschungszentrum Jülich, Germany; [2]University of Cologne, Germany; [3]The University of British Columbia, Canada

Accelerating the development of electrochemical devices is pivotal for the societal shift towards a sustainable and de-fossilized energy economy. Imaging is crucial to quantify structural characteristics of materials, as well as to detect and monitor structural changes during fabrication and normal operating cycles of the device (battery, fuel cell, electrolysis cell). The escalating use of imaging infrastructure in the energy materials domain drives a significant growth of data in terms of their amount and complexity. This leaves the applications of standard machinery for image processing often ad hoc, indiscriminate, and empirical which in turn makes the quantification metrics for analysis elusive. Moreover, the use of standard techniques for materials characterization is expensive, slow and often involves several pre-processing steps. In this contribution, we present a deep learning-based approach to automate the analysis of particle size distribution (PSD) from Transmission Electron micrographs (TEM) of carbon supported catalyst electrodes for Polymer Electrolyte Membrane (PEM) Fuel Cells or PEM electorlyzers. The catalyst layer components are fabricated based on catalyst nanoparticles (e.g. Pt) on a high-surface-area carbon support material. The automation was enabled via a multi-step approach based on supervised learning, by 1. manual annotation of TEM images [1], 2. training a U-Net model for instance segmentation [2] of catalyst nanoparticles, followed by 3. employing computer vision techniques for the diameter measurement of individual particles and 4. generating particle size distribution plots. Results on the validation set are in well agreement with PSD analysis by our experimental experts, presenting an efficient use case of ML-enabled materials characterization.

A Statistical Study of Corrosion Dynamics in Atomically-Thin Nanomaterials Utilising *In Situ* SEM Ryo Mizuta[1], Ye Fan[1], Peter Voorhees[2] and Stephan Hofmann[1]; [1]University of Cambridge, United Kingdom; [2]Northwestern University, United States

The ‘lifetime’ of materials is a central topic in the field of corrosion science and is a crucial consideration for any real-world use of emerging materials. Recent years have witnessed a surge in the development of low-dimensional nanomaterials (e.g. 2D materials) towards commercial applications, driven by discoveries of novel, record-breaking material properties. However, systematic studies on their ageing dynamics are comparatively rare and the fundamental processes that dictate their lifetime remain poorly understood [1].
Meanwhile, statistical variations are expected to significantly impact dynamic processes at the nanoscale, including ageing. Despite this, the collection of sufficiently large datasets that permit their statistical analysis remains challenging and is commonly not emphasised when studying the properties of low dimensional nanomaterials. Recent reports which combine high-throughput image processing workflows with large electron microscopy datasets of “static” nanomaterials, illustrate a promising approach for rapidly extracting quantitative datasets of statistically relevant sizes [2,3]. However, such methods have rarely been extended to studies of nanoscale dynamics, given the lack of suitable characterisation platforms that can probe nanomaterials *in-situ*, under realistic working conditions.
Here, we combine a custom *in-situ* environmental scanning electron microscope (ESEM), equipped with localised gas injection and heating capabilities, with automated image analysis to observe and collect statistically large datasets that quantify nanoscale dynamics. The formation of corrosion pits during the thermal oxidation of atomically-thin 2D materials is selected as a prototype system to demonstrate the capabilities of our workflow. By leveraging the ESEM’s large field of view and our high-throughput experimental design, the expansion dynamics of $10^3 – 10^4$ corrosion pits are tracked and quantified simultaneously in each experiment. Our statistically relevant datasets of pit formation permit conventional corrosion theories to be statistically tested in the 2D limit. The collection and analysis of gigabyte to terabyte levels of kinetic data are semi-automated, with heavy reliance on developing suitable computer image recognition algorithms. Our research paradigm, in which the statistical analysis of large in-situ experimental data is emphasized, promises a more repeatable and reliable experimental analysis of nanoscale processes.

Deep Learning for On-the-Fly Visualization of Large Datasets and Out-of-Distribution Data Detection Lars Banko[1], Phillip M. Maffettone[2], Daniel Olds[2] and Alfred Ludwig[1]; [1]Ruhr-Universität Bochum, Germany; [2]Brookhaven National Laboratory, United States

Artificial intelligence agents offer great opportunities for accelerating materials discovery by autonomous data analysis. With advanced methods of high-throughput experimentation producing increasingly larger datasets, autonomous analysis and decision making by AI is required in collaboration with the deep reasoning provided by expert scientists. While AI should be focused on autonomously analyzing the standard cases, expert scientist resources should be centered around the most interesting or challenging tasks. A persistent issue of AI models is associated with drawing conclusions from uncertain settings, e.g. when the information stored in the data does not allow for a definite decision or the training data does not support aberrations encountered in experimental data.

In this contribution, we demonstrate that variational autoencoders (VAE) provide a powerful toolset for the analysis of large X-ray diffraction datasets. Visualization of the latent vectors can reveal intrinsic features of the dataset that allow for an assessment of possible failures modes during a classification task. The representation can further be used for on-the-fly visualization of a dataset distribution across different structures. Here, latent space proximity can be used as a structural estimator. A strategy based on the evaluation of the reconstruction error and the clustering of latent variables for the detection of out-of-distribution data is reported and demonstrated on experimental data. By inclusion of experiment specific domain knowledge (e.g. chemical composition) the model can be tuned to produce valid solutions under awareness of constraints. Transferability to other experimental sources of spectral data is demonstrated. We envision the VAE working cooperatively together in a federation of specialized AI agents.

9:00 AM CH04.08.05
Decoding the Shift-Invariant Data—Applications for Band-Excitation Scanning Probe Microscopy Yongtao Liu[1], Rama K. Vasudevan[1], Kyle P. Kelley[1], Dohyung Kim[2], Yogesh Sharma[3], Mahshid Ahmadi[2], Sergei V. Kalinin[1] and Maxim A. Ziatdinov[1,1]; [1]Oak Ridge National Laboratory, United States; [2]The University of Tennessee, Knoxville, United States; [3]Los Alamos National Laboratory, United States

In this work, we introduced a shift-invariant variational autoencoder (shift-VAE), which is an unsupervised method developed for analyzing 1D spectra data disentangling the physically-relevant shifts from other latent variables. Using synthetic datasets, we show that the shift-VAE latent variables are linear functions of the ground truth parameters, indicating the strength of shift-VAE in disentangling physically-relevant variables in a model-free unsupervised manner. The application of shift-VAE is illustrated for band-excitation piezoresponse force microscopy (BE-PFM) data. From two BE-PFM data sets, we consistently observed that shift-VAE successfully disentangles ferroelectric polarization and crosstalk-induced resonance frequency peak shift from BE curves. In addition, shift-VAE also shows the strength in denoising raw curves without sacrificing real response. Overall, shift-VAE proves to be a powerful technique for learning spectra, which should have very broad applications in many fields. This approach can also be extended to analysis of X-ray diffraction, photoluminescence, Raman spectra, and other data sets.

Late News: Machine Learning Assisted Identification of Threading Dislocations Bohdan J. Starosta and Benjamin Hourahine; University of Strathclyde, United Kingdom

Electron channeling contrast imaging (ECCI) is a non-destructive scanning electron microscope (SEM) surface imaging technique that is sensitive to distortion of planes in crystal lattices. It detects the diffraction intensity of electrons incident on a sample, where the angles between detector, sample normal, and the SEM electron beam, are carefully chosen so that the orientation of diffracting planes with respect to the incident electron beam is approaching their Bragg angle, creating strong contrast in the image. Local lattice strain induced deviations to the crystallographic orientation or lattice constant will then affect the intensity of the back scattered electrons, and produce a variation in contrast in the resulting surface image that indicates the presence of a defect. These images are over a relatively wide area (~100 μm^2), with a spatial resolution of ~20 nm, and allow us to detect and classify threading dislocations, grain boundaries, and other defects at semiconductor surfaces [1].

Of particular interest is the ability to conduct a quantitative analysis of threading dislocations (TDs) present in a GaN thin film, which manifest an ECC image as spots with a dipolar black-white (B-W) contrast. One obstacle to this is the need for the painstaking marking and manual analysis of each individual experimental image by a skilled researcher. Bulk epitaxial GaN thin films often have TD area densities of 10^8 to 10^9 cm^{-2} [2], adding to the scale of the problem. This creates a need for a fast, automated, and relatively accurate method of extracting defect data from multiple images.

Supervised machine learning techniques have been proven in recent years to be able to achieve a high degree of success in detecting predetermined features, particularly in the medical imaging field [3]. We have utilized previously documented techniques for quickly identifying TDs on III-Nitrides [1,4] to build a training dataset for a U-Net based deep fully convolutional network architecture [5,6]. This includes images of defects both with a strong B-W contrast as well as dislocations at close to the invisibility criteria which are faintly resolved.

The neural network that is trained on this set can then relatively reliably detect the positions of TDs in ECCI of GaN with an accuracy on the order of 75-90% for independent testing data (i.e. marked images unseen by the network during training), with the main source of errors being false positives due to strong non-TD features, and false negatives due to either TD faintness at certain diffraction conditions, or overlapping, closely spaced TDs affecting the predictive binary mask. The recognition process for a 2576×1936px image currently takes around 90 seconds when using a modern 8-core consumer grade CPU. For our current dataset size the network can be trained to convergence in 30±10 minutes when using a single NVIDIA V100 GPU. Fig. 1 shows the marked locations for a cluster of dislocations in GaN.

A Physics-Based Model to Index Crystal Orientation Using Directional Reflectance Microscopy Chenyang Zhu and Matteo Seita; Nanyang Technological University, Singapore

Characterizing crystallographic quantities in crystalline materials—including crystal structure, grain orientation, and defects character—is the realm of diffraction-based techniques. We have developed a simple and affordable method—which we call directional reflectance microscopy (DRM)—to capture this information using an optical microscope. DRM relies on producing orientation-dependent features on the surface of crystalline solids and measuring the reflectance they generate when illuminated from different angles. Point-by-point indexing of optical reflectance across the sample surface enables mapping the underlying crystallographic orientation in a similar fashion to electron backscatter diffraction. Here we discuss the advantages of indexing the optical signal using a forward model approach. Our method consists of producing a dictionary of reflectance patterns generated by a discrete sampling of orientation space using a physics-based reflection model. We then compare these simulated patterns with the experimental one to find the best match, which is selected as the nominal orientation. This dictionary indexing method overcomes limitations that are inherent to previous approaches, which relied on fitting good quality patterns. We demonstrate the improved accuracy of the forward-model method on a centimeter-scale aluminum sample.

Late News: Machine Learning for Optimization of Optical Super-Resolution Microstructure Analysis Alex Ulyanenkov[1], Alexander Mikhalychev[2,3], Konstantin Zhevno[2], Svetlana Vlasenko[3] and Dmitri Mogilevtsev[3]; [1]Atomicus LLC, United States; [2]Atomicus OOO, Belarus; [3]B.I.Stepanov Institute of Physics, NAS of Belarus, Belarus

Optical methods are appealing for application to microstructure analysis due to their simplicity, direct observation of details, and availability of versatile elemental base. However, diffraction of light blurs the collected images and sets the fundamental limit on the achievable resolution [1]. Recently, a number of super-resolving techniques based on nano-particles fluorescence were developed for overcoming the classical resolution limit, for instance stimulated-emission depletion (STED) microscopy [2], photoactivated localization microscopy (PALM) [3], and structured illumination microscopy (SIM) [4]. Super-resolution optical fluctuation imaging (SOFI) is also among promising quantum-inspired techniques [5]. The resolution enhancement in SOFI stems from special statistical analysis of the intensity correlations of randomly fluctuating fluorescent sources: quantum dots [5], organic dyes [6], or other fluorescent particles. Namely, a cumulant image is formed instead of usual intensity images and provides a narrower point-spread function (weaker blurring of the image). The approach is applicable for both investigation of inorganic samples and imaging of living cells and subcellular structures.

Initially, SOFI was believed to provide infinite growth of resolution with the increase of cumulants order. Recently, it has been shown that the inevitable statistical noise imposes fundamental limits on the achievable resolution; the optimal cumulant order is finite (and depends on the imaged object); and combined analysis of several cumulant orders may be profitable [7,8]. The research was based on maximization of Fisher information and included some simplifying limitations: either just two point emitters were considered [8], or the statistical switching noise of the fluorescent sources themselves was neglected [7]. In the current contribution, we follow that line of Fisher information-based research, but consider a general case of several emitters, finite observation time, and realistic fluctuations model.

A measurement in SOFI is fast and provides an image with a large number of pixels (up to 1 million). To benefit from those advantages of the technique (especially, when fast living-cell processes are analyzed), one needs to be able to perform fast on-the-fly processing of the acquired data. For that reason, it is desirable to know and process the optimal cumulant order soon after the dataset is collected. While Fisher information approach is much faster and more reliable than direct Monte-Carlo simulations, it is still computationally expensive for taking such real-time decisions. Here, we show that machine learning is capable of solving that issue. An artificial neural network (a 5-layer perceptron) takes an intensity image of the object (easily generated from a SOFI dataset) as an input and decides, which cumulant order or combination of cumulant orders would yield the maximal information gain for the same computational resources. The training datasets are prepared with the help of Fisher information approach. The preliminary results show that the probability of taking the correct decision among 4 options with approximately equal probabilities exceeds 80%. The proposed tandem approach of Fisher information and machine learning is universal and applicable to many other techniques for optimization of on-the-fly analysis or taking real-time decisions which measurement to perform next.

Twinning Network Graph Analysis on Ingot-Scale Multicrystalline Structure Takuto Kojima[1], Kentaro Kutsukake[2], Tetsuya Matsumoto[1], Hiroaki Kudo[1] and Noritaka Usami[1]; [1]Nagoya University, Japan; [2]RIKEN, Japan

Multicrystalline materials can be relatively easily fabricated with a large crystal growth furnace leading to cost-effective yield, whereas non-uniformity of

crystal properties is a problem for large ingots. Therefore, it is important to extract the ingot-scaled features of the multicrystalline structure. The multicrystalline structure grown by the unidirectional solidification method develops from the nucleus at the bottom of the crucible into a columnar structure, and successive twinning inside the columnar structure causes various grain boundaries. The orientation relationship between the individual nuclei is random, while the orientation relationship due to twinning is crystallographically determined, which consequently contains information about the grain development relationship. We have developed a method to analyze multicrystalline structures using network graphs where edges represent successive twinning from crystal orientations of grains in 30×40 mm^2 multicrystalline silicon, obtained by electron backscatter diffraction pattern (EBSD) method [1-3]. In this study, we attempted to extract ingot-scaled features of multicrystalline structures by performing network analysis on crystal orientations obtained by the Laue scanner method [4] on 156×156 mm^2 substrates sliced from the bottom, middle, and top parts of a multicrystalline silicon ingot. The network analysis was performed by coding with a Python package NetworkX [5].
The crystal orientations of 1918, 1490, and 1390 grains (at the center of gravity of each grain) were obtained from the bottom, center, and top of the ingot, respectively. The orientation relationship between grains was attributed to an nth-order ($0 \leq n \leq 3$) twinning relationship ($\Sigma 3^n$) that gives the minimum residual angle θ. A graph G was generated with edges for the twinning relation satisfying $\theta/\theta_{th}+d/d_{th} \leq 1$, where $\theta_{th}=2°$ and $d_{th}=40$ mm were thresholds for θ and the distance d between grains. Connected subgraphs contained four or more nodes were plotted on the grain boundary mapping extracted from the optical image, where grains in the same subgraph are considered to have grown from the same nucleus. As the crystal growth proceeded, the number of nodes in a subgraph and the area occupied by a subgraph with a large number of nodes also tended to increase. The analysis using network graphs made it possible to extract ingot-scaled features of multicrystalline structures.

Quasi-Continuous Representation of Crystal Structure of Thin Films with Two-Dimensional X-Ray Diffraction and Non-Negative Matrix Factorization Akihiro Yamashita[1,2], Takahiro Nagata[2], Shinjiro Yagyu[2], Toru Asahi[1] and Toyohiro Chikyow[2]; [1]Waseda University, Japan; [2]National Institute for Materials Science, Japan

Materials informatics (MI) is a data-driven approach to discover novel materials. In this approach, structure information such as crystal structure is one of important information because it has strong relationship to inorganic materials' properties. In conventional MI approaches, crystal structure is often represented in form of a categorical variable of corresponding space group, but this limits applicable machine learning (ML) methods compared to a continuous variable. Therefore, other representations of structure, such as crystal graph [1], have been proposed to convert structure information into quasi-continuous variable. To apply this kind of methods, crystal structure must be known, this means that structure of sample is analyzed by experts in advance. However, this is time-consuming and will be bottleneck in data-driven materials discovery.
We propose to use ML results of direct application to measurement data as crystal structure representations instead of experts-analyzed data. To proof our concept, we used non-negative matrix factorization (NMF) [2]. NMF approximates non-negative matrix V, a set of measurement data, with multiplication of two non-negative matrices W and H. This method is already studied with one-dimensional X-ray diffraction (1D-XRD) patterns from single composition spread [3]. We studied under more practical situation: we used 2D-XRD patterns from multiple samples with variety in substrate types and fabrication conditions. 2D-XRD is convenient in thin film research compared for 1D-XRD because it includes reflections from various out of planes.
2D-XRD patterns of In-Ga-O thin films were studied. We first analyzed NMF results in terms of generative model to confirm that NMF converts 2D-XRD patterns into variables which follows a continuous probability distribution. NMF results can be recognized that W is a set of factor vectors and H is that of feature vectors. The feature vectors were evaluated whether they represent propensities in original 2D-XRD patterns. We also compared results of samples fabricated by pulsed laser decomposition and those by sputtering. The detail will be discussed in the presentation.

Active Learning of Reactive Bayesian Force Fields—Application to Heterogeneous Catalysis Dynamics of H/Pt Jonathan Vandermause, Yu Xie, Jin Soo Lim, Cameron J. Owen and Boris Kozinsky; Harvard University, United States

Atomistic modeling of chemically reactive systems has traditionally relied on either expensive ab initio methods or bond-order force fields requiring arduous parametrization. Here, we introduce FLARE++, a Bayesian active learning method for training reactive many-body force fields "on the fly" during molecular dynamics (MD) simulations. At each timestep, the predictive uncertainties of a sparse Gaussian process (SGP) are evaluated to automatically determine whether additional ab initio data are needed. The resulting SGP is mapped onto a polynomial model whose prediction cost is independent of the training set size. Using this method, we perform large-scale MD simulations of a prototypical system in heterogeneous catalysis---H2 chemisorption on Pt(111)---at chemical accuracy. The model, trained within three days of wall time, performs at twice the simulation speed of an available ReaxFF model while maintaining ab initio accuracy to a much higher fidelity. Our method enables efficient automated training of fast and accurate reactive force fields for

chemically complex systems.

1:15 PM CH04.10.03
Bayesian Inverse Design of High-Strength Aluminum Alloys at High Temperatures Shimpei Takemoto[1], Takeshi Kaneshita[1], Kenji Nagata[2], Yoshishige Okuno[1], Junya Inoue[3] and Manabu Enoki[3]; [1]Showa Denko K.K., Japan; [2]National Institute for Materials Science, Japan; [3]The University of Tokyo, Japan

2000 series aluminum alloys or Al-Cu-Mg series are high-strength alloys, but it is known that their strength decreases rapidly at high temperatures above 150°C. Therefore, improving the strength at high temperatures is essential for industrial applications, especially automotive and aircraft applications. In this study, we perform a Bayesian inverse design of high-strength aluminum alloys at high temperatures.
We build a neural network to predict mechanical properties from process parameters, including additive elements and heat treatment. By choosing the appropriate activation function and features, neural networks show high prediction accuracy even at high temperatures. Specifically, we show that the hyperbolic tangent or sigmoidal activation functions well reproduce the rapid decrease in strength of aluminum alloys at high temperatures. We also show that by treating the holding temperature and holding time as input nodes in the neural network, we can predict mechanical properties measured at various temperatures. The neural network constructed with this approach can even perform extrapolation prediction, learning the mechanical properties at lower temperatures and predicting at higher temperatures.
In this study, Bayesian inference of neural network parameters is performed using the replica-exchange Monte Carlo method, an extended Markov chain Monte Carlo (MCMC) method. This approach allows us to evaluate the probability distribution and uncertainty of mechanical property predictions. By maximizing the probability of satisfying the desired properties, we explore combinations of process parameters for designing high-strength aluminum alloys at high temperatures.
The thermodynamic calculations are also performed using the Thermo-Calc software to analyze the strengthening mechanism of the alloy designs proposed by the neural network. We investigate how a fine grain structure caused by the Mn addition and the competition between the Al-Cu, Al-Cu-Mg, and Mg-Si compounds formation affect the alloy strength.

1:30 PM CH04.10.04
Incorporating Physical Priors Into Probabilistic Models in Bayesian Framework Ayana Ghosh, Sergei V. Kalinin and Maxim A. Ziatdinov; Oak Ridge National Laboratory, United States

Progress in any scientific research area in physical and life sciences is primarily driven by assessments produced by numerous experimental and simulation-based techniques. Computational approaches ranging from lattice models and molecular dynamics to advanced density functional theory and quantum Monte Carlo methods provides a wealth of information on electronic, magnetic, thermodynamics properties, phase transitions of materials, to name a few. Electron and scanning probe microscopies and neutron and X-ray scattering methods provide huge volumes of structural and functional data leading to fundamental insights into structural properties and high-temperature superconductivity, visualization of the light elements, and many others. Both theoretical and experimental aspects of research require search over broad parameter spaces to discover optimal experimental conditions, regions of interest in the image space, or parameter space of computational models. The direct grid search of the parameter space tends to be exceedingly time consuming, leading towards advancing strategies to balance between exploration of unknown parameter spaces and exploitation towards required performance metrics. The classical approach for this is Gaussian process (GP)-based Bayesian optimization (BO).
However, classical BO strategies do not readily allow for the incorporation of the known physical behaviors or past knowledge.
Here, we explore hybrid approaches combining unstructured (non-parametric) and structured (semi-parametric and parametric) BO approaches. The former utilizes Gaussian process (GP) as the surrogate model while the latter one uses GP augmented with a probabilistic model of the system's physical behavior based on partially known analytical, hierarchical, or numerical models. Hence, this approach seeks to guide the exploration of parameter space when refining the physical understandings describing functional behavior over this space and using combined aleatoric and estimated epistemic uncertainty to guide the exploration. This approach is demonstrated for Ising model followed by looking at magnetism in 2D materials. We further discuss extending this capability towards perform automated experiment in the context of automated materials synthesis, scanning probe microscopy, and electron microscopy by injecting prior knowledge in the form of physical models and past data in this BO framework.

This effort (machine learning) is based upon work supported by the U.S. Department of Energy (DOE), Office of Science, Office of Basic Energy Sciences Data, Artificial Intelligence and Machine Learning at DOE Scientific User Facilities (A.G., S.V.K.) and was also supported (STEM experiment) by the DOE, Office of Science, Basic Energy Sciences (BES), Materials Sciences and Engineering Division (O.D.), and was performed and partially supported (M.Z.) at the Oak Ridge National Laboratory's Center for Nanophase Materials Sciences (CNMS), a
DOE Office of Science User Facility.

1:45 PM CH04.10.05
Physics-Informed CoKriging Model of a Redox Flow Battery Amanda Howard[1], Alexandre Tartakovsky[1,2] and Panagiotis Stinis[1]; [1]Pacific Northwest National Laboratory, United States; [2]University of Illinois at Urbana-Champaign, United States

Redox flow batteries (RFBs) offer the capability to store large amounts of energy cheaply and efficiently, however, there is a need for fast and accurate models of the charge-discharge curve of a RFB to potentially improve the battery capacity and performance. We develop a multifidelity model for predicting the charge-discharge curve of a RFB. In the multifidelity model, we use the Physics-informed CoKriging (CoPhIK) machine learning method trained on experimental data and constrained by the so-called ``zero-dimensional" physics-based model. In this talk, we demonstrate that the CoPhIK model shows good agreement with experimental results and significant improvements over existing zero-dimensional models. We show that the proposed model is robust as it is not sensitive to the input parameters in the zero-dimensional model. We also show that only a small amount of high-fidelity experimental datasets are needed for accurate predictions for the range of considered input parameters, which include current density, flow rate, and initial concentrations.

2:00 PM CH04.10.06
A Facile Method to Extract a Constitutive Relation for Granular Materials Using Bayesian Optimization-Based Analysis Kyuho Jang and In-Suk Choi; Seoul National University, Korea (the Republic of)

Granular materials are widely used in various fields such as sintering process, tablet manufacturing, and geotechnical engineering. To predict its constitutive behavior in the finite element method (FEM), the modified Drucker-Prager/Cap model (DPC model) is commonly adopted. However, the conventional method requires multiple triaxial compression experiments and even heuristic approaches to determine a great number of parameters in the DPC model. In this study, we propose an alternative method for the DPC model that utilizes the entire stress-strain curves from triaxial compression testing and the Bayesian optimization algorithm to extract the parameters. The method was applied to acquire the constitutive relation of FE simulation for unsaturated sand-bentonite mixtures which successfully predicted experimental depth-sensing indentation results. Since our method dramatically reduces

the number of experiments and even eliminates heuristic determination of some parameters, we believe that it will facilitate efficient exploration of the mechanical behavior of granular materials.

8:00 AM CH04.11.01
Identifying the Activity Origin of a Cobalt Single-Atom Catalyst for Hydrogen Evolution Using Supervised Learning Xinghui Liu; Department of Chemistry, Sungkyunkwan University (SKKU), 2066 Seoburo, Jangan-Gu, Suwon 16419, Republic of Korea., Korea (the Republic of)

Single-atom catalysts (SACs) have become the forefront of energy conversion studies, but unfortunately, the origin of their activity and the interpretation of the synchrotron spectrograms of these materials remain ambiguous. Here, systematic density functional theory computations reveal that the edge sites—zigzag and armchair—are responsible for the activity of the graphene-based Co (cobalt) SACs toward hydrogen evolution reaction (HER). Then, edge-rich (E)-Co single atoms (SAs) were rationally synthesized guided by theoretical results. Supervised learning techniques are applied to interpret the measured synchrotron spectrum of E-Co SAs. The obtained local environments of Co SAs, 65.49% of Co-4N-plane, 13.64% in Co-2N-armchair, and 20.86% in Co-2N-zigzag, are consistent with Athena fitting. Remarkably, E-Co SAs show even better HER electrocatalytic performance than commercial Pt/C at high current density. Using the joint effort of theoretical modeling, thorough characterization of the catalysts aided by supervised learning, and catalytic performance evaluations, this study not only uncovers the activity origin of Co SACs for HER but also lays the cornerstone for the rational design and structural analysis of nanocatalysts.

8:15 AM CH04.11.02
ALIGNN—Atomistic Line Graph Neural Network for Improved Materials Property Predictions Kamal Choudhary and Brian L. DeCost; National Institute of Standards and Technology, United States

Graph neural networks (GNN) have been shown to provide much improved performance for representing and modeling atomistic materials compared with descriptor-based machine-learning models. While most existing GNN models for atomistic predictions are based on atomic distance information, they do not explicitly incorporate bond angles, which are critical for distinguishing many atomic structures. Furthermore, many material properties are known to be sensitive to slight changes in bond angles. We develop Atomistic Line Graph Neural Network (ALIGNN) using a GNN architecture that performs message passing on both the interatomic bond graph and its line graph corresponding to bond angles. We demonstrate that angle information can be explicitly and efficiently included for materials to provide much improved performance. We train 44 models for predicting several solid-state material properties available in the JARVIS-DFT and materials-project databases. ALIGNN can outperform some of the previously known GNN models by up to 43.8 %.

8:30 AM CH04.11.03
Late News: Predicting the Heat Storage Properties of Salt Hydrates Using Density Functional Theory and Machine Learning Steven G. Kiyabu[1] and Donald Siegel[2]; [1]University of Michigan, United States; [2]The University of Texas at Austin, United States

Salt hydrates demonstrate promise as heat storage materials as they possess high energy densities and reversibility at moderate temperatures. Despite their promise, a great number of salt hydrate compositions have not been explored. The goal of this work is to identify new salt hydrates that can outperform known materials in terms of energy density and are predicted to be thermodynamically stable. Around ten thousand hypothetical salt hydrates were generated by substituting cations and anions into salt hydrate crystal structures mined from the Inorganic Crystal Structure Database. These hypothetical hydrates were characterized according to their enthalpy of dehydration (from which stability, energy density, and heat-storing temperature are derived) using high-throughput density functional theory calculations. Machine learning models were then trained on this large dataset. Many different compositional and structural feature sets from the Matminer library were attempted, as well as several different machine learning algorithms, such as random forests, support vector machines, and neural networks. Several models were highlighted, either for their ability to predict the heat storage characteristics of other hypothetical salt hydrates or their identification of property-performance relationships in salt hydrates. In addition to this, several promising hypothetical hydrates were identified with higher energy densities than experimentally-known salt hydrates.

8:45 AM CH04.11.04
Uranium Compounds with High Thermal Conductivity Proposed by Machine Learning Meigyoku Kin[1], Masaya Kumagai[1,2,3], Yuji Ohishi[4] and Ken Kurosaki[1,5]; [1]Kyoto University, Japan; [2]SAKURA internet Inc., Japan; [3]RIKEN, Japan; [4]Osaka University, Japan; [5]University of Fukui, Japan

In recent years, materials informatics (MI), which is a fusion of materials science and information science, has been attracting attention. Although MI is becoming a mainstream research field such as magnetic materials and thermoelectric materials, there are few reports on MI in materials research in nuclear fields. In this study, we propose a method to comprehensively explore uranium compounds with high thermal conductivity by using machine learning in order to apply MI to nuclear fuel development in the nuclear field.
We constructed a machine learning model using Starrydata, a database of experimental properties developed by our research group. The features were designed using the basic physical properties based on chemical composition, and the target variable is thermal conductivity. The model was trained using Random Forest, and the prediction accuracy of 93% was obtained. Using the trained machine learning model, the thermal conductivity of uranium compounds that could exist in the world was comprehensively predicted. Based on the predicted thermal conductivities, 20 uranium compounds were extracted from the top and bottom of the list, respectively. Uranium compounds experimentally synthesizable are going to be synthesize, and the relevance of the machine learning model is going to evaluate by comparing the measured values with the predicted values. Based on the evaluation, we are going to propose a new uranium compound with high thermal conductivity.

9:00 AM CH04.11.06
Reinforcement Learning in Materials Science—Atomic Fabrication and Materials Design in Simulated Environments Rama K. Vasudevan, Ayana Ghosh, Erick Orozco, Maxim A. Ziatdinov and Sergei V. Kalinin; Oak Ridge National Laboratory, United States

Although by now machine learning is commonplace within virtually all sectors of materials science, the use of reinforcement learning (RL) agents is only now gaining traction. This is partly because of the extensive compute requirements for RL, and the paucity of scalable algorithms. Recent advances in the field have enabled the training of agents to tackle previously difficult challenges in fields such as online gameplay and board games, but their application to the physical sciences has been very limited. Here, we explored the use of RL agents for two particular tasks: one of atomic fabrication by an electron beam, and another of design of ferroelectric materials by defect engineering.

For both situations, we created a virtual environment in which the RL agent can interact and learn by trial and error, and designed reward functions to achieve specific gains. We then trained agents using both policy gradient and implicit (Q learning) methods, in a model-free setting. For the atomic fabrication case, we employed an environment utilizing molecular dynamics simulations, and trained agents to move multiple Si dopants towards each other on a graphene lattice by specifying quantities of momentum transfer at different steps during the episode. For the second case, we explored RL agents for moving and manipulating defects in a ferroelectric sample, simulated via a discrete Landau model, to affect the type and quantity of topological defects generated. We argue that not only are these agents capable of discovering policies that are novel, but also that the policies encode important information regarding the dynamics of the system, and thus inspection of policies can be an important source of physics knowledge discovery. This work was conducted at and supported by the Center for Nanophase Materials Sciences, a US DOE Office of Science User Facility.

9:15 AM CH04.11.07
Molecularly Resolved Segmentation of Non-Fullerene Acceptor Bulk Heterojunction—Lessons from Manifold Learning and Ensemble Clustering Jochen A. Kammerer[1,2], Wolfgang Köntges[1], Pavlo Perkhun[3], Christin Videlot-Ackermann[3], Jörg Ackermann[3], Rasmus R. Schröder[1] and Martin Pfannmöller[1]; [1]Heidelberg University, Germany; [2]Karlsruhe Institute of Technology, Germany; [3]Aix-Marseille Université, France

High performing devices often rely on multiphase nanostructures with complex interfacial effects. Transmission electron microscopy (TEM) has proven indispensable to understand these effects and reveal the structure-property-relationship of these devices. One example are bulk heterojunctions (BHJs) for organic solar cells, where the excitons are split at the interface between donor and acceptor domains.[1] A precise segmentation of the donor and acceptor domains is crucial for understanding the process of charge separation. However, low contrast between chemically similar donor and acceptor materials makes classical imaging challenging and does not allow for molecular resolution at the interface. The combination of low loss energy loss signal based hyperspectral imaging and machine learning has proven to efficiently overcome this challenge.[2] However, the spectral difference for modern non-fullerene acceptor (NFA) systems is weak.[3] Thus, the segmentation becomes obscured by experimental influences (such as noise, signal delocalization, multiple scattering and non-isochromaticity of the imaging tool). More sophisticated approaches are needed to obtain molecular resolution for non-fullerene acceptor BHJs.
Unsupervised segmentation and spectral unmixing of the hyperspectral datasets are typically approached by linear dimensionality reduction alone — e.g. principal component analysis (PCA), independent component analysis (ICA) and non-negative matrix factorization (NMF)—, by clustering algorithms alone, or the combination of both.[4,5] For the latter, the influence of linear dimensionality reduction on the cluster result is not clear, especially in the context of the given experimental influences. Furthermore, unequally performing cluster algorithms introduce non-negligible uncertainties.
We use an ensemble clustering approach to obtain a more robust unsupervised segmentation of hyperspectral low loss TEM datasets. Furthermore, we systematically investigate experimental influences as well as the effects of linear and nonlinear dimensionality reduction on the clustering results. Nonlinear dimensionality reduction (manifold learning) improves the tolerance to experimental restrictions from multiple scattering and non-isochromaticity. The combination of the manifold learning algorithm UMAP[6] and ensemble clustering enables segmentations with an unrivaled tolerance against noise.
We applied this combination of manifold learning and ensemble clustering to hyperspectral images in the TEM low loss regime from PBDB-T:ITIC non-fullerene acceptor BHJs. Segmentations at molecular resolution allowed us to exclude a mixed materials phase at the NFA donor acceptor interface. This contrasts with their fullerene acceptor predecessors and sheds new light on the charge separation in modern BHJs. The combination of TEM based hyperspectral imaging and the machine learning workflow with UMAP and ensemble clustering can be applied to other low contrast material combinations. The machine learning workflow itself is unsupervised, fully automated[7] and has already been successfully applied to non-TEM hyperspectral datasets.

Late News: Accessing Negative Poisson`s Ratio of Graphene by Machine Learning Interatomic Potentials Jing Wu[1], E Zhou[1], Zhenzhen Qin[2], Xiaoliang Zhang[3] and Guangzhao Qin[1]; [1]Hunan University, China; [2]Zhengzhou University, China; [3]Dalian, China

The negative Poisson's ratio (NPR) is a novel property of materials, which enhances the mechanical feature and creates a wide range of application prospects in lots of fields, such as aerospace, electronics, medicine, etc. Fundamental understanding on the mechanism underlying NPR plays an important role in designing advanced mechanical functional materials. However, with different methods used, the origin of NPR is found different and conflicting with each other, for instance, in the representative graphene. In this study, based on machine learning technique, we constructed a moment tensor potential (MTP) for molecular dynamics (MD) simulations of graphene. By analyzing the evolution of key geometries, the increase of bond angle is found to be responsible for the NPR of graphene instead of bond length. The results on the origin of NPR are well consistent with the start-of-art first-principles, which amend the results from MD simulations using classic empirical potentials. Our study facilitates the understanding on the origin of NPR of graphene and paves the way to improve the accuracy of MD simulations being comparable to first-principle calculations. Our study would also promote the applications of machine learning interatomic potentials in multiscale simulations of functional materials.

To Mix or not to Mix? Settling the Matter of the Role of Vibrations in the Stability of High-Entropy Carbides Stefano Curtarolo; Duke University, United States

Disordered multicomponent systems occupying the mostly uncharted centers of phase diagrams, have been studied for the last two decades as innovative materials. By maximizing their entropy (configurational and/or vibrational) and stabilizing (near) equimolar mixtures, it has been possible to achieve robust systems with promising applications. Still, effective computational discovery of useful materials remains challenged by the immense number of configurations: the synthesizability of high-entropy ceramics is typically assessed using ideal entropy along with the formation enthalpies from density functional theory, with simplified descriptors or machine learning methods. With respect to vibrations — even if they may have significant impact on phase stability — the contributions are drastically approximated to reduce the high computational cost, or often avoided with the hope of them being negligible, due to the technical difficulties posed in calculating them for disordered systems. As such, in high-entropy ceramics, the vibrational contributions remain a matter of conjecture — their inclusion left to researchers' guesswork. In this presentation we illustrate the problem, its implications, and suggest simple solutions.

11:00 AM CH04.12.03
Continuous Evaluation of Carrier Recombination Velocity of Grain Boundaries in Multicrystalline Si Using Machine Learning Kentaro Kutsukake[1], Kazuki Mitamura[2], Takuto Kojima[2] and Noritaka Usami[2]; [1]RIKEN, Japan; [2]Nagoya University, Japan

Grain boundaries (GBs) in multicrystalline Si (mc-Si) are still of interest in research because mc-Si will maintain a certain share in the substrate for solar cells to consume low-grade Si raw materials that cannot be used for Czochralski Si in addition to its importance as fundamental physics. One of the research issues is a quantitative evaluation of spatially local electrical activities to reveal the influence of local structures such as atomically reconstructed structures at curved GBs. Measurable spatial images of electrical activities, such as photoluminescence (PL) and electron beam induced current (EBIC) images, provide qualitative distributions, however, quantitative analysis of the images, in which parameter fitting is required, needs a large calculation cost. In this study, we developed a fast and continuous evaluation method of carrier recombination velocity (V_{GB}) along a GB from a photoluminescence image using carrier simulation and its machine learning. A dataset of 3000 PL profiles was made through PL image simulation, which was developed incorporating the influence of inclination angle of GB (θ) [1], using random values of parameters of V_{GB}, θ, and carrier diffusion length in left and right crystal grains (L_{left} and L_{right}). A fully connected feedforward neural network model was constructed with the inputs of the PL profile and θ, which is determined by measuring the position shift of the GB between the front and rear surface [1], and the outputs of V_{GB}, $L_{left,}$ and L_{right}. The coefficient of determination and the root mean squared error of the trained model for V_{log}, which is the common logarithm of V_{GB}, for the test dataset were 0.97 and 0.24, respectively. This prediction error was sufficiently low for the practical estimation of V_{GB}. The calculation time for the prediction is less than 0.01 seconds. By utilizing this fast prediction method, continuous evaluation of V_{GB} along a GB was demonstrated. V_{GB} was clearly visualized, and small fluctuations were detected quantitatively. V_{GB} increases around the curved region and fluctuates even in straight regions. This quantitative and high spatial resolution evaluation of the property will lead to a deep and quantitative understanding of defects by combining it with microscopic structural and computational analysis.

11:15 AM CH04.12.04
Disentangling Ferroelectric Wall Dynamics and Identification of Pinning Mechanisms via Deep Learning Yongtao Liu[1], Roger Proksch[2], Chun Yin Wong[3], Maxim A. Ziatdinov[1,1] and Sergei V. Kalinin[1]; [1]Oak Ridge National Laboratory, United States; [2]Asylum Research, An Oxford Instruments Company, United States; [3]The University of Tennessee, Knoxville, United States

Field-induced domain wall dynamics in ferroelectric materials underpins multiple applications ranging from actuators to information technology devices and necessitates a quantitative description of the associated mechanisms including giant electromechanical couplings, controlled non-linearities, or low coercive voltages. While the advances in dynamic Piezoresponse Force Microscopy measurements over the last two decades have rendered visualization of polarization dynamics relatively straightforward, the associated insights into the local mechanisms have been elusive. Here we using a workflow combining deep learning-based segmentation of the domain structures with non-linear dimensionality reduction using multilayer rotationally-invariant autoencoders (rVAE). A Canny filter and ResHED network were utilized to detect domain walls based on the PFM images. Then, sub-images centered at 180º domain walls were used for rVAE analysis to encode information of domain switch and wall dynamics. Through analyzing the time dynamics of domain switch and interactions between ferroelastic and ferroelectric domain walls by rVAE, we discovered new factors affecting the ferroelectric wall dynamics and pinning mechanism. We believe that the approach developed in this work will be universally useful for time-dependent dynamics of complex materials.

Deep Learning Enables Crystallographic Information from Electron Diffraction Images Joydeep Munshi[1], Alexander Rakowski[2], Benjamin Savitzky[2], Colin Ophus[2] and Maria K. Chan[1]; [1]Argonne National Laboratory, United States; [2]Lawrence Berkeley National Laboratory, United States

We present one of the targeted analysis pipelines, *4D>Crystal*, in an aim to generate a series of reduced crystalline diffraction vectors from a given combination of STEM probe in vacuum with typical 4D-STEM diffraction dataset. 4D>Crystal pipeline is composed of three main workflows namely – 1) crystal selection and data scraping (4D-MANIPULATT), 2) training data generation (4D-MAKE) and 3) Bragg disk detection network training and evaluation (4D-DISK). We use python-based pymatgen package and the materials project (MP) API to fetch crystal structures from more than 120,000 materials present in the MP database. Additionally, AFLOW library is levaraged to fetch structure prototypes from over 250 different structure types of crystals based on their structural similarity. Finally, we select a fraction of structures from the MP database, resembling each structure prototype, following the square-root distribution law. Following the crystal structure selection, we employ supercell manipulation algorithm (4D-MANIPULATT) to manipulate unit cell structures to create randomly rotated supercells. Finally, simulated electron diffraction data (CBED) and the simulated atomic potential for each of these supercells are simulated leveraging the Multislice algorithm implemented. For the deep learning training to predict Bragg disks locations and their intensities we implement a modified complex U-Net type encoder-decoder based network. Complex convolution based network in this work showed improved performance of disk predictions for overlapped diffraction disks at larger thickness.

Tuesday Afternoon, December 7, 2021
CH04-Virtual

1:00 PM CH04.13.01
Design of Features Based on X-ray Diffraction Patterns for Prediction of Mechanical Properties Naoki Hato[1], Masaya Kumagai[1,2,3] and Ken Kurosaki[1,4]; [1]Kyoto University, Japan; [2]SAKURA internet Inc., Japan; [3]RIKEN, Japan; [4]University of Fukui, Japan

The development of new materials requires many steps, such as sample preparation, X-ray diffraction measurement and analysis, property measurement, and performance evaluation, and requires an enormous amount of time. In recent years, high-throughput material synthesis and high-speed X-ray diffraction measurements have made sample preparation and X-ray diffraction measurements more efficient. However, the analysis of crystal structures has not yet become efficient. In this study, we constructed an optimal feature vector based on the X-ray diffraction pattern to predict the crystal structure with high accuracy, and also predicted the mechanical properties that are highly related to the crystal structure.
Various feature vectors based on the intensity, angle, and number of peaks in the X-ray diffraction pattern were constructed and their effects on the prediction accuracy were clarified. Since the number of diffraction peaks varied greatly among the different crystal systems, it was confirmed that the number of peaks made a difference in the prediction accuracy. The prediction accuracy for Cubic among the seven crystal systems was about 97% at maximum. On the other hand, the prediction accuracies of Monoclinic and Triclinic were lower than that of the other crystal systems due to the similarity of their X-ray diffraction patterns. By constructing an optimal feature vector that can predict crystal structures with high accuracy, highly accurate prediction of mechanical properties such as volume modulus can also be expected.

1:15 PM CH04.13.02
Combinatorial Synthesis of Heteroepitaxial, Functional Thin Films of Complex Materials with High-Throughput, *In Situ*, Chemical and Structural Characterization Eun Ju Moon and Amit Goyal; University at Buffalo, The State University of New York, United States

Materials informatics applied to a range of advanced materials applications can identify a range of compositions of complex materials (having multiple cations and anions) within which combinatorial synthesis is needed to obtain materials with ideal compositions for optimized properties. Combinatorial synthesis via a continuous composition spread is an excellent route to develop thin-film libraries from a single experiment on a single wafer, which is both time- and cost-efficient for developing new materials with ideal compositions and having optimized properties for next-generation applications. A reliable, high-throughput, *in-situ* characterization analysis method is required to meet the crucial need to screen materials libraries. Creating libraries of functional multi-component complex oxide films requires excellent control over the synthesis parameters combined with high-throughput analytical feedback across a given substrate area. Here, we report on the use of a newly developed *in-situ* compositional analysis technique, called low-angle x-ray spectroscopy (LAXS), to map the chemical composition profile of combinatorial heteroepitaxial complex oxide film deposited in a continuous composition spread using pulsed laser molecular beam epitaxy (MBE). This state-of-the-art combinatorial growth system facilitates a fully synchronized four-axis mechanical substrate stage without shadow masks, alternating acquisition of chemical compositional data using LAXS at various different positions on the ~41mm x 41mm range and sequential deposition of multilayers of $SrTiO_3$ and $SrTi_{0.8}Ru_{0.2}O_3$ on a 2-inch (50.8mm) $LaAlO_3$ wafer in a single growth. Reflection high-energy electron diffraction (RHEED) and x-ray diffraction (XRD) are used to confirm the epitaxy of the combinatorial oxide films, $SrTi_{1-x}Ru_xO_{3-\delta}$, deposited across the wafer. Rutherford backscattering spectrometry (RBS) is used to calibrate and validate the measurement data produced by the LAXS on the composition spread across the substrate. The calibrated LAXS data exhibits a gradual composition elevation, thus showing a good agreement with the RBS results ($0 \leq x \leq \sim 0.2$). This study shows the feasibility of combinatorial synthesis extended to heteroepitaxial, functional complex oxide films at wafer-scale using a new *in-situ* high-throughput characterization technique. The combination of laser-MBE growth with high-throughput LAXS for probing composition and RHEED for epitaxy is a powerful route to obtain new materials with optimized compositions, epitaxy, and functional properties.

1:30 PM CH04.13.03
Advanced Feature Extraction with Machine Learning and Combinatorial Methodologies for Thin-Film Photovoltaic Materials Enric Tomas T. Grau-Luque[1], Maxim Guc[1], Fabien Atlan[1], Andreas Zimmermann[2], Sergio Giraldo[1], Ignacio Becerril-Romero[1], Alejandro Perez-Rodriguez[1,3] and Victor Izquierdo-Roca[1]; [1]IREC, Spain; [2]Sunplugged GmbH, Austria; [3]Universitat de Barcelona, Spain

Spectroscopic characterization techniques, such as Raman spectroscopy (RS), photoluminescence (PL), or X-ray fluorescence (XRF) are becoming widely spread for advanced material characterization due to their easy application and highly informative output about different materials properties in a fast and non-destructive manner. Spectroscopic data is mostly processed through simple analytical procedures that are time-consuming and undermine their potential. This is especially critical in the context of research in new material-based technologies which often present a high degree of complexity (e.g. multilayer, multiscale or multiprocess) and require the use of several characterization techniques in a combinatorial way in order to obtain an advanced understanding of their fundamental properties and failure mechanisms. The use of simple analytical procedures for this complex analysis results in long conception-to-market development times (normally 10-20 years) using large amounts of resources.

Recently, combinatorial analysis (CA) and machine learning (ML) have started to become common methodologies in the analysis of complex systems. It is foreseen that these advanced methodologies will shorten technology development times by a factor of 10. However, they require deep theoretical, analytical, and programming knowledge as well as big-data experimental generation which sets a barrier for their widespread implementation. In this context, the development of practical methodologies is paramount to accelerate the broad adoption of CA and ML and ultimately shorten technology development times.

This work proposes a novel methodology based on ML and CA to accelerate experimentation, analysis, and development. We present a step-by-step explanation of the methodology that includes the following key aspects: i) defining features and targets, ii) pre-processing and scaling experimental data, iii) selecting and using a ML algorithm, iv) analyzing and interpreting the outputs, v) visualizing the results, and vi) combining ML with CA for feature extraction. When applied successfully, this workflow produces consistent results that offer impactful insights into materials research. We illustrate this methodology by presenting its application to two practical examples of complex materials with high relevance for the thin-film PV community: the development of the earth-abundant $Cu_2ZnGeSe_4$ (CZGSe) at laboratory scale and of mature $Cu(In,Ga)Se_2$ (CIGSe) PV technologies. These materials exhibit several difficulties in their development due to the high amount of parameters involved in their multi-step fabrication and their impact on material properties. In the case of CZGSe, it is a high band gap absorber material with a high potential for tandem or semitransparent PV applications. The study was carried out in a combinatorial sample with graded composition characterized by XRF, RS, and current-voltage (I-V). In the case of CIGSe, it is a mature PV technology but with high improvement and cost reduction potential. In this study, CA (using RS, PL, and I-V) and ML methodologies were applied to optimize the fabrication of solar modules on flexible substrates in SUNPLUGGED GmbH's innovative roll-to-roll (RtR) production line. In both cases, the applied CA and ML methodologies are demonstrated to enable defining the critical deposition parameters and conditions that allow reaching the

optimum material properties in terms of their application in PV devices.

Finally, we also introduce a free open-source library based on Python for the presented methodologies to facilitate researchers and developers to perform CA and ML analysis of spectroscopic data. We strongly believe that this work represents the foundations for the future research of complex materials, which aims for more robust, faster, and automated work structures. In the particular case of thin-film PV, this will lead to a more efficient, versatile, and cheaper production of PV devices for a greener future.

1:45 PM CH04.13.04
signac—Data Management and Workflows for Computational Materials Discovery and Design Bradley D. Dice, Brandon Butler and Sharon C. Glotzer; University of Michigan, United States

The open-source signac data management framework (https://signac.io) helps researchers execute reproducible computational studies, scaling from laptops to supercomputers and emphasizing portability and fast prototyping. With signac, users can track, search, and archive data and metadata for file-based workflows and automate workflow submission on high performance computing (HPC) clusters. We will showcase current research by the materials community using signac, and discuss how recent improvements to the software's feature set, scalability, and usability are enabling new scientific applications of the framework. Newly implemented synced data structures, workflow subgraph execution, and performance optimizations will be covered. Motivated by the needs of computational materials scientists for heterogeneous data processing with bespoke parallel execution patterns on widely varying hardware, we will demonstrate how these new capabilities enhance signac's integrated approach to materials simulations and facilitate the high level of flexibility required by this domain of research.

2:00 PM CH04.13.05
Combining Crystal Structure Prediction and High-throughput Powder Pattern Refinement for Organic Solid Form Selection Kiran Sasikumar, Jacco van de Streek and Marcus Neumann; Avant-garde Materials Simulation GmbH, Germany

On some occasions, a crystal structure that has been prepared and marketed for years is unexpectedly superseded by a thermodynamically more stable polymorph, rendering the initial crystal structure almost impossible to obtain—a so-called "disappearing polymorph" [1]. Despite the relative rarity of such events, famous cases such as the drug compounds Ritonavir and Rotigotine, where costly reformulations were required to manufacture the product again, underlined the commercial need for extensive screening of solid-state forms. Sometimes christened virtual polymorph screening, crystal structure prediction (CSP) emerged as a complement to experimental solid-form screens in order to evaluate the risk of a "disappearing polymorph" event. With the technology achieving maturity, CSP is now increasingly being used in the pharmaceutical industry to predict the relative thermodynamic stability of solid-state forms and to guide small-molecule solid form selection [2, 3].

A key component of the risk assessment and solid form selection workflow is to map the experimentally synthesized solid forms onto the predicted crystal-energy landscape. As CSP is increasingly used early in the drug development cycle, experimental single crystal structures are often unavailable, and X-ray powder diffraction patterns are the best available experimental representation of the synthesized solid form. Furthermore, several factors can affect the pattern quality, such as preferred orientation of crystallites in the powder sample, amorphous background or peak position offset. The available powder sample may also correspond to disordered crystal structures and/or be phase mixtures of multiple solid forms. Hence, it is imperative to have a sophisticated high-throughput matching functionality to place the experimentally observed forms on the predicted landscape.

In this contribution, we present the results of high-throughput refinement of powder diffraction patterns involving phase mixtures of pharmaceutically relevant compounds. Specifically, we compare the powder diffraction pattern against an extensive list of input crystal structures from an early-stage CSP study by refining or optimizing ~1 million parameter-sets that involve different combinations of structures, phase volume fractions and preferred orientation directions. Further, we discuss the ambiguities inherent to structure solution from powder diffraction data and the importance of calculated lattice energies (often also free energies where vibrational contributions are factored in) in the robust bridging of experimental and computational data.

Similarity of Materials and Data-Quality Assessment by Unsupervised Learning Claudia Draxl, Simon Gabaj, Martin Kuban, Santiago Rigamonti and Markus Scheidgen; Humboldt-Universität zu Berlin, Germany

Data-centric approaches are already complementing our daily research and will even significantly change materials science in the near future. In this respect, data-analytics and machine-learning approaches are being developed and applied to various problems, and high-throughput screening (HTS) is going hand in hand with the establishment of small- and large-scale data collections. These resources allow us finding trends and patterns that cannot be obtained from individual investigations. Moreover, one can search for materials which exhibit features that are similar to those of other materials but are superior with respect to other criteria.

We have developed a platform that implements various similarity measures and employ this tool to explore the materials available in the NOMAD Encyclopedia [1]. Besides finding materials that resemble each other, e.g. in their electronic properties, this toolbox can also be used for assessing data quality. As such, one can compare the performance of different methodologies for one and the same material or the impact of approximations and computational parameters on calculated properties. We also make use of un unsupervised learning to find trends in the data and rationalize their physical origin. We will also discuss how we are currently expanding our efforts towards other materials properties of interest and developments towards inclusion of experimental data.

2:45 PM CH04.13.07
High-Throughput Study of Antisolvents on the Stability of Multicomponent Metal Halide Perovskites Through Robotics-Based Synthesis and Machine Learning Approaches Kate Higgins[1], Maxim A. Ziatdinov[2], Sergei V. Kalinin[2] and Mahshid Ahmadi[1]; [1]University of Tennessee, Knoxville, United States; [2]Oak Ridge National Laboratory, United States

Considerable research attention has focused on metal halide perovskites (MHPs) over the recent years because of the combination of exceptional optoelectronic properties and low fabrication cost, making them ideal candidates for a variety of applications[1-4]. Even so, the development of MHPs for commercialization must overcome an obstacle, namely stability in the pure or device-integrated form[5]. Overcoming adverse effects stemming from external stimuli can be minimized or avoided by utilizing established encapsulation techniques and device engineering[6,7]. Simultaneously, another strategy is to improve the intrinsic stability by cation and/or halide alloying to synthesis multicomponent MHPs[8,9]. A multitude of studies have demonstrated how the incorporation of other cations, particularly Cs^+ and formamidinium (FA^+) into methylammonium (MA^+) systems, leads to improve stability in ambient and operational conditions. Mixing halides, has also proven to be an effective strategy toward stable perovskite materials.
Antisolvent crystallization methods are frequently used to fabricate high quality perovskite thin films, to produce sizable single crystals, and to synthesize nanoparticles at room temperature. However, a systematic exploration of the effect of specific antisolvents on the intrinsic stability of multicomponent metal halide perovskites has yet to be demonstrated. We have previously reported the development of a workflow for materials discovery utilizing both automated synthesis and machine learning (ML)[10,11]. Similarly in this study, we develop a high-throughput experimental workflow that incorporates robotic synthesis, automated characterization, and ML techniques to explore how the choice of antisolvent affects the intrinsic stability of binary perovskite systems in ambient conditions[12]. Different combinations of the endmembers are used to synthesize 15 combinatorial libraries, each with 96 unique combinations. In total, roughly 1100 different compositions are synthesized. Each library is fabricated twice using two different antisolvents: toluene and chloroform. Once synthesized, photoluminescence spectroscopy is automatically performed every 5 minutes for approximately 6 hrs. Non-negative Matrix Factorization (NMF) is then utilized to map the time- and compositional-dependent optoelectronic properties. Through the utilization of this workflow for each library, we demonstrate that the selection of antisolvent is critical to the stability of MHPs in ambient conditions. We explore possible dynamical processes, such as halide segregation, responsible for either the stability or eventual degradation as caused by the choice of antisolvent. Overall, this high-throughput study demonstrates the vital role that antisolvents play in the synthesis of high quality multicomponent MHP systems.

A Fundamental Training Paradigm for Graph Neural Networks to Characterize Complex Features in Atomic Microstructures Yu-Ting Hsu, James Chapman, Penghao Xiao, Xiao Chen and Brandon Wood; Lawrence Livermore National Laboratory, United States

Graph neural networks (GNNs) are an emerging machine learning methodology for processing irregularly structured data. They have shown promise in learning/predicting properties of atomistic structures due to their intrinsically physically-informed nature, with graph nodes representing atoms and graph edges symbolizing interatomic bonds. In atomistic modelling, the application of GNNs has generally been limited to small-scale molecular structures or crystalline materials represented by small unit cells. In contrast, describing more complex structural and microstructural features such as grain boundaries, voids, and surfaces requires scaling the application space of GNNs to vastly larger atomistic microstructures. To this end, we have developed a GNN training paradigm to characterize microstructural features without the need for GNN to explicitly identify such information during training. Our methodology aims to capture a fundamental aspect of complex atomic environments, in which one can generalize local geometries on a scale from fully ordered (perfect crystal) to completely disordered. This atomic-level classification system allows our GNN to extrapolate widely to configurations that it has not explicitly seen before. Our methodology also overcomes limitations associated with existing methods where the local environments are predefined to a “hard-coded” reference of specific structural motifs, which often leads to incorrect classification of complex structural environments such as grain boundaries. The notion of scaling between order and disorder presents a much smoother classification system of these geometric domains. We highlight the application of our GNN scheme to the automated detection and characterization of aluminum microstructures, derived from polycrystalline structures containing a variable number of grains and temperatures. We show that with a limited training set, our method correctly identifies and characterizes microstructural features such as surfaces, grain boundaries, voids, or other defect-likeenvironments on a much larger scale than that encountered during training. The examples presented here showcase the ability of our GNN methodology to characterize atomistic structures with unprecedented accuracy and transferability, opening the door to understanding structure-property relationships in complex materials in greater detail.

Physics-Informed Machine Learning Enhances Predictive Design of Fluorescent DNA-Stabilized Silver Clusters Peter Mastracco[1], Joshua Evans[2], Anna Gonzalez-Rosell[1], Petko Bogdanov[3] and Stacy Copp[1]; [1]University of California, Irvine, United States; [2]Chaffey College, United States; [3]University at Albany, State University of New York, United States

DNA-stabilized silver clusters (Ag_N-DNAs) are a model system for developing machine learning approaches to materials discovery. These clusters of 10-30 Ag atoms are encapsulated in short DNA strands, whose nucleobase sequences tune fluorescence emission from 500 nm to at least 1000 nm by selection of cluster size and morphology. With high quantum yield fluorescence, unique rod-like geometries, compatibility with DNA, and sensitivity to certain analytes, Ag_N-DNAs are promising for applications including sensing, bioimaging, and nanophotonics. However, the complex relationship between DNA sequence and Ag_N-DNA fluorescence color and the enormous combinatorial space of DNA sequences to choose from has hindered rational design of Ag_N-

DNAs for such applications. Previously, we applied supervised machine learning classification together with high-throughput experiments to learn the connection between DNA sequence and Ag_N-DNA color, using data mining together with feature selection to engineer features for these models. Here, we present new efforts to engineer physically motivated features, presenting new features hypothesized based on observations from the first reported crystal structures of Ag_N-DNAs. We show that models using these physics-informed features perform comparably well or better than more complex models with features engineered by naive data mining, and the dimensionality of the new models is one order of magnitude less than the previous naive models. Furthermore, we rank features by a metric of importance to further reduce the dimensionality of our learned models and to inform the understanding of how DNA stabilizes silver clusters. This work demonstrates the importance of merging first-principles knowledge with machine learning and high throughput experimentation for the discovery of sequence-encoded biomolecular materials.

Automating Data Interpretation with Deep Reasoning Networks John M. Gregoire[1], Di Chen[2], Yiwei Bai[2], Sebastian Ament[2], Wenting Zhao[2], Lan Zhou[1], Bart Selman[2], R. Van Dover[2], Carla Gomes[2] and Dan Guevarra[1]; [1]California Institute of Technology, United States; [2]Cornell University, United States

As materials discovery efforts increasingly expand in high-order composition spaces and/or far-from-equilibrium syntheses, characterizing the phase behavior of the materials becomes increasingly challenging. The limited ability of algorithms to automate phase mapping – the generation of the composition map of crystalline phases from a set of x-ray diffraction patterns – creates a bottleneck in high throughput and autonomous materials discovery. For properties where only phase-pure materials are of interest one needs to screen out the mixed-phase diffraction patterns, although properties from catalysis to light harvesting materials may be optimized through interfaces and other multi-phase interactions. As a result, mixed-phase x-ray diffraction patterns must be de-mixed, which can be very challenging when candidate structures contain overlapped features and the diffraction patterns of prototype structures vary due to, for example, alloying. In such cases, experts analyze the data by collectively considering a collection of related mixed-phase diffraction patterns and invoking thermodynamic rules that govern phase mixtures in the given materials space. Previous methods have used such rules to “fix” phase mapping solutions from de-mixing patterns, but when dozens of phase mixtures exist within a dataset and the materials space has multiple degrees of freedom that require hundreds of diffraction patterns to characterize, the data complexity exceeds the capabilities of both human experts and state of the art algorithms. In such cases, the prior knowledge about phase prototypes of thermodynamic rules must be integrated into the demixing process. Application of the rules inherently involves computational reasoning and recognition of the phase-pure patterns in the data inherently involves computational learning. The combination of reasoning and learning to solve challenging problems is a hallmark of human intelligence, and we introduce Deep Reasoning Networks (DRNets) to seamlessly integrate reasoning and learning. DRNets are designed with an interpretable latent space for encoding prior-knowledge domain constraints and integrating constraint reasoning into neural network optimization. DRNets are demonstrated for solving complex phase behavior in 3-cation oxide composition spaces.

Predicting Temperature-Dependent Oxide Redox Reactions with Machine-Learning Augmented First-Principles Calculations José A. Garrido Torres, Vahe Gharakhanyan, Tobias Hoffmann Eegholm, Nongnuch Artrith and Alexander Urban; Columbia University, United States

Understanding the conditions for the formation and reduction of metal oxides at high temperatures is of great industrial relevance, e.g., for corrosion prevention and for metal production. However, the experimental characterization of high-temperature redox chemistry is challenging and requires specialized equipment. Simulations with the Calculation of Phase Diagrams (CALPHAD) method can be an alternative but require assessed phase diagrams for the system of interest. First-principles calculations, on the other hand, can provide robust estimates of redox potentials at zero Kelvin without experimental input, but simulating redox reactions at high temperatures is computationally demanding and often too approximate.

Here, we will discuss initial progress towards the efficient computational prediction of high-temperature redox chemistry using machine-learning augmented first-principles calculations. We show that a combination of results from zero-Kelvin density-functional theory (DFT) calculations and a machine-learning model trained on temperature-dependent reaction free energies allows predicting reduction temperatures of metal oxides that the model was not trained on. Hence, this initial application for crystalline binary and ternary oxides demonstrates that the temperature dependence of the free energy can indeed be cross-learned from other oxides, thereby removing the limitation to compounds that have previously been thermodynamically assessed.

9:15 AM CH04.14.07
Machine Learning for Revealing Spatial Dependence Among Nanoparticles: Understanding Catalyst Film Dewetting via Gibbs Point Process Models Ahmed Aziz Ezzat[1] and Mostafa Bedewy[2]; [1]Rutgers, The State University of New Jersey, United States; [2]University of Pittsburgh, United States

How can we simulate a complex nanoscale phenomena involving coupled physical and chemical processes and interactions that are hard to model? In this work we show that combining *in situ* environmental transmission electron microscopy (E-TEM) with automated image processing and statistical machine learning uniquely enables formulating interpretable mathematical models as well as creating accurate simulation tools. In particular, there is a need for a better understanding, characterization, and prediction of the proximity effects among dense populations of metal nanocatalysts as they form and evolve over time. Here, we leverage point process theory—a branch of statistical machine learning—to “learn” the spatial dependencies among ensembles of adjacent alumina-supported iron nanoparticles from a time sequence of E-TEM images. We construct a set of point process models to make statistical inferences about the nature of spatial dependencies that govern the rapid formation, or “popping” of nanoparticles during thin film dewetting, concomitant with metal reduction in the presence of acetylene at 750 °C. We show that nanoparticles exhibit strong dispersion behavior, i.e. new nanoparticles pop in dispersed locations at a predictable distance from their existing territorial neighbors. We also show that the Softcore model, a class of Gibbs point processes, adequately describes the pairwise interactions underlying such time-dependent spatial variations. Further, we leverage the probabilistic nature of our statistical models to develop a computational simulation tool capable of producing accurate simulations of the spatio-temporal evolution of formation patterns of nanoparticles at both finer time resolutions and larger spatial domains than experimental observations. This is a much needed capability, wherein the behavior of hard-to-model coupled nanoscale phenomena involving complex chemical and physical processes are accurately captured in machine-learned mathematical formulations; thus overcoming current limitations in computational methods supporting the design and analysis of collective nanocatalyst populations.

9:20 AM CH04.14.08
Defects Engineering to Design Tough Graphene Chang-Yan Wu[1], Markus J. Buehler[2] and Chi Hua Yu[1,2]; [1]National Cheng Kung University, Taiwan; [2]Massachusetts Institute of Technology, United States

Fracture behaviors of brittle materials have been a crucial problem when it comes to safety and reliability. Unlike the one-sided understanding that defects result in a negative effect on materials, a new perspective from recent studies indicates that nano-defects could strengthen the material if rationally designed. Nevertheless, fracture behaviors of graphene under defective conditions remain unclear and need more comprehensive studies. With deep learning (DL) recently drawing attention in the material field, several studies have applied machine learning techniques on predicting crack growth of

brittle materials. This study aims to use a deep sequential model to predict the fracture path of graphene under two systems of defective configuration. One involves graphene with different crystalline, and the other involves graphene with various porous defects. First, we built 20 nm 16 nm graphene sheets with different orientations or pores defects. The 20 nm pre-existing crack is set at the edge of each graphene sheet. Subsequently, we performed uniaxial tensile tests by implementing molecular dynamics simulation and process the results into grayscale images. We sliced every single image into pieces so that the ConvLSTM-based model can learn the spatiotemporal features from the sequential images. The input matrices are mapped from the sequential images, and the output matrices are mapped from the crack images of the next timestep. After iterating the prediction process, we can obtain the final crack path of the graphene. We first used 100 crack images (graphene with ten different orientations in 10 sets) to train the model. The model shows 99.45% binary accuracy and can predict the crack path of graphene under different orientations, whether it is single crystal or bicrystal. We used other 300 crack images (arbitrary porous graphene) to train another model. The model shows 94.50% binary accuracy and can predict crack propagation of arbitrary porous graphene. This study applied deep learning on graphene fracture predictions, which work as a more efficient tool than conventional simulation methods, which is potential for next-generation material design.

SESSION CH04.15: Physics-Assisted ML Methods for Knowledge Extraction III

Realizing Physical Discovery in Imaging with Machine Learning Sergei V. Kalinin, Yongtao Liu, Ayana Ghosh, Kyle P. Kelley, Kevin Roccapriore and Maxim A. Ziatdinov; Oak Ridge National Laboratory, United States

Machine learning and artificial intelligence (ML/AI) are rapidly becoming an indispensable part of physics research, with domain applications ranging from theory and materials prediction to high-throughput data analysis. In parallel, the recent successes in applying ML/AI methods for autonomous systems from robotics through self-driving cars to organic and inorganic synthesis are generating enthusiasm for the potential of these techniques to enable automated and autonomous experiment (AE) in imaging. The implementation of this vision requires the synergy of three intertwined components, including the engineering controls of the imaging tools, the algorithmic developments that allow to define non-trivial exploratory patterns, and physics-driven interpretation.
In this presentation, I will discuss recent progress in automated experiment in electron and scanning probe microscopy, ranging from feature to physics discovery via active learning. The applications of classical deep learning methods in streaming image analysis are strongly affected by the out of distribution drift effects, and the approaches to minimize though are discussed. We further present invariant variational autoencoders as a method to disentangle affine distortions and rotational degrees of freedom from other latent variables in imaging and spectral data. The analysis of the latent space of autoencoders further allows establishing physically relevant transformation mechanisms. Extension of encoder approach towards establishing structure-property relationships will be illustrated on the example of plasmonic structures. Finally, I illustrate transition from post-experiment data analysis to active learning process. Here, the strategies based on simple Gaussian Processes often tend to produce sub-optimal results due to the lack of prior knowledge and very simplified (via learned kernel function) representation of spatial complexity of the system. Comparatively, deep kernel learning (DKL) methods allow to realize both the exploration of complex systems towards the discovery of structure-property relationship, and enable automated experiment targeting physics (rather than simple spatial feature) discovery. The latter is illustrated via experimental discovery of the edge plasmons in STEM/EELS and ferroelectric domain dynamics in PFM.

This research is supported by the by the U.S. Department of Energy, Basic Energy Sciences, Materials Sciences and Engineering Division and the Center for Nanophase Materials Sciences, which is sponsored at Oak Ridge National Laboratory by the Scientific User Facilities Division, BES DOE.

11:00 AM *CH04.15.01
Learning Rules for Materials Properties and Functions by Artificial Intelligence Matthias Scheffler; The NOMAD Laboratory at the FHI, Germany

In materials science and engineering, one is typically searching for materials that exhibit exceptional performance for a certain function, and all these searches face the following situation[1]

-- The number of possible materials is practically infinite.

-- The electronic and atomistic processes that rule a desired materials function are many, and their concerted action is typically highly complex and intricate, resulting in an immense number of possibly relevant mechanisms.

-- The number of data that are “clean” (i.e. comprehensively characterized and high-quality) and relevant for the function of interest are typically very low.

Under these daunting conditions we aim to identify the rules that govern the rare phenomena corresponding to particularly exceptional materials. Thus, the scientific discovery typically resembles the proverbial hunt for the needle in a haystack.
This talks describes two methods that guide the way towards solutions of the challenge: *Subgroup Discovery* [2] and *Sure Independent Screening and Sparcifying Operator* (SISSO) [3]. Both methods enable us to identify the “materials genes”, i.e. the basic physico-chemical parameters that are relevant for the property of interest. In analogy to biology, these “materials genes” are correlated to processes that trigger, actuate, or facilitate, or hinder the property of interest.

In the coordinate systems of these genes we identify maps of materials properties, i.e. (small) regions where the desired high-performance materials can be found.

The talk describes the concepts and illustrates them with specific examples, e.g. crystal-structure prediction, topological semiconductors, materials that may convert green-house gases into useful chemicals and fuels, and more.

11:30 AM *CH04.04.01
Matrices, Graphs and Natural Language—Ways to Represent Materials for Machine Learning Keith T. Butler[1,2], Ricardo Grau-Crespo[2], Luis Antunes[2], Scott Midgley[2], Jeyan Thiyagalingam[1], Johannes Allotey[3], Aron Walsh[4] and Alexander Moriarty[4]; [1]Rutherford Appleton Laboratory, United Kingdom; [2]University of Reading, United Kingdom; [3]University of Bristol, United Kingdom; [4]Imperial College London, United Kingdom

In this talk I will present some of our recent work on different ways of representing materials for various machine learning applications. Starting with a simple case of using the well-known Coulomb matrix representation for solid-solutions and alloys, I will demonstrate how this significantly outperforms the cluster expansion approach, which has been the standard method for atomistic modelling of alloys for several decades. The Coulomb matrix representation, in combination with neural networks is shown to be highly effective in predicting non-linear relationships, exemplified by the case of band gaps in a solid-solution of (Zn, Mg)O. Next I will consider graph-neural networks (GNNs), which encode the topology of a material as a message passing graph – typically these GNNs are coupled with a standard neural network to predict a given material property. I will demonstrate how GNNs can be used instead to learn a representation of the material as a compressed vector, which can then be used in a Bayesian approach to predict properties, but with added value of a principled estimate of the uncertainty in the estimation. By using this GNN-fed Gaussian process, we are then able to develop an active learning protocol whereby we select the next best experiment (or high-level calculation) to obtain new labelled data. We find that this active learning process leads to model improvement at twice the rate of adding data without guidance. Finally I will demonstrate how principles from natural language processing (NLP) can be applied to learn representations of atoms and then to assemble these atoms into compounds. Using this approach we can leverage existing databases, such as the Materials Project to rapidly learn distributed embeddings and then apply these embeddings to predict compound properties – I will show how this NLP-inspired approach outperforms many existing approaches on a number of standard materials science benchmark tests.

12:00 PM *CH04.15.02
Statistical Physics of Machine Learning Bruno Loureiro, Lenka Zdeborová and Florent Krzakala; École Polytechnique Fédérale de Lausanne, Switzerland

The past decade has witnessed a surge in the development and adoption of machine learning algorithms to solve day-a-day computational tasks. Yet, a solid theoretical understanding of even the most basic tools used in practice is still lacking, as traditional statistical learning methods are unfit to deal with the modern regime in which the number of model parameters are of the same order as the quantity of data - a problem known as *the curse of dimensionality*. Curiously, this is precisely the regime studied by Physicists since the mid 19th century in the context of interacting many-particle systems. This connection, which was first established in the seminal work of Elisabeth Gardner and Bernard Derrida in the 80s, is the basis of a long and fruitful marriage between these two fields.

In this talk I will motivate and review the connections between Statistical Physics and problems in high-dimensional Statistics, such as the ones stemming from the fields of Machine Learning and Signal Processing. Finally, I will exemplify this discussion with some recent concrete applications of the Statistical Physics toolbox to different problems of interest.

SYMPOSIUM DS01

Accelerating Experimental Materials Research with Machine Learning
November 29 - December 6, 2021

Symposium Organizers
Kristen Brosnan, Superior Technical Ceramics
Keith Brown, Boston University
A. Gilad Kusne, National Institute of Standards and Technology
Alfred Ludwig, Ruhr-University Bochum

Symposium Support
Bronze
Matter | Cell Press

* Invited Paper

8:30 AM
Introduction to Machine Learning and Materials Data Science A. Gilad Kusne; National Institute of Standards and Technology, United States

A high level introduction to the basic concepts of Machine Learning and central challenges in applying these concepts to materials data.

9:15 AM
Introduction to Gaussian Processes for Regression and Classification A. Gilad Kusne; National Institute of Standards and Technology, United States

A high level introduction to the basics of Gaussian Processes (GP), their applications to regression and classification tasks, and their relationship to deep learning and linear regression. We will also have a brief hands-on demonstration of GPs applied to materials data. For attendees interested in following along, please bring a laptop and have a Google account.

10:00 AM BREAK

10:30 AM
A Gentle Introduction to Deep Learning Stefan Sandfeld; Forschungszentrum Jülich GmbH, Germany

A brief introduction to artificial neural networks (Neural Network Definition and Elements, Custom layers, Activation Functions, Loss functions) as well as to Deep Neural Networks (CNN, RNN) will be given. This is complemented by examples that focus on materials science applications, such as semantic segmentation of images.

12:00 PM BREAK

1:30 PM
Sequential Bayesian Experimental Design Kris Reyes; University at Buffalo, The State University of New York, United States

In this module, we shall discuss sequential experimental design, and the Bayesian modeling of experimental responses. Key to this is the idea of a decision-making policy. We shall give many examples of such policies for various design tasks. Topics discussed will include Gaussian Processes, Multi-armed Bandits and Bayesian Optimization.

3:00 PM BREAK

3:30 PM
Active Learning Competition Shijing Sun; Toyota Research Institute, United States

A hands-on demonstration of active learning in action. This includes a competition where attendees will compete in using Bayesian Optimization to identify the global extrema of a hidden function. Attendees who would like to participate in the competition should bring a laptop and have a Google account. Prizes will be awarded.

SESSION DS01.01: Human Machine Partnership
Session Chairs: Jason Hattrick-Simpers and Mrigi Munjal
Tuesday Morning, November 30, 2021
Sheraton, 5th Floor, Riverway

10:30 AM *DS01.01.01
Applied Machine Learning in Industry—Case Studies, Successes and Challenges Andrew Detor, Vipul Gupta, Nathaniel Mckeever and Daniel Ruscitto; GE Research, United States

Access to machine learning methods has grown significantly over the past decade. Robust, open-source tools are readily available allowing materials scientists to explore the benefits of a modern materials informatics approach. Here, we present a selection of recent case studies covering a range of problems intended to test the application of machine learning to accelerate materials research at GE. New alloy and coating development projects, component life prediction, and part inspection are all discussed. Successes are highlighted where machine learning has directly led to new insights, but we also address challenges in applying these methods to complex industrially relevant problems. We cover the perennial lack-of-data issue and ongoing efforts at GE to tackle this problem through a deliberate data strategy, integrating both internal and external sources of information to improve model performance. The role of high-throughput experiments is also discussed as a critical enabler for machine learning. While many successes have been published in the academic literature, we cover some of the unique challenges in applying a modern materials informatics framework in industry and ongoing work at GE to modernize the way we conduct materials research and development.

11:00 AM DS01.01.02
Experiments and Data-Driven Modeling of Graphene Synthesis by Chemical Vapor Deposition Aagam Shah, Mitisha Surana, Jad Yaacoub, Elif Ertekin and Sameh Tawfick; University of Illinois at Urbana-Champaign, United States

Despite that graphene synthesis via chemical vapor deposition (CVD) was first demonstrated in 2009, today economically-viable manufacturing of continuous single crystals of graphene is still elusive. Hundreds of coupled synthesis parameters and complex kinetic pathways impede the development of recipes that, for instance, are reproducible, environmentally sustainable and compatible with electronics fabrication. Building an accurate model for synthesis is challenging due to the coupled chemistry-multi-physics, multi-time and -length scale nature of the growth process. To overcome these challenges, we have adopted a data driven approach to address the complexities of CVD synthesis of graphene. First, we will present a data project called Gr-ResQ (Graphene Recipes for Synthesis of High-Quality Materials). Gr-ResQ is a platform enabling the sharing and use of synthesis data towards building a more accurate predictive model for graphene synthesis. At the core of Gr-ResQ is a crowd-sourced database of CVD recipes and characterization. A suite of associated tools enable fast, automated, and standardized processing of Raman spectra and scanning electron microscopy images. To facilitate community-based efforts, Gr-ResQ provides tools for cyber-physical collaborations among research groups, allowing experiments to

be designed, executed, and analyzed by different teams. Second, we present a data set of synthesis experiments where the selected parameters have a reasonably trackable influence on the outcome. Finally, we apply a Bayesian optimization technique to exploit the results of these experiments. This data-driven approach could facilitate more efficient discovery of complex synthesis recipes, where experimentation is time or capital intensive. This technique can guide the selection of the next experiment and iterate through the process till a predictive model is prepared.

11:15 AM DS01.01.03
From Instruments to Insights—A Platform Approach to Lab Data Automation Max Petersen and Rob Brown; Dotmatics, United States

The ability to deliver innovative products to the marketplace is at the core of many chemicals and materials companies. One of the main obstacles in doing so are high R&D cost and long development timelines. As a promising solution, data-driven R&D has made its way on executive agendas. At the same time, the underlying IT infrastructure required to provision R&D data to these data-modeling initiatives is often overlooked and/or under resourced. Consequently, many initiatives that aim at implementing data-driven R&D are facing data accessibility challenges, including insufficient data quality, lack of data contextualization or incomplete data sets because of poor system adoption.

The solution to this problem is a uniform platform approach that can directly ingest data from their point of creation and serve up these data to lab managers, scientists, or directly to data modeling tools. This approach is a departure from traditional R&D IT infrastructure designs, as it avoids compartmentalizing data in silos e.g., in LIMS, ELN, or SDMS databases. This is especially important for materials innovation, as workflows are highly variable and generated by scientists from multiple disciplines, leading to data aggregation and curation issues across data silos.

Our unified, data-driven platform that allows for flexible configuration of workflows and roles that naturally contextualizes R&D data. This is paired with a set of scientific data intelligence capabilities, that spans data querying across heterogeneous data sources, data analytics, and advanced scientific data visualization applications. The platform can operate in conjunction with other IT systems and data sources or as a standalone system that includes lab digitalization. This presentation reviews the general aspects of this approach and discusses various customer scenarios of digitalization efforts in the chemicals and materials space.

11:30 AM DS01.01.04
Interactive Graphical Software for the Automatic Characterization of Nanoscale Objects Using Computer Vision Phillip Williams, Joseph H. Absi and Benoit Lessard; University of Ottawa, Canada

In previous work[1], it was established that the use of Artificial Intelligence (AI) and Computer Vision (CV) can augment the current approaches used for thin film analysis. By applying cutting edge Machine Learning techniques to Atomic Force Microscopy (AFM) images, fast, accurate and reproducible analysis can be done at much larger scales and levels of detail than previously feasible. The analysis pipeline uses the AFM height data to calculate metrics that are currently collected manually – such as linear density – as well as providing entirely new information not available from any machine or manual technique, such as the positions, orientations, and lengths of each individual carbon nanotubes in a device.
However, the main drawback of my previous work[1] is that an experienced Machine Learning practitioner is required to properly operate the software and algorithms. In practice, there are many parameters and configurations possible for each algorithm, and processing the data requires a very specific software environment as well as access to the source code. In this work, the previous approaches are implemented in a graphical interface, allowing chemists and materials scientists to leverage the cutting edges techniques without any technical support from a Machine Learning researcher. Various parameters can be tuned, configurations explored, and the results can be computed and visualized in near real-time.

In the analysis software, there are several steps to the data analysis procedure. First, the AFM height data is ingested in the form of a color or black-and-white image. Next, there are several pre-processing steps available; the image can be cropped, converted to black-and-white and even remove outliers (pixels that are particularly bright or dark). Once the image has been preprocessed, a scientist can apply various segmentation algorithms to the AFM data, this segmentation will produce a bitmap which represents the presence or absence of a nanoscale object at a given position in the microscope image. The segmentation processes consist of several steps which are designed to identify if a given point in a film belongs to a nanoscale object or not. In the previous work[1] this is accomplished by using adaptive thresholding techniques such as Otsu's method or Yen thresholding. However, improved algorithms have been added to augment the capabilities of m Thresholding techniques and more sophisticated algorithms such as Deep Neural Networks. The final output of this segmentation process is a matrix of true and false values, indicating if a given pixel belongs to a nanotube (true) or if belongs to the substrate that the nanotube was deposited on (false). Once the segmentation is complete, a variety of solvers can be applied to extract quantitative measures of the nanoscale objects (or film morphologies in the case of thin film devices). We even propose the use of an algorithm in which a scientist can select automatic segmentation or manually specify points of interest, which are then used to segment and extract the polygonal boundary of crystal grains.
Using our graphical interface, materials scientist will be able to quickly and easily apply a wide range of cutting-edge Machine Learning techniques to extract detailed quantitative descriptors of their thin film devices or nanoscale objects without the need for any special hardware or Machine Learning expertise.

1. Mirka, B. et al. ACS Nano 15, 8252–8266 (2021)

SESSION DS01.02: Data—Born Digital and Ingested
Session Chairs: Daniel Schwalbe Koda and Duncan Sutherland
Tuesday Afternoon, November 30, 2021
Sheraton, 5th Floor, Riverway

1:30 PM *DS01.02.01
Hard Fought Lessons on Open Data and Code Sharing and the *Terra Infirma* of Ground Truth Jason R. Hattrick-Simpers[1,2], Zachary Trautt[3], Brian L. DeCost[3] and Howie Joress[3]; [1]University of Toronto, Canada; [2]NRCan CanmetMATERIALS, Canada; [3]National Institute of Standards and Technology, United States

The use of artificial intelligence (AI) or machine learning (ML) in the physical sciences has exploded over the past 5 years - 10 years. In that time frame several truly remarkable discoveries have been made including the discovery of new phase change materials, amorphous alloys, and catalysts. The continued success of these methods relies upon the availability of open data, meta-data and scientific code conforming to the findable, accessible, interoperable and reusable (F.A.I.R.) guidelines. Here I will briefly discuss successes and failures at NIST in collaboration with NREL, SLAC and the

University of Maryland to create the first multi-institution combinatorial dataset and code repository to comply with F.A.I.R. guidelines. But even scientifically sound AI models built from open data sets can only be as trusted as the labels and values contained within them. The second part of my talk will focus on the tenuousness of ground truth and the need for an honest and open accounting for experimental uncertainties within our data sets. An example to be discussed will be of phase attribution from x-ray diffraction data. This will drive home the difficulties in forming unanimous expert consensus and how a consensus with variance impacts the perceived performance of ML model attributions.

2:00 PM DS01.02.02
Data Driven Framework for Development of Large Scale 'Virtual' Battery Material Databases Scott Broderick[1], Kaito Miyamoto[2,1] and Krishna Rajan[1]; [1]University at Buffalo, United States; [2]Toyota Research Institute of North America, United States

We introduce an approach for the prediction of capacity for over 100,000 spinel compounds relevant for battery materials, from which we propose the few most promising candidate materials. In the design of batteries, selecting the proper material is difficult because there are so many metrics to consider, including capacity which is a fundamental engineering property. Using reported experimental data as our starting point, we demonstrate how we can build a dataset that provides a guide for the selection of battery materials. Although we focus on capacity of Li based spinel structures for electrode materials relevant for usage in batteries, the methodology developed and demonstrated here can be adapted to other properties, structures, and site occupancies. This work integrates non-linear manifold learning, prediction approaches accounting for co-linearity in the data, and uncertainty assessments. This addresses important issues in design of materials, where often the underlying physics is complex and difficult to visualize, while also accounting for challenges with limited data. Our methodology provides a reasonably accurate computational representation of experimental data while accounting for model uncertainty.

2:15 PM DS01.02.03
A Framework for Shared, Distributed Autonomy in Additive Manufacturing Research and High-Mix Low-Volume Manufacture James O. Hardin[1], Robert Weeks[2], Nicholas Arn[3,1], Jennifer Ruddock[3,1], Jennifer Lewis[2] and J. D. Berrigan[1]; [1]Air Force Research Laboratory, United States; [2]Harvard University, United States; [3]UES Inc, United States

The future of research and manufacturing is autonomous and data-driven. Well-curated data is the fuel for this change, but research and high-mix low-volume manufacturing tend to produce highly dynamic and complex data. To date, most solutions have been limited to single pieces of equipment in highly controlled environments, thus limiting the applicability of solutions to the originating environments. Despite this limit, standardized portions of the data can be added to communal material data repositories like NOMAD or Materials Cloud. The tools to interact with the data in these cloud repositories are growing quickly, but there is very limited support for the process data, non-standardized data, and integration of the repository into closed-loop control of research or manufacturing automation. The authors propose that the ROSEDA (Repository of Operations & Subject Expertise for Decision Autonomy) framework may close these gaps, enabling autonomous learning, not just as a lab, but as a national manufacturing/research system. The ROSEDA framework includes an agile cyber-physical framework involving automation, dynamic database engineering, cloud/edge computing, human-machine interfacing, and artificial intelligence. As a first demonstration, the authors are attempting to give a ROSEDA system an "intuition" about new inks similar to the intuition possessed by expert print technicians. This presentation will cover the structure of the ROSEDA framework and current progress toward this demonstration.

2:30 PM DS01.02.04
Text-Mined Dataset of Solution-Based Inorganic Materials Synthesis Recipes for Predictive Synthesis Zheren Wang[1,2], Olga Kononova[1,2], Kevin Cruse[1,2], Tanjin He[1,2], Haoyan Huo[1,2], Yuxing Fei[1,2], Yan Zeng[2], Yingzhi Sun[1,2], Zijian Cai[1,2], Wenhao Sun[3] and Gerbrand Ceder[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]University of Michigan–Ann Arbor, United States

In the past decade, the Materials Genome Initiative (MGI) effort has significantly facilitated and accelerated materials discovery and design by deploying large-scale ab-initio computation and building computational databases of structure-property relationships, thereby significantly accelerating the design of novel compounds. In contrast, important experimental properties aspects of materials research are only available in manually curated databases, or are not collected at all as large data sets. In this presentation, we focus on inorganic synthesis recipes, as a comprehensive large-scale collection of synthesis formulations would assist in the development of more quantitative and AI-driven approaches to synthesis routes for novel compounds.

Scientific publications represent the largest repository of knowledge about material synthesis and could be used as a reliable source of data. However, human-written descriptions of syntheses require additional levels of interpretation in order to be converted into a codified, machine-operable format. In this work, we built an extraction pipeline consisting of algorithms and models which use various advanced machine learning and natural language processing techniques to extract essential solution-based inorganic materials synthesis information from the scientific literature. By applying the extraction pipeline, we extracted 35,675 codified solution-based inorganic materials synthesis "recipes" from over 4 million papers. Each recipe includes precursors, targets, the quantities of materials used, and synthesis actions with the corresponding attributes. Information about targets and precursors was used to build the reaction formula for every synthesis procedure. This work has created the first large-scale, freely available dataset of solution-based inorganic materials synthesis recipes. The dataset not only paves the way for future data-driven approaches to investigate inorganic materials synthesis and synthesizability, but also allows researchers to design optimized synthesis procedures for automated experimentation.

Estimation of Flory- Huggins Interaction Parameter Using Machine Learning Janhavi Nistane, Lihua Chen and Rampi Ramprasad; Georgia Institute of Technology, United States

For crude oil separation, polymer membranes consume as little as 10 percent of the total energy as required by thermal distillation processes, hence showing potential to surpass traditional distillation processes in terms of carbon emissions and energy efficiency. To build a polymer membrane, it is of utmost importance to investigate thermodynamic properties like solubility, miscibility, diffusivity, absorption, etc. The Flory-Huggins Interaction Parameter (χ) is often used to describe the polymer-solvent behavior in terms of these thermodynamic quantities.

This work focuses on building a temperature-dependent machine learning model for the prediction of χ for a given polymer-solvent pair, by making use of existing experimental data from numerous literature sources.

The experimental data was collected from over 130 research articles, to build a database of temperature-dependent χ, for over 50 polymers and 130 solvents. This dataset was also augmented with a dataset of Hildebrand solubility parameters for polymers and solvents. Both datasets were used to build a Gaussian Process Regression (GPR) based model in the "multi-task" learning mode. To further boost the performance of the model, feature engineering using Recursive Feature Elimination (RFE) and LASSO reduction was employed. Multi-task learning, which involves dataset fusion, has recently proved powerful in treating situations with data sparsity. We show that the resultant model is superior in performance to the conventional approach of estimating χ using empirical relationships.

Informing Manufacturing Scalability with Text and Data Mining Elsa Olivetti and Mrigi Munjal; Massachusetts Institute of Technology, United States

This presentation will cover learnings around the manufacturing scalability of experimental research through automatic mining of published text for key phrases and facet similarity across multiple disciplines. In this way we inform at least three principal consequences of materials selection: (1) the availability, scaling capacity, and price volatility of the chosen materials' constituents, (2) the manufacturing processes needed to integrate the chosen materials towards manufacturable devices, and (3) the performance that may be practically achieved with the chosen materials and processes. While each of these factors is, in isolation, a pivotal determinant of manufacturing scalability, we show that consideration and optimization of their collective effects and trade-offs is necessary to more completely chart a scalable pathway towards experimental research that moves more rapidly towards manufacturability. Successful scale up and integration of these novel materials is conditioned on a multitude of factors that are difficult to simultaneously optimize, particularly given the wide range of chemical and structural archetypes currently under investigation. Here we discuss key materials and processing considerations that could impact the scale up to production.

***A priori* Control of Zeolite Synthesis with High-Throughput Simulations** Daniel Schwalbe Koda[1], Soonhyoung Kwon[1], Cecilia Paris[2], Estefania Bello-Jurado[2], Zachary Jensen[1], Elsa Olivetti[1], Tom Willhammar[3], Avelino Corma[2], Yuriy Román-Leshkov[1], Manuel Moliner[2] and Rafael Gómez-Bombarelli[1]; [1]Massachusetts Institute of Technology, United States; [2]Universitat Politècnica de València-Consejo Superior de Investigaciones Científicas, Spain; [3]Stockholm University, Sweden

Computational methods can guide materials discovery by screening relevant compositions and structures prior to experimentation. Despite the acceleration provided by these approaches, synthesis efforts still rely on trial-and-error to realize computationally designed materials. Here, we combine high-throughput simulations, automated literature extraction, human-computer interaction, and experimentation to control materials synthesis from first principles. We focus on zeolite structures, whose challenging synthesis hinders the discovery of new catalysts. We start developing algorithms that accelerate zeolite simulations by two orders of magnitude when compared to traditional methods. Then, we compute more than half a million zeolite-molecule pairs, thus simulating relevant synthesis conditions for these materials. The calculations explain synthesis outcomes from more than one thousand articles extracted from the literature. In addition, computational predictions enable the design of organic structure-directing agents (OSDAs) with tailored selectivity towards the materials of interest. To visualize the generated data, we developed a web-based platform that provides a visual interface for data exploration by human experts. This human-computer partnership enables researchers to compare templates, obtain information on prior art and literature for zeolite-OSDA pairs, and downselect molecules based on their selectivity, synthetic accessibility, or physical descriptors prior to attempting the synthesis. Experimental results show that the proposed synthesis routes are effective in crystallizing the target materials and additionally enhance the catalytic properties of the obtained frameworks. This work offers a design platform for zeolite synthesis and can be extended to other classes of materials.

4:15 PM DS01.03.02
Machine Learning Design of Low-Cost, Selective Organic Templates for Zeolites Omar A. Santiago Reyes, Daniel Schwalbe Koda and Rafael Gómez-Bombarelli; Massachusetts Institute of Technology, United States

Zeolites are porous, crystalline aluminosilicate materials that have a wide range of industrial uses. These materials exhibit a variety of pore sizes and shapes, which enable them to selectively and efficiently catalyze specific chemical reactions. To template the formation of target frameworks, organic structure-directing agents (OSDAs) are incorporated into the zeolite synthesis route. However, selecting appropriate OSDAs to synthesize a desired zeolite often requires exhaustive experimentation and trial-and-error. While atomistic simulations can suggest favorable OSDAs for zeolites, their computational cost hinders a vast exploration of the combinatorial host-guest space. Here, we developed a machine learning approach to address this combinatorial design challenge. We started by creating an interpretable representation to capture OSDA shapes and sizes. Then, we trained machine learning models on more than 500,000 simulated zeolite-OSDA pairs to predict binding energies at a fraction of the computational cost from simulations. To thoroughly explore the chemical space of OSDAs, we created a library of candidates using a computational synthesis approach. The molecules were combinatorially generated from known precursors taken from vendors and ranked by their final cost. Finally, we evaluated the potential of millions of molecules as selective OSDAs for hundreds of zeolites using the ML-predicted energies. Our library covers a wide portion of the OSDA molecular-shape space and can drastically accelerate zeolite discovery.

4:30 PM DS01.03.03
Discovering New Concrete Materials by Machine Learning and Bayesian Optimization Mathieu Bauchy; University of California, Los Angeles, United States

Concrete—which is by far the most manufactured material in the world—is responsible for 5-to-10% of human CO_2 emissions. Here, we present an uncertainty-aware, machine-learning-enabled optimization scheme that aims to accelerate the discovery of new optimized concrete mixes featuring minimum embodied CO_2 while meeting target performance and manufacturing constraints. We first develop an unprecedented dataset comprising more than 10,000 concretes with varying mixture proportions, together with their measured properties (compressive strength, slump, etc.). The dataset is used to train a series of Gaussian Process regression (GPR) models that accurately map concretes' mixture proportions to their properties, and uncertainty thereof. We then adopt Bayesian optimization to guide the discovery of new concrete mixtures featuring minimum embodied CO_2 while presenting required performance metrics (e.g., with a strength meeting or exceeding a given target) and obeying manufacturing constraints (e.g., with compliant slump). This pipeline leads to the discovery of several new concrete mixtures presenting a >50% decrease in embodied CO_2.

4:45 PM DS01.03.04
Unified GNN Architecture Design for High-Throughput Material Screening Petar Griggs, Lin Li and Rajmonda Caceres; MIT Lincoln Laboratory,

United States

Given the natural graph structure in crystalline materials, numerous graph neural network (GNN) architectures have been developed to learn robust and generalizable representations that enable fast property prediction and accelerate the design of crystalline materials. However, with a vast array of material properties of interest, many of which differ from one another in fundamental ways, a one-size-fits-all approach to designing machine learning (ML) models is ill-suited to property prediction tasks. In this work, we develop the Integrated Graph Neural Network (I-GNN) framework to systematically explore the architecture design space for GNNs over a wide range of material property prediction tasks, ranging from mechanical properties, thermal properties to electronic properties. We construct an expansive design space of GNNs to enable methodical exploration of design choices. We show how the design space can be searched to find a task-specific optimal architecture by performing Bayesian optimizations over the model architecture itself. We demonstrate that the I-GNN framework is able to find architectures that outperform existing GNN architectures, such as CGCNN, MEGNet and GATGNN, on a wide range of properties, and the optimal architecture is indeed property-dependent. To provide insights into individual GNN designs for predicting specific material properties, we analyze the correlation between property similarities and the associated optimal architecture similarities, and study the transferability of the best GNN design across different properties. In summary, the I-GNN framework offers a methodical and scalable approach to explore the GNN design space, identifies the relationship between the best GNN designs and the target material properties, and provides insights into selecting the appropriate GNN to train given the target prediction task.

5:00 PM DS01.03.05
Bayesian Experimental Optimization of Photonic Curing Process for Flexible Perovskite Photovoltaics Devices Zhe Liu[1], Robert Piper[2], Weijie Xu[2] and Julia Hsu[2]; [1]Northwestern Polytechnical University, China; [2]The University of Texas at Dallas, United States

Perovskite solar cells have attracted significant attention in the PV community, because >25% power conversion efficiency was recently demonstrated in lab-scale small-area devices. However, manufacturing scaleup of perovskite solar cells is one of the critical areas requiring further innovations [1]. Photonic curing process is an industrially compatible technique that could facilitate crystallization of large-area perovskite thin films in milliseconds without heating the substrate [2]. This key feature enables perovskite device manufacturing on a flexible substrate that cannot sustain high temperature at high web speed. Due to the vast number of possible experimental combinations, process optimization typically requires a systematic effort of experimental planning to find an optimal window of process conditions.

In this work, we demonstrate rapid optimization of photonic curing with four process variables (namely, $MAPbI_3$ precursor concentration, additive concentration, exposure time and radiant energy during photonic curing) and aim at achieving the power conversion efficiency improvement from the current baseline of 10% on 100 µm thick Willow glass substrates [3]. Machine-learning-based Bayesian optimization framework is deployed to search the optimal process conditions in a high-dimensional experimental space. Using this framework, we can quickly establish the numerical regression model between process variables and device efficiency, and suggest new experimental planning based on evaluating an acquisition function that balances between exploitation and exploration. Especially, to increase human-machine interactions and reduce the possibility of potential mistakes in the model, we provide human-understandable 2D visualization (e.g., contour plot, tSNE plot) in every iteration and produce real-time feature importance ranking by the Shapley Additive Explanation (SHAP) method. The Bayesian optimization framework is shown to be efficient in process optimization and could accelerate the transition from the conventional thermal annealing process to photonic curing. Furthermore, we explore the potential of transferring the knowledge of fabricating the perovskite absorber layer to the hole and electron transport layers. We envision machine learning could be a useful tool to accelerate the development of manufacturing scale-up in perovskite PV devices.

10:30 AM DS01.04.01
Design of Polymers for High-Temperature Capacitors via a Migration-Assisted Evolutionary Algorithm, Machine Learnin, and Retrosynthetic Analysis Joseph D. Kern, Lihua Chen, Chiho Kim and Rampi Ramprasad; Georgia Institute of Technology, United States

Polymer film capacitors are favored by engineers because of their graceful failure mechanisms and low cost. However, certain applications, such as electrified aircraft, require capacitors that can withstand temperatures over 250 C, which is at least 100 C higher than the operating temperature of state-of-the-art polymer film capacitors. We combined machine learning with a genetic algorithm to predict hypothetical polymers with bandgaps above 5 eV, glass transition temperatures above 500 K, and dielectric constants above 4 at 100 Hz. These are useful properties, as a large bandgap can be used as a proxy for dielectric breakdown field strength, a high glass transition temperature indicates the polymer is thermally stable at high temperatures, and a high dielectric constant improves energy density per volume.

Basic genetic algorithms, however, suffer from low chemical diversity. To solve this challenge, we implemented a migration-assisted genetic algorithm where polymers evolved on separate islands, with each island enforcing a different design criterion, and then migrated. This increased the chemical space explored and improved the speed at which polymers achieving target properties were discovered. This is a robust design that could be used for other design applications as well. After predicting polymers that achieved target properties, a retrosynthetic algorithm was used to screen them for ease of synthesizability and likely reactants. A list of synthesis-friendly polymers achieving target properties and their likely reactants is shown.

10:45 AM DS01.04.02
Machine Learning for Accelerated Discovery of Polymer Electrolytes Gabriel Bradford, Jeffrey Lopez, Richard Osterude, Tian Xie, Jeffrey C.

Grossman, Rafael Gómez-Bombarelli and Yang Shao-Horn; Massachusetts Institute of Technology, United States

Polymer electrolytes (PEs) have the potential to improve safety and enable higher energy densities in energy storage devices. However, PEs suffer from significantly lower ionic conductivity than liquid electrolytes[1], preventing their adoption in functional devices. Additionally, because PE synthesis and characterization are time consuming, relatively few PE formulations have been experimentally tested despite decades of study. In this work we leverage advances in machine learning (ML) and high throughput experimentation[2] to accelerate the design and discovery of PEs. The ML model we've developed incorporates Arrhenius behavior into a state-of-the-art message passing neural network[3] to predict ionic conductivity of PEs. To train the model, we've compiled the largest known PE ionic conductivity dataset with nearly 15,000 values, which were gathered from experimental PE characterization publications and hand checked for quality. Ionic conductivity values were predicted for several thousand previously untested PE formulations, from which promising candidates—subject to synthesizability and processability requirements—will be selected for high throughput testing. The resulting data from high throughput experiments will be used to retrain the ML model, improving model predictions in an active learning fashion. The ML model shows marked improvement with increasing training data, indicating that data scarcity is a key limitation in machine learning PE ionic conductivity that our high throughput experimental setup addresses. This work offers an integrated computational-experimental platform to accelerate materials discovery for energy storage applications.

polyG2G—A Novel Machine Learning Algorithm Applied to the Generative Design of Polymer Dielectrics Rishi Gurnani, Deepak Kamal, Huan Tran, Harikrishna Sahu and Ramamurthy Ramprasad; Georgia Institute of Technology, United States

Polymers, due to advantages such as low-cost processing, chemical stability, low density and tunable design, have emerged as a powerhouse class of materials for a wide range of applications, including dielectrics. In certain applications, the performance of dielectrics is limited by low electric breakdown strength. Using this real-world application as a technology driver, we describe a novel artificial intelligence (AI) based approach for the design of polymers. We call this *polyG2G*. The key concept underlying *polyG2G* is graph-to-graph translation. In graph-to-graph translation, the distribution of subtle chemical differences between high- and low-performing polymers is learned and then sampled to generate novel, high-performing, hypothetical materials. Our approach, with respect to a host of presently adopted design methods, exhibits a favorable trade-off between generation of chemically valid materials and available chemical search space. *polyG2G* finds thousands of potentially high-value targets (in terms of glass-transition temperature, band gap, and electron injection barrier) from an otherwise intractable search space. Density functional theory simulations of band gap and electron injection barrier confirm that a large fraction of the polymers designed by *polyG2G* are indeed high-value. Finally, we find that *polyG2G* is able to learn established structure-property relationships.

11:15 AM DS01.04.04
Multi-Task Predictor for Homopolymers, Copolymers and Polymer Blends Shivank S. Shukla, Christopher B. Kuenneth and Rampi Ramprasad; Georgia Institute of Technology, United States

Polymer blends is one of the most rapidly growing fields in the plastics industry. These multicomponent systems can satisfy complex material requirements by blending known polymers. There is a huge demand for property prediction models to find superior materials in the vast chemical space of polymer blends. In this study, we train a multi-task deep neural network to predict the glass transition, melting, and degradation temperature of homopolymers, copolymers, and polymer blends in a single model. For this, we propose a universal fingerprinting scheme applicable to all three polymer types that shows excellent performance. Our models were built on a joint dataset of more than 20,000 data points containing experimental values of the thermal properties of homopolymers, copolymers, and polymer blends. Our developed models are accurate, fast, flexible, and scalable, and aim to supersede previously developed models for only homopolymers and copolymers.

11:30 AM DS01.04.05
Machine Learning Models to Predict Properties Relevant to Depolymerization of Polymers Aubrey R. Toland, Huan Tran, Lihua Chen, Yinghao Li, Chao Zhang and Rampi Ramprasad; Georgia Institute of Technology, United States

High performance polymers which can exhibit controlled degradation to monomer feedstock at end-of-use are essential to solve the global polymeric waste problem. This work focuses on polymers which undergo ring-opening-polymerization (ROP), as these polymers have shown promise within the context of high performance, depolymerizable polymers. We attempt to accelerate the development of such ROP depolymerizable polymers using machine learning to predict properties indicative of whether or not a polymer can undergo stable depolymerization. These properties, which include ceiling temperature (T_c), enthalpy of polymerization (ΔH_p), and entropy of polymerization (ΔS_p), are reported in literature for only a small subset of ROP polymers. In order to overcome this problem of data scarcity, classical molecular dynamics and density functional theory based simulations were utilized to compute ΔH_p for several hundreds of ROP polymers spanning a much larger chemical diversity than studied thus far. The computational dataset (treated as a "low-fidelity" version of the true measured ΔH_p) was combined with the much smaller dataset of experimentally measured ΔH_p (treated as the "high-fidelity" data) to develop predictive models of ΔH_p at the high-fidelity level. A variety of multi-fidelity learning approaches, including co-kriging and multi-task learning, were adopted. Finally, the computed ΔH_p, measured ΔH_p, and T_c datasets were utilized together to develop predictive models of T_c, the temperature above which depolymerization will be thermodynamically favored. A critical analysis of the performance of the models, challenges that remain in terms of data sparsity and diversity, the true benefits and limitations of the information fusion approaches, and guidelines on chemical factors that control ΔH_p and T_c will also be presented.

SESSION DS01.05: Closed-Loop and Autonomous I

Accelerated Development of Colloidal Nanomaterials Enabled by Autonomous Robotic Experimentation in Flow Milad Abolhasani; North Carolina State University, United States

Despite the intriguing properties and widespread applications of colloidal nanomaterials in energy and chemical technologies, their discovery, synthesis, and manufacturing are still based on Edisonian trial-and-error-based techniques. Existing nanomaterials development strategies using resource-intensive batch reactors with irreproducible and uncontrollable heat/mass transport rates very often fail to overcome the demands of the vast synthesis and processing universe of colloidal nanomaterials, resulting in a slow and expensive discovery and development timeframe (8-10 years). Recent advances in lab automation and machine learning (ML)-guided modeling/decision-making strategies provide an exciting opportunity to reshape the discovery and manufacturing of colloidal nanomaterials.[1] In this talk, I will present an intelligent closed-loop nanomaterial synthesizer for on-demand development, formulation optimization, and manufacturing of colloidal nanomaterials through the convergence of robo-fluidic experimentation and *in-situ* nanomaterial characterization with machine learning.[2] I will discuss how modularization of different stages of colloidal nanomaterials synthesis and processing in tandem with a modular neural network ensemble modeling and decision-making under uncertainty can enable resource-efficient navigation through an experimentally accessible high dimensional space. An application of the developed modular robotic experimentation workflow for the autonomous synthesis of colloidal metal halide perovskite nanocrystals will be presented.

2:00 PM DS01.05.02
Autonomous Discovery of Perovskite Nanocrystals and Nanoplatelets Tony C. Wu, Andrew Johnston, Daniel Flam-Shepherd, Yitong Dong, Edward H. Sargent and Alan Aspuru-Guzik; University of Toronto, Canada

Halide perovskite materials have gained significant interest in recent years for their optoelectronic applications such as photovoltaics and light-emitting diodes. Colloidal perovskite nanocrystals (NCs) and nanoplatelets (NPLs) are promising specifically for light-emitting applications, due to bright luminescence, tunable energy levels, narrow emission spectrum, confined excitons, and facile synthetic process. Perovskite NCs and NPLs are in the form of ABX_3 or $L_2[ABX_3]_{n-1}BX_4$, where A is a monovalent cation, B is a divalent cation, X is a halide ion, and L is a ligand for stabilization. There is a large combinatorial space of ions, ligands, concentration, ratios, solvents for optimizing perovskite NCs and NPLs. An autonomous system that combines parameter exploration and automated experimentation can accelerate the development of perovskite NCs and NPLs.
In this work, we will demonstrate our automated system for Ligand Assisted Reprecipitation (LARP) synthesis. This system has the advantage of using batch synthesis conditions, compared to other flow synthesis approaches. The system can also easily include a wide variety of reagents, ligands, and solvents. For characterization, a custom-built optical setup with flow cells is used for measuring absorption, emission, and photoluminescence quantum yield (PLQY). The system also features a wash design protocol to clean the reactors and flow cells for the next experimental cycle. We use Bayesian Optimization to search for perovskite synthesis conditions that maximize PLQY, color, or emission widths. For the results, we demonstrate how the system can help us optimize experimental conditions autonomously.

2:15 PM DS01.05.03
AI-Guided Autonomous Continuous Flow Synthesis for Accelerated Colloidal Quantum Dot Discovery Paul Kenis; University of Illinois at Urbana-Champaign, United States

Semiconducting colloidal quantum dots hold promise for and are starting to be applied in a number of applications ranging from optoelectronics and photovoltaics to bioimaging. Their properties can be tuned by controlling their composition, structure, size, and size distribution. Given the vastness of synthesis parameter space, identifying optimal compositions and structures as well associated optimal synthesis recipes for them, however, remains a major hurdle for accelerated screening and discovery. The implementation of modular flow reactors, integrated with real-time reaction monitoring, automation and data science, for resource-efficient synthesis has the potential to accelerate this material discovery and synthesis screening process.
This presentation will highlight the development and application of a modular continuous flow reactor platform for synthesis of heavy-metal-free colloidal quantum dots with improved size-uniformity and enhanced optical properties. For example, our efforts, in collaboration with experts from industry and academia, have led to multiple promising insights into the synthesis of InP-based quantum dots. Second, the presentation will feature the development of a flow reactor platform that integrates inline spectroscopy with artificial intelligence-based feedback algorithms for efficient exploration of the multidimensional chemical synthesis parameter space. This platform autonomously learns the parameter space from a small number of experiments (<100), develops a predictive model, and synthesizes InP quantum dots of targeted bandgap and polydispersity (with no-prior-knowledge of the reaction space) all through self-driven experiments in less than 30 hours. Our results underscore the promise and critical role of data-science-assisted experimentation for accelerating the screening and discovery of semiconducting colloidal nanocrystals with desired properties, but also for maximizing synthesis insights across multidimensional parameter space for different classes of colloidal materials.

2:30 PM DS01.05.04
Machine Learning with Knowledge Constraints Accelerates Process Optimization of Perovskite Solar Cell Manufacturing Nicholas Rolston[1], Zhe Liu[2], Austin Flick[1], Thomas W. Colburn[1], Zekun Ren[2], Justin Chen[1], Tonio Buonassisi[2] and Reinhold H. Dauskardt[1]; [1]Stanford University, United States; [2]Massachusetts Institute of Technology, United States

Perovskite solar cell technology has achieved rapid, unprecedented development in the research lab in terms of its record power conversion efficiency (PCE); however, successful commercialization requires the development of low-cost, scalable, and high-throughput manufacturing techniques. One of the key challenges to develop a new fabrication technique is the high-dimensional process optimization. Sequential learning, an iterative framework of machine learning for experimental planning, has been adopted for high-dimensional optimization tasks in many fields of physical science. This framework has been adopted to achieve research autonomy for optimization tasks, which is often combined with robotic research equipment, and in some research studies, sequential learning method can overperform the experimental plan made by human experts.

The current reports of sequential learning studies for process optimization have some common drawbacks: e.g., disregarding knowledge from related background studies, or neglecting qualitative insights from human experts. For example, during manual optimization of perovskite thin films, a visual assessment of film thickness, color, and large asperities has been used as an effective screening method. Based on this idea, we introduce an ML

manufacturing process optimization framework that combines the output of a regression-based model (learning by doing) with probabilistic knowledge constraints (physical intuition and previously collected data) in sequential learning.

We optimized six parameters in the rapid spray plasma processing (RSPP) technique — substrate temperature, linear process speed, spray flow rate, plasma gas flow rate, plasma height, and plasma duty cycle. Process optimization enables 19% efficiency, which is on par with the highest performance reported to date for open-air spray coating processing technique. The resulting acceleration factor to achieve this highest efficiency is > 3X compared to conventional pseudo-random or factorial design of experiments sampling methods. Additionally, the model has an enhancement factor of greater than 30X in finding the top-one-percentile process conditions, identifying 10 new conditions that produce efficiencies comparable to previous top performing devices before implementing the machine learning approach.

In closing, we observe a disconnection between the machine learning community and photovoltaics research community, where machine learning methods tend to take human out of the loop. Herein, we developed this sequential learning framework to provide an alternative demonstration, where researchers' inputs and background data can be easily incorporated with decision making during the iterative experimental planning.

2:45 PM DS01.05.05
Joint Property-Process Optimization of Halide Perovskites: Active Learning on Computed Property Manifolds in High-Throughput Experiments Rishi Kumar[1], Deniz N. Cakan[1], Moses Kodur[1], Connor Dolan[1], Maria K. Chan[2], Gal Mishne[1], Arun Kumar Mannodi Kanakkithodi[3] and David P. Fenning[1]; [1]University of California, San Diego, United States; [2]Argonne National Laboratory, United States; [3]Purdue University, United States

The path from computational prediction to realization of new materials is clouded by processing parameters and kinetics. We present a new approach to unify computational and experimental data sets, wherein the computed material properties and processing parameters form a joint property+process search space for experimental efforts. Active learning over the manifold defined by computed properties utilizes their topology rather than their absolute values. This approach leverages similarities in computed and measured property manifolds while sidestepping problems arising from absolute errors in computed properties.

We demonstrate high-throughput optimization of composition and processing conditions for hybrid halide perovskites thin-films using a robotic platform guided by active learning on a joint property-process manifold. The property manifold is constructed using a limited set of density functional theory (DFT) calculations, augmented by trained materials graph networks (MEGNet [1]). The graph network densely interpolates the DFT-computed properties over the compositional search space, the manifold of which forms the "property space". Process variables (annealing temperature, solvent, antisolvent, etc) form the "process space". The joint property+process space constitutes our overall search space.
We search this property+process space using a high-throughput, automated thin-film deposition platform, Automated Materials by Solution Synthesis (AMaSS). AMaSS deposits solution-based thin films and characterizes them by darkfield, brightfield, and photoluminescence imaging and transmission and photoluminescence spectroscopy. These characterizations are processed to extract features describing film morphology, homogeneity, and optoelectronic behavior. AMaSS experiments are guided by Bayesian Optimization, in which the inputs are points in property+process space and the outputs are features extracted from the in-line characterization.

We will present several examples of validation of the approach, using optimizations within well understood search spaces, followed by results from discovery in new materials spaces. By simultaneously optimizing over property predictions and process variables, we bridge computational and experimental results. Our approach is broadly applicable to materials systems for which properties can be computed and offers a framework for translation of computed property manifolds into experimentally realized materials.

Accelerated Design of Architected Solids with Bayesian Optimization for Optimal Failure Properties Chengyang Mo, Xiaoheng Zhu, Paris Perdikaris and Jordan R. Raney; University of Pennsylvania, United States

With the widespread adoption of 3D printing processes, it is now a simple matter to build architected solids with complex geometries, such as cellular structures with non-uniform struts and non-periodic arrangements, to achieve desirable mechanical properties. However, finding the structures that optimize a set of mechanical properties, particularly nonlinear and/or failure properties, is challenging due to the large number of parameters that arise. To design more complex architected lattices, machine learning algorithms such as neural networks can help in the design process by generating all possible geometric patterns and finding candidates that match the desired properties. However, this approach is limiting, as it is only feasible for low dimensions and can only be experimentally validated for a few design candidates that have been identified. Here, we discuss the use of a framework based on Bayesian optimization which accelerates the convergence process. Bayesian optimization is a closed-loop design process based on Gaussian process regression which guides the choice of design variables for each iteration of experiments. We show the efficacy of the framework by first examining 3D-printed single edge notched bend bars with embedded cellular inclusions that act as defects. These defect regions can deflect cracks and lead to higher energy absorption during bending-induced fracture. Our Bayesian optimization framework explores the entire parameter space to find the geometry that leads to the globally optimal energy absorption, thereby identifying the parameters to use for the next experimental specimen. In a second application, we apply this framework to maximize energy absorption of cellular solids during in-plane compression. Groups of struts in the cellular solid are allowed to have non-uniform thickness, resulting in sixteen parameters. To accelerate the convergence process we use multiple data streams, including "high-fidelity" (but costly) experimental sources and "low-fidelity" (but inexpensive) finite element simulations using ABAQUS. We show that by including low-fidelity sources, the framework can converge more quickly than by using high-fidelity sources alone, thereby reducing the time and cost needed to discover an optimal design.

4:15 PM DS01.06.02
A Data-Driven Framework for Accelerating Mechanical Characterization at Small Scales Christos E. Athanasiou[1], Xing Liu[1], Nitin P. Padture[1],

Brian W. Sheldon[1] and Huajian Gao[2]; [1]Brown University, United States; [2]Nanyang Technological University, Singapore

Investigating mechanical properties at small scales is a challenging endeavor. It requires sophisticated micro-/nano-scale experimental methods combined with laborious/time-intensive finite element computations. In this talk, a new framework for materials characterization at small scales using the latest developments in machine learning will be presented. This framework involves multi-fidelity deep learning and active learning methods limiting the need for finite element simulations. Its application for predicting the fracture toughness of microscale pentagonal cross-sectional ceramic cantilevers will be showcased, demonstrating that it can significantly accelerate fracture toughness characterizations at small scales.

4:30 PM DS01.06.03
Late News: PRESTO: Rapid Protein Mechanical Strength Prediction with an End-to-End Deep Learning Model Frank Y. Liu, Bo Ni and Markus J. Buehler; Massachusetts Institute of Technology, United States

Proteins can form biomaterials with exceptional mechanical properties equal or even superior to synthetic materials. Currently, using experimental atomic force microscopy or computational molecular dynamics to evaluate protein mechanical strength remains costly and time-consuming, limiting large-scale *de novo* protein investigations. Therefore, there exists a growing demand for fast and accurate prediction of protein mechanical strength. To address this challenge, here we present PRESTO, a rapid end-to-end deep learning model to predict protein resistance to pulling directly from sequences. By integrating a natural language processing model with simulation-based protein stretching data, we first demonstrate that PRESTO can accurately predict the maximal pulling force, F_{max}, for given protein sequences with unprecedented efficiency, bypassing the costly steps of conventional methods. Enabled by this rapid prediction power, we further find that PRESTO can successfully identify specific mutation locations that may greatly change protein strength in a biologically plausible manner, such as at the center of polyalanine regions. Finally, we apply PRESTO to design de novo protein sequences by randomly mixing two known sequences at varying ratios. Interestingly, PRESTO predicts that the strength of these mixed proteins follows up- or down-opening "banana curves", breaking away from the general law of mixtures in conventional material systems. By discovering key insights and optimal sequences, we demonstrate the versatility of PRESTO as a tool in a rapid protein design pipeline. Our model may offer new pathways for protein material science that focus on analysis and testing of large-scale novel protein sets, as a discovery tool that can be complemented with other modeling methods, and ultimately, experimental synthesis and testing.

4:45 PM DS01.06.04
Direct Ink Writing—An *In Situ* Platform for Measuring Ink Rheology Robert Weeks[1], Jennifer Ruddock[2], Ezra Ameperosa[3], James Hardin[3], J. D. Berrigan[3] and Jennifer Lewis[1]; [1]Harvard University, United States; [2]UES, Inc., United States; [3]Air Force Research Laboratory, United States

Direct ink writing (DIW) is capable of patterning viscoelastic structural, functional, and biological inks into planar and 3D architectures. During extrusion-based printing, these inks are fluidized under an applied stress enabling their flow through fine nozzles. However, upon exiting the nozzle, they rapidly recover a solid-like state allowing the extruded filaments to retain their shape. For identical printing conditions (i.e., nozzle size, printing pressure, and speed), modest changes in ink rheology can significantly impact the printed feature size and fidelity. However, the optimization of key printing parameters for a given ink is time consuming. Here, we describe a data-driven approach to estimate the critical rheological parameters from images of printed standardized patterns. Our model is trained on data generated with automated experimentation using multiple samples of several different inks that exhibit a wide range of flow behavior. Using oscillatory shear rheometry, we collect sets of data that serve as "truth" for a machine learning model. Our work represents a significant step towards the establishment of autonomous, material-aware 3D printing platforms.

5:00 PM DS01.06.05
Using Machine Learning to Study Classification and Correlation of AFM Images with Bulk Properties Dalia G. Yablon[1] and Ishita Chakraborty[2]; [1]SurfaceChar LLC, United States; [2]Stress Engineering, United States

AFM images were collected on a variety of polymer blend samples that differ in bulk mechanical properties and microstructure. A deep learning model based on a convolutional neural net (CNN) successfully classified various combinations of images pointing to real and meaningful differences in their microstructure. A separate regression-based CNN was built to correlate the AFM images with various bulk mechanical properties. The results observed from the deep learning model reveal a relationship between the microstructures as captured by the AFM images with the different bulk material properties.

Inorganic Synthesis Planning for Zeolites Enabled by Data Extraction and Generative Modeling Zachary Jensen[1], Soonhyoung Kwon[1], Daniel Schwalbe Koda[1], Rafael Gómez-Bombarelli[1], Yuriy Román-Leshkov[1], Manuel Moliner[2] and Elsa Olivetti[1]; [1]Massachusetts Institute of Technology, United States; [2]Instituto de Tecnoologia Quimica, Spain

Zeolites are crystalline, nanoporous materials extensively studied for a variety of industrial applications including catalysis, absorption, and separations. Zeolites are typically synthesized hydrothermally using an organic structure-directing agent in combination with other inorganic precursors. While a number of studies have used simulation and data-driven methods to examine the effect of the organic component of zeolite studies, very little research has studied the inorganic aspects including the gel composition, reaction conditions, and precursor selection with similar techniques. Through data extraction and generative modeling, we examine and develop tools to improve these inorganic aspects of zeolite synthesis. We use natural language processing and human-in-the-loop data cleaning to optimize data extraction from the literature resulting in an exhaustive data set of approximately 20,000 zeolite synthesis routes. We then construct a conditional variational autoencoder trained to generate the inorganic synthesis components including gel composition, reaction conditions, and precursors given an OSDA and zeolite structure. This model is capable of generating synthesis conditions for newly predicted OSDA-zeolite pairs and can be paired with other models and simulations designed to optimize the organic aspect of zeolite synthesis. Additionally, we estimate basic kinetic information including the nucleation and growth rates by fitting crystallization curves found in the data set. We estimate synthesis systems missing intermediate crystallization points by fitting the parameters of existing curves as a function of the synthesis variables. We then examine the effect of various synthesis variables on these kinetic variables.

DS01.07.03
An Informatics Approach for Designing Doped Conjugated Polymers Hongmo Li, Harikrishna Sahu, Lihua Chen, Arunkumar C. Rajan, Chiho Kim, Natalie Stingelin and Rampi Ramprasad; Georgia Institute of Technology, United States

Conjugated polymers have garnered great interest as potential candidates for a wide variety of applications, ranging from electronics to biomedical usages. Doping conjugated polymers is an effective strategy for manipulating their electrical conductivity by generating charge carriers via addition of p-type or n-type dopants. However, identifying a suitable polymer:dopant combination generally relies on heuristic experimental approaches, and is exceptionally time- and labor-consuming due to the vastness of the chemical, configurational and morphological space. Here, we present high-performance surrogate models that are developed to predict the electrical conductivity of p-type and n-type doped polymers. Based on support vector machine (SVM) and Gaussian process regression (GPR) algorithms, the models are trained with available experimentally measured data, and are subsequently used to screen more than 800,000 polymer and dopant candidates to identify promising polymer:dopant combinations. Additionally, we extract new design guidelines that extend knowledge on important molecular fragments that correlate to high conductivity. Our work, thus, provides a roadmap towards robust and rapid material discoveries for doped conjugated polymers. Models are deployed at www.polymergenome.org for broader open-access community use.

DS01.07.04
Comparison of State-of-the-Art Machine Learning Descriptors for Property Prediction of Materials Janna Domenico[1], Nam Q. Le[1], Alexander New[1], Ian McCue[1], Christine Piatko[1], Michael Pekala[1], Elizabeth Pogue,[1], Tyrel McQueen[2] and Christopher Stiles[1]; [1]Johns Hopkins University Applied Physics Laboratory, United States; [2]Johns Hopkins University, United States

Machine learning (ML) approaches have the potential to accelerate and transform materials discovery and property prediction. One challenge is the development of accurate material descriptors, i.e., accurate ways to describe the characteristics of a real material to a ML model**.** Several techniques to generate descriptors have already been developed, such as RooSt and Magpie, which convert a material's composition string to a long-form descriptor: a weighted graph or a matrix of attributes. In contrast, Crystal Graph Convolutional Neural Networks (CGCNN) ML framework develops a descriptor using a material's full crystal structure – its crystallographic information file (CIF) – creating a multigraph. Until now, no rigorous comparison of descriptors has been performed. We assess these descriptors and their performance in ML models for predicting band gap, formation energy, and crystal system, for a database of ~800,000 material composition strings and CIFs. Insights into relative performance of descriptors can help assess what level of materials knowledge is required for accurate prediction of specific materials properties.

DS01.07.05
Accelerate Synthesis of Metal-Organic Frameworks by an Automated Robot and Machine Learning Algorithms Yunchao Xie, Chi Zhang, Heng Deng and Jian Lin; University of Missouri-Columbia, United States

Synthesis of materials with desired structures, e.g. metal-organic frameworks (MOFs), involves optimization of highly complex chemical and reaction spaces due to multiple choices of chemical elements and reaction parameters/routes. Traditionally, realizing such an aim requires rapid screening of these nonlinear spaces by experimental conduction under human intuition, which is quite inefficient and may cause errors or bias. In this work, we report a platform that integrates a synthesis robot with machine learning algorithms to accelerate the synthesis of MOFs. The robotic platform consists of an automatic direct laser writing apparatus, precursors injecting and Joule-heating components. It can automate the synthesis upon fed reaction parameters which are recommended by the genetic algorithm or the Bayesian optimization algorithm. Without any prior knowledge, this integrated platform continuously improves the crystallinity of ZIF-67, a demo MOF employed in this study, as the operation iterations of the two algorithms increase. This work represents a methodology enabled by a data-driven synthesis robot which achieves the goal of material synthesis with improved crystal structures, thus greatly shortening the reaction time and reducing energy consuming. It can be easily generalized to other material systems and paves a new route to the autonomous discovery of a variety of materials in a cost-effective way in future.

DS01.07.06
Application of Bayesian Optimization and Regression Analysis to Ferromagnetic Materials Development Alexandria Will-Cole[1], A. Gilad Kusne[2,3], Peter Tonner[2], Cunzheng Dong[1], Xianfeng Liang[1], Huaihao Chen[1] and Nian Sun[1]; [1]Northeastern University, United States; [2]National Institute of Standards and Technology, United States; [3]University of Maryland, United States

Bayesian optimization is a well-developed machine learning field for black box function optimization. In Bayesian optimization a surrogate predictive model, here a Gaussian process, is used to approximate the black box function. The estimated mean and uncertainty of the surrogate model are paired with an acquisition function to decide where to sample next. Bayesian optimization with Gaussian processes can be used for structure-property relationship optimization in materials systems with second order phase transitions or gradual disordering without a distinct phase transition. In this study we applied this technique to known ferromagnetic thin film materials such as ferromagnetic $(Fe_{100-y}Ga_y)_{1-x}B_x$ (x=0–21 & y=9–17) and $(Fe_{100-y}Ga_y)_{1-x}C_x$ (x=1–26 and y=2–18) to demonstrate optimization of structure-property relationships, specifically the dopant concentration or stoichiometry effect on magnetostriction and ferromagnetic resonance linewidth. These systems both experience gradual disordering without distinct phase transition with increase in boron and carbon concentration, thus are great case systems for Bayesian optimization with Gaussian processes. We have shown that using simulated Bayesian optimization methods to guide experiments, the number of samples required to statistically determine the optimum was reduced by 50 % compared with traditional research methods. Our results suggest that Bayesian optimization can be used to save time and resources to optimize ferromagnetic films. This method is transferrable to other ferromagnetic material structure-property relationships, providing an accessible implementation of machine learning to magnetic materials development.

DS01.07.08
Phase Classification of High Entropy Alloys Using Interpretable Machine Learning Kyungtae Lee[1], Mukil Ayyasamy[1], Timothy Hartnett[1], Paige Delsa[2] and Prasanna Balachandran[1]; [1]University of Virginia, United States; [2]Louisiana School for Math, Science, and the Arts, United States

High entropy alloys (HEAs) are multicomponent materials with nearly equal amount of four or more principal elements. Compared to conventional metal alloys, HEAs exhibit excellent mechanical, thermal, and electrochemical properties with immense potential for materials design due to a vast compositional space. HEAs are typically solid solutions with face centered cubic (FCC), body centered cubic (BCC), or hexagonally closed packed (HCP) phases. There is a long-standing in the application of machine learning (ML) methods to accurately classify the HEA phases as a function of chemistry and composition.

In this work, we develop an ML model with post hoc interpretability capability for HEA phase prediction. We accomplished our objective by combining an ensemble support vector machines (eSVM) algorithm with a variable attribution method. A dataset of 1,821 compositions was compiled from surveying the published literature. Each composition was represented by a high-dimensional space of 125 features that include atomic size, electronegativity, valence electron number, enthalpy of formation, and mixing entropy to name a few. The purpose of eSVM was to build a data-driven multi-class classification

learning model that establishes a quantitative relationship between chemical composition and experimentally determined phase information. We also compared the performance of the eSVM model with a random forest model. Both models had an accuracy of ~85% on the independent test set. We then performed post hoc interpretability of the trained eSVM models to quantify the relative contribution of each feature to the ML prediction score with respect to each instance in the training data. We developed a new clustering algorithm that identifies the similarity between training instances based on the variable attribution scores. Our analysis uncovers previously unknown phase-specific correlations between key features and the HEA phases.

SESSION DS01.08: Data-Driven Analysis I

10:30 AM *DS01.08.01
Building a Grain Growth Model by Deep Reinforcement Learning Amanda Krause[1], Weishi Yan[1], Lin Yang[1], Michael S. Kesler[2], Michael R. Tonks[1] and Joel B. Harley[1]; [1]University of Florida, United States; [2]Oak Ridge National Laboratory, United States

Abnormal grain growth, where a few grains grow faster at the expense of their neighbors, is hypothesized to occur because of anisotropic grain boundary (GB) character and unique GB networks. In a polycrystalline material, there are thousands of potential GB types and unlimited combinations of those GBs that makeup the 3D topology of a GB network. This combinatorial, high-complex space is too large for conventional data analysis methods to identify the physical descriptors that are necessary to build anisotropic grain growth models. Reinforcement learning is a machine learning tool that can capture the underlying behavior of an evolving Markov decision process and "teach" it to maximize the "rewards" regarding the agreement between prediction and simulation. Here, we applied a deep reinforcement model to emulate grain growth by conducting learning on Monte Carlo Potts grain growth simulations. Relative to other machine learning networks, reinforcement learning is a relatively interpretable model since the outputs of the models are tied directly to action. The developed reinforcement model can also be used to test different microstructural architectures and, thus, identify how GBs evolve over time. The accuracy of our short and long-term predictions for grain growth will be evaluated. Additionally, the potential and challenges associated with this method for exploring the cause of abnormal grain growth will be discussed.

11:00 AM DS01.08.02
Late News: Predicting Stability of Alloying Si Electrodes for Multivalent Cations by Support Vector Regression Joy Datta, Vidushi Sharma and Dibakar Datta; New Jersey Institute of Technology, United States

Data driven methodology has become a key tool in predicting material properties computationally at low cost. We present a detailed analysis on predicting stability of Si electrodes for multivalent ion batteries using Support Vector Regression (SVR). Emphasis is on transferability of machine learning (ML) SVR model trained on a set of Si alloys to new Si electrodes for multivalent ion batteries. SVR has the ability to deal with non-linear higher dimensional data in feature space by using kernel trick. We utilize previously reported Si based alloys derived from database for training and testing. Hyperparameters are tuned using two different approaches namely, Grid search CV and Bayesian optimization. The performance of the two approaches is compared in predicting energies and packing fraction of the structures. Furthermore, dependence of these two output properties on the crystal structures calls for an additional analysis on structural representation to the ML model. Three different featurizers are used to represent material structures as input features for ML. Our results show that featurizer Orbital Field Matrix performed best on validation dataset against featurizers X-Ray Diffraction and Sine Coulomb Matrix, while it predicted poor energy values of test data. In contrast, Sine Coulomb Matrix data achieved the lowest error between actual energies and predicted energies of test structures. Our work highlights the potential of ML methodologies in accurately foretelling the stability of reaction intermediates in alloying electrodes for ion batteries beyond Li and guides the experimental studies in selecting appropriate battery materials.

11:15 AM DS01.08.03
Recovering Atomic-Scale Chemistry from Multi-Modal Electron Microscopy Jonathan Schwartz[1], Yi Jiang[2], Zichao Wendy Di[2], Steve Rozeveld[3] and Robert Hovden[1,1]; [1]University of Michigan, United States; [2]Argonne National Laboratory, United States; [3]Dow, United States

Modern scanning transmission electron microscopes (STEM) can focus sub-angstrom electron probes to extract quantitative atomic structure and chemistry from elastic and inelastic scattering processes. The chemical composition of specimens is revealed by spectroscopic techniques produced by inelastic interactions in the form of energy dispersive X-rays (EDX) or electron energy loss of the transmitted electrons (EELS). Each atom's chemical identity and coordination provides essential information about the performance of nanomaterials across a wide range of applications from clean energy, batteries, and optoelectronics, among many others. Unfortunately, the dose requirements for high-resolution chemical-spectroscopy (e.g. 10^6 e/Å^2) often far exceeds the dose limits of a specimen—chemical maps are noisy or missing entirely. More reliable interpretation of material structure is made in combination with elastically scattered electrons that can measure structure, but not chemistry, at high signal-to-noise ratios (SNR). These inelastic and elastic signals (i.e. modalities) are typically analyzed separately. However, inspired by machine learning and compressed sensing methods, we show high-SNR recovery of chemical maps down to atomic resolution can be achieved by linking information between modalities.

Here we introduce multi-modal electron microscopy, a technique that offers high SNR recovery (500% increase in favorable cases) of nanoscale material chemistry by leveraging correlated information encoded within both high-angle annular dark-field (HAADF**)** and EDX / EELS. We recover chemical maps by reformulating the inverse problem as an optimization that seeks a solution which surpasses traditional dose limits. First, we model the physics of elastic scattering process to the inelastic spectroscopic chemistries. Second, we ensure the recovered chemical maps maintain a high degree of agreement with the initial measurements using a maximum log-likelihood. Lastly, following recent achievements in compressed sensing, we ensure the recovered chemical maps are maximally sparse in the gradient domain.

We demonstrate chemical recovery at the nanoscale in commercial CoS_2 catalysts for oxygen-reduction and atomic length scales for $Co_{1.51}Mn_{1.49}O_3$ and $ZnS/Cu_{1.81}S$ interfaces. In all cases, noise in the raw chemical maps is dramatically reduced, even at lower doses, while maintaining structure at and around interfaces. Moreover, our multi-modal approach also recovers the specimen's chemical relative concentration, allowing researchers to measure local stoichiometry. Uncertainty can be further quantified using confidence intervals from Fisher Information maps. This data-driven approach opens new pathways for high-throughput chemical characterization and the investigation of radiation sensitive specimens.

As a result, multi-modal electron microscopy reveals atomic scale chemistry with enhanced clarity at significantly lower electron doses than traditionally allowed.

11:30 AM DS01.08.04
A Real-Time, Physically Informed, Probabilistic Phase Labeling Algorithm for High-Throughput X-Ray Diffraction Studies Ming-Chiang Chang, Sebastian Ament, Maximilian Amsler, Duncan Sutherland, Carla Gomes, R. Van Dover and Michael O. Thompson; Cornell University, United States

High-throughput experimentation is widely used to rapidly assess phase behavior across composition and processing space. Fast and accurate phase identification (on the timescales of active learning loops) from synchrotron-based X-ray diffraction data is a critical step in many of these experiments. In contrast to conventional nonnegative matrix factorization(NMF) algorithms or modern neural network(NN) methods, we have developed a probabilistic algorithm to search and label the specific phases existing in processed libraries. The algorithm builds from a database of potential phases, exploiting the crystallography space group to model physically possible peak shifts (e.g., due to alloying or strain). This makes this method training free, lightweight and flexible. Finally, by modeling the peak shifting, peak ratio deviation, and other variations in the spectrum using Bayesian statistics, we are able to give a probabilistic prediction of the phases that are presented in each diffraction pattern, including the probability of an uncatalogued phase. The algorithm has been benchmarked using a range of binary and ternary oxide systems, with analysis speeds that are commensurate with the lateral-gradient Laser Spike Annealing high throughput technique.

11:45 AM DS01.08.05
***In Situ* Phase Determination Through Deep Learning Analysis of RHEED Data** Haotong Liang[1], Valentin Stanev[1], A. Gilad Kusne[2,1], Alex Wang[1], Logan M. Saar[1], Mikk Lippmaa[3] and Ichiro Takeuchi[1]; [1]University of Maryland, United States; [2]National Institute of Standards and Technology, United States; [3]The University of Tokyo, Japan

A key challenge in materials development is the ability to identify material phase in-situ during synthesis and processing. In this talk we present a phase mapping and phase determination method based on Reflection High Energy Electron Diffraction (RHEED) data. RHEED is an in-situ surface-structure characterization technique commonly used to observe the growth of thin films that produces diffraction patterns containing a wealth of static and dynamic information. However, the ability to extract this information is limited by the lack of versatile systems for automated analysis of the patterns. We used a Deep Learning-based tool for automating the analysis of RHEED diffraction patterns. Our method combines several supervised and unsupervised learning methods and permits the extraction of important qualitative and quantitative information characterizing the structure. As a test of the developed pipeline, we applied it to map the phase diagram of hematite structures grown under different conditions. With the increased robustness of the information extracted from the RHEED measurements, one would be able to attain quantitative insight as to the underlying structural phase as well as how the surface structure of a thin film is evolving during the deposition.

SESSION DS01.09: Closed-Loop and Autonomous II

1:30 PM *DS01.09.01
Autonomous Research Systems Current and Future Directions Benji Maruyama; AFRL/RXA, United States

The current materials research process is slow and expensive; taking decades from invention to commercialization. The Air Force Research Laboratory pioneered ARES™, the first autonomous research systems for materials development. A rapidly growing number of researchers are now exploiting advances in artificial intelligence (AI), autonomy & robotics, along with modeling and simulation to create research robots capable of doing iterative experimentation orders of magnitude faster than today. We will discuss concepts and advances in autonomous experimentation in general, and associated hardware, software and autonomous methods.

We expect autonomous research to revolutionize the research process, and propose a “Moore’s Law for the Speed of Research,” where the rate of advancement increases exponentially, and the cost of research drops exponentially. We also consider a renaissance in “Citizen Science” where access to online research robots makes science widely available. This presentation will highlight advances in autonomous research and consider the implications of AI-driven experimentation on the materials landscape.

2:00 PM *DS01.09.02
Decision-Making Under Uncertainty for Multi-Stage Experimental and Computational Pipelines Kris Reyes; SUNY Buffalo, United States

Many experiments in materials science and chemistry are executed within multi-stage experimental and computational pipelines. Examples of such pipelines include the sequential screening and filtering of candidate materials or drugs through a sequence of computer models of increasing fidelity, or multi-step materials synthesis and characterization. In this talk, we present some models and algorithms for executing multi-stage experimental and computational pipelines under the context of optimal experimental design and decision-making under uncertainty. In particular, we present techniques that capture the multi-stage nature of the experimental procedure, including both the need to model experimental decisions for intermediate stages and the ability to characterize the outputs of such stages. We demonstrate how such models and decision-making algorithms can lead to improvements over other methods that treat the experimental structure as a black box, or techniques that perform sequential screening without measuring and mitigating uncertainty.

2:30 PM DS01.09.03
Scientific AI for Autonomous Neutron Diffraction Experiments Austin McDannald[1], William Ratcliff[1,2], Daniel Samarov[1], Efrain Rodriguez[2], Ichiro Takeuchi[2], Matthias Frontzek[3], Andrei Savici[3], Mathieu Doucet[3] and A. Gilad Kusne[1,2]; [1]National Institute of Standards and Technology, United States; [2]University of Maryland, United States; [3]Oak Ridge National Laboratory, United States

Beamtime at neutron diffraction instruments is a valuable resource uniquely capable of characterizing the magnetic structure of materials but with very limited availability. Here we develop a Scientific AI (SciAI) that is able to autonomously discover the magnetic transition temperature, and thus make efficient use of the beamtime. Several physical principles of the problem are encoded into this Bayesian algorithm, such as the Poissonian-like detector physics and the relationship between diffraction intensity and material magnetization. Furthermore, this system demonstrates hypothesis testing wherein the algorithm identifies which physical principles govern the magnetic transition. This SciAI has been implemented on the BT-4 beamline at NCNR at NIST as well as at WAND[2] at the HB-2C beamline at HIFR at ORNL, and has been used to autonomously discover the magnetic transition temperature of

both MnO and $Fe_{1.09}Te$, materials with different magnetic behaviors. Compared to an *a priori* scheduled experiments, this system reduced the number of measurements needed for the experiment by a factor of approximately 5.

2:45 PM DS01.09.04
Physics-Informed Bayesian Approach for Autonomous Grain Map Discovery with EBSD Austin McDannald[1], Amit Verma[2], Sukbin Lee[3], Gregory Rohrer[2] and A. Gilad Kusne[1,4]; [1]National Institute of Standards and Technology, United States; [2]Carnegie Mellon University, United States; [3]Ulsan National Institute of Science and Technology, Korea (the Republic of); [4]University of Maryland, United States

Electron Backscatter Diffraction (EBSD) mapping is a powerful technique that can be used to study the crystal grain orientations in a material, but it can be time consuming to exhaustively collect diffraction data at every location in the sample. Here we present a Scientific AI (SciAI) that autonomously discovers the grain map, collecting data at the most informative locations. This SciAI encodes physics to predict the grain map such as: the crystal symmetry of the material under study, and the rule that crystal grains should be contiguous. Crucial to the success of the active learning scheme employed in this SciAI is the quantification of uncertainty in the assigned grain membership and propagation of that uncertainty to the prediction of the grain map. This SciAI is able to discover a grain map for ZnO with only ~10% of the data used in a traditional measurement.

3:00 PM DS01.09.05
Autonomous Synthesis of Metastable Materials Maximilian Amsler[1], Sebastian Ament[1], Duncan Sutherland[1], Ming-Chiang Chang[1], Dan Guevarra[2], Aine Connolly[1], John M. Gregoire[2], Michael O. Thompson[1], Carla Gomes[1] and R. Van Dover[1]; [1]Cornell University, United States; [2]California Institute of Technology, United States

Autonomous experimentation enabled by artificial intelligence (AI) offers a new paradigm for accelerating scientific discovery. Non-equilibrium materials synthesis is emblematic of complex, resource-intensive experimentation whose acceleration would be a watershed for materials discovery and development. The mapping of non-equilibrium synthesis phase diagrams has recently been accelerated via high throughput experimentation but still limits materials research because the parameter space is too vast to be exhaustively explored.

In this talk we will present our efforts to accelerate synthesis and exploration of metastable materials through hierarchical autonomous experimentation governed by the Scientific Autonomous Reasoning Agent (SARA). SARA integrates robotic materials synthesis and characterization along with a hierarchy of AI methods that efficiently reveal the structure of processing phase diagrams. SARA designs lateral gradient laser spike annealing (lg-LSA) experiments for parallel materials synthesis and employs optical spectroscopy to rapidly identify phase transitions. Efficient exploration of the multi-dimensional parameter space is achieved with nested active learning (AL) cycles built upon advanced machine learning models that incorporate the underlying physics of the experiments as well as end-to-end uncertainty quantification. With this, and the coordination of AL at multiple scales, SARA embodies AI harnessing of complex scientific tasks. We demonstrate its performance by autonomously mapping synthesis phase boundaries for the Bi_2O_3 system, leading to orders-of-magnitude acceleration in establishment of a synthesis phase diagram that includes conditions for kinetically stabilizing δ-Bi_2O_3 at room temperature, a critical development for electrochemical technologies such as solid oxide fuel cells.

4:00 PM *DS01.10.01
Closed-Loop Autonomous Combinatorial Experimentation for Streamlined Materials Discovery Ichiro Takeuchi; University of Maryland, United States

We are incorporating active learning in screening of combinatorial libraries of functional materials. The array format with which samples of different compositions are laid out on combinatorial libraries is particularly conducive to active learning driven autonomous experimentation. For some physical properties, each characterization/measurement requires time/resources long/large enough that true "high"-throughput measurement is not possible. Examples include detection of martensitic transformation and superconducting transitions in thin film libraries. By incorporating active learning into the protocol of combinatorial characterization, we can streamline the measurement and the analysis process substantially. We have previously demonstrated discovery of a new phase change memory (PCM) material using the closed-loop autonomous materials exploration and optimization (CAMEO) strategy. The discovered PCM material has been tested in various scaled-up device formats and continues to exhibit superior performance to industrial standards. Recent efforts in developing synthesis – measurement closed loops on a combinatorial thin film platform will be discussed. This work is performed in collaboration with A. Gilad Kusne, V. Stanev, H. Yu, H. Liang, M. Li, E. Pop, and A. Mehta. This work is funded by SRC, ONR, AFOSR, and NIST.

4:30 PM DS01.10.02
A Low-Cost Education Platform for Teaching Autonomous Physical Science Logan M. Saar[1], Haotong Liang[1], Alex Wang[1], Austin McDannald[2], Ichiro Takeuchi[1] and A. Gilad Kusne[2,1]; [1]University of Maryland, United States; [2]National Institute of Standards and Technology, United States

Autonomous physical sciences is a rapidly developing field, where artificial intelligence controls experiment design, execution, and analysis in a closed-loop. The field promises to revolutionize the physical sciences, with the next generation of scientists using autonomous systems to address research challenges that are out of reach of Edisonian trial and error methods. However, as of yet, there are no education platforms for teaching the necessary skills to the next generation workforce. In this talk, we present a low-cost education platform which was used during an undergraduate course on machine learning for materials science at the University of Maryland. Through python code, students are taught the fundamentals of machine learning to identify trends from chemistry experiments. Students can also deploy active learning to guide sequential experiments to investigate chemical reactions and perform hypothesis testing.

CAMEO 2.0—Physics-Informed Machine Learning for Materials Exploration, Optimization and Discovery A. Gilad Kusne[1,2], Austin McDannald[1], Brian L. DeCost[1], Apurva Mehta[3] and Ichiro Takeuchi[2]; [1]National Institute of Standards and Technology, United States; [2]University of Maryland, United States; [3]SLAC National Accelerator Laboratory, United States

Technology motivates the perpetual need for novel advanced materials. As a result, materials scientists are driven to investigate materials of increasing complexity. However, with each new synthesis or processing parameter, the materials search space grows exponentially, making human-driven exhaustive experimentation infeasible. In this talk we will compare the use of physics-informed machine learning to off-the-shelf machine learning in their ability to accelerate materials exploration, optimization, and discovery. We will explore different levels of physics integration in the updated Closed-Loop Autonomous Materials Exploration and Optimization 2.0 (CAMEO) algorithm and its impact on the coupled challenges of phase mapping and materials optimization. In particular, we will look at the use of probabilistic priors based on exogenous data, the integration of phase mapping and functional property physics and heuristics, and exploiting mutual information shared between phase mapping and materials optimization for physics-informed active learning. Performance is evaluated on combinatorial library data including the Fe-Ga-Pd benchmark dataset.

SESSION DS01.11: Closed-Loop and Autonomous IV

DS01-Virtual

8:00 AM *DS01.11.01
Materials Discovery Using an Artificially Intelligent Mobile Robotic Scientist Benjamin Burger, Phillip M Maffettone, Vladimir V Gusev, Catherine M Aitchison, Yang Bai, Xiaoyan Wang, Xiaobo Li, Ben M Alston, Buyi Li, Rob Clowes, Nicola Rankin, Brandon Harris, Reiner Sebastian Sprick and Andrew I Cooper; University of Liverpool, United Kingdom

Technologies such as batteries, biomaterials, and heterogeneous catalysts have functions that are defined by mixtures of molecular and mesoscale components. As yet, this multi-length scale complexity cannot be fully captured by atomistic simulations, and the design of such materials from first principles is still rare. Likewise, experimental complexity scales exponentially with the number of variables, restricting most searches to narrow areas of materials space. Robots can assist in experimental searches but their widespread adoption in materials research is challenging because of the diversity of operations, instruments and measurements that is required. Here we use a mobile robot to search for improved photocatalysts for hydrogen production from water (*Nature*, **2020**, *583*, 237). The robot operated autonomously over 8 days, performing 688 experiments within a 10-variable experimental space that has more than 46 million points, driven by a batched Bayesian search algorithm. This autonomous search identified photocatalyst mixtures that were six times more active than the initial formulations, selecting beneficial components and deselecting negative ones. Our strategy uses a dexterous free-roaming robot, automating the researcher rather than the laboratory instruments, which are largely unmodified. This modular approach may have applications across a broad range of research problems. The mobility and non-linearity of the robot scientist offers the potential to unlock the power of artificial intelligence and machine learning – for example, to make complex, conditional decisions about what measurements and experiments to do next.

8:30 AM DS01.11.02
Machine-Learning-Accelerated Experimental Characterization and Multiobjective Design Optimization of Natural Porous Materials Giulia Lo Dico[1,2,3], Veronica Carcelén[2] and Maciej Haranczyk[1]; [1]Foundation IMDEA Materials, Spain; [2]Tolsa Company, Spain; [3]University of Carlos III, Madrid, Spain

Natural porous materials such as nanoporous clays are recognized as green and low-cost adsorbents and catalysts. The industrial development of novel products requires properties optimization tailored to specific application. Machine learning-aided material design cut time and costs accelerating the experimental research. In our approach we apply predictive algorithms to diverse experimental datasets, obtained by a clay-manufacturer company, for multiobjective optimization. The methods were exploited for the development of (1) acid nanocatalyzers, (2) mycotoxin detoxifiers (3) and rheological additives for drilling fluid application.
In the (1) project, we applied tree-based algorithms trained on experimental datasets to accelerate the characterization of the morphology and the surface activity of processed clay-based materials. We proposed a design function finding optimal processing conditions for clays exploitable in acid catalysis. One of such identified materials was synthesized and tested in catalytic degradation of chlorophyll-a, achieving the 79% of removal.
In the (2) project, we explored promising mycotoxin detoxifiers which form bulky non-absorbable complexes with toxic molecules, reducing their bioavailability. The machine learning models were trained using an extensive set of *in vitro* adsorption experiments imitating the gastrointestinal tract of the animals. The powerfulness of the models allowed to identify high performing formulations for the regulated toxins, predict the detoxification of a wide set of yet-unregulated mycotoxins, and gain insights into the *in vitro* detoxification mode of action through model feature importance analysis. Furthermore, the machine learning algorithms were used to design the *in vivo* experiment for validating the performance of the selected composite material, i.e., the most challenging detoxification experiment. The biomarker detection-based *in vivo* detoxification of deoxynivalenol in broiler chickens confirmed the outcomes of our approach.
The (3) project was focused on the optimization of the thixotropic properties (apparent viscosity and yield point) of clay-based additives for drilling fluid process. In this case we generated experimental data by advanced space-filling design of experiments (latin hypercube sampling with multidimensional uniformity). The latter provided a powerful solution to generate the maximum information by the minimum number of needed experiments. The homogenous dataset allowed to build high predictive models enabling exploration of novel optimal formulations by multiobjective optimization based on pareto-front. Four optimal materials were prepared and tested finding correspondence with the virtual experiments.

8:45 AM DS01.11.03
Benchmarking Active Learning Strategies for Materials Optimization and Discovery Alex Wang[1], Austin McDannald[2], Logan M. Saar[1], Haotong Liang[1], Ichiro Takeuchi[1] and A. Gilad Kusne[2,1]; [1]University of Maryland, United States; [2]National Institute of Standards and Technology, United States

Autonomous physical science has the ability to revolutionize how materials science is performed: algorithmically searching materials systems for optimal materials. This reduces the time and cost of the experiments by optimally collecting knowledge-rich data. Such an approach is becoming ever more popular with developments in active learning and scientific AI. We present a benchmarking study to compare the efficacy of popular off-the-shelf active learning methods and those designed with incorporated knowledge of the materials optimization challenge. A primary focus is the data fusion of structural and functional properties information. In this study we benchmark the active learning methods on 5 ternary composition materials datasets containing composition, structure, and functional property data and evaluate the impact of prior knowledge on materials optimization.

9:00 AM DS01.11.04
Towards the Automation of Structural Discovery in Scanning Transmission Electron Microscopy Nicole Creange, Ondrej Dyck, Rama K. Vasudevan, Maxim A. Ziatdinov and Sergei V. Kalinin; Oak Ridge National Laboratory, United States

Electron microscopy has been on the forefront of materials discovery in numerous fields ranging from ceramics to biology [1-3]. Advancements in instrument controls and detectors have expanded the available pathways for uncovering physical phenomenon. However, despite the technological progression, the fundamental principle of scanning microscopies has remained largely the same, namely the sequential acquisition of data and the data collection workflow. The majority of workflows remain human operated, vastly limiting the data acquisition and feature identification through the latency time of a human operator. Thus, the integration of artificial intelligence and automated manipulation of microscope parameters opens new avenues for experiments with higher control, lower beam damage, and an overall decreased time per experiment. Here, we develop various approaches for automated experiment workflows in scanning transmission electron microscopy (STEM) based on building feature of interest descriptors using the raw image, image segmentation, deep convolutional neural networks (DCNN), and rotationally-invariant variational autoencoders (rVAE). The descriptor is used as a basis for the acquisition function which guides the Bayesian optimization algorithm. Each workflow is applied to three datasets, with a range of feature sizes, comprised of NiO pillars within a La: $SrMnO_3$ matrix, ferroelectric domains in $BiFeO_3$, and topological defects in graphene. This approach is compared with the simpler method based on the linear transform-based AE workflows. This work was performed at the Center for Nanophase Materials Sciences, a US Department of Energy Office of Science User Facility.

9:15 AM *DS01.10.04
Better Batteries and Catalysts by Automation, Data Management and Integration of Machine Learning Helge S. Stein; Karlsruhe Institute of Technology, Germany

Scaling electrochemical energy storage to TWh/a requires the proliferation of new post-Li ion battery chemistries to overcome materials supply constraints. Identification of lead materials for electrodes, electrolytes and the associated optimal electrochemical protocols do, however, remain elusive for many emergent chemistries like Na-, Mg-, Ca- or Al-ion batteries. This talk will present first results obtained from the platform for accelerated electrochemical energy storage research located at the Helmholtz Institute in Ulm as part of the Karlsruhe Institute of Technology. The talk will showcase transfer learning from high-throughput millimeter scale electrochemistry towards high-throughput coin and pouch cell manufacturing and beyond. The talk will also highlight bottlenecks in deploying a highly integrated laboratory and demonstrate how strict implementation of data management protocols and analysis servers fast track machine learning guided experimentation across the entire battery research value chain.

SESSION DS01.12: Data-Driven Analysis II

10:30 AM *DS01.12.01
Materials Representation and Transfer Learning for Prediction in New Composition Spaces John M. Gregoire[1], Shufeng Kong[2], Dan Guevarra[1] and Carla Gomes[2]; [1]California Institute of Technology, United States; [2]Cornell University, United States

Active or sequential learning holds great promise for accelerating materials experiments, although full realization of this promise relies on the ability of machine learning models to be predictive in new composition spaces where no training data is available. Expert scientists make such predictions based on their materials chemistry knowledge, i.e. how the individual elements and interactions among them give rise to properties in composition spaces that have not been measured. Additionally, experts transfer knowledge about materials chemistry from other domains. To emulate these aspects of expert extrapolative predictions, we introduce the Hierarchical Correlation Learning for Multi-property Prediction (H-CLMP) framework that seamlessly integrates (i) prediction using only a material's composition, (ii) learning and exploitation of correlations among target properties in multi-target regression, and (iii) leveraging training data from tangential domains via generative transfer learning. H-CLMP accurately predicts non-linear composition-property relationships in composition spaces for which no training data is available, which broadens the purview of machine learning to the discovery of materials with exceptional properties. This achievement results from the principled integration of latent embedding learning, property correlation learning, generative transfer learning, and attention models. The best performance is obtained using H-CLMP with Transfer learning (H-CLMP(T)) wherein a generative adversarial network is trained on computational density of states data and deployed in the target domain to augment prediction of optical absorption from composition. H-CLMP(T) aggregates multiple knowledge sources with a framework that is well-suited for multi-target regression across the physical sciences.

11:00 AM DS01.12.02
Molecular Transformer-Aided Biocatalysed Synthesis Planning Daniel Probst, Matteo Manica, Yves G. Nana Teukam, Alessandro Castrogiovanni, Federico Paratore and Teodoro Laino; IBM Research Europe, Switzerland

Enzyme catalysts are an integral part of green chemistry strategies towards a more sustainable and resource-efficient chemical synthesis. However, the retrosynthesis of given targets with biocatalysed reactions remains a significant challenge: the substrate specificity, the potential to catalyse unreported substrates, and the specific stereo- and regioselectivity properties are domain-specific knowledge factors that hinders the adoption of biocatalysis in daily laboratory works. [1,2]
Here, we use the molecular transformer architecture [3] to capture the latent knowledge about enzymatic activity from a large data set of publicly available enzymatic data, extending forward reaction and retrosynthetic pathway prediction to the domain of biocatalysis. We introduce class tokens based on the EC classification scheme that allows to capture catalysis patterns among different enzymes belonging to same hierarchical families. The forward prediction model achieves a top-5 accuracy of 62.7%, while the single step retrosynthetic model shows a top-1 round-trip accuracy of 39.6%. The enzymatic data and the trained models are available through the RXN for Chemistry platform (https://rxn.res.ibm.com and https://github.com/rxn4chemistry).

11:15 AM DS01.12.03
Uncertainty Prediction for Machine Learning Models of Material Properties Francesca Tavazza, Kamal Choudhary and Brian L. DeCost; National Institute of Standards and Technology, United States

Uncertainty quantification in AI-based predictions of material properties is of immense importance for the success and reliability of AI applications in material science. While confidence intervals are commonly reported for machine learning (ML) models, prediction intervals, i.e. the evaluation of the uncertainty on each prediction, are seldomly available. In this work we compare 3 different approaches to obtain such individual uncertainty, testing them on 12 ML-physical properties. Specifically, we investigated using the Quantile loss function, machine learning the prediction intervals directly, and using Gaussian Processes. We identify each approach's advantages and disadvantages and compare their results. All data for training and testing were taken from the publicly available JARVIS-DFT database, and the codes developed for computing the prediction intervals are available through JARVIS-tools.

11:20 AM DS01.12.04
AI for Material Formulations Victor Viterbo, Federico Zipoli, Oliver Schilter and Leonid Kahle; IBM Research Zurich, Switzerland

Over the years a tremendous amount of data on materials have been gathered whether by academic experimentalists building up databases, or during manufacturing process investigations. The shear amount of data makes the use of it intractable by humans at a global scale and is hence limited to very specific uses by specialists. We present a data-driven approach for formulations of novel materials via autoencoders-based models. Using deep-learning techniques, we are trying to find important correlations and patterns in the underlaying data and by doing so, improve existing products and design new ones[1], using the groundwork laid by Kingma[2] and Bombarelli.[3] Starting from data that can consists of various inputs like compositions, processes or even aging conditions, and as outputs, product properties. We encoded the input into three latent representations utilizing encoder-decoder neural-network structures. From these trained latent space vector, the property can be predicted by a separate feed-forward neural network. Alternatively, one can optimize any given property with a given target value, by searching the latent space using a Gaussian process, to retrieve the corresponding compositions and processes. The scheme has been successfully applied to various material case studies in the past: ranging from polymers and epoxy resin to different alloys and it is general enough to be applied to much broader types of industrial problems. As an example of the broad potential use of such an algorithm, we present an application to the phase prediction of ceramic materials. We used commercially available databases consisting of binary and ternary diagrams to train an AI system able to predict properties such as the phases resulting from the mixture of compounds at any given temperatures and pressures conditions.

11:35 AM DS01.12.05
Prediction of Solid–State Synthesizability for Ternary Metal Oxides Using Information from the Literature Vincet Chung, David J. Payne and Aron Walsh; Imperial College London, United Kingdom

Material discovery is bottlenecked by the validation of the vast number of promising hypothetical materials generated from high-throughput calculations. The main reason is that the traditional experimental approach relies on trial-and-error. Therefore, time is wasted in attempting to synthesize non-synthesizable material or using the wrong conditions or methods. In recent years, natural language processing (NLP) techniques have been utilized to extract material synthesis conditions from the literature. By leveraging text mined dataset (TMD), researchers have developed data-driven approaches for experiment planning and synthesizability prediction, such as predicting the synthesis outcomes[1] and choosing the correct precursors for solid state reaction (SSR)[2], in hopes to reduce the number of failed synthesis attempts and accelerate material discovery. High quality data is required for any data-driven approaches to avoid error propagation. While it is generally agreed that the accuracies of TMD are lowered than their manually collected counterparts[3], there is no quantitative comparison between the two in the material domain.

In this study, SSR information of 4103 ternary metal oxides was manually collected from the literature. The information includes whether the oxide has been synthesized via SSR in the past and the SSR conditions. The accuracy of this dataset was quantitatively compared with reported performances of recent TMDs in materials, which highlights the limitation of current NLP to extract relatively complicated synthesis information. An example is the mixing/grinding conditions, where the manually collected dataset has a precision of 0.96 as opposed to 0.62-0.82 for a TMD[4]. The accuracy of this manually extracted dataset can serve as a milestone for future NLP applications in materials. A filter based on the distribution of heating temperature and binary oxide melting point of the manually collected dataset was created to identify over 100 erroneous entries in a subset of the TMD of solid state reaction[4]. Aside from common errors observed in the literature, some issues with the NLP set up and their implications to the TMD usages were found and discussed.

As a demonstration, this manually collected dataset was used to train a positive-unlabelled learning model to predict the solid state synthesizability of hypothetical ternary oxides. This approach can aid researchers to decide the suitability of using SSR to synthesize new materials.

Connecting Pathways of Microscopic Images and First-Principles Simulations via Deep Learning Ayana Ghosh, Sergei V. Kalinin and Maxim A. Ziatdinov; Oak Ridge National Laboratory, United States

Over the last decades, electron and scanning probe microscopies have evolved as one of the primary tools to study systems in the domain of physical and life sciences on the atomic and mesoscale levels. These measurements give rise to highly reliable structural and spectral data containing a wealth of information on structures and functionalities of the systems. On the other hand, development and availability of more computational capabilities including accessible CPU/GPUs, efficient algorithms and corresponding implementations have significantly boosted the advancement of physical simulations. Physical models constructed using first-principle calculations to quantum Monte Carlo and finite-element methods, spanning over quantum-mechanical to

continuum scales leads to abundance of insights on thermodynamic, and electronic properties of materials. There has also been a surge in applications of deep learning and data-driven techniques in each of these avenues in recent years. However, studies utilizing a combination of all three of these avenues to establish a bridge between such learnings is still in its infancy.
In this work, we show how deep learning can bridge together the knowledge learned from microscopic images and first-principles simulations to develop a comprehensive understanding of the physics of the materials of interest. Here we focus on how deep convolutional neural networks can be employed to identify atomic features (type and position) in graphene, use them to construct supercells perform density functional theory simulations to find optimized geometry of the structures followed by studying temperature-dependent dynamics of system evolutions with ad-atoms and defects. The results along with associated uncertainties in predictions at various levels as obtained utilizing this framework may be used to evaluate and modify experimental conditions and regions of interest. We aim to further expand this approach to incorporate edge-computing involving direct transfer of image-based data from microscopes via Jetson AGX Xavier and then analyze, train deep neural networks using a GPU-based platform followed by performing simulations using CPU-based high-performance computing resources and feed back to the human in the loop, altogether on-the-fly, to better guide experiments while learning from theoretical models.

This effort (machine learning) is based upon work supported by the U.S. Department of Energy (DOE), Office of Science, Office of Basic Energy Sciences Data, Artificial Intelligence and Machine Learning at DOE Scientific User Facilities (A.G., S.V.K.) and was also supported (STEM experiment) by the DOE, Office of Science, Basic Energy Sciences (BES), Materials Sciences and Engineering Division (O.D.), and was performed and partially supported (M.Z.) at the Oak Ridge National Laboratory's Center for Nanophase Materials Sciences (CNMS), a
DOE Office of Science User Facility.

11:45 AM DS01.12.08
Understanding the Composition–Property Relationships of Glasses Using Interpretable Machine Learning Ravinder Bhattoo, Suresh Bishnoi, Mohd Zaki and N M Anoop Krishnan; Indian Institute of Technology Delhi, India

The stoichiometry of inorganic glasses controls their material property. Therefore, understanding the compositional dependence of glass properties is critical in developing novel glasses. Herein, we use a glass database (>450,000 glass compositions) with up to 232 glass components to train XGBoost (Extreme Gradient Boosting) models for 25 glass properties (including optical, physical, electrical, and mechanical properties). Further, we determine the role of each input glass component in controlling the glass property us SHAP (Shapely additive explanations) analysis. The SHAP analysis reveals a strong interdependence among the glass components for properties like liquidus temperature and glass transition, whereas no such interdependence for properties like density. While some of this interdependence can be explained as "boron anomaly" and "mixed modifier effect", the others need further exploration. Thus, our work is critical in understanding the component–structure–property relationship of inorganic glasses and discovering novel inorganic glasses.

1:30 PM DS01.13.02
Autonomous Microfluidic Synthesis of Metal Cation-Doped Perovskite Quantum Dots Fazel Bateni, Kameel Abdel-Latif, Robert Epps and Milad Abolhasani; North Carolina State University, United States

All-inorganic lead halide perovskite (LHP) quantum dots (QDs) have recently emerged as a promising class of semiconducting nanomaterials for a wide range of solution-processed photonic devices, including color-tunable light-emitting diodes (LEDs), solar cells, and lasers. Despite the outstanding optoelectronic properties of LHP QDs, their widespread adoption in chemical and energy technologies has been limited due to the health and environmental concerns associated with the high amount of lead ions (Pb^{2+}) present in their crystalline network. Partial cation exchange of Pb^{2+} ions with less toxic impurity dopants (i.e., manganese, Mn^{2+}) has been promoted as an effective strategy to simultaneously mitigate the toxicity concerns associated with Pb and incorporate new optical/magnetic properties into the pristine LHP QDs.
The synthesis, fundamental studies, and development of metal cation-doped LHP QDs, similar to other colloidal QDs, are conventionally conducted using time-, material- and labor-intensive flask-based techniques. In contrast, microfluidic synthesis strategies with their tunable and reproducible heat/mass transport rates as well as their reduced chemical consumption and waste generation compared to batch reactors (e.g., round-bottom flasks) have been demonstrated as a reliable time- and material-efficient tool for accelerated fundamental and applied studies of colloidal QDs. Despite the high-throughput nature of microfluidic QD synthesis strategies, the user-guided experiment selection restricts a comprehensive mapping of the multivariable chemical universe and complicates the search for the optimal formulation of metal cation-doped LHP QDs. Recently, the use of deep neural networks (DNNs) and reinforcement learning algorithms have enabled accelerated chemical space exploration in organic syntheses and discovery and optimization of advanced LHP QDs. In this work, we present a self-driven modular robotic QD synthesizer for closed-loop metal cation doping of LHP QDs with desired optoelectronic properties. The robotic QD synthesizer is equipped with (i) a formulation, (ii) multiple flow synthesis reactors, and an (iii) *in-situ* spectral monitoring module. Through convergence of automated robotic QD synthesis with machine learning (ML)-guided modeling (DNN ensemble) and decision-making under uncertainty, we demonstrate accelerated formulation discovery of high-quality Mn-doped LHP QDs. We study the effect of black-box vs modular ML modeling and decision-making on the overall experimental cost for multiple formulation optimization campaigns of Mn-doped LHP QDs. Additionally, we demonstrate the role of in house-generated prior knowledge within the same modular flow reactor on the performance of the autonomous QD synthesizer. The developed ML-guided material synthesis strategy provides a smart workflow for data-driven formulation optimization and continuous manufacturing of metal cation-doped LHP QDs.

In this research, SCAPS (Solar Cell Capacitance Simulator) was utilized to build and probe non-toxic Cs-based perovskite solar devices, and investigate modulations of key materials parameters on ultimate power conversion efficiency (PCE). The input materials parameters of the absorber Cs-perovskite layer were incrementally changed, and with the various resulting combinations, 63,500 unique devices were formed and probed to produce device PCE. Versatile and well-established machine learning algorithms were thereafter utilized to train, test and evaluate the output dataset with a focused goal to delineate and rank the input materials parameters for their impact on ultimate device performance and PCE. The most impactful parameters were then tuned to showcase unique ranges that would ultimately lead to higher device PCE values. As a validation step, the predicted results were confirmed against SCAPS simulated results as well, highlighting high accuracy and low error metrics. Overall, the results from this investigation provide much-needed insight and guidance for researchers at large, and experimentalists in particular, towards fabricating commercially viable non-toxic inorganic perovskite alternatives for the burgeoning solar industry.

Late News: AI Accelerated Asynchronous Experimentation for Battery Materials Discovery Fuzhan Rahmanian[1,2], Jackson K. Flowers[1,2], Dan Guevarra[3], John M. Gregoire[3] and Helge S. Stein[1,2]; [1]Karlsruhe Institute of Technology, Germany; [2]Helmholtz-Zentrum Ulm, Germany; [3]Institute of Technology, United States

The optimization space for battery materials is vast, requiring better instrumentation and orchestration for efficient exploration. Herein, we present a hierarchical experimental laboratory automation and orchestration (HELAO) framework that is capable of operating multiple distributed and resource sharing instruments at once. HELAO is a versatile, highly modular, user-friendly, lightweight framework that incorporates active learning, AI-assisted data analysis, and high-level hardware abstraction to support globally distributed laboratories. We will demonstrate the open source HELAO framework both through a distributed multi-instrument active learning run and through a combinatorial investigation of multi-cation electrodeposition optimization for battery electrodes using a scanning droplet cell. We will demonstrate the development and discovery of a Lithium and a Mg-cathode post-Li ion battery material and optimal charging protocols. These demonstrations will illustrate the processes required in partially autonomous workflows as envisioned for the Platform for accelerated electrochemical energy storage research (PLACES/R) at the Karlsruhe Institute of Technology and Helmholtz Institute Ulm.

2:15 PM DS01.07.07
SPM at the Edge—Bayesian Optimization with Prior Knowledge for Accelerating Spectroscopy in Scanning Probe Platforms Rama K. Vasudevan, Jacob Hinkle, Kyle P. Kelley, Arpan Biswas, Stephen Jesse, Maxim A. Ziatdinov and Sergei V. Kalinin; Oak Ridge National Laboratory, United States

Scanning probe microscopy (SPM) has become a mainstay of nanoscience, enabling nanoscale measurements of a vast array of different materials. SPM hosts an immense number of modalities of both imaging as well as spectroscopy, to enable functional property measurements to then be correlated with nanoscale (or atomic scale) features of the sample. Despite over three decades since the initial SPM developments, the method of spectroscopy acquisition has remained largely the same, restricted to either individual point measurements, or those on a uniformly spaced grid. This is problematic both due to high levels of redundancy (neighboring pixels are likely to contain the same behavior) as well as inefficiency (time taken per spectra can be prohibitive), thus resulting in tradeoffs between spectral and spatial resolution.

Here, we explored methods to improve the efficiency of spectroscopy in SPM via utilization of Bayesian optimization schemes, implemented via incorporation of edge hardware in the form of GPU servers connected to SPM instrumentation. We first collect hysteresis loops on a ferroelectric thin film from random locations, and then train a surrogate model via Gaussian process regression to predict specific spectral features at the unmeasured sites with quantified uncertainty. We then use an acquisition functions in the Bayesian optimization algorithm to determine the optimal locations to sample to maximize the target spectral feature of interest. We find efficiency gains on the order of 2-3x over conventional grid-based methods. We further incorporate prior knowledge into the algorithm through use of high-resolution imaging, via deep kernel learning, to further improve the predictions of the surrogate model. The tradeoffs between the cost of computation of the more advanced approaches and the cost of actual measurements are discussed. In sum, we show that it is possible to substantially reduce the quantity of spectra captured whilst maintaining highly accurate spectral reconstructions with sparse data on samples with a significant degree of spatial correlation. Notes on how to extend the framework to other spectroscopies will be discussed. This work was conducted at and supported by the Center for Nanophase Materials Sciences, a US DOE Office of Science User Facility.

The Transition from Automated to Autonomous Material Optimization at the Hand of Semiconducting Materials Christoph J. Brabec[1,2] and Larry Lueer[1]; [1]FAU Erlangen-Nuremberg, Germany; [2]Research Center Julich, Germany

Evaluating the potential of novel functional materials and devices for industrial viability is a multi-dimensional large parameter space exploration. Manual experimentation is extremely limited in throughput and reproducibility. Automated platforms for fabricating and characterizing complete functional devices can accelerate experimentation speed within tight processing parameter variations. In this talk I will introduce the concept for the automated research platform AMANDA Line 1 and outline the R&D challenges such a research platform is able to address by today in the broad scope of semiconducting materials
As a first test case I will demonstrate a multi-target evaluation of photovoltaic materials at full device level. About 100 processing variations and nearly 1000 devices have been tested for one photovoltaic absorber on AMANDA Line 1 and evaluated by a Gaussian process regression-based data evaluation. The unique data quality in combination with GPR allowed to discover hidden structure – property relationships within 70 hours only which otherwise would have taken months to establish. Similar acceleration factors are found for further material systems. Engineering efficient and stable perovskite devices was recently demonstrated as well, and the automated material research quest is now directed towards Pb free perovskites. The outlook projects the transition from high throughput engineering towards autonomous optimization. The design, synthesis, testing and optimization of hundreds of interface materials out of a library with more than a million candidates is discussed as a real world scenario for ML guided and autonomous material invention.

Developing Active Learning Enabled Materials Exploration System with Enhanced Crystal Structure Representation Guangshuai Han, Yining

Feng and Na Lu; Purdue University, United States

Materials discovery from infinite earth repository is always considered as the bottleneck of each revolutionary technological progress. The technique is hindered by the labor-intensive and time-consuming process. Although the collection of the machine learning techniques has shown excellent capability for speeding up materials discovery, the material feature representation, especially crystal structural information, is still a challenge.
This work focuses on developing an active learning-enabled adaptive materials exploration system for accelerating piezoelectric materials discovery. The system works in a closed-loop mode, which starts from the material's stoichiometry and crystal structure representation. As the piezoelectric properties highly depend on the materials crystal structure, this work graphically encodes crystal structure by newly adopted adjacency matrix. Further, the system learned the materials' properties by the implemented machine learning algorithm and well-established piezoelectric properties database. In this way, the materials exploration system could provide general guidance for piezoelectric properties optimization. Evaluated by the realistic experimental data, the system outcome will yield feedback within each cycle. This adaptive materials exploration system has demonstrated the efficiency of optimizing piezoelectric properties. The presented work mode can also be utilized when speeding up the material exploration system for properties other than piezoelectricity, such as photovoltaic, thermoelectricity, etc. This knowledge will have a broad interest in materials science and the machine learning community.

Inverse Design of High Entropy Alloys with Exceptional Properties Using Generative Deep Learning Arindam Debnath and Wesley Reinhart; The Pennsylvania State University, United States

Ni-based superalloys are the preferred choice of materials for high temperature applications like turbines due to their exceptional properties at such elevated temperatures. However, the current generation of Ni-based components are operating at close to their melting point (1100 °C). Therefore, there has been an increase in the demand for metallic alloys that display superior mechanical properties at temperatures as high as 1600 °C. High-Entropy Alloys (HEAs) are suitable candidates as they show promising properties at these operational temperatures. However, very few HEAs have been discovered so far that surpass the performance of Ni based superalloys. Designing new HEAs that can meet these requirements is therefore a challenging task that not only requires domain knowledge, but also depends on fortuitous discovery from expensive experiments and computation.
Due to the complexity of the problem, generative deep learning is a prime candidate to accelerate the discovery of HEAs. Generative Adversarial Networks (GANs) are a promising method for learning complex distributions and have been demonstrated to great success in the field of computer vision. When trained on HEA compositions, these models can generate candidate materials rapidly as well as interpolate continuously between desirable structures. Our approach involves training a continuous conditional GAN (ccGAN) model on the HEA compositions with their corresponding figures of merit (such as high-temperature mechanical properties) as the conditioning vector. This allows us to generate novel HEAs which approach the desired figure of merit by querying the network for new samples with a given conditioning vector. We train the model on composition-property pairs found in the literature and evaluate the results using cross-validation and DFT calculations.

Integrating Knowledge Representations into Machine Learning for Materials Research Tonio Buonassisi; Massachusetts Institute of Technology, United States

Machine learning (ML) has evolved to become a powerful cognitive assistant for optimizing processes and materials, as evidenced by numerous academic examples and industrial applications. However, the ability of ML to integrate and generate generalizable scientific knowledge generally still requires a human. In this talk, I'll review the state of the art of ML-based knowledge representation in scientific research broadly. Then, I'll discuss nascent examples applying knowledge representations to materials for sustainability, including elucidating the root cause(s) of perovskite degradation. In conclusion, I'll summarize by sharing a personal perspective of where the field can evolve over the coming years, what classes of discovery may be enabled by further evolution of knowledge representations, and the ethical imperatives associated with this evolution.

Informatics for Functional Materials: A User-Friendly Implementation of Multi-Objective Bayesian Optimization Kyohei Hanaoka[1] and Junichi Kuwata[2]; [1]Showa Denko Materials Co., Ltd., Japan; [2]Hitachi, Ltd., Japan

In past several years, the material industry has paid much effort to accelerate material design by introducing data driven methods. Usually design problems attacked by the material industry are more challenging than those reported in the literature in some aspects. For example, in functional materials design, there are often more than three target properties (usually 5 to 10) whose experimental errors are not negligible, and this situation is much more complex than most data-driven material design studies reported in the literature. Moreover, in most cases, the number of possible experiments for functional materials design is extremely limited, because the evaluation of some target properties, such as the durability, requires extremely long-time experiments, and the speed of materials design is always important in order to win the competition among material manufacturers. Furthermore, efficient screening methods, such as virtual and real-world high throughput screenings, are still not available for most functional material design problems, due to the complexity and diversity of their experimental systems. Multi-objective Bayesian optimization is promising for such design problems, which can be applied to any multi-objective design problems requiring time-consuming experiments in order to accelerate their design processes. However, in contrast to single objective Bayesian optimization, which is rapidly spreading in the materials industry, the industrial application of multi-objective Bayesian optimization remains in its nascent stages, and trials and errors by experienced data scientists are required to design materials that satisfy multiple customer requirements using multi-objective Bayesian optimization.

In this study, we developed a straightforward graphical user interface (GUI) based system for multi-objective Bayesian optimization. This system was designed for a common situation of industrial functional materials design where there are multiple target properties with quantitative goals that are defined to satisfy customer requirements and material design efforts will be stopped after finding materials achieving quantitative goals for all target properties.

The developed system employs the joint probability of the achievement of all goals (PA) as an acquisition function[1]. This allows users to easily control Bayesian optimization with many objectives and to efficiently achieve the goals only by inputting the target value for each objective. This system also provides users an interpretable visualization of the progress of multi-objective Bayesian optimization based on the PA, which allows material scientists not familiar with data science to see whether optimization efforts should be continued, whether the current choice of the design space is promising, and which material is the best solution. Furthermore, using this system, material scientists can easily feed experimental data obtained in past material design projects to the machine learning model driving Bayesian optimization, which further accelerate multi-objective Bayesian optimization. The development of the straightforward GUI-based system, which does not require experienced data scientists, will popularize multi-objective Bayesian optimization in the material industry. The developed system will be used for the actual functional material design of Showa Denko Materials Co., Ltd. from the beginning of 2022.

9:35 PM DS01.15.03
Informatics for Functional Materials—Finding the Global Optimal Solution from a Vast Experimental Space of Functional Materials. Yuuki Nagai and Kyohei Hanaoka; Showa Denko Materials Co., Ltd, Japan

Many products called functional materials are made by mixing multiple raw materials in order to achieve various properties. The design of such materials requires both tuning of the composition ratio of materials and selection of optimal combination of raw materials from many candidate materials. However, it is difficult to optimize both raw material combination and their composition ratio simultaneously due to their vast experimental space. Therefore, experimenter usually fix compositional or combinational freedom in order to optimize the other freedom. However, such experiment largely limits accessible experimental space even with acceleration by data-driven methods, and true global minimum in the vast experimental space is difficult to be found. It is expected that Bayesian optimization employing machine learning model that can learn both structural and compositional information of functional materials can be a potential solution to this problem, however, its efficiency remains unclear due to difficulty in data acquisition. Unlike other material systems, for functional materials, it is difficult to generate data by simulation, because, functional materials are extremely complex systems that are usually consisted of such as multiple polymeric raw materials and nano-particles. Moreover, for real experiments, it is difficult to acquire many data due to experimental costs and time issues. In this study, we demonstrate the efficiency of Bayesian optimization for tuning of both structural and compositional freedoms of functional materials by developing an experimental system specially designed for the rapid evaluation of the performances of optimization approaches. The developed experimental system is a multi-component polymeric film consisting of around 20 raw materials in maximum and was tuned to allow rapid evaluation of target properties. The target property chosen for the demonstration is the adhesiveness of the film which is expected to show non-linear responses to compositions of materials and is also expected to be difficult to optimize. As expected, by using machine learning model that can learn both structural and compositional freedoms of materials, we successfully found the optimal design within the large experimental space of the developed system. Additionally, we compared the performances of optimization strategies employing Bayesian optimization, classical design of experiment method, and experiments based on knowledge of materials experts, and we report both advantages and disadvantages of each strategy. From the early 2022, we plan to release the PA system as in-house plat-form for speeding up the actual functional material design.

9:40 PM DS01.15.04
Informatics for Functional Materials—Demonstration of Multi-Objective Inverse Design for Functional Materials by Newly Developed Bayesian Optimization Naotaka Tanaka, Yuuki Nagai and Kyohei Hanaoka; Showa Denko Materials Co,Ltd., Japan

Data-driven materials design methods are rapidly spreading in the functional materials industry. Among them, Bayesian optimization is especially helpful for inverse design problems of materials. Single-objective (single target property) Bayesian optimization is known to work well under common situations in the materials industry where the amount of available data is small and the number of experiments that can be conducted is also small. However, we actually need to overcome trade-off for multiple target properties in order to satisfy several customer demands. Currently, most applications of Bayesian optimization are limited to single-objective systems or computational problems, and the efficiency of multi-objective Bayesian optimization in industrial functional material design remains unclear.
In previous our study, we proposed a new Bayesian optimization method for tuning the multiple target properties with quantitative goals that satisfy customer demands[1]. The proposed method employs the joint probability of achievement (PA) of predefined quantitative target values for all objective properties as the acquisition function. We have represented the efficiency of Bayesian optimization with the PA for a virtual multi-objective inverse design of functional materials employing regression models obtained from the previous experimental study[2].
In this study, we actually demonstrated a real-world multi-objective inverse design for functional materials using Bayesian optimization with the PA. Only by inputting the quantitative goal values for each target properties, the PA efficiently navigated the multi-objective optimization trajectory in the space of multiple target properties. We therefore successfully designed the film-shaped polymeric functional materials that satisfy three desired properties within moderate number of experiments. As far as we know, this is the first achievement that validates multi-objective inverse design for the functional material targeting multiple quantitative goals by Bayesian optimization. We plan to release the PA system as the in-house plat-form in the early 2022 for speeding up the actual functional material design.

9:45 PM DS01.15.05
Prediction of Discharge Characteristics of Lead-Acid Batteries by Machine Learning Utilizing a Part of Time Series Data Hiroshi Ohkubo; Showa Denko Materials Co., Ltd., Japan

Lead-acid batteries are a type of rechargeable battery that uses lead, lead dioxide, and dilute sulfuric acid. They are used in batteries for automobiles, uninterruptible power supplies (UPS) for industrial use (for example, in data centers, in hospitals) and other infrastructure facilities, and main power supplies for electric vehicles such as battery-powered electric forklifts.
One of the important characteristics of lead-acid batteries and other storage batteries is their discharge characteristics, such as battery capacity and internal resistance. Discharge characteristics are evaluated from the transition of voltage values as time series data, which are obtained from measurements that a fully charged storage battery is discharged to the end-of-discharge voltage at a certain temperature and current. Since the battery capacity is evaluated from the above discharge data, the measurement is a time-consuming process.
For lithium-ion batteries, which are a type of rechargeable battery like lead-acid batteries and are widely used in the world, researches on time series analytics (for example, residual life prediction) has been actively conducted. However, there have been few reports of research on time series prediction for lead-acid batteries.
The purpose of this study was to shorten the measurement time of data required to evaluate the discharge characteristics of lead-acid batteries. Therefore,

we focused on whether it is possible to predict the actual discharge characteristics from the first half of the time series data obtained in the discharge experiment.
In this study, we used about 11,000 discharge data obtained from in-house measurements. These data consist of a time series data of voltage values every second. A machine learning model for discharging time prediction was developed using support vector regression (SVR).
As a result, it was found that the SVR model can accurately predict the time from start to finish discharge by using both the first 30% or 50% of the time series data and the difference every 10 seconds as an explanatory variable.
This result suggests that the measurement time required to predict battery characteristics can be shortened and that the present method has a potential to speed up the evaluation and development process of lead-acid battery materials.

Development of the Efficient Optimization Method for High Dimensional Incomplete Datasets Ryosuke Arai[1,2]; [1]Showa Denko Materials, Japan; [2]Research Association of High-Throughput Design and Development for Advanced Functional Materials, Japan

Regression-based optimization methods are known to be effective tools in the field of material developments. However, in practical applications, we often face methodological problems of the poor performance in the case of utilizing high dimensional and incomplete datasets. Bayesian Optimization (BO) is a well-known regression-based optimization method. Although BO works well to reach global minimum/maximum to objective functions in many cases, its efficiency decreases as the dimension of design spaces become higher, such as molecular descriptors. Furthermore, BO cannot deal with incomplete initial datasets without arbitrary treatments for missing values, such as imputation. Gaussian mixture regression-based optimization (GMRBO) is proposed as an efficient optimization method with direct inverse analysis, which works better than BO in high dimensional design space [1]. However, GMRBO also has the same drawback as BO, that it cannot deal with incomplete datasets.
In this study, we have developed an optimization method by extending GMRBO to deal with incomplete datasets. The performance of the extended GMRBO (exGMRBO) was investigated and compared with BO and GMRBO. For the investigation, we used the benchmark function ZDT1 with 30 design variables and two objective functions. The percentage of missing data in the initial dataset was maintained from 10% to 70%.
The results show that while the exGMRBO performance difference between GMRBO and BO was smaller for higher missing rates (above 60%), it achieved a higher performance difference for missing rates between 10 to 50%. However, the performance of exGMRBO outperformed that of GMRBO and that of BO in all cases. Therefore, it was verified that exGMRBO indicates a better performance than BO and GMRBO when the initial dataset contains missing values.
We have also applied the exGMRBO to find Pareto front of the conflict properties of polymers.

Web Platform of a Molecular Generative Model for Experimental Chemists Seiji Takeda, Toshiyuki Hama, Hsianghan Hsu, Akihiro Kishimoto, Lisa Hamada and Daiju Nakano; IBM Research Tokyo, Japan

1. Introduction
Meticulous design of molecules is a key of material development. However, molecular design processes heretofore has been driven by human expert's trial-end-error cycles, therefore, a typical lead time to design new material takes more than 10 years. Over the past half a decade, data-driven approaches leveraging artificial intelligence (AI) have been introduced to this field, especially on the context of generative model. The primary requirement for molecular generative models is industrial practicality, including high speed design with large structural variety. Another important requirement is that a model should be accessible for researchers and engineers of experimental chemistry, who are not necessarily familiar with software-related works; writing Python scripts, using a command line interface, etc. Releasing a state-of-the-art molecular generative model to a wide variety of potential users is important.
In this paper, we will present on our web application (webapp) – based molecular design platform that has practical advantages in terms of speed and diversity of molecule generation, interpretability of model, no requirement of pre-training. The user interface (UI) is designed so to make the tool accessible for experimental chemists.

2. Method
The main workflow is composed of four steps. (1) Training a model: the system encodes input molecular structures to a set of feature vectors by graph kernel approaches. Those feature vectors are used to build a regression model to predict target properties. (2) Setting target properties: a user sets target properties values that should be satisfied by new molecules. (3) Structure generation: molecular graphs are built by repeatedly connecting *graph resources*, which consists of atoms, rings, and user-defined substructures, while avoiding isomorphic duplications. (4) Online evaluation : during running the graph generation algorithm, each generated structure is encoded to a feature vector and then evaluated on the regression model. If the predicted property satisfies the user-set target value, the structure is accepted and stored in the candidate list. Repeating the above process (3) and (4), molecular structures satisfying target properties are generated.

3. Results
First, we used a small subset (300 sample) of QM9 dataset to evaluate the performance. We trained a property prediction model on the energy of the highest occupied molecular orbital (HOMO); E_homo. Carrying out property prediction by changing models and sweeping hyper parameters, the system produced reasonable accuracy when using kernel ridge regression. We use this model for the following molecular generation process. In structure generation, we used three target properties; E_homo ~ -0.28 (Ha), -0.25 (Ha), and -0.20 (Ha). Depending on the target E_homo value, the generation speed (i.e. the number of molecules generated per second) ranges from 29 to 77 per sec. The speed of other state-of-the-art molecular generative models is typically 1 to 10 per sec when QM9 is used, that confirms our method's significant acceleration in terms of speed.
For more practical use, we design new photoacid generator (PAG). We trained our model with ~1,300 PAG structures extracted from U.S. patents, and corresponding property data which we calculated by DFT simulation. We targeted five properties; LogW, LogP, T_bio, LD50, and lamda_max, satisfying specific ranges set by a PAG chemist. After running MolGX for 6 hours, more than 2,000 molecular structures were generated, that is more than 100 time of acceleration in design speed. The designed PAG structures were experimentally synthesized.

4. Web Application
We implemented the algorithms as a GUI-based web application for a wide variety of users especially experimental chemists. We designed the workflow from a viewpoint of user experience (UX), developed API set, and implemented it on a Kubernetes-based cloud environment. The system is today in-service on IBM Cloud.

10:10 PM DS01.15.08
Training Data Optimization and Error Analysis for Machine Learning-Based Crystal Orientation Estimation Kyoka Hara[1], Takuto Kojima[1], Kentaro Kutsukake[2], Hiroaki Kudo[1] and Noritaka Usami[1]; [1]Nagoya University, Japan; [2]RIKEN, Japan

Multicrystalline materials are often the most immediate choice for various applications including solar cells because of their affordable price and productivity. As for solar cells, the conversion efficiency based on multicrystalline materials is generally inferior to that based on monocrystalline ones. This is mainly explained by the presence of dislocation clusters, which is closely related to crystal structure components such as crystal orientations. We aim to control the formation of dislocation clusters by clarifying the generation mechanisms with the aid of an ingot-scale analysis of crystal orientations, grain boundaries, and dislocation clusters.
For this purpose, we have developed a machine learning-based method for estimating crystal orientations from multiple optical images of textured multicrystalline wafers and reported that the estimation accuracy can be improved by data augmentation. In this study, we report on further improvement of the prediction accuracy by optimizing training data through statistical analysis of the estimation results in different conditions.
In the first step, we perform alkaline texturing on the wafer surface. This shaves off some surface particles and leaves only {111} planes on the surface, creating a pyramid-like structure. Shining light on this pyramid will generate specific reflection patterns that inherit crystal orientation information. A house-made apparatus is used to generate and capture these patterns. The apparatus mainly consists of a camera, a rotating collimate light for illumination, and a stage. As the illumination light rotates around the sample, optical images are taken within every 5 degrees of rotation. We integrate these 72 images into a 72-dimensional signal intensity matrix which we call the “reflection profile.”
In the second step, we carry out the machine learning-based orientation estimation. An LSTM neural network and some connected layers constitute our model. The pre-obtained reflection profile is used as the input to the model, and quaternions as the output. Correct grain orientations are measured by the Laue scanner method as teacher data. Note that the training, validation, and test datasets consist of the reflection profiles of 3838, 960, and 6373 grains, respectively.
Successful training of the model resulted in an estimation error median of 8.61 degrees. Based on the assumption that a diverse reflection profile should enhance estimation accuracy, we increased the size and diversity of the training data. Diverse data was created by a variety of incident light angles. We set the elevation angle of the incident light to three different values; 30, 45, and 60 degrees. Using all three elevation data we improved accuracy by 15%. Comparing the results trained on each angle, we discovered that there is an optimal elevation angle. The estimation accuracy varied by ~30% depending on the elevation angle. To acquire the best results most efficiently, we then performed double angle training using two elevations to train the model. Considering results from single angle training, we selected the two angles with higher accuracy;30 and 45 degrees, and trained the model, expecting better results compared to other selections. However, this resulted in a poorly trained model, indicating that the combination of angles with good results alone does not always train the model effectively. Further evaluation of results revealed that the three elevations were capable of correctly estimating different orientations. For example, at 30 degrees, planes {100} were correctly estimated while {111}~{101} were poorly estimated. At 60 degrees, {111}~{100} were poorly estimated. By calculating the correlation coefficiency between each two elevations, we revealed that the selection of angles with smaller correlation resulted in a better-trained model. This indicates that the selection of angles with different estimation capabilities should train the model most effectively.

10:25 PM DS01.15.10
Automating the Design of Dendronized Vesicles—The PACE^2 Framework Akash Banerjee, Srinivas Mushnoori, Ethan Zang and Meenakshi Dutt; Rutgers, The State University of New Jersey, United States

Nanoparticles that block fundamental bacterial functions like quorum sensing could potentially replace conventional antibiotic therapies. Vesicles that bind interfacially to charged biomolecules could be used to block these quorum sensing pathways. Here, lipid-based vesicles consisting of dipalmitoyl-sn-glycero-3-phosphocholine lipids and polyamidoamine dendron-grafted amphiphiles (PDAs) are studied. PDAs have charged terminal groups that can electrostatically bind to oppositely charged biomolecules. Variation of the generation and relative concentration of PDAs could affect the functionality and stability of the vesicle. To identify the optimal control parameters, i.e., PDA generation and concentration, a large phase space of vesicles is studied as a function of the two parameters. For each model, a flat membrane is simulated under conditions that forces the membrane to bend its edges, eventually forming a spherical vesicle. This process, also known as membrane closing, entails several structural changes and hence there are numerous fluctuations in the system. This often leads to simulation failure. In this situation, a new set of conservative parameters, e.g. a smaller integration timestep, could be used to successfully proceed with the simulation. However, if the conservative parameter is used for the remaining duration of the simulation, the entire process will turn out to be computationally expensive and time consuming. In this study, a computational workflow is designed to divide the entire membrane closing process into multiple stages, each associated with a short simulation. Each simulation has a predetermined set of regular and conservative parameters. Analysis routines are weaved into the design of this workflow. On the basis of the performance of the previous simulation (success/failure), the analysis routines adaptively decide on an appropriate set of parameters (regular/conservative) for the next simulation. In this way, the membrane closing process is conducted efficiently without any human intervention. The workflow is generalized for biomolecular simulations and has been named PACE^2 (Pipeline for Automating Compliance Based Elimination and Extension). The PACE^2 framework lays out the process to investigate a large molecular parameter phase space to identify optimal designs for nanoparticles.

Machine Learning for Polyamide Carbon Nanotube Composite Membranes Aaron Morelos-Gomez and Morinobu Endo; Shinshu University, Japan

Given the increase in global population and the continuous depletion of fresh water sources, it is necessary to keep developing technologies to provide fresh water. Thus, seawater desalination is increasing in adoption and development. For this, membrane technology is capable of removing salts from water and providing fresh water, the most common membranes for this task are based on polyamide. Membrane desalination is characterized by permeate flux and salt rejection. Previously we have developed polyamide carbon nanotube composite membranes, with enhanced antifouling properties. In this work, we developed a machine learning (ML) model to predict permeate flux and salt rejection according to membrane synthesis conditions such as carbon nanotube concentration, m-phenylenediamine concentration, trimesoyl chloride concentration, and others. To construct the machine learning model we used feature selection and soft voting ensemble using data collected through two years of experimentation with salt rejections above 90%. The obtained ML model could predict permeate flux and salt rejection with R^2 of 0.8 and 0.4, respectively. Furthermore, we used Shapley additive explanations to extract feature importance that could give further insights of the ML model and membrane synthesis.

10:35 PM DS01.15.12
Autonomous Thin-Film Fabrication System for Exploring Solid Electrolytes Shigeru Kobayashi[1], Ryota Shimizu[1], Yasunobu Ando[2] and Taro Hitosugi[1]; [1]Tokyo Institute of Technology, Japan; [2]National Institute of Advanced Industrial Science and Technology (AIST), Japan

We recently developed a system that autonomously searches for the best conditions to fabricate thin-film materials. The system integrates a sputter deposition system, electrical resistance measurement system, and Bayesian optimization algorithm; the samples are transferred using robots to perform the closed-loop optimization. The system autonomously optimizes the deposition conditions to obtain the TiO_2 thin film with minimum electrical resistance.

[1]
In this study, the autonomous system was used to search for new lithium solid electrolyte materials. Two target materials, Li_3PO_4 and Li_2CO_3. were co-sputtered onto a quartz substrate with comb-shaped Au electrodes. The sputtering power of each target was separately tuned to control the composition of films. The sputtering power and the flow rate of Ar/N_2 process gas were optimized using the Bayesian optimization algorithm. The ionic conductivity of thin films was evaluated using AC impedance spectroscopy.
The ionic conductivity of thin films improved to 2~3 times higher than the simple amorphous Li_3PO_4 or Li_2CO_3 solid electrolytes within twelve experimental cycles. Such an autonomous system will accelerate the development of new materials from an expanded chemical space.

Recent Advances in the PAOFLOW Method—Electronic and Optical Properties of Real Materials from Projections on Atomic Orbital Bases Marco Buongiorno Nardelli; University of North Texas, United States

First-principles electronic structure calculations are the state-of-the-art for solid-state physics, chemistry, and materials science; however, their predictive capability is constrained by the limitations on simulated length- and time-scale due to computational cost and the unfavorable scaling of the algorithms. In this talk, I will review recent progress in theoretical and computational tools for data generation and advanced characterization, and in particular, discuss the development and validation of the PAOFLOW framework for the generation of local basis representations for effective ab-initio tight-binding schemes. PAOFLOW is a software tool to efficiently post-process standard first principles electronic structure plane-wave pseudopotential calculations in order to promptly compute, from interpolated band structures and density of states, several quantities that provide insight on transport, optical, magnetic and topological properties such as anomalous and spin Hall conductivity, magnetic circular dichroism, spin circular dichroism, and topological invariants. After reviewing recent advances in the establishment of theoretical framework, including the generation of efficient atomic basis sets, I will illustrate the method with a few recent examples from our research on 2D ferroelectric materials, including the demonstration of a transistor prototype based on electrically switchable persistent spin helix and a memory device that exploits the domains of switchable spin textures and spin-to-charge conversion.

Explanation of the Pressure Induced Invar Effect in Ni-Rich $Fe_{1-x}Ni_x$ Alloys Using Non-Collinear Magneto-Structural Relaxations from First Principles Amanda Ehn, Bjorn Alling and Igor A. Abrikosov; Linköping University, Sweden

Fcc structured Fe-Ni alloys containing 36 at.% Ni are known as Invar alloys. They are characterized by an anomalous low, practically zero, thermal expansion at room temperature and ambient pressure, a finding that awarded C.E Guillaume the Nobel Prize in Physics already 1920. It is clear that the origin of the Invar effect is linked to the magnetic properties of the material but a complete explanation for the effect is not yet agreed on. Phenomena such as Fe-moment spin flips, high-to-low-spin transitions, non-collinear magnetism, local chemical environments, and strong electron correlations have been considered as possible origins, which together possess a challenge for the state-of-the-art first-principles methods for disordered magnetic alloys. [1,2]

The Invar effect is known to disappear when the Ni composition is even slightly increased.[2] However, it was observed that the Invar effect could be

induced by high pressure also for Fe-Ni alloys with high Ni concentrations.[3]

In this study we investigate the origin of the pressure induced Invar effect in the disordered fcc $Fe_{1-x}Ni_x$ alloy for x = 0.36, 0.50, and 0.75 from first principles calculations. We perform a large pool of different non-collinear supercell electronic structure calculations, and let the magnetic state and atomic structure gradually relax towards their most preferred states. Using this approach we observe a transition from ferromagnetic states to noncollinear or almost collinear spin-flipped states as the volume decreases for all three compositions. The volumes at which the transitions occur correspond to the volumes observed to display volume-pressure anomalies in previous experiments. Our study confirms that the pressure induced Invar effect is a result of a magnetic transition from a ferromagnetic state to a complex magnetic state in Fe-Ni alloys.

Transferable Models and Efficient Nonlocal Descriptors for Machine Learning Exchange-Correlation Functionals Kyle W. Bystrom and Boris Kozinsky; Harvard University, United States

Machine Learning (ML) is a promising approach to improve the accuracy of exchange-correlation (XC) functionals for Density Functional Theory (DFT). Two key developments are necessary to successfully leverage ML for XC functionals. First, because of the limited information provided by semi-local ingredients like the density and its gradient, computationally efficient, physically relevant, and nonlocal descriptors of the density or density matrix must be designed as input to the model. Building on our recently developed CIDER functional for the exchange energy, we explore possible improvements to the model as well as its computationally efficient implementation. We also investigate the application of ML to efficient, orbital-dependent ingredients like Rung 3.5 functionals [1]. Second, robust ML architectures and workflows must be developed to train functionals that are both accurate and transferable. We discuss how Gaussian Processes yield smooth and transferable models and how different regularization and training schemes impact the performance of parametric functionals.

Late News: *Ab Initio* Electron Dynamics in High Electric Fields—Accurate Predictions of Velocity-Field Curves Ivan Maliyov, Jinsoo Park and Marco Bernardi; California Institute of Technology, United States

Electron dynamics in external electric fields governs the behavior of solid-state electronic devices. First-principles calculations enable precise predictions of charge transport in low electric fields. However, studies of high-field electron dynamics remain elusive due to a lack of accurate and broadly applicable methods. Here we develop an efficient approach to solve the real-time Boltzmann transport equation with both the electric field term and *ab initio* electron-phonon collisions. These nanosecond-long simulations provide field-dependent electronic distributions with a femtosecond resolution, allowing us to investigate both transient and steady-state transport in electric fields ranging from low to high (>10 kV/cm). The broad capabilities of our approach are shown by computing nonequilibrium electron occupations and velocity-field curves in Si, GaAs, and graphene, obtaining results in quantitative agreement with experiment. Our approach sheds light on microscopic details of transport in high electric fields, including dominant scattering mechanisms and valley occupation dynamics. Our results demonstrate quantitatively accurate calculations of electron dynamics in low-to-high electric fields. This method, implemented in our open-source code Perturbo [1], provides a timely and robust tool to advance the discovery and design of novel electronic materials.

SESSION DS02.03: Molecular Dynamics Models
Session Chair: Marco Buongiorno Nardelli
Monday Afternoon, November 29, 2021
Hynes, Level 2, Room 209

2:45 PM DS02.03.01
Late News: Voltage Equilibration for Reactive Atomistic Simulations of Electrochemical Processes Alejandro Strachan[1], Nicolas Onofrio[2], Xavier Cartoixa[3] and Laura Urquiza[4]; [1]Purdue University, United States; [2]Institut Européen des Membranes, IEM, UMR 5635, Univeristé Montpellier,, France; [3]Universitat Autònoma de Barcelona, Spain; [4]Laboratoire des Solides Irradiés, École Polytechnique, Institut Polytechnique de Paris, France

We introduce electrochemical dynamics with implicit degrees of freedom (EChemDID), a model to describe electrochemical driving force in reactive molecular dynamics simulations. The method describes the equilibration of external electrochemical potentials (voltage) within metallic structures and their effect on the self-consistent partial atomic charges used in reactive molecular dynamics. An additional variable assigned to each atom denotes the local potential in its vicinity and we use fictitious, but computationally convenient, dynamics to describe its equilibration within connected metallic structures on-the-fly during the molecular dynamics simulation. This local electrostatic potential is used to dynamically modify the atomic electronegativities used to compute partial atomic changes via charge equilibration. Validation tests show that the method provides an accurate description of the electric fields

generated by the applied voltage and the driving force for electrochemical reactions. We demonstrate EChemDID via simulations of the operation of electrochemical metallization and valence change cells. The simulations predict the switching of the device between a high-resistance to a low-resistance state as a conductive filament is formed and resistive currents that can be compared with experimental measurements. In addition to applications in nanoelectronics, EChemDID could be useful to model electrochemical energy conversion devices.

3:00 PM DS02.03.02
Late News: All-Atom Simulation Method for Zeeman and Dipolar Assembly of Magnetic Nanoparticles Akhlak-ul Mahmood and Yaroslava Yingling; North Carolina State University, United States

Magnetic Nanoparticles (MNPs) can organize into novel structures in solutions with excellent order and geometry that are important for many industrial and biomedical applications. Studies of self-assembly of smaller MNPs is challenging due to the complicated interplay between VDW, electrostatic, dipolar, steric, hydrodynamic, and external magnetic field interactions. An all-atom molecular dynamics (AMD) simulation technique can decipher such complex interactions and can account for the effect of the MNP core, surfactant layers, solvent molecules. Here we present a novel AMD simulation method to study the dynamics, self assembly and properties of MNPs structures with various particles size and shapes, surfactant and solvents. We demonstrate the use and effectiveness of the model by simulating the self-assembly of several commonly obtained equilibrium structures like ring, line, chain, clusters by oleic acid surfactants coated spherical and cubic Magnetite (Fe_3O_4) nanoparticles in vacuum and in explicit solvents and under the presence of a uniform external magnetic field. We found that the long-range electrostatic interactions can favor chain formation over rings, the VDW and steric interactions by the surfactants promote MNPs cluster growth and the interplay of solvent and increased surface energy can reduce the rotational diffusion of the MNPs. The algorithm has been parallelized to take advantage of multiple processors of a modern computer and can be used as a plugin for the popular LAMMPS simulation software to study the behavior of small magnetic nanoparticles and gain insights into the physics and chemistry of different magnetic assembly processes with atomistic details.

10:30 AM DS02.04.01
REACTER 2.0: Quantum-Informed Reaction Constraints and Automated Interaction Typing Jacob Gissinger and Kristopher E. Wise; NASA Langley Research Center, United States

REACTER is a heuristic method for modeling chemical reactions in classical molecular dynamics simulations, implemented in LAMMPS as *fix bond/react*. The authors recently extended LAMMPS to support alphanumeric labels for atom types, bond types etc., which enables the pre- and post-reaction templates required by the REACTER protocol to be portable between different simulations and greatly simplifies the task of creating simulation-ready reaction templates. To further increase the generality of reaction templates, support for wildcard characters within atom types has been added, along with the automatic assignment of interaction types for new bonds, angles, etc. based on the involved atom types. In some cases, this feature can express a class of reactions with one pair of reaction templates, where previously dozens may have been required. Advanced reaction constraints have also been added, including an Arrhenius constraint to enforce an effective activation energy, a root-mean-square-deviation option for complex geometrical constraints, as well as a custom constraint that leverages LAMMPS' powerful built-in variable framework. Other new features include variable support for various inputs (e.g. to allow reaction rates or cutoffs to be dependent on overall conversion), on-the-fly update of molecule IDs, and the ability to create new atoms positioned with respect to the reaction site. The new features are applied to modeling polymeric, thermosetting and composite materials, and advanced applications of the new reaction constraints are demonstrated. For example, REACTER is shown to accurately reproduce mechanically-induced bond breaking, as characterized by third-order DFT-based tight-binding (DFTB3) simulations, via a constraint on the total potential energy of the involved atoms.

10:45 AM DS02.04.02
Extension of an Atomistic Grain Tracking Algorithm for Analysis of CdTe/CdS Structures Sharmin Abdullah[1], Xiaowang Zhou[2], Rodolfo Aguirre[1] and David Zubia[1]; [1]The University of Texas at El Paso, United States; [2]Sandia National Laboratories, United States

Grain structures impact Cadmium Telluride/ Cadmium Sulfide (CdTe/CdS) solar cells since grain boundaries can act as recombination centers for carriers. Computer simulations such as molecular dynamics (MD) can be a convenient and cost-effective method for investigating the evolution of grain structures during the growth of materials. Recently, MD simulations have been successfully applied to study the growth of polycrystalline CdTe/CdS structures, revealing complex zincblende and wurtzite grains along with highly disordered atoms that are often observed in experiments. However, little efforts have been made to quantify the grain structures observed in MD simulations in literature. In this work, the grain tracking algorithm originally developed by Panzarino et al. has been extended for polycrystalline CdTe/CdS structures. Specifically, we focus on the face-centered-cubic (fcc) sublattice of the zincblende crystal structure. The common neighbor analysis and centrosymmetric parameter values are used to calculate the orientation of each atom in the grain tracking algorithm. We then apply this modified approach to analyze the CdTe/CdS films obtained from our MD polycrystalline growth simulations. We demonstrate that our method can provide a variety of useful information such as grain domains, grain orientations, plane indices, and sample texture. Moreover, kinetic analysis of microstructure evolution of the materials can be performed. These results will add to the understanding of granular microstructure that can describe physical, chemical, mechanical, and electronic properties.

11:00 AM DS02.04.03
Atom-Centered Electronic Heat Transport Within Electron-Ion Coupled Classical Molecular Dynamics Artur Tamm and Alfredo A. Correa; Lawrence Livermore National Laboratory, United States

Atomistic modeling of metallic systems needs the inclusion of electron-ion interactions in order to have realistic dynamics. For example, it is generally known that around 20% of the projectile's kinetic energy could be absorbed by the electrons and redistributed within the metallic system outside the collision cascade. Capturing this in classical molecular dynamics is rather challenging as these simulations usually do not include explicit electrons. We present a novel model that captures both the electron-ion interactions as well as energy transport within the electronic system. Our Langevin based stochastic model is able to catpure the non-adiabatic collective dynamics of phonons. Moreover, we have demonstrated that we can also apply the same model to the high energy events, such as radiation damage. In this work, we present an important aspect of electronic heat transport - we have developed an

atom based diffusion model where energy is transferred directly between atoms, taking into account convective transport of electronic energy. Our model reproduces the macroscopic heat diffusion behaviour, but is also able to incorporate environment dependent and hydrodynamics effects. Furthermore, the model is coupled to the Langevin based electron-ion model, thus creating a unified approach for enabling classical molecular dynamics with electronic effects. We will present the theoretical aspects of the model as it is implemented in an extension for LAMMPS code. Finally, we present an application of compression shockwave dynamics through a system consisting of a metal and an insulator. This example demonstrates the strength of our approach, as electronic heat is transported both by diffusion and convection.

This work performed under the auspices of the U.S. Department of Energy
by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

11:15 AM DS02.04.04
Using Virtual Sites for Coarse-Grained Simulations of Conjugated Polymers and Organic Semiconductors Puja Agarwala, Shreya Shetty, Enrique D. Gomez and Scott T. Milner; The Pennsylvania State University, United States

The local structure of conjugated polymers is vital for many optoelectronic properties, such as charge conduction and charge photogeneration at donor-acceptor interfaces. We perform molecular dynamics simulation in Gromacs to study the local arrangement of these polymers. Conjugated polymers have aromatic rings as repeat units. Due to the stiffness and large size of these polymers, atomistic simulations are computationally expensive. Hence, to increase simulation efficiency, we exploit the stiffness of aromatic moieties using virtual sites to represent multiple atoms within each ring. These virtual sites do not have mass but contain electronic properties; hence, we significantly reduce degrees of freedom while retaining the shapes and dipole moments of the aromatic rings. As a result, these simulations are ~10 times faster compared to atomistic simulations. We simulate poly(3-hexylthiophene-2,5-diyl) (P3HT) and rhodanine-benzothiadiazole-coupled indacenodithiophene (O-IDTBR), as well as mixtures of these two materials. Our simulations predict a persistence length of 3.8 nm, a density of 0.91 kg/m^3 for P3HT, and an amorphous scattering profile that compare well to experimental results. In addition, the crystal structure of IDTBR is stable when arranged in experimentally-determined unit cell parameters. Our simulations allows us to examine equilibrated molecular configurations at the interface of P3HT and IDTBR, and reveal preferences in terms of contacts between specific moieties.

Machine-Learning-Aided Development of Analytical Empirical Forcefields for Glasses Mathieu Bauchy; University of California, Los Angeles, United States

Modeling glasses requires extended timescales—since their simulation involves the slow cooling of a liquid into an out-of-equilibrium disordered solid. As such, reliable, yet computationally efficient empirical interatomic forcefields are key to facilitate the modeling of glasses. Although analytical forcefields offer optimal computational efficiency, their parametrization is challenging as the high number of parameters renders traditional optimization methods inefficient or subject to bias. Here, we present a new parameterization method based on machine learning, which combines *ab initio* molecular dynamics simulations, Gaussian Process Regression, and Bayesian optimization. By taking the examples of silicate and chalcogenide glasses, we show that our method yields new interatomic forcefields that offer an unprecedented agreement with *ab initio* simulations, at a fraction of computational cost. This method offers a new route to efficiently parametrize new interatomic forcefields for disordered solids in a non-biased fashion.

1:45 PM *DS02.05.02
An Entropy-Maximization Approach for the Generation of Training Sets for Machine-Learned Potentials Joshua Brown[1], Mariia Karabin[2] and Danny Perez[1]; [1]Los Alamos National Laboratory, United States; [2]Oak Ridge National Laboratory, United States

The last few years have seen considerable advances in the development of machine-learned interatomic potentials. A very important aspect of the parameterization of transferable potentials is the generation of training sets that are sufficiently diverse, yet compact enough to be affordably characterized with high-fidelity reference methods. We formulate the generation of a training set as an optimization problem where the figure of merit is the entropy of the distribution of atom-wise descriptors. This can be used to create a fictitious potential to explicitly drive the generation of new configurations that maximally improve the diversity of the training set. I will show how this strategy can provide an automated and scalable solution to generate large training sets without human intervention.

2:15 PM DS02.05.03
Active Learning of Many Body Coarse Grained Potentials with Gaussian Process Regression Blake Duschatko, Jonathan Vandermause, Nicola Molinari and Boris Kozinsky; Harvard University, United States

In recent years, machine learning has been used to improve the training and simulation efficiency of “bottom-up” coarse grained potentials, which guarantee the preservation of thermodynamic quantities in the coarse grained space [1]. While these potentials can be used to capture the physics of systems on large length and time scales that are traditionally inaccessible with molecular dynamics, they are known to generally have a high degree of complexity.

It has been shown that Gaussian process regression can be used as a framework for active learning of force fields from ab initio data [2], and we extend this idea to coarse grained models. In particular, we study the utility of active learning over passive learning schemes in the efficient modeling of coarse grained potentials. Moreover, we examine how Gaussian processes can be used as a tool to better understand the importance of model complexity in coarse grained problems.

2:30 PM *DS02.05.04
Empirical Potentials for Complex Systems Steven D. Kenny, Iain Brown, Jiawei Zhou and Roger Smith; Loughborough University, United Kingdom

Many Materials Science problems of interest involve a number of atomic species and this often makes deriving potentials for these systems very challenging. In this work we will present simulations on dopants and interfaces in systems based on ZnO that have been modelled using a ReaxFF potential approach, using machine learning methods to fit the potentials. This is an important transparent conducting oxide system and the doping of it and the interfaces of it and other materials are often critical in the mechanical performance of devices that utilise this. We will also present work on using a machine learning potential to study high entropy ceramic materials and compare this with ab-initio calculations on these systems.

SESSION DS02.06: Machine Learning Aided Modeling I
Session Chair: Danny Perez
Tuesday Afternoon, November 30, 2021
Sheraton, 5th Floor, Public Garden

4:00 PM DS02.06.01
Building Useful Machine-Learned Interatomic Potentials Gus L. Hart[1], Hayden Oliver[1], Brayden Bekker[1], Alexander Shapeev[2], van der Oord Cas[3] and Gabor Csanyi[3]; [1]Brigham Young University, United States; [2]Skolkovo Institute of Science and Technology, Russian Federation; [3]University of Cambridge, United Kingdom

Machine-learned interatomic potentials are far more expressive than traditional physically motivated interatomic potentials like Lennard-Jones, Stillinger-Weber, Embedded Atom Potentials, etc. While they can be far more accurate, they are also more likely to be completely wrong outside of the training domain, are more difficult to train reliably, and are computationally expensive. We have developed MLIPs for the Hf-Ni-Ti shape memory alloy. We share cautionary tales, best practices for generating training sets, and demonstrate how community tools make for "easy entry" to realistic thermodynamic modeling with these potentials.

4:15 PM DS02.06.02
Unsupervised Machine Learning for Autonomous Parameterization of Classical Hamiltonian Aditya Koneru[1,2], Henry Chan[1,2], Sukriti Manna[1,2], Troy Loeffler[1,2] and Subramanian Sankaranarayanan[1,2]; [1]University of Illinois at Chicago, United States; [2]Argonne National Laboratory, United States

We introduce an unsupervised machine learning workflow to autonomously parameterize Tersoff Bond Order Potential using two-dimensional (2D) materials as a representative example. This is a 14-dimensional space and even with the state-of-the-art techniques, the decision of fixing the search boundaries still remains a daunting task. This has been tackled by continually sampling the potential energy surface using the Latin Hypercube Sampling (LHS) technique starting with an arbitrary search bounds. The high dimensional parameter space is projected into a low-dimensional space using Principal Component Analysis (PCA) and are tagged with corresponding energy values estimated from molecular dynamic simulations using LAMMPS. We next employ clustering techniques to identify the range of parameter sets that fall in the desired energy space. A simplex optimization is performed next to identify the parameter set with energies close to the actual energies and guide the range selection for the next iteration. We demonstrate that the search can autonomously achieve target minima on the potential energy surface - a bond order model developed for Carbon 2D polymorphs outperforms existing parameterizations. Our workflow represents an elegant method to overcome issues with selection of parameter ranges and weights for multiobjective high-dimensional optimization of force-field parameters.

4:30 PM DS02.06.03
Graph Attention Networks for Predicting Materials Properties Taylor D. Sparks[1], Debjit Sarkar[2] and Sourodeep Roy[2]; [1]Univ of Utah, United States; [2]Jadavpur University, India

Graph neural networks are powerful tools for representing a wide variety of subjects. In recent years these tools have become state of the art for the social network domains and elsewhere. However, they are relatively new in the field of materials science. Prior approaches utilizing graphs such as CGCNN or MolCLR do not utilize the breadth of feature tools available in social networks and these could offer advantages when representing compounds. In this work, we apply graph attention networks (a variant of graph neural networks) on a graph representation of inorganic compounds including unique global, edge, and node features to create representation vectors for the whole graph. Emphasis is placed on learning relations of bonds rather than nearest neighbors by relying on chemical domain knowledge such as dipoles and electronegativity. Node features are extracted through clustering algorithms and neighbor-based encoding. Global features will include bonding motifs, structural topology characteristics, composition-based feature vector, clustering coefficients, and thermodynamic descriptors. Models are constructed to predict material properties and the attention map attribute of the graph attention network is used to learn and visualize the importance of the information obtained from neighboring nodes.

4:45 PM *DS02.06.04
Estimation of Errors in the Prediction of Long Time Scale Properties with Machine Learning Potentials for Fusion Materials Laura J. Lopes and Danny Perez; Los Alamos National Laboratory, United States

In the development of new machine learning potentials, it is essential to guarantee the correct description of the properties of interest. Our goal is to correctly describe long time scale properties of fusion materials to simulate the surface degradation caused by the contact with the plasma. In order for that to be accomplished, it is necessary to estimate the errors made for those properties by candidate potentials. In this work we developed a method to estimate confidence intervals for the calculation of energy barriers using the SNAP potential.

5:15 PM DS02.06.05
Multitask Machine Learning of Collective Variables for Enhanced Sampling of Rare Reaction Events Lixin Sun, Jonathan Vandermause, Simon L. Batzner, Yu Xie, Steven B. Torrisi, Wei Chen and Boris Kozinsky; Harvard University, United States

Collective variables (CVs), a low dimensional representation of atomic structures, are the cornerstone of many enhanced sampling techniques that enable efficient free energy landscape explorations. Conventionally, CVs are simple geometric descriptors, such as atomic bonds and angles. However, it often needs intuition and trial-and-error testing to determine which CV can lead to accurate free energy calculations and efficient sampling.

In this work, we demonstrate a data-driven method to learn CV with a multitask learning framework. Short molecular dynamics simulations around the transition states and basins are used to train a multitask network consisting of an encoder that encodes atomic structures to a low dimensional latent space and two separate downstream parts that map the latent space to predictions of basin class labels and potential energies. The trained latent space can be used as an effective CV for umbrella sampling bias and free energy calculations. This learning framework is demonstrated on model systems, small molecules, and metal surfaces.

DS02.07.01
Investigating the Protein Corona and Bio-Nanointerface Interactions of the CNT-BSA with Molecular Dynamics Simulations Ankarao Kalluri[1], Catherine Tang[2], Bhushan V. Dharmadhikari[3], Prabir Patra[4,4] and Challa V. Kumar[1,2,2]; [1]University Of Connecticut, United States; [2]University of Connecticut, United States; [3]University of Minnesota, United States; [4]University of Bridgeport, United States

Fundamental understanding of the nanotube-protein interactions at the interface is a crucial issue for the development and rational design of the various biocompatible and hybrid bionanomaterials for applications in bio-sensing, biocatalysis, and drug delivery. We investigated the interactions of bovine serum albumin (BSA) with multi-walled carbon nanotubes (MWCNT) by all-atom molecular dynamics (MD) simulation. MD simulations indicated that hydrophobic, van der Waals (VDW), electrostatic, and hydrogen bonding interactions contribute to the total binding, and these components have been separated out in our work. As a cutoff distance of 5A^{o} used to see the bio-nano surface interactions observed between CNT and BSA surface for 80 ns MD simulation. Analysis of binding components of the total interaction energy (-63 Kcal/mol) shows that the driving force of the binding is mainly hydrophobic (-30 Kcal/mol) interactions by the non-polar side chain residues (valine314, proline302 & 303, ala311). CNT interacts with positively charged residues (Arg and lysine312) negatively charged residues (Glu 299 & 310, Asp 311) in proteins through the cation-π and anionic-π interactions, respectively. Notably, the BSA molecular structure and function preserved largely after its adsorption on the CNT surface. By investigation of the protein adsorption on the CNT surface would be helpful to better understand the stability and bio-nanosurface interactions at a molecular level.

SESSION DS02.08: Coarse Grain Models I
Session Chair: Kristen Fichthorn
Wednesday Morning, December 1, 2021
Sheraton, 5th Floor, Public Garden

10:30 AM *DS02.08.01
Time-Scale Decoupling in Mass Transport Computations Reveals a Law of Total Diffusion Manuel Athenes[1], Gilles Adjanor[2] and Jérôme Creuze[3]; [1]Université Paris-Saclay, CEA, France; [2]EDF Lab, France; [3]Université Paris-Saclay, CNRS, France

Directly computing mass transport coefficients in stochastic models requires integrating over time the equilibrium correlations between atomic displacements. Here, we show how to accelerate the computations by decoupling short- and long-time correlations, which statistically amounts to conditioning the mass transport estimator through a law of total diffusion. We illustrate the approach with kinetic path sampling simulations of atomic diffusion in alloys where percolating solute clusters trap the mediating vacancy. There, Green functions serve to generate first-passage paths escaping the traps and to propagate the long-time dynamics. When they also serve to estimate mean-squared displacements via conditioning, colossal reductions of statistical variance are achieved.

11:00 AM DS02.08.02
Energy Renormalization for Coarse-Graining of Conjugated Polymer for Prediction Thermomechanical Behaviors Zhaofan Li; North Dakota State University, United States

Conjugated polymers (CPs) possessing the characterization of relatively rigid conjugation backbone and peripheral flexible side chain have attracted considerable attention toward the application of organic electronic and optoelectronic devices. The computational prediction of the thermomechanical behavior of CPs to serve the needs of materials design and prediction of their functional performance is a grand challenge due to the prohibitive computational times of all-atomistic (AA) molecular dynamic (MD) simulations. Atomistically informed coarse-grained (CG) modeling is an essential strategy for making progress on this problem. In this work, focusing on the widespread explored regioregular poly(3-hexylthiophene) (P3HT), we develop a temperature-transferable CG model based upon the energy-renormalization (ER) approach that allows for modeling of CPs dynamics over a wide temperature range and accessing greater spatiotemporal scales. The results show that the CG model faithfully and accurately capturing the short- and long-timescale dynamics, *i.e.*, Debye-Waller factor and segmental relaxation time. Systematically exploration of the mechanical properties, such as tensile and shear, reveals that the cohesive interaction exhibits a great impact on the mechanical response. Our work highlights the necessity and feasibility of ER when modeling a conjugated polymer that possesses branched architecture, and sheds new light on the rational design of the temperature-transferable CG model of complex polymers for their thermomechanical and conformational prediction.

11:15 AM DS02.08.03
Late News: Combined Molecular Dynamics/Monte Carlo Simulation Study of the Mechanism(s) of Cu Thin Film Growth on TiN Substrates Reza

Namakian, Brian R. Novak, Xiaoman Zhang, Wen Jin Meng and Dorel Moldovan; Louisiana State University, United States

We tailored and calibrated a sequential molecular dynamics (MD)/time-stamped force-bias Monte Carlo (tfMC) simulation methodology to investigate the growth mode, the resulting crystalline structure, and orientation of Cu thin films obtained by sputter deposition on epitaxial TiN substrates. Our studies reveal for the first time that at the very early stage of growth, BCC-Cu grows pseudomorphically on the TiN(001) substrate as a very thin continuous film with the BCC-Cu[001]//TiN[001] growth direction. As the Cu thin film thickness increases the film transforms, through the Nishiyama-Wasserman mechanism, from BCC into predominantly FCC-Cu with abundant nanotwins, which is the same type of structure obtained in the experiment conducted here via a dc magnetron sputter deposition technique to grow Cu on TiN001 at 105 °C [1]. The MD/tfMC simulations also reveal that on the N-terminated TiN(111), Cu shows a very poor wettability and the the FCC-Cu(111) film grows vertically in the form of tall 3D islands. On Ti-terminated TiN(111) surface, however, FCC-Cu(111) initially grows in the form of 2D islands with high wettability. With additional Cu deposition, a triangular misfit dislocation network is generated at the Cu(111)//Ti terminated TiN(111) interface with subsequent formation of a two-layer nanotwin with its twinning plane parallel to the surface substrate. The present simulation results provide deep insights into some complexities of the growth mechanisms operating during Cu growth on TiN and shed light on related thin film growth in weakly-interacting metal/substrate systems.

An Efficient Computational Framework for Prediction of Charge Density Symmetry in Twisted Bilayer Graphene Tawfiqur Rakib[1], Elif Ertekin[1], Pascal Pochet[2] and Harley Johnson[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]Univ. Grenoble-Alpes and CEA, France

The discovery of correlated insulating states at half filling at a twist angle of 1.08^0 known as t the magic angle has stirred tremendous interest in twisted bilayer graphene (TBG). Such exotic physics and electronic properties are intrinsically dependent on the atomic structure of the material. In TBG, a periodic variation of different stacking regions emerges from the relative rotation between the graphene layers. At large twist angles ($> 1.47^0$), the positions of the atoms are well-described by considering a rigid rotation between the individual graphene layers. However, the symmetry changes significantly for low twist angles ($< 1.47^0$) due to atomistic relaxations that expand the stable AB stacking region while shrinking the size of the AA and SP stacking regions. While this atomic relaxation is very well-described in the literature, the effect of the symmetry change on the charge density of TBG remains unexplored since electronic structure calculations at small twist angles require large, and often computationally infeasible, supercells. Therefore, we develop a computationally efficient framework that enables the exploration of the charge density symmetry of low twist angle TBG. Our approach is based on the evolution of the high intensity Bragg peaks in the Fourier representation of the charge density, obtained from density functional theory, as the twist angle decreases. The structural relaxation is found to correspond to low intensity satellite peaks in the Fourier representation. By accounting for these satellite peaks, it is possible to observe the transformation of symmetry in the charge density distribution from high to low twist angle TBG. One striking outcome of our framework is the observation of electron localization in the AA region of low twist angle TBG. The framework shows clearly the effects of atomistic relaxations on the symmetry of the charge density of TBG at small twist angles, which may be useful for better understanding of the exotic physics of TBG.

Photopolymer Resin Design with Reactive Coarse-Grained Molecular Dynamics—Reaction Mechanism as a Variable John J. Karnes[1], Todd H. Weisgraber[1], Caitlyn C. Cook[1], Daniel N. Wang[1], Jonathan C. Crowhurst[1], Christina A. Fox[1,2], Bradley Harris[2], James S. Oakdale[1], Roland Faller[2] and Maxim Shusteff[1]; [1]Lawrence Livermore National Laboratory, United States; [2]University of California, Davis, United States

Coarse-graining (CG) approaches reduce the total number of particles in molecular dynamics (MD) simulations and often enable the use of longer integration time steps. Both of these effects serve to reduce computational expense and therefore provide access to larger length and time scales for a given system. The Martini model is a widely used CG force field, flexible and transferrable enough to find applications ranging from biological to polymer-based systems, including reactive CG MD simulations. However, CG models like Martini typically combine several atoms into a representative 'bead,' meaning that individual reaction sites effectively disappear as atomic identities are absorbed into the Martini beads. In this work we use this loss of specificity as a tool that enables the simulation of different chemical reaction mechanisms that may arise from the same CG model. This approach therefore isolates reaction mechanism as the variable in these simulations.

As proof of concept, we consider monomers that share a similar molecular mechanical description but polymerize by different mechanisms: radical chain-growth polymerization and radical step-growth polymerization. We represent these physically similar monomers with the same CG model, a 'Universal Monomer,' and use reactive CG MD simulations to prepare highly crosslinked thermosets of each monomer. Since the monomers are represented by precisely the same model, differences observed in the polymerization reactions or in the mechanical properties of the resulting thermosets are a function of the reaction mechanism. We compare on-the-fly simulated polymerization, network topology, and simulated mechanical testing of the two reactive CG MD systems and discuss related experimental results. Further, we suggest that this Universal Monomer approach is a reasonable survey of 'mechanism-space' with application to the rational design of chemical feedstocks for photopolymerization-based additive manufacturing techniques.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344, IM release number LLNL-ABS-823466.

Atomistic Propagation of the Aluminum Oxide/Aluminum Interface Vrindaa Somjit and Bilge Yildiz; Massachusetts Institute of Technology, United States

Identifying the aluminum oxide/aluminum (Al_2O_3/Al) interfacial structure is important to improve the performance of the wide range of applications that employ this interface, such as to mitigate sources of noise in superconducting electronic devices and to improve the chemical and mechanical properties of corrosion coatings and structural composites. It will also help gain deeper understanding of oxide propagation into the metal in this fundamental system. However, the structure of the interface has not been resolved at the atomic scale, and the stages of growth of the oxide into the metal are unknown. Experimental studies claim that the interface is sharp, coherent and indicate the presence of undercoordinated aluminum atoms, but provide no information on the atomic arrangement at the interface. Computational studies have primarily only looked into the stability of different terminations of the oxide on the metal, computed the work of adhesion, electronic structure, etc. Given that the interface presents an environment vastly different from either the bulk oxide or metal, it is likely that it has different structural features and properties. In this study, we utilize ab initio Grand Canonical Monte Carlo, a physically motivated, bias-free method, to accurately search the interface configuration space and understand the structure and evolution of the interface. We show that 12.5% aluminum vacancies are present at the interface at the oxide/metal equilibrium. As the oxygen chemical potential is gradually increased, the interface propagation appears to occur in a layer-by-layer fashion. Oxygen is first incorporated at the FCC hollow sites at the interface, and then at the tetrahedral interstitial sites. This resembles oxygen incorporation at the Al(111) surface, after which the stacking sequence of Al_2O_3 is regained. We also discuss the trends in bond lengths, coordination environment and electronic structures of these interfacial configurations. The results of this study have implications for interfacial defect transport, charge trapping and adhesion.

Kinetic Monte Carlo Simulations of Nanowin Formation in FCC Metal Thin Films Shefford P. Baker, Nathaniel G. Rogers and Derek H. Warner; Cornell University, United States

FCC metal thin films produced by atom-by-atom deposition methods can be formed with dense arrays of parallel coherent twin boundaries (CTB's) having average spacings in the nanometer regime. There has been great interest in these nanotwinned structures due to their expected unusual properties. To access those properties, it must be possible to control the average CTB spacing. Yet demonstrations of experimental control remain elusive and existing models (molecular dynamics simulations, phase field and analytical models) provide conflicting predictions. We have simulated nanotwin formation as a function of deposition rate and temperature on (111) surfaces in FCC metal thin films using a rejection-free kinetic Monte Carlo (KMC) approach. In our simulations, atoms are added to a 2-D hexagonal lattice and moved according to an energy landscape that accounts for the differences in transitions between twin and FCC sites using an adaptation of the variable step size method. Rates and temperatures that mimic experimental conditions are used. Layer growth occurs by nucleation, growth, and island interaction. However, interactions with simulation cell boundaries strongly influence results and a choice between cell sizes small enough to run many times for good statistics and large enough to obtain realistic behavior limited predictive capabilities. We find that for experimentally relevant rates, temperatures, and grain sizes, nanotwin formation takes place in the nucleation-dominated regime and developed an analytical model based on the KMC methods to describe this. Predictions for nanotwin formation are described.

2:00 PM *DS02.09.03
An Adaptive Hyperdynamics Method Kristen A. Fichthorn; The Pennsylvania State University, United States

Accelerated molecular dynamics methods have the capability to increase the time scales probed in rare-event simulations by orders of magnitude, with no loss in accuracy. However, these methods have not been widely applied because of several drawbacks. In hyperdynamics, one of these drawbacks is the appropriate choice of the boost potential. If the boost is too high, the simulation can be inaccurate. If the boost is too low, the method is ineffective. Obtaining an optimal boost requires detailed knowledge of the underlying free-energy surface, which is computationally demanding. However, with advances in parallel computing, this problem is becoming tractable. In this work, we introduce an adaptive hyperdynamics method for global hyperdynamics that can predict optimal parameters for the bond-boost potential. By quantifying the probability distribution for a rare event to occur within a time *t* as a function of the boost, we observe a stair-like property. We can correlate stair steps with features of the boosted potential surface in a way that allows us to avoid inaccuracies associated with too large of a boost. We have implemented this method using a Python wrapper that allows us to test boosts for many replicas of a system in parallel, so a near-optimal boost can be identified relatively rapidly. The method is currently applicable to rare events governed by a potential-energy barrier, but extensions are possible in the future. We demonstrate the method in simulations of metal nanostructures in solvent with adsorbed capping molecules, a problem relevant to the shape-selective growth of metal nanocrystals.

2:30 PM DS02.09.04
Generalizable Kinetics Models of Hydrocarbon Pyrolysis from Molecular Dynamics Simulations for Combined Solid and Molecular Phases Vincent Dufour-Decieux[1], Rodrigo Freitas[2] and Evan Reed[1]; [1]Stanford University, United States; [2]Massachusetts Institute of Technology, United States

Building a chemical kinetics model traditionally requires conducting many experiments over the course of several years. Recently developed atomistic simulations had made it possible to develop kinetics models within months, using the large amount of data generated by these simulations. These kinetics models allow scientists to predict the chemical evolution of complex systems that can involve several thousands of reactions and species, while reducing computation time by up to four orders of magnitude compared against atomistic simulations. When building these kinetics models, there are usually two frameworks depending on the size of the species that are being studied. First, a kinetics model usually used for gas phase systems: this type of kinetics model has been thoroughly studied and can involve several thousands of molecules and reactions. The reactions are described using molecules, but this description prevents such a kinetics model from studying larger molecules, because these kinetics models fail to predict the creation and the reactivity of unobserved molecules. The second type is used for long chains or solids, like in polymer growth or soot formation. These models are usually simplified to include only a few reactions occurring at some reacting sites. This description is not adapted to smaller molecules, and the reduced number of reactions cannot always reflect the complexity that these processes have. These two frameworks have shown successes throughout the years, but there is a lack of kinetics models that would span across all these different systems, starting from small molecules and going all the way to solid particles.

In this work, we propose a new description for reactions in kinetics models that allows us to study small particles and large clusters: the atomic-level features. In our proposed approach, the reactions are described by the atoms surrounding the reactive site. This description resonates with the approach used for long chains and solids, but it is also applied to small molecules, resulting in a model that can describe both sizes. To demonstrate the efficiency of our approach, we study carbon particle growth in the atmosphere of icy giant planets. In this application, the initial composition is liquid methane which then grows into long hydrocarbons chains. The mechanism here is not fully understood, and a kinetics model that could describe accurately the three different states that this system goes through is needed. We demonstrate that the atomic description of reactions outperforms the molecular description on the prediction of the larger chain growth, while maintaining similar accuracy on the small molecules. This is achieved because the atomic features allow the creation of molecules unobserved in the training set, in addition to accurately predicting their reactivity. Furthermore, the atomic-level model requires fewer unique reactions than a conventional molecular-level model. This induces a more accurate estimation of the reaction rates and the ability to parametrize the kinetics model with less data. A corollary of this ability is that it is possible to extrapolate in time and in size using the atomic-level features. Finally, the atomic kinetics model can be transferred to different starting molecules while maintaining a high level of accuracy. Therefore, we find

that our proposed atomic featurization of reactions enables simultaneous description of small molecules and large clusters.

2:45 PM DS02.09.05
Atomistic Multi-Lattice Kinetic Monte Carlo (KMC) Modeling of Hyperthermal Oxidation of Multi-Layer Graphene Sharon Edward and Harley Johnson; University of Illinois at Urbana Champaign, United States

Thermal protection systems (TPS) in hypersonic vehicles are primarily made from carbon-based materials, due to the high heat capacity and high energy of vaporization of carbon, which protects the vehicles from damage in reentry conditions. However, at very high temperatures, reactions with oxygen cause the erosion of the TPS through formation of CO and CO_2. In this work, we model defect generation in multi-layer graphene due to adsorption and diffusion of oxygen using an atomic scale multi-lattice KMC approach. Simulations based on this KMC model reveal details of the pitting process driven by atomic oxygen in multi-layer graphene for specific temperatures and partial pressures of atomic and molecular oxygen. The model is developed using separate, interacting lattices for the carbon and oxygen sites. The carbon lattice includes all possible carbon sites in a multilayer graphene structure representative of an HOPG material. In every time step of the simulation, a change in the state of a site in the oxygen lattice affects the possible states of the neighboring sites in the carbon lattice. The use of separate lattices makes it possible to effectively distinguish the oxygen and carbon sites and allow them to communicate throughout the simulation as various chemical interactions are tracked. The model implemented here consists of 20 surface reactions and 23 reactions on graphene edge sites, for a total of 43 reactions. Surface groups such as lactone-ethers and ether-lactone-ethers are formed on the surface as a result of reactions between neighboring epoxies and are shown to have a low energy barriers to CO and CO_2 formation. These groups are thus crucial to the initial formation of defects as they lead to formation of CO and CO_2 from initially defect free surfaces. For computational efficiency, only active oxygen sites around the previously executed site in the last timestep are checked for available events and are updated to the existing list of available events. We use the approach to show the effects of high symmetry grain boundaries and terraces on the formation and growth of defects in the oxidation process, and we observe pit formation enhanced by the presence of the exposed edges. Using the multi-lattice KMC model it is possible to simulate much longer times than in direct MD simulation. Scales of milliseconds are easily reached on a laptop computer without significant effort to optimize efficiency. Thus, the approach enables analyses of relatively large domains over experimental laboratory time scales.

4:00 PM *DS02.09.06
Self-Interstitial-Based Diffusion in Concentrated Binary Alloys Simulated Using Classical Molecular Dynamics and Accelerated Dynamics Laurent K. Béland[1], Keyvan Ferasat[1], Thomas D. Swinburne[2], Yuri Osetsky[3], Alexander Barashev[4], Peyman Saidi[1] and Mark Daymond[1]; [1]Queen's University, Canada; [2]CNRS/CINaM, France; [3]Oak Ridge National Laboratory, United States; [4]University of Michigan, United States

Self-interstitial atoms (SIAs) are almost exclusively observed in irradiated materials. In part because of their presence, unique materials science phenomena occurs during irradiation of materials, such as radiation-induced segregation and radiation-induced (dis)ordering. While SIAs in pure metals typically diffuse very rapidly, within the timescale accessible by molecular dynamics, SIA kinetics in disordered alloys can be inhibited by configurational traps. In this talk, I will present two examples. First, I will present the case of SIA diffusion in Ni(x)Fe(1-x) concentrated solid solution alloys. Second, I will present the case of SIA-based reordering of irradiated Ni3Al alloys.
In the case of the Ni(x)Fe(1-x) alloys, we use a mix of micro-second scale molecular dynamics, the kinetic Activation Relaxation Technique and accelerated lattice kinetic Monte Carlo to explain why the SIA diffusion coefficient is a non-monotonic function of alloy chemical composition.
In the case of Ni3Al, we use molecular dynamics and temperature-accelerated Markov models with
Bayesian estimation of rates (TAMMBER), which show that even though the SIA diffusion coefficient increases as it re-orders the system, the re-ordering kinetics, counterintuitively, slow down. We demonstrate that a relatively simple mean-field rate theory is able to quantitatively predict this behavior.

SESSION DS02.10: Coarse Grain Models II

10:30 AM *DS02.10.01
Multiscale Atom-Continuum Coupling Using Lattice Greens Functions William A. Curtin and Ankit Gupta; Ecoloe Polytechnique Federale Lausanne, Switzerland, Switzerland

Atomistic/Continuum coupling methods have now been developed for over 25 years. However, methods in which non-elastic behavior is occurring in the continuum domain remain computationally challenging due to the need for full 3d solutions in the continuum domain using finite elements. Greens function methods have the potential to greatly reduce the computational costs and enable large multiscale simulations. Here, progress toward a GFM method is described. First, the Flexible Boundary Condition Method of Sinclair et al., which is a GFM for an atomistic region in an infinite elastic space, does not give unique solutions even for linear problems. Second, efficient/usable GFM methods require a transition from a full lattice GF to a continuum GF, and this is shown to create numerical errors. However, these errors can be controlled and reduced. Third, starting from a fully-atomistic description, a coarse-graining of the outer (continuum) boundary is presented that greatly reduces the computational costs with essentially no loss of accuracy. These results show that an emerging GFM method will solve the bottleneck of current multiscale methods.

11:00 AM DS02.10.02
Spectral Denoising for Accelerated Analysis of Correlated Ionic Transport Nicola Molinari[1], Yu Xie[1], Ian Leifer[1], Aris Marcolongo[2], Mordechai Kornbluth[3] and Boris Kozinsky[1,3]; [1]Harvard University, United States; [2]Universität Bern, Switzerland; [3]Robert Bosch LLC, United States

In this work, we propose a new general method for analyzing and calculating diffusivity and ionic conductivity in media with strong ionic correlations from molecular trajectories [1]. Previously, the only two options were the dilute uncorrelated approximation, which converges rapidly but it is inaccurate, and the exact Green-Kubo method that is prohibitively expensive for complex and large systems. The herein presented approach automatically extracts and utilizes the collective diffusion eigenmodes of the displacement correlation matrix to denoise the calculation of the transport properties. The proposed approach is universally applicable, simple, and provably superior to previously available methods, exhibiting speed ups of several orders of magnitude. Thus, it opens wide opportunities to study correlated diffusion in previously inaccessible complex electrolytes.

8:00 AM *DS02.11.01
Calculations of Electronic Excited States Using Time Independent Functional Approach Hannes Jonsson; University of Iceland, Iceland

A method is presented for time independent density functional calculations of excited electronic states using direct orbital optimization [1,2]. The calculations are variational and converge on stationary states, so they provide estimates of atomic forces in the excited state. Calculations of materials can be calculated using either a real space grid or a plane wave basis set. The functional can be orbital density dependent (ODD) as in self-interaction corrected functionals or be of the Kohn-Sham (KS) form as in the generalized gradient approximation. The implementation for KS functionals involves two nested loops: (1) An inner loop for finding a stationary point in a subspace spanned by the occupied and a few virtual orbitals corresponding to the excited state; (2) an outer loop for minimizing the energy in a tangential direction in the space of the orbitals. For ODD functionals, a third loop is used to find the unitary transformation that minimizes the energy functional among occupied orbitals only. Combined with the maximum overlap method, the algorithm converges in challenging cases where conventional self-consistent field algorithms tend to fail. The benchmark tests presented include charge-transfer excitations, defect states in diamond and excitons in silica.

Discrete Discontinuous Basis Projection (DDBP) Method for Large-Scale Electronic Structure Calculations Qimen Xu[1], Phanish Suryanarayana[1] and John Pask[2]; [1]Georgia Institute of Technology, United States; [2]Lawrence Livermore National Laboratory, United States

The large number of grid points per atom required for accurate real-space Kohn-Sham Density Functional Theory (DFT) calculations restricts their efficiency. In this work, we present an approach to accelerate such calculations severalfold, without loss of accuracy, by systematically reducing the cost of the key computational step: the determination of the Kohn-Sham orbitals spanning the occupied subspace. This is achieved by systematically reducing the dimension of the discrete eigenproblem that must be solved, through projection into a highly efficient discrete discontinuous basis. In calculations of quasi-1D, quasi-2D, and bulk metallic systems, we find that accurate energies and forces are obtained with 8–25 basis functions per atom, reducing the dimension of full-matrix eigenproblems by 1-3 orders of magnitude.

8:45 AM DS02.11.03
SPARC—Real-Space Density Functional Theory for Large Length and Time Scales Phanish Suryanarayana; Georgia Institute of Technology, United States

In this talk, the speaker will present SPARC: Simulation Package for Ab-initio Real-space Calculations. SPARC can perform Kohn-Sham density functional theory calculations for isolated systems such as molecules as well as extended systems such as crystals and surfaces, in both static and dynamic settings. It is straightforward to install/use and highly competitive with state-of-the-art planewave codes, demonstrating comparable performance on a small number of processors and increasing advantages as the number of processors grows. Notably, SPARC brings solution times down to a few seconds for systems with O(100-500) atoms on large-scale parallel computers, outperforming planewave counterparts by an order of magnitude and more.

9:00 AM DS02.11.04
Late News: Cu Atoms Induce a New Reconstruction in the MnGa(001) Surface—An Ab Initio Study Ricardo M. Ruvalcaba[1], Joseph P. Corbett[2] and Jonathan Guerrero[1]; [1]National Autonomous University of Mexico, Mexico; [2]The Ohio State University, United States

MnGa alloys possess a set of properties that give them a wide range of highly interesting applications: from magnetic tunnel junctions [1] to semiconductor-magnetic hybrid devices [2]. In the present study, we report a first-principles investigation on a surface reconstruction based on the $L1_0$-ordered MnGa (001) with Cu atoms incorporated at the surface. We present a comprehensive analysis of the viability of all the possible reconstructions, as well as the structural, electronic, and magnetic properties of the most stable one: a 1×2 reconstruction with a Cu-by-Ga substitution at the surface, similar to the one reported in a previous study [3]. We propose that this structure may pose as a magnetic catalyst, adding yet another interesting application to MnGa alloys.

9:15 AM DS02.11.05
Spectral Quadrature for Large Scale First Principles Simulations of Crystal Defects Swarnava Ghosh; Oak Ridge National Laboratory, United States

Defects in crystalline solids play a crucial role in determining properties of materials at the nano, meso- and macroscale, such as the coalescence of vacancies at the nanoscale to form voids and prismatic dislocation loops or diffusion and segregation of solutes to nucleate precipitates. First principles Density Functional Theory (DFT) simulations can provide a detailed understanding of these phenomena, however the number of atoms needed to correctly simulate these systems is often beyond the reach of current DFT codes. We present an accurate and efficient finite-difference formulation and parallel implementation of Linear Scaling Kohn-Sham Density (Operator) Functional Theory (DFT) for non-periodic systems embedded in a bulk environment. We discuss the parallel scalability of the framework, acceleration on the state-of-the-art Graphics Processing Units, and will present the results of applying the framework to study isolated defects in lightweight Magnesium alloys. Finally, we will talk about integrating Machine Learning methods into the framework to further extend the scope of simulations.

9:30 AM *DS02.11.06
A New *Ab Initio* Tool for Uncovering the Ultrafast Response of Functional Correlated Materials Volodymyr Turkowski, Shree Ram Acharya and Talat S. Rahman; University of Central Florida, United States

Accurate description of the temporal evolution of correlated electron materials, when perturbed by an external field, is a challenging and sought-after problem in condensed matter physics and material science. This is particularly the case for the ultrafast (femtosecond) response of the system since it may be dominated by electron correlations, unhindered by interactions, for example with the lattice. Suitable *ab initio* computational methods would thus need to extend beyond the standard density functional theory (DFT). Time-dependent density-functional theory (TDDFT) when equipped with appropriate exchange-correlation (XC) functional offers a way forward. This necessarily implies development of XC functionals beyond the standard local density or the generalized gradient approximations because of the need to treat on-site orbital-resolved correlations and/or time dependent interactions. In this presentation, we first provide some details of our new methodology in which we combine dynamical mean-field theory (DMFT) and TDDFT to examine the ultrafast response of materials in which electron-electron correlations play an important role. We obtain a non-adiabatic XC kernel (potential for nonlinear response) from the electron charge susceptibility (self-energy) by solving an effective Hubbard model using DMFT. This XC kernel or potential when implemented in TDDFT provides a computationally feasible approach for examination of nonequilibrium properties of systems in question. We next demonstrate the viability of the approach through computation of the ultrafast demagnetization of Ni [1], for which we calculate the pre-thermalization of the electron and hole subsystems and related spin-resolved properties. We show that the system magnetic moment reaches its lower, transient-state value (demagnetized) in tens of femtoseconds, and that the charge (electron and hole) pre-thermalization occurs after ~10 femtoseconds, both results in agreement with experimental data. Since at such short time scales electron-electron interaction is the only source of scattering in the system, these results capture the power of the TDDFT+DMFT methodology for isolating the femtosecond physics of strongly correlated materials.

Modeling Polaron Transport in Defected Spinel Oxides Maytal Caspary Toroker; Technion-Israel Institute of Technology, Israel

The small-polaron hopping model has been used for several decades for modeling electronic charge transport in oxides. Despite its significance, the model was developed for binary oxides, and its accuracy has not been rigorously tested for higher-order oxides. To investigate this issue, we chose the $Mn_xFe_{3-x}O_4$ spinel system, which has exciting electrochemical and catalytic properties, and mixed cation oxidation states that enable us to examine the mechanisms of small-polaron transport. Using a combination of experimental results and DFT+*U* calculations, we find that the charge transport occurs only between like-cations (Fe/Fe or Mn/Mn). And due to asymmetric hopping barriers and formation energies, we find that the polaron is energetically preferred to the polaron, resulting in an asymmetric contribution of the Mn/Mn pathways. The effect of vacancies near and far from the polaron will be emphasized in this talk.

Large-Scale Real-Space Electronic Structure Calculations Sambit Das[1], Bikash Kanungo[1], Phani Motamarri[2] and Vikram Gavini[1]; [1]University of Michigan, United States; [2]Indian Institute of Science, India

Electronic structure calculations, especially those using density functional theory (DFT), have been very useful in understanding and predicting a wide range of materials properties. Despite the success of DFT, and the tremendous progress in theory and numerical methods over the decades, the following challenges remain. Firstly, the state-of-the-art implementations of DFT suffer from cell-size and geometry limitations, with the widely used codes in solid state physics being limited to periodic geometries and typical simulation domains containing a few thousand electrons. This limits the complexity of materials systems that are accessible to DFT calculations. Further, there are many materials systems (such as strongly-correlated systems) where the widely used model exchange-correlation functionals are inaccurate. Addressing these challenges will enable large-scale quantum-accuracy DFT calculations, and can significantly advance our predictive modeling capabilities of complex materials systems.

This talk will discuss our recent advances towards addressing the aforementioned challenges. In particular, the development of computational methods and numerical algorithms for large-scale real-space DFT calculations using adaptive finite-element discretization will be presented, which form the basis for the recently released DFT-FE open-source code. The computational efficiency, scalability and capability of DFT-FE will be presented, and contrasted with other widely used codes. Further, ongoing efforts, and related thoughts, on developing a framework for a data-driven approach to improve the exchange-correlation description in DFT will be discussed.

11:30 AM DS02.12.04
Systematic Evaluation of First Principles DFT+U+J Algorithms for the Fast and Accurate Modelling of Transition Metal Oxides Daniel S. Lambert and David D. O'Regan; Trinity College Dublin, Ireland

Hubbard U corrections are a widely used approach for overcoming the characteristic band gap underestimation in approximate Density Functional Theory (DFT) calculations, without incurring significant computational costs. However, Hubbard U corrections for transition metal oxides (TMOs) are often chosen on a somewhat arbitrary basis and tend to over-correct. This has led to a search for improvements to the U correction such as DFT+U+J, which includes a correction based on the Hund's coupling parameter J that accounts for the dependence of interactions on the spin orientation.

In our research, a standardised first-principles algorithm is implemented for calculating U and J for both metal and oxygen subspaces, based on the linear response to an applied potential. This procedure is benchmarked with several TMO materials to assess the effect of DFT+U+J on the band gap, effective mass, bond lengths and unit cell volume.

We find that in certain materials, first-principles DFT+U+J can give band gap values that are close to experimental values, out-performing PBE and standard DFT+U and, in some cases. even outperforming hybrid functional results. It is also shown that DFT+U+J does not appear to introduce significant distortions in material ionic geometry or band-structures, suggesting that this methodology could be useful for the computationally efficient modelling of TMOs.

11:45 AM DS02.12.05
Symmetry-Adapted Density Functional Theory Abhiraj Sharma and Phanish Suryanarayana; Georgia Institute of Technology, United States

One-dimensional nanostructures such as nanotubes, nanowires, nanohelices, nanospirals, and nanocoils have received increased attention over the past three decades due to their fascinating elastic, electronic, vibrational, optical, and thermal properties. In this work, we present a cyclic and helical symmetry-adapted formulation and large-scale parallel implementation of real-space Kohn-Sham DFT for 1D nanostructures, with application to the mechanical and electronic response of carbon nanotubes subject to torsional deformations. Specifically, we derive symmetry-adapted variants for the energy functional, electronic ground state's variational problem, Kohn-Sham equations, atomic forces, and axial stress, all posed on the fundamental domain, while employing a semilocal exchange-correlation functional and a local electrostatic formulation. Within this framework, we develop a representation for nanotubes of arbitrary chirality subject to external twists. We develop a high-order finite-difference parallel implementation capable of performing cyclic and helical symmetry-adapted Kohn-Sham calculations in both the static and dynamic settings. Using this implementation, we study the mechanical and electronic response of carbon nanotubes to twist-controlled deformations, at both small and large deformations.

***Ab Initio* Random Structure Searching for Nonhydrostatic Environments** William C. Witt and Chris J. Pickard; University of Cambridge, United Kingdom

Thermodynamics dictates that a crystal under pressure will prefer the structure of lowest enthalpy, provided the temperature is sufficiently low. Structure prediction techniques like random structure searching rely on this insight, optimizing candidate structures to balance the applied pressure, then ranking them by enthalpy. This procedure becomes more complicated when the applied stress is nonhydrostatic. Numerous formulations of enthalpy for nonhydrostatic environments appear in the literature, tracing back to early work by Gibbs, but many are unsuitable for large deformations or have other undesirable features. We illustrate the various difficulties and present our solution in a form suitable for random structure searching, illustrating it with a few simple examples.

Computational Modeling of Materials for Organic Light Emitting Diodes Alexander Yakubovich, Alexey Odinokov and Hyeonho Choi; Samsung Advanced Institute of Technology, Russian Federation

Rational design of novel materials for organic light emitting diodes (OLED) requires deep understanding of the processes accompanying device operation at the molecular scale, such as charge and energy transfer, generation and relaxation of excited states, photochemical reactions leading to the degradation of the material, etc. Modern computational chemistry provides versatile tools to study morphology and properties of the OLED materials that often cannot be accurately addressed with experimental techniques.
We present an overview of theoretical methods applied for computational OLED materials development and intend to cover the following subjects:
● prediction of photoluminescence efficiency and CIE coordinates for cyclometalated Platinum and Iridium complexes, which requires evaluation of radiative and non-radiative decay constants, Frank-Condon progressions [1, 2]
● simulations of functional materials using quantum mechanically derived force fields, including modeling of sublimation process of large organometallic compounds, which is an essential step in OLED device fabrication [3-4]
● computational prediction of photochemical stability of OLED materials and more general problem of OLED devices operational stability, including the isotope effects and the problem of charge recombination rate prediction in OLED emitting layers [5-7]
● computational design of OLED materials using generative artificial neural networks: application to triplet-triplet fusion materials

Atomic Cluster Expansion: Practice and Theory Christoph Ortner; University of British Columbia, Canada

Accurate molecular simulation requires computationally expensive quantum chemistry models that makes simulating complex material phenomena or large molecules intractable. The relatively recent trend of "data-driven" models intended to overcome this barrier. I will focus on a specific class, based on the Atomic Cluster Expansion (Drautz, 2019) and explain how such models are constructed from symmetry-adapted "features" which can be used in regression schemes including classical linear regression, kernel ridge regression or ANNs, and show some concrete examples highlighting successes and potentials. I will then discuss some of the more theoretical aspects and try to explain *why* the ACE approach (and ML in general) has been so succesful: a necessary condition is that there must be a relatively low-dimensional representation of the potential energy landscape. I will focus on three aspects, locality, low body-order and self-consistency, and try to explain rigorously how these occur in the potential energy landscape of ab initio models, and connect this back to the ACE model.

1:30 PM DS02.13.02
A Machine Learning Based Inorganic Crystal Forcefield Optimizer Filip Dinic, Zhibo Wang and Oleksandr Voznyy; University of Toronto, Canada

For expansive structures, the individual energy calculations per optimization step becomes non-trivial and therefore rapidly expands the computational resources required for full optimization. In comparison, ML predictions can be agile even on small machines as many computationally expensive matrix diagonalization algorithms are substituted with neural network layers. The model was trained on a wide range of materials, which were systematically stretched/compressed to simulate unoptimized structures. In order to speed up structural optimization, a gradient descent is applied and used to continually adjust atomic positions in order minimize the total energy of the material. This presentation will discuss the universality of the optimizer generated and the overall accuracy achieved.
There are several potential applications of this optimizer, such as speeding up costly energy relaxation calculations. Furthermore, it can be used to as a pre-cleaning tool for novel materials before being further analyzed by other ML models. In addition, a similar strategy of employing stretched/compressed materials was used to improve the performance of bandgap prediction. This presentation will demonstrate the capabilities of the optimizer in improving bandgap predictions for inorganic materials, and how this can be applied in the search for novel blue-UV emitting materials.

1:45 PM DS02.13.03
Active Learning of Surrogate Interatomic Potentials from Large-Scale Simulations Max Hodapp and Alexander Shapeev; Skolkovo Institute of Science and Technology, Russian Federation

One of the main open challenges in computational materials science is the construction of interatomic potentials which achieve quantitative agreement with fully—but infeasible—ab initio models for large-scale problems, possibly involving tens of thousands of atoms. Empirical potentials, arguably the most popular type of interatomic potentials, generally fail in making quantitative predictions. Therefore, they largely remain inadequate for a predictive modeling of multicomponent systems and, thus, for a computational discovery of new materials.

The advent of machine learning interatomic potentials (MLIPs) for small systems of order 10–100 yet holds promise that overcoming these limitations appear within sight (see [1] for a review). On the other hand, a well-known drawback of state-of-the-art MLIPs is their poor ability to extrapolate beyond the training domain. This demands for carefully chosen, problem-dependent training data which can hardly be defined by the user prior to a simulation due to the vast amount of possible atomic neighborhoods to be considered. Therefore, solution algorithms for atomistic problems using MLIPs have to incorporate error estimators which measure the degree of extrapolation in order to “find” the right training data during a simulation.

Here, we present such an algorithm based on active learning and apply it to screw dislocation motion in bcc tungsten [2,3]. Using structural identification methods, we locate the dislocation line, check the extrapolation grade of the MLIP around its core, and construct new training configurations, sufficiently small to be computable with plane-wave density functional theory, if the extrapolation grade exceeds some threshold. We show that the algorithm reproduces classical results from the literature (i.e., core structure, Peierls barrier/stress), in addition to its anticipated application to more complex problems involving interactions of dislocations with other types of defects, e.g., interstitials, which are out of scope with ab initio methods solely.

2:00 PM DS02.13.04
Late News: Ultra-Fast Force Fields (UF3) Framework for Fitting Interpretable Machine-Learning Potentials Stephen R. Xie[1,2], Matthias Rupp[3] and Richard Hennig[1]; [1]University of Florida, United States; [2]NASA Ames Research Center, United States; [3]University of Konstanz, Germany

Although ab initio methods are indispensable tools for predicting properties of materials and simulating chemical processes, the tradeoff between computational efficiency and predictive accuracy limits their application to large systems and long simulation times. The Ultra-fast Force Fields (UF3) framework is an open-source software package for fitting machine-learning models of the energy landscape that are fast to train and evaluate, interpretable in form, and accurate even for relatively small training sets. Specifically, these interatomic potentials are based on a general many-body expansion combined with a cubic B-spline basis and regularized linear regression. We benchmark speed and accuracy using a bcc tungsten dataset, including melting point calculations with thousands of atoms. We find that our potential is two to four orders of magnitude faster than state-of-the-art machine-learning potentials while achieving comparable accuracy. Finally, we discuss the application of the introduced potentials in accelerating structure prediction.

2:15 PM *DS02.13.05
A Density-Based Machine Learning Force Field for Nonbond Interactions Lin-Wang Wang; Lawrence Berkeley National Laboratory, United States

Using machine learning model to yield a machine learning force field (ML-FF) from ab initio calculation data has becoming a powerful approach to simulate material properties with both size and temporal scales much larger than what can be handled by direct ab initio methods. The common ML-FF approach describes the energy of one atom as a function of its neighboring atom positions. This however cannot describe the long range electrostatic interactions. Furthermore, the point charge based electrostatic model in classical force field might not be accurate enough due to the lack of dipole moment, as well as the polarization. Besides, the nonbonding interaction can be rather complicated in terms of its atomic configuration, which makes direct machine learning training difficult. Here, we present an electron charge density based machine learning model to deal with the nonbond interactions. In this model, the electron charge density is fittied, and used for nonbond interactions directly, including electrostatic and exchange-correlation interactions. We also developed an accurate polarization model, describing the polarization energy of a molecule under external potential. We have used battery organic electrolyte as our testing example for this development.

2:45 PM DS02.13.06
Machine Learning the Local Yield Surface in Model Glasses Rahul Meena, Spencer Fajardo, Dihui Ruan, Yannis Kevrekidis, Michael Shields and Michael L. Falk; Johns Hopkins University, United States

The Local Yield Stress (LYS) method involves directly probing local regions of atoms in atomistic simulations to quantify the incremental stress necessary to induce plastic rearrangements [1,2]. This quantity is key to informing meso-scale and continuum models of plastic deformation and flow in glasses and other amorphous solids. In doing so the LYS seeks to quantify scalar functions of a tensor quantity, the normalized applied shear strain, for a given assemblage of a few tens to hundreds of atoms. While the LYS algorithm is scalable and highly generalizable, it is also computationally intensive. This is particularly true in 3D, which is most relevant for practical application. For this reason, we seek to develop a machine learning methodology to utilize the direct simulation data obtained on a given material to enable efficient and highly generalizable quantification of the LYS. We begin by developing a novel distance metric to quantify the relatedness of atomistic assemblages. We then apply a dimension reduction scheme to the atomistic data in order to determine the most relevant degrees of freedom for our learning algorithm. We make a direct comparison between the atomistic quantification and the learned results in order to validate the method.

DS02-Virtual

8:00 AM DS02.14.01
Exciton-Phonon Coupling of Real-Size Quantum Dots by Machine-Learning Potential—An Excellent Agreement Between Theory and Experiment Sungwoo Kang[1], Youngho Kang[2] and Seungwu Han[1]; [1]Seoul National University, Korea (the Republic of); [2]Incheon National University, Korea (the Republic of)

Recently, quantum dots (QDs) have acquired much attention as promising materials for optical applications. To fully realize the potential of QD, it requires to exhibit a sharp luminescence spectrum. Therefore, many efforts have been taken into minimizing the luminescence line widths of QDs. While it is well known that the luminescence linewidth of a single QD arises from exciton-phonon coupling (EPC), the mechanism and origin of EPC are not fully resolved yet. For example, it is still controversial which mode between acoustic and optical phonon dominates EPC in QDs. A theoretical investigation by density functional theory (DFT) calculations can provide fundamental insights into EPC as well as its impact on the line broadening at an atomic scale. In our previous study, we reported an *ab initio* method to evaluate luminescence line shapes of QDs due to EPC, combining the DFT and Frank-Condon approximation [1]. However, DFT calculations require large computational time so that the size of QD is restricted to ~500 atoms while real-size QDs are much larger (usually consist of 1,000-100,000 atoms).
In this study, we combine DFT and machine-learning potential to simulate real-size InP/ZnSe QD which consists of ~4000 atoms. The calculated lineshape and its temperature dependence are in excellent agreement with the experiments. In addition, we also find that acoustic phonon modes significantly couple with an exciton in core/shell QDs, which is in stark contrast to the widely accepted perception that exciton-optical phonon coupling dominates the luminescence line broadening.

8:15 AM DS02.14.02
Synergistic Coupling in QM/MM Simulations of Dislocations via Machine Learning Petr Grigorev[1], James Kermode[2], Mihai-Cosmin Marinica[3] and Thomas D. Swinburne[1]; [1]CINaM Centre Interdisciplinaire de Nanoscience de Marseille, France; [2]School of Engineering, University of Warwick, United Kingdom; [3]CEA, Service de Recherches de Métallurgie Physique, France

Ab initio modelling of dislocations is essential to gain quantitative insight into a vast range of important material phenomena, from elementary glide or

climb mechanisms to predictive models of solute solution strengthening or post irradiation annealing. The simulation data can be used directly in phenomenological micro-structural models or in the construction of empirical interatomic potentials in a multi-scale framework. With some notable exceptions, ab initio size limitations mean that most dislocations cannot be contained in periodic supercells, requiring the use of flexible boundary techniques which either couple to an elastic Green's function or an empirical interatomic potential in QM/MM simulations. In the latter case, the potential should ideally have identical elastic properties as the ab initio medium. A key limitation of these flexible boundary methods is that whilst the ionic positions and forces can be extracted, the total energy becomes ill-defined.
In recent work [1,2], we showed how this information could be used to extract energetic barriers for glide or segregation through the principle of virtual work. A very good agreement was found with special cases treatable with periodic supercells, whilst in general our ab initio results deviate significantly from predictions of empirical potentials, particularly for prismatic (edge) dislocations. In this work, we show how linear-in-descriptor machine learning (ML) potentials [3] can be used to exactly match ab initio elastic properties, typically leading to efficiencies over "traditional" empirical potentials during QM/MM relaxations. We then go further, using the ionic positions and forces to train the ML potential, showing that the resultant "classical" migration barriers are in excellent agreement with that obtained from QM/MM. Our work shows that QM/MM methods can qualitatively expand the range of atomic structures in the training database of machine learning interatomic potentials, with significant impact on their transferability, or predictive power, for materials modelling.

Realistic Description of Processes at Solid/Liquid Interfaces by *Ab Initio* Molecular Dynamics Simulations with Potential Control Mira Todorova, Sudarsan Surendralal, Stefan Wippermann, Florian Diessenbeck and Jorg U. Neugebauer; Max Planck Institute fuer Eisenforschung, Germany

Many present day technological challenges related to battery materials, electro-catalysis, fuel cells, corrosion and others, centre around understanding and controlling processes at solid/liquid interfaces. A targeted design of desired functionalities critically relies on understanding and quantifying the underlying fundamental mechanisms. However, understanding them is equally challenging to both theoretical modelling and experimental characterisation.

The presentation will discuss our recent advances achieved by developing a novel potentiostat design [Surendralal *et al.*, Phys. Rev. Lett. **120**, 246801 (2018)] and a canonical thermopotentiostat [Deißenbeck *et al.*, Phys. Rev. Lett. **126**, 136803 (2021)] approach. These enable us to control the electrode potential of the system by tuning the excess charge of the working electrode and use ab-initio molecular dynamics simulations to study solid/liquid interfaces under realistic conditions of applied bias. The opportunities opened by the availability of these new approaches will be discussed for a few prototype examples related to electro-catalysis and corrosion: The mechanisms leading to the onset of the hydrogen evolution reaction (HER) in the $H/Pt/H_2O$ system [Surendralal *et al*., Phys. Rev. Lett. **126**, 166802 (2021)] and corrosion at the Mg/water interfaces.

Predicting Hydrogen Diffusivity in Amorphous Titania using Machine Learning-Assisted Adaptive Markov Chain Kinetic Monte Carlo Simulations James Chapman, Kyoung E. Kweon and Nir Goldman; Lawrence Livermore National Laboratory, United States

Understanding hydrogen transport is vital to industries focused on discovering new materials for energy storage and corrosion mitigation. However, knowledge of the physical nature of hydrogen’s diffusion pathways is often limited, especially for materials that exhibit a multitude of phases/defect classes. These materials typically have three rate-limiting structural domains: (1) bulk (2) grain boundaries, and (3) surfaces. In this work we have chosen to study hydrogen diffusion through titania due to its importance in the aforementioned application spaces. Here, we aim to understand diffusion through titania grain boundaries, which are approximated via the amorphous phase. Density functional theory (DFT) was used to calculate thousands of activation energies of hydrogen diffusion in the amorphous phase via nudged elastic band (NEB) calculations using an automated hydrogen pathway generation scheme. Amorphous structures, on the order of tens of nanometers, were generated using a machine learning force field via classical molecular dynamics (MD). Markov chains (MC) were generated using the MD-derived atomic structures as their reference. The MC edge weights, which employ the activation energy between hydrogen hopping sites, were calculated via a Gaussian process regression model, which was trained on the DFT-NEB data. Kinetic Monte Carlo simulations were then performed over a variety of temperatures and amorphous structures. Both stoichiometric and non-stoichiometric amorphous structures were chosen to understand the relationship between hydrogen diffusion and oxygen concentration. The machine learning-assisted adaptive Markov Chain Kinetic Monte Carlo scheme employed in this work allows us to quantitatively describe hydrogen diffusion rates for systems without pre-defined sites and/or activation energies. This work sets the stage for one to perform long time-scale and/or length-scale simulations of transport phenomena

for practically any material system, removing the need to simplify the system either structurally and/or kinetically.

11:15 AM DS02.15.03
Degradation Evolution of Pt Alloy Nanoparticle via Kinetic Monte Carlo Simulation Driven by Neural Network Potentials Jisu Jung, Suyeon Ju, Purun-hanul Kim, Jisu Kim and Seungwu Han; Seoul National University, Korea (the Republic of)

Global warming caused by the excess use of fossil fuels has become a critical issue in modern society. The proton-exchange membrane fuel cell (PEMFC) has attracted wide attention as the environmentally friendly renewable energy device that is used in hydrogen-fueled vehicles. The performance of PEMFC relies on the nanoscale electrocatalyst on the cathode electrode. Over the last several decades, experimental and computational researches have focused on the sluggish oxygen reduction reaction (ORR) and the cost of a precious metal catalyst. However, as the activity of the catalyst increases, their low durability problem also rises. Therefore, an atomistic picture of the degradation of nanoscale catalysts is needed to improve the stability of nanoscale catalysts.
While several works describe the long-term degradation evolution with kinetic Monte Carlo (kMC) simulation, they are limited due to the inaccurate classical potential or computationally expensive quantum calculation. Recently, neural network potential (NNP) has been applied to various systems, delivering the accuracy of quantum calculation at a much lower cost.
In this talk, we combine NNP and kMC simulation to explore the degradation of various shapes of Pt alloy nanoparticles with 3–5 nm under electric bias. We found that our simulation results agree with the experimental observation. This work would pave the way to design more durable nanoparticle electrocatalysts.

11:20 AM DS02.15.04
Kinetic Monte Carlo Study of the Atomic Layer Deposition of Titanium Nitride Sangtae Kim, Hyungmin An, Sangmin Oh, Jiho Lee and Seungwu Han; Seoul National University, Korea (the Republic of)

Titanium nitride (TiN) belongs to the family of refractory transition metal nitrides and represents useful properties such as chemical inertness, thermodynamic stability, extreme hardness, good thermal and electrical conductivity. Atomic layer deposition (ALD) of TiN has been used for protecting layers in tungsten as the minimum feature size of the devices decreased and a high aspect ratio was required. Accordingly, experimental and theoretical research on the TiN-ALD thin film process using various reducing agents (NH_3, H_2) based on the $TiCl_4$ precursor was published. However, observations on the sub-nanometer scale surface reaction are limited due to the characteristics of the ALD process that grows at the atomic scale. In the case of previous theoretical studies, there is a gap in understanding the actual process because it is limited to indirect analysis through thermodynamic energy based on density functional theory (DFT) calculation. So in this study, we introduce the multi-scale modeling for TiN-ALD. We investigate the overall growth of the TiN thin films grown via $TiCl_4/NH_3$. Multi-scale modeling with DFT and on-lattice kinetic Monte Carlo (kMC) is adopted to reproduce the whole ALD process. To determine the most probable pathway, all individual reactions are considered and calculated with DFT, and a set of corresponding activation energies are implemented in the kMC code as a transition probability for the surface reactions on the TiN (111) surface. To verify the compatibility with the experiment ALD process, the growth rate and mass gain according to the process conditions (temperature, pulse time, pressure) were compared with the simulation results. The temperature-dependent growth profile obtained from our model is in good qualitative agreement with the experimental data. These kinetic results should help to explain TiN ALD growth rates observed at different reactant exposures and substrate temperatures.

11:25 AM *DS02.15.05
Active Learning for Accelerated Structure Search with BOSS Milica Todorovic; University of Turku, Finland

Atomistic structure search for organic/inorganic heterostructures is made complex by the many degrees of freedom and the need for accurate but costly density-functional theory (DFT) simulations. To accelerate structure determination in heterogenous functional materials across lengthscales, we employ active learning with the Bayesian Optimization Structure Search (BOSS) approach [1].

Here, Bayesian optimization is employed to build N-dimensional surrogate models for the energy or property landscapes and infer global minima. The models are iteratively refined by sequentially sampling DFT data points that are promising and/or have high information content. Representing heterogenous materials with compact chemical ‘building blocks’ allowed us to build in prior knowledge and reduce search dimensionality. The uncertainty-led exploration/exploitation sampling strategy delivers global minima with modest sampling, but also ensures visits to less favorable regions of phase space to gather information on rare events and energy barriers.

We applied this active learning scheme to study adsorption at the organic/inorganic interfaces: C_{60} on TiO_2(101) anatase [1] and camphor on Cu(111) [2,3]. At larger lengthscales, we investigated the substrate-decoupled F4TCNQ-TTF charge transfer complexes. Global minima configurations in 6 dimensions are identified with reasonable computational efficiency. BOSS produces chemically-intuitive adsorption energy landscapes that are parsed for local minima and the minimum energy paths between them, allowing us to extract complex barrier-related atomistic pathways. With a recent batch implementation for active learning, BOSS can make use of exascale computing resources to solve largescale structural problems without sacrificing quantum-mechanical accuracy.

11:55 AM DS02.15.06
Evaluation of Sampling Methods on Performance of Bayesian Parameter Estimation During Refinement of Empirical Molecular Dynamics Potentials Troy Gustke[1], Abhishek T. Sose[1], Gaurav Anand[1], Fangxi Wang[1], Aditya (Ashi) Savara[2] and Sanket Deshmukh[1]; [1]Virginia Tech, United States; [2]Oak Ridge National Laboratory, United States

Uncertainty quantification (UQ) methods such as Bayesian methods have been recently used to quantify the uncertainty associated with the force-field parameters and their predictions. However, the reliability and accuracy of these UQ algorithms depend on the sampling methods used to perform the analysis. Here, as a test case, we have performed UQ on a new all-atom (AA) embedded atom method (EAM) potential of gold developed in our group. The AA model itself was aimed at reproducing physical, thermodynamic, and mechanical properties of interest obtained through experimental methods and/or density functional theory. The robustness and parametric sensitivity of the gold model was analyzed using Sobol sequencing and calculating sensitivity indices. Bayesian Parameter Estimation with UQ was performed using different sampling methods including Metropolis-Hastings (MH),

Ensemble-slice (ESS), Uniform, and Grid as implemented in CheKiPEUQ, an open-source Bayesian parameter estimation package. This allowed us to investigate the performance and dependence of Bayesian predictions on these sampling methods. The sampling process was accelerated through surrogate modeling by developing Gaussian Process Regression (GPR) models trained with data obtained from molecular dynamics (MD) simulations. The Bayesian framework was used to obtain the highest posterior density interval and the highest probability parameter set, which better reproduces the properties with respect to the confidence levels of experimental and/or DFT observations.

12:10 PM DS02.15.07
Extending the KineCluE Code to the Computation of Transport Coefficients in Concentrated Alloys Pamela Camilos, Thomas Schuler and Maylise Nastar; Commissariat à l'énergie atomique et aux énergies alternatives, France

Modeling diffusion from the atomic scale is necessary because experimental studies are only feasible at high temperatures and in most systems, it is not possible to measure the full Onsager matrix. The problem is mostly solved in pure and dilute alloys, for instance using the KineCluE code. Computing the full Onsager matrix in concentrated alloys remains a challenge due to the vastness and complexity of the configuration space and the connected ones associated with jump sequences. Current approaches rely either on mean-field approximations or atomic kinetic Monte Carlo simulations, however each of them has its own limitations; with the former, kinetic correlations are not fully taken into account while with the latter statistical errors arise, especially when calculating off-diagonal transport coefficients. Therefore, a comprehensive deterministic diffusion model is needed. In this work, we aim to extend the kinetic cluster expansion formalism to concentrated alloys in order to get an efficient evaluation of transport coefficients, time life and mobility of clusters in concentrated alloys based on atomic-scale data. Our formalism relies on the Self-Consistent Mean Field Theory and it is implemented in the KineCluE code. We treat the local configuration of the diffusing species exactly, while further away atoms are replaced by a homogeneous mean-field. This allows us to treat short-range kinetic correlations exactly and to construct the long-range kinetic paths under controlled approximations while reducing the computational load and keeping the calculations feasible. In the case of a random alloy, we compare our model's performance to previous analytical theories and Monte Carlo simulations. The model will also be tested in the case of Fe-Cr concentrated alloys where thermodynamic short-range order cannot be neglected, and the results will be compared to Monte Carlo simulations as well as experimental studies.

Accelerated Sampling in Bidimensional Particle Systems Manon Michel and Arnaud Guillin; CNRS - Université Clermont-Auvergne, France

In the context of the high-dimensionality and multimodality of the potentials encountered in chemical physics, massive efforts have been devoted into the development of efficient simulation methodologies. Since the first works of Molecular dynamics (MD) and Markov-chain Monte Carlo (MCMC) methods, bidimensional particle systems, in particular with hard-core interactions, have played the role of a challenging test bed. In spite of their apparent simplicity, they exhibit a rich behavior where topological defects bind or unbind themselves in pair, ruling by doing so the transition phases. I will first review successful MCMC simulation strategies in sphere systems. These methods are based on the introduction of non-reversibility in the underlying stochastic sampling processes, upgrading them into piecewise deterministic Markov processes (PDMP) and competitors to their MD counterparts. Then I will present how to adapt these strategies in the context of anisotropic particles by exploiting recent progress in PDMP-based sampling.

1:30 PM DS02.16.02
Late News: Predictive Monte Carlo Modeling of Secondary Electron Emission Based on First Principles Calculations Maciej Polak[1], Ivana Matanovic[2], Raul Gutierrez[2], John Booske[1], Edl Schamiloglu[2] and Dane Morgan[1]; [1]University of Wisconsin - Madison, United States; [2]The University of New Mexico, United States

Monte Carlo modeling of secondary electron emission from metal surfaces usually requires information on material properties obtained from experimental measurements, in particular the energy loss function, a quantity derived from the dielectric function is needed, as well as the Fermi energy and the work function. In addition, the momentum space representation of the energy loss function is often approximated with the use of extrapolation schemes. Here we present a new approach and a first open-source Monte Carlo code for secondary electron yield modeling [1], where all the necessary quantities are calculated from first principles, density functional theory (DFT) methods. In particular, the energy and momentum dependent dielectric function is obtained from time-dependent DFT calculations explicitly, removing the necessity for experimentally measured quantities as well as momentum space extrapolation. In addition DFT calculated density of states is used in secondary electron generation, and DFT obtained work functions are used. This approach allows for predictive modeling of systems where experimental measurements are not available or are very challenging to obtain with high accuracy, such as metal alloys [2]. Successful verification of the approach on well known systems such as Cu and Al, encouraged calculations of secondary electron emission from elemental metals across the whole periodic table. The calculations revealed clear periodic trends in the maximum secondary electron yield, which has not been shown previously, and provided the largest computational database of secondary electron yield curves for elemental metals up to date.

Langevin Processes in Bounded-in-Position Domains—Application to Quasi-Stationary Distributions Mouad Ramil; CEA, France

Quasi-stationary distributions can be seen as the first eigenvector associated with the generator of the stochastic differential equation at hand, on a domain with Dirichlet boundary conditions (which corresponds to absorbing boundary conditions at the level of the underlying stochastic processes). Many results on the quasi-stationary distribution hold for non degenerate stochastic dynamics, whose associated generator is elliptic. The case of degenerate dynamics is

less clear. In this work, together with T. Lelièvre and J. Reygner (Ecole des Ponts, France) we generalize well-known results on the probabilistic representation of solutions to parabolic equations on bounded domains to the so-called kinetic Fokker Planck equation on bounded domains in positions, with absorbing boundary conditions. Furthermore, a Harnack inequality, as well as a maximum principle, is provided for solutions to this kinetic Fokker-Planck equation, as well as the existence of a smooth transition density for the associ- ated absorbed Langevin dynamics. The continuity of this transition density at the boundary is studied as well as the compactness, in various functional spaces, of the associated semigroup. This work is a cornerstone to prove the consistency of some algorithms used to simulate metastable trajectories of the Langevin dynamics, for example the Parallel Replica algorithm.

Nested Sampling—Finding the Stable Phases and Calculating Phase Transitions Without a Fuss Livia Bartok-Partay[1], Noam Bernstein[2], Albert P. Bartok[1], Gyorgy Hantal[3] and Gabor Csanyi[4]; [1]University of Warwick, United Kingdom; [2]U.S. Naval Research Laboratory, United States; [3]University of Natural Resources and Life Sciences, Austria; [4]University of Cambridge, United Kingdom

In recent years we have been working on adapting a novel Bayesian statistical approach, called nested sampling, for studying atomistic systems. Nested sampling automatically generates all the relevant atomic configurations, unhindered by high barriers, and one of its most appealing advantages is that the global partition function can be calculated very easily, thus thermodynamic properties, such as the heat capacity or compressibility becomes accessible.

Nested sampling is a top-down sampling technique, starting from the high-energy region of the potential energy landscape (gas phase) and progressing towards the ground state structure through a series of nested energy levels, estimating the corresponding phase space volume of each. This way the method samples the different basins proportional to their volume, and instead of providing an exhaustive list of the local minima, it identifies the thermodynamically most relevant states without any prior knowledge of the structures or phase transitions. This means that unlike other methods, nested sampling may be fully automated, allowing high-throughput calculations of novel materials.

The use and advantages of the nested sampling method has been demonstrated in sampling the potential energy landscape of simple model system, calculating the pressure-temperature phase diagram of several metals and alloys[1]. Studying phase transitions and structural properties of small Lennard-Jones[2] and water clusters[3] highlighted the importance of identifying those local minimum basins which contribute the most to the total partition function. Our recent work on the core softened double ramp potential, the Jagla-model, has demonstrated that nested sampling plays an important role in discovering high temperature thermodynamically stable phases, redrawing what we knew about the system's liquid-liquid transitions[4].

Optimal Resource Allocation in Parallel Trajectory Splicing Andrew Garmon, Vinay Ramakrishnaiah and Danny Perez; Los Alamos National Laboratory, United States

Widely considered a workhorse in materials simulation, MD has struggled to maintain strong-scalability as it only weak-scales with traditional parallelization methods. One method aimed towards improving the strong-scalability of MD is Parallel Trajectory Splicing (ParSplice); a specialized MD method designed to accelerate the dynamics of rare-event systems without compromising the accuracy of MD. It works by generating a large number of independently-generated trajectory "segments" in such a way that they can later be assembled into a single statistically-correct state-to-state trajectory. Due to the impossibility of deterministically forecasting the future evolution of the trajectory (which would be required to perfectly assign the execution of segments), ParSplice relies on stochastic speculation as it assigns segments via a KMC-like model that is parameterized on-the-fly. In this talk we present a method for extracting an estimate of the likelihood that any given segment will be used as part of the simulation. Then, using these probabilities, we derive an optimization framework for dynamically allocating resources among the set of possible tasks (i.e, potential segments). We detail the improvements in performance resulting from our optimized framework as compared to more naive allocation schemes including the maximum-task-throughput and minimum-time allocations. Performance results are illustrated through the use of several models of varying complexity, lending to fully interpretable results. These models enable an understanding as to when and why other allocation schemes fail, thus further highlighting the versatility/importance of our optimized allocation method. We observe that this new strategy can improve throughput up to 20x, thus greatly improving the scalability of a traditionally scale-limited application.

Transport Flux, One Unified Concept, Numerous Formulations and One Common Mistake Youping Chen and Adrian Diaz; University of Florida, United States

Irving and Kirkwood (IK) derived the transport equations from the principles of classical statistical mechanics using the Dirac delta to define local densities. Thereby, formulas for fluxes (local stress and heat flux) were obtained as point functions in terms of molecular variables. The IK formalism has inspired numerous formulations. Many of the later developments, however, believed it more rigorous to replace the Dirac delta with a continuous volume-weighted averaging function and subsequently define fluxes as a volume density. Although these volume-averaged (VA) flux formulas have dominated the literature for decades and are widely implemented in popular molecular dynamics (MD) software, they are a fundamental departure from the well-established physical concept of fluxes.
In this talk, we review the historical developments that led to the unified physical concept of transport fluxes. We then use MD simulations to show that replacing the Dirac delta with a volume weighting function changes the fundamental nature of fluxes as a surface density. As a result, the dynamic balance

between the rate of change of the total momentum or energy in a volume element and the fluxes across the surface boundary cannot be established. This then leads to the failure of VA flux formulas in satisfying the momentum and energy conservation laws or typical transport boundary conditions. We also use two different approaches to derive fluxes for general many-body potentials. The results show that atomistic formulas for fluxes can be fully consistent with the physical definitions of fluxes and conservation laws.

Simulation of Bistable [2]Rotaxane for Molecular Memory Application Peiqiao Wu[1], Prabir Patra[1], Bhushan V. Dharmadhikari[2] and Xingguo Xiong[1]; [1]University of Bridgeport, United States; [2]Minnesota State University Mankato, United States

VLSI (Very-Large Scale Integration) industry is shifting the paradigm from microelectronics to nanoelectronics so that Moore's law can be extended. Molecular electronics directly utilizes individual molecules to construct circuits and systems, leading to ultra-high efficiency and device density. For digital molecular electronics, a suitable molecule with controllable and stable electrical switching between "ON" and "OFF" states is desired. Among various potential candidates, bistable [2]rotaxane has attracted extensive attention from researchers due to its repeatable switching characteristics and the ability to be driven electrically. Many studies have been performed on characterizing the [2]rotaxane molecule, its I-V characteristics, and molecular dynamics mechanism. In this paper, we reported our findings of molecular simulation of [2]rotaxane utilizing Nanoscale Molecular Dynamics (NAMD) and Visual Molecular Dynamics (VMD) platforms. The simulation illustrates the switching mechanism of [2]rotaxane between its two stable states, and what factors might affect the switching process. The simulation shows the switching process of [2]rotaxane is repeatable and controllable, resulting it to be an excellent candidate for molecular memory application. The signal "crosstalk" – interference between neighboring [2]rotaxane molecules, is also investigated with simulation. A mathematical model is proposed to describe the minimum pitch of the memory array to ensure the reliability of the data stored in the memory. Based on this, a set of design rules, the analogy to DRC (Design Rule Check) in CMOS VLSI, are proposed to tolerate the process variation and signal interference of the [2]rotaxane-based molecular memory. The simulation results verify [2]rotaxane as a promising candidate for molecular memory application.

4:35 PM DS02.17.04
Understanding the Molecular-Level Interactions Between Polymers and Functionalized Metal-Organic Frameworks Abhishek T. Sose, Fangxi Wang and Sanket Deshmukh; Virginia Tech, United States

The need to develop environmentally friendly and energy efficient technology for gas separations can be fulfilled by polymer mixed matrix membranes (MMMs) of metal-organic frameworks (MOFs). In these MMMs, polymers, MOFs and the polymer-MOF interface are known to play an important role in determining the gas separation mechanism. However, fundamental understanding of the parameters determining the compatibility of the polymer-MOF interface is still unknown. In this study, we have performed all-atom (AA) molecular dynamics (MD) simulation of a model polymer-MOF MMMs of hydrophobic/hydrophilic polymers with IRMOF-1 and IRMOF-10 as fillers. These systems include the polymer matrix of hydrophobic polymers *viz. polyvinylidene fluoride (PVDF), polyethylene (PE),* and hydrophilic polymers *viz. polymethylmethacrylate (PMMA), polyethylene glycol (PEG)*. To understand the effect of MOF functionalization on the polymer-MOF interface, we decorated IRMOF-1 with the four functional groups *viz. methyl (-CH_3), amine (-NH_2), hydroxy (-OH)* and *fluorine (-F)*. A stronger structural correlation for the polymer-MOF interface was observed in the systems with functionalized MOFs compared to unfunctionalized MOFs embedded in hydrophilic (or hydrophobic) polymer matrix. Thus, different functional groups can be added to control the compatibility of polymer-MOF interfaces.

Molecular Dynamics Using Non-Linear Charge Relaxation Models Anders M. Niklasson; Los Alamos National Laboratory, United States

Molecular dynamics simulations are currently undergoing a revolution thanks to modern machine learning tools that can provide very accurate short-range interatomic potentials. Unfortunately, without a dramatic increase in the computational cost, these new techniques fail to account for the critically important long-range electrostatic interactions and their associated polarization and charge relaxations – rendering them practically useless for many real-world problems. In this talk I will show how the computational overhead associated with the long-range charge equilibration problem in molecular dynamics simulations based on non-linear charge relaxation models can be avoided. The technique relies on the construction of approximate shadow energy functionals whose relaxed ground state charge distributions closely follow the fully equilibrated solutions of the corresponding exact non-linear charge relaxation models. This makes it possible to perform accurate molecular dynamics simulations with non-linear charge relaxation models using only a single Coulomb summation per time step.

5:20 PM DS02.17.06
Molecular Dynamics Simulations to Explore Crack Tip Behaviour in High Entropy Alloys Sandeep K. Singh and Avinash Parashar; Indian Institute of Technology, India

In the last couple of decades, high entropy alloys (HEAs) or multi-element alloys are emerging as potential candidates for many diversified structural applications. Molecular dynamics based simulations were performed in conjunction with 2NN MEAM potential to study the fracture behaviour in ternary, quaternary, and quinary alloy configurations. Simulations were performed after aligning the crack plane with three different principle planes of FCC crystal. Deformation in each of the orientations was primarily governed by dislocations, twinning, and stacking faults emanating front the crack tips or from the surface of the crack plane. Medium and high entropy alloys have shown higher resistance to fracture and were capable of retaining strength up to a larger extent as compared to low entropy alloy and pure Ni crystal. The higher dislocation density and uniform distribution of dislocation in medium and high entropy alloys lead to plasticity in the crystal after the onset of yielding. Blunting of the crack tip in medium and high entropy alloys was predicted in orientation 1 and 2, whereas crack propagates in orientation 3. This study will help in elucidating the capabilities of medium and high entropy alloys in resisting the opening mode of crack propagation, which can be further utilized to enhance the diversified structural applications of these emerging multi-elemental alloys.

Interaction of Electron Beam and Gold Nanoparticles Cuauhtémoc N. Valencia, Jakob Schiotz, Matthew Helmi Leth Larsen, Thomas W. Hansen, William Bang Lomholdt and Pei Liu; Denmark Technical University, Denmark

Beam damage in High-Resolution Transmission Electron Microscopy (HRTEM) is poorly understood theoretically, and not yet well described phenomenologically. For example, it is not yet known whether it is the total dose (electrons per area) or the dose rate (electrons per area per time) that is most critical for inducing beam damage [1,2]. In order to study the dependence of the total dose, a molecular dynamics simulation can be an appropriate tool to understand the atomic level behavior, when coupled to experimental observations.
Using molecular dynamics, we study the beam damage in gold nanoparticles caused by high-energy electron beam irradiation. We assume that the main damage mechanism in metallic nanoparticles is knock-on damage, where an energetic electron transfers momentum and energy to an atom through

Rutherford scattering.
In this work, we focus on the simplest mechanism for beam damage: direct transfer of momentum between the energetic electrons and the nuclei through Rutherford scattering. Several molecular dynamics studies have previously focused on electron head-on collision in carbon nanomaterials [3,4]. Here, we extend these methods to include collisions with non-zero impact parameter, and build a model including both complete removal of atoms as well as beam-induced surface diffusion on the nanoparticle, in the context of HRTEM. We use a stochastic approach for the momentum transfer to the atoms in the nanoparticle, focusing on momentum transfer to the easily removed surface atoms. In this way, for each nanoparticle size, we get a rate of atom removal and a rate of induced surface diffusion proportional to the beam intensity. We compare these rates with observation of beam induced surface diffusion and beam induced damage in gold nanoparticles on a cerium dioxide (CeO_2) substrate, as observed in HRTEM. The analysis of the experimental data leverages convolutional neural networks to identify when the structure changes [5].
If the momentum transferred to an atom is insufficient (such as non-zero impact parameters) to remove the atom from the nanoparticle, the induced motion will be primarily in the beam direction. In this case the nanoparticle may heal through thermal diffusion processes. We model this qualitatively through a short molecular dynamics annealing step between each energy transfer event. This may lead to a dependency on not only the total dose, but also on the dose rate.
In addition, effects of the dose rate are expected to be shown predominantly through the heating of the nanoparticle due to the increase of the events per unit of time as we increase the dose rate. In addition to heating from the many Rutherford scattering events with too low momentum transfer to inflict direct damage, there may also be a heating effect due to interactions between the beam electrons and the conduction electrons of the metals. Simple models can be made for these effects, and rough estimates of the heating of the nanoparticle can then be used to extend the current molecular dynamics simulations to higher temperatures, where beam damage will occur more readily.

Late News: Multiscale Simulation of Atomic Structure in the Vicinity of Nanovoids and Evaluation of the Shifting Rates of the Void Surface Elements in bcc and fcc Metals Andrei V. Nazarov[1,2], Aleksey P. Melnikov[1], Alexander A. Mikheev[3] and Irina V. Ershova[1]; [1]National Research Nuclear University MEPhI, Russian Federation; [2]Institute for Theoretical and Experimental Physics named by A.I. Alikhanov of NRC "Kurchatov Institute", Russian Federation; [3]The Kosygin State University of Russia, Russian Federation

We simulate structure in the vicinity of different size nanovoids using a new variant of the Molecular Statics, wherein atomic structure in the vicinity of nanovoids and the parameters that define the displacements of atoms placed in elastic continuum around main computation cell are determined in a self-consistent manner. Atomic structure are calculated in vicinity of nanovoids for bcc and fcc metals. Should pay attention that in bcc structures displacements of atoms located in the direction <100> or close to it are positive, whereas the atom displacements located in other directions is negative [1,2,3]. For fcc structures all displacements are negative but may vary significantly in value depending on the direction. Strain fields calculated based on the displacement fields lead to anisotropy of vacancy fluxes. Then we simulate structure of the surface of different crystallographic planes. Kinetic equations for shifting rate of void surface elements are obtained [2] that take into account the dependence of the vacancy flux on strain fields and the surface energies of the crystallographic planes that located normal to the void surface. The shifting rates of void surface elements are calculated for different crystallographic directions in a wide range of temperatures and different supersaturations of vacancies. Rates of displacements in different crystallographic directions for bcc and fcc metals differ significantly, and for the <100> direction they are greatly lower than for other directions. This effect can lead to a change in the shape of the initially spherical nanovoids and cause their transformation into pores of a cuboid shape. The influence of the calculated values of the surface energies for various crystallographic planes on the shifting rates in the corresponding directions is also evaluated.

Late News: Simulation Features of Atom Jumps at Constant Temperature and Under Different Pressure by Molecular Dynamics Madina Boboqambarova[1] and Andrei V. Nazarov[1,2]; [1]National Research Nuclear University MEPhI, Russian Federation; [2]Institute for Theoretical and Experimental Physics named by A.I.Alikhanov of NRC "Kurchatov Institute", Russian Federation

At present, Molecular Dynamics (MD) is the most suitable approach to gain information at the atomic scale. However, a simulation of diffusion by MD faces some difficulties in implementation. In particular, we noticed that when modeling diffusion by MD and molecular statics (MS) using the same potentials, the found values of the migration energy differ markedly [1]. In our work we discuss features of atomic jump simulation. Then we present a new approach (approach of natural thermostat) that fully takes into account the fluctuating character of atomic jumps at the constant temperature MD simulation. In addition the combination of MD and modified method of MS [2] allowed within this model to take into account thermal expansion of the lattice and long-range elastic displacement of the atoms in the vicinity of defects. With the developed model, we study features of atom diffusion in iron by

vacancy mechanism at different temperatures using a many-body potential [3]. Migration energy and pre-exponential factor are obtained and a comparison of the calculated diffusion parameters with the results of the other authors' work whose used various modeling methods is carried out. We then developed our approach to take into account the effect of pressure on diffusion jumps of atoms. This approach made it possible to calculate the temperature dependence of the migration volume. In addition, the model developed by us makes it possible to select and construct the trajectories of motion of atoms making a diffusion jump, and therefor to analyze the features of various types of diffusion jumps, in particular, to detect such events as double jumps of atoms and jumps leading to the return of an atom to a vacancy. Analysis of a large number of diffusion jump trajectories allows us to estimate the contribution of double jumps in the diffusion mobility at different temperatures.

Unraveling Mechanisms of Interface Diffusion and Interfacial Creep in Metals, Semiconductors and Metal-Ceramic Composites Ian Chesser, Raj Koju and Yuri Mishin; George Mason University, United States

Interface diffusion and interfacial slip are two key processes controlling the high-temperature creep deformation of metal-matrix composites. Fundamental understanding of these processes remains poor. Atomistic simulations are a promising route toward understanding, but reliable methodology for measuring kinetic coefficients and disentangling competing mechanisms has not been developed in this context. In this work, we compare interface diffusion and sliding coefficients in pure Al and Si grain boundaries to those in AlSi phase boundaries using direct molecular dynamic simulations at high and intermediate homologous temperatures. Diffusion along AlSi phase boundaries is found to be quite fast, depending on interface orientation and structure, with activation energies on par with GB diffusion in pure Al. Clusters of highly mobile Si atoms at these phase boundaries often have activation energies similar to Al. Interface diffusion and interface slip are found to be distinct, but correlated processes with characteristic fractal dimensions, cluster size distributions, and nucleation and growth dynamics. Universal and system dependent features of atomic motion during diffusion and sliding are identified over a large parameter space including multiple interface geometries, temperatures and strain rates. Key results are verified with an accurate PINN potential.

8:45 AM *DS02.18.05
Diffusion in Stationary and Moving Interfaces in Alloys Raj K. Koju, Ian Chesser and Yuri Mishin; George Mason Univ, United States

While it is well-established that atoms diffuse along interfaces much faster than in the perfect lattice, atomistic understanding of this "short-circuit" diffusion phenomenon remains incomplete. This talk will discuss several topics related to interface diffusion: atomic mechanisms of grain boundary (GB) diffusion, the effect of GB segregation on the GB diffusion rate, and the role of GB diffusion in the solute drag phenomenon. These effects are studied by atomistic computer simulations combining molecular dynamics, Monte Carlo methods, and other computational approaches. It is shown that solute segregation can cause either acceleration or retardation of GB diffusion, depending on the thermodynamics of the system, GB structure, and the segregation mechanism. In a solute-drag study, the drag force has been investigated systematically as a function of temperature, alloy composition, and the GB velocity. It is shown that solute diffusion along the GB can dramatically impact the GB mobility by redistributing the solute atoms non-uniformly in the form of nano-clusters or islands and causing additional pinning. GB diffusion coefficients and diffusion mechanisms are compared with those for metal/semiconductor phase boundaries with different orientation relationships between the phases.

9:15 AM DS02.18.06
Charge Equilibration Model with Shielded Long-Range Coulomb for Molecular Dynamics Simulations Udoka, Nwankwo, Nicolas Onofrio and Chi-Hang Lam; The Hong Kong Polytechnic University, Hong Kong

Dynamic charge distribution and polarization effects are often difficult to describe using traditional force field models, especially for crystalline and amorphous systems. Reactive molecular dynamics has become a panacea for describing the potential chemistry between atoms and molecules, and the environment-dependent charge distribution and polarization effects. Charge equilibration as well reactive force field models such as ReaxFF can include these effects in large systems. However, the numerical implementation of these models include Coulomb interaction up to a "short-distance" cutoff for computational speed, limiting their application to devices with unrealistic small sizes. Although designing an effective atomic charge model to reproduce the electrostatic fields in electrochemical systems has always been a challenge, ignoring long-range Coulomb interaction affects the ability to describe charge distribution and polarization effects in electrochemical systems. We include long-range effects to partial charge calculations (QEq) using shielded long-range Coulomb potential and then evaluate long-range effect between charged particles. By including long-range effect, we anticipate better account of Coulomb interaction for dynamic charge distribution and polarization in atomic and molecular systems. The accuracy of our model to compute charges on a number of metal organic frameworks and simple systems compare to conventional QEq and quantum mechanics (QM) shows that charges computed without long-range are slightly overestimated. A test of our QEq technique against standard QEq on a simple capacitor configuration under external potential shows some significant differences between charges computed with/without long-range Coulomb. The difference results from long-range influence on ions of the capacitor. The difference indicates clearly that the excluded ions via short-distance cut-off treatment of conventional QEq coupled molecular dynamics affect the interaction potential. Further improved investigation of our approach shows that inclusion of orbital overlap function and/or bond-dependent electronegativity as in split charge (SQE) method correctly exhibits dissociation property for largely separated atoms. The later improvement would enable the atomic description of electrochemical systems involving bond breaking while preserving long-range Coulomb interaction effect on charged electrodes throughout the dielectric layer such as in battery and emerging solid-state memory.

Energy Absorption Capabilities of BNNS Reinforced Polyethylene Nanocomposites—A Compressive Shock Behavior Ankur Chaurasia and Avinash Parashar; Indian Institute of Technology Roorkee, India

The present study aims to investigate the effect of two-dimensional (2D) inorganic nanofiller boron nitride nanosheet (BNNS) on the shock compressive response of polyethylene (PE) based nanocomposites. A non-equilibrium molecular dynamics (NEMD) based simulations were performed in conjunction with reactive force field (Reaxff) parameters to capture the interatomic interactions within 2D nanofiller BNNS and polyethylene chains, whereas interfacial properties were triggered with the help of non-bonded interactions. Nanocomposite reinforced with monolayer BNNS is predicted to be a superior nanofiller for attenuating the shock strength across the interface BNNS/PE nanocomposites as compared to pristine PE. In continuation with the monolayer reinforced nanocomposites, compressive shock hugoniot response of dispersed BNNS reinforced nanocomposites were also predicted and compared with the monolayer BNNS reinforced nanocomposites. It was reported that dispersed BNNS significantly increases the energy dissipation capability via deformation and temperature rise of the dispersed BNNS nanosheet. These present study outcomes will help developing inorganic nanofiller reinforced nanocomposites with superior shock mitigation fin lightweight armor and space structures.

Recent Theoretical Development of Py-Chemshell for Calculating Vibrational Properties of Transition Metal Containing Zeolites Jingcheng Guan[1], You Lu[2], Thomas W. Keal[2], Andrew Beale[3], C. Richard A. Catlow[1] and Alexey A. Sokol[1]; [1]University College London, United Kingdom; [2]Daresbury Laboratory, STFC, United Kingdom; [3]Rutherford Appleton Laboratory, STFC, United Kingdom

We report a theoretical development of a fully anharmonic method for the calculation of local vibrational properties of transition metal-containing zeolites modelled by the hybrid QM/MM approach. The scheme is closely related to the vibrational self-consistent field (VSCF) method [1] applied to localised modes in gas-phase molecules [2] but includes the effects of the environments and accurate numerical solutions of the VSCF equations in real space using Schrödinger solvers. The method is implemented as a new module/library of the Py-Chemshell (PCS) [3]. These zeolites calculations are integrated with the QM/MM models, which have been reported previously [4] and implemented in PCS. This work continues the recent extension in PCS to support calculations of infrared and Raman intensities based on the harmonic approximations. Our VSCF implementation tackles anharmonicities, coupling and delocalisation of normal modes - these are recognised as key challenges for first-principle computations of vibrational properties. We carry on from the VSCF calculations to talk about how to assign band positions for intermediates of a selective catalytic redox cycle over Cu-SSZ-13 [5]. We conclude with a discussion of further intermodal correlation and evolution effects.

Phase Field Crystal Modelling of Orientation Gradients in Rapidly Solidified Aluminum Paul Jreidini[1], Tatu Pinomaa[2], Jörg M.K. Wiezorek[3], Joseph McKeown[4], Anssi Laukkanen[2] and Nikolas Provatas[1]; [1]McGill University, Canada; [2]VTT Technical Research Centre of Finland Ltd, Finland; [3]University of Pittsburgh, United States; [4]Lawrence Livermore National Laboratory, United States

This talk discusses recent rapid solidification experiments on thin film aluminum samples that reveal the presence of lattice orientation gradients within crystallizing grains. To study this phenomenon, a new phase-field crystal (PFC) model that captures the properties of solid, liquid, and vapor phases is proposed to model pure aluminum quantitatively. A coarse-grained representation of this model is used to study rapid solidification in samples approaching micrometer scales. We present recent results of this model that reproduce the experimentally observed orientation gradients within crystallizing grains grown at experimentally relevant rapid quenches, discussing a causal connection between defect formation and orientation gradients.

11:45 AM DS02.19.06
Computing the Local Yield Surface in 3D Model Glasses to Predict Plastic Events Spencer Fajardo[1], Dihui Ruan[1], Sylvain Patinet[2] and Michael L. Falk[1]; [1]Johns Hopkins University, United States; [2]École Supérieure de Physique et de Chimie Industrielles, France

Using 2D model glasses as a theoretical base for studying amorphous materials, the Local Yield Stress (LYS) method has ranked highly among available predictors for determining the location of plastic events. By probing local regions of atoms, the LYS method quantifies the amount of incremental stress

necessary to induce plastic rearrangements. In 2D, the computed local yield stress ($\Delta\tau\_c$) is dependent on the direction in which the stress was applied on the local region. Thus, a more accurate prediction is made by sampling multiple loading directions in each local region. In 3D, in order to fully quantify the local yield surface, we sample 432 distinct loading orientations. The resulting yield surface can be used to calculate the projected local yield stress ($\Delta\tau\_y$) with respect to the loading on the boundary. We then quantify the difference in predictive capabilities of the LYS method when using the full local yield surface, compared to predictions made using only a single local probing direction aligned with the loading on the boundary.

High-Performance Quasicontinuum for Multilattice 3D Systems Ellad B. Tadmor[1], Stephen M. Whalen[1] and Woo Kyun Kim[2]; [1]University of Minnesota, United States; [2]University of Cincinnati, United States

The quasicontinuum (QC) method is a multiscale method that extends the length and time scales accessible to fully-atomistic simulations by orders of magnitude. This talk will describe the development over recent years of a high-performance implementation of QC for three-dimensional (3D) polycrystalline materials of arbitrary multilattice crystal structures. Features include finite temperature support (hot-QC), temporal acceleration via hyperdynamics (hyper-QC), and support for the KIM API (allowing usage of interatomic potentials archived on https://openkim.org). The code is optimized for a heterogeneous computing infrastructure including a mix of shared memory (OpenMP) and distributed memory (MPI) parallelism. A graph partitioning load balancing algorithm has been developed for efficient resource usage. State-of-the art software engineering techniques are applied including Git revision control, test-driven development (TDD), and continuous integration (CI) to minimize errors in this complex software platform (120K lines of code). The code features, structure and performance will be discussed as well as example applications to fracture, nanoindentation and friction in semiconductors, metals and thermal shielding materials.

1:30 PM DS02.20.02
Novel Methodology for Computing Interactions Between Curved Fibers Anirban Pal; West Texas A&M University, United States

Simulating athermal fiber-networks involves the computation of cohesive energies between fiber segments. A general fiber in three-dimensional space can be represented as a connected sequence of straight-line segments or as an assembly of Bezier curves. The former can result in poor representation of fiber curvature and has been addressed in previous work. The latter is treated in this work. The computation of energy (and force) between two Bezier curves can be implemented using a distance distribution function. This distribution function lacks a closed form expression and is computed using a mix of contouring techniques, interval trees and quadtrees. This method reduces some of the artificial friction associated with the discretization of continuous fibers.

Towards Predicting Non-Equilibrium Material Response Celia Reina[1], Shenglin Huang[1] and Steve Fitzgerald[2]; [1]University of Pennsylvania, United States; [2]University of Leeds, United Kingdom

Non-equilibrium material behavior is still riddled with many open questions: is it possible to predict the far-from-equilibrium material behavior under arbitrary loading from equilibrium data? Is it possible to predict the effect of element transmutation in the mechanical behavior of materials? In this talk, a statistical mechanics framework for non-equilibrium material response will be presented to address these questions.

2:15 PM DS02.20.04
Coarse-Grained Molecular Dynamics Simulations of poly(N-isopropylacrylamide)-Peptide Conjugates Soumil Y. Joshi and Sanket Deshmukh; Virginia Tech, United States

Polymer-peptide conjugates have been of great interest over the years because of their proposed applications in biotechnology, medicine and nanotechnology. Conjugation of peptides and polymers can result in hybrid materials with increased biological functions like enzymatic action or receptor recognition as well as suppressed surface activity to prevent its degradation by proteolytic enzymes. Thermosensitive polymers like poly(N-isopropylacrylamide) (PNIPAM) that have a lower critical solution temperature (LCST = ~305 K) can undergo a reversible coil-to-globule transition in response to changes in temperature. When conjugated with peptides, PNIPAM has been shown to create temperature-induced phase switches to alter the substrate activity of the peptide, self-assembled mesoglobules etc. However, precise molecular details of these PNIPAM-peptide architectures as well as the effects of PNIPAM chain lengths and peptide type are largely unexplored, especially using computational methods. In this study, we employ coarse grained (CG) molecular dynamics (MD) simulations to simulate PNIPAM-peptide systems using PNIPAM and amino acid models previously developed in the group. We explore a number of peptides formed using combinations of hydrophobic (Leu, Phe, Trp etc.), hydrophilic (Arg, Lys, Asn etc.) and neutral (Gly, Ser, His etc.) amino acids like Gly-Arg-Lys-Phe-Gly. By performing detailed structural analysis, we investigate the molecular-level structure of these conjugates and solvent at the interface.

2:30 PM DS02.20.05
Bayesian Uncertainty Quantification of Coarse-Grained (CG) Embedded Atom Method (EAM) Potentials for FCC Metals Abhishek T. Sose[1], Troy Gustke[1], Fangxi Wang[1], Aditya (Ashi) Savara[2] and Sanket Deshmukh[1]; [1]Virginia Tech, United States; [2]Oak Ridge National Laboratory, United States

New coarse-grained (CG) embedded atom method (EAM) potentials have been developed to describe the interatomic interaction for face-centered cubic (FCC) metals *viz. Gold (Au), Palladium (Pd), Nickel (Ni), Copper (Cu), Aluminum (Al) and Platinum (Pt)*. These CG metal models could reproduce several physical, mechanical, and thermodynamic properties obtained from experimental and/or quantum methods. The reliability and robustness of each EAM potential is assessed by performing sensitivity analysis using Sobol sampling. Subsequently, the model was refined with the Bayesian parameter estimation (BPE) and further uncertainty quantification (UQ) using CheKiPEUQ, a Bayesian parameter estimation tool. The refinement and UQ process was accelerated by integrating Gaussian Process (GP) based machine learning (ML) models. The Bayesian refined CG model predicted the metal properties within reasonable confidence levels of experimental data. This improved computational framework can be extended to develop the reliable and accurate CG interatomic potentials for other hard- and soft-materials.

4:00 PM *DS02.09.07
Bounding and Propagating Uncertainty in Atomistic Exploration Thomas D. Swinburne[1,2]; [1]CNRS, France; [2]CINaM, Aix-Marseille Université, France

Atomistic models of materials are always approximate, giving rise to uncertainty. One source is from the cohesive model, due to e.g. the treatment of electronic correlation in density functional theory or the functional form / descriptor basis of an empirical interatomic potential. In many cases, some form of error bound can be derived, and a variety of propagation schemes have been developed.

An equally common, but often unquantified, uncertainty arises when targeting some observable whose mechanism is *a priori* unknown. As this requires computational exploration, via sampling methods such as acclerated molecular dynamics or saddle search routines, any estimate will be vulnerable to additional sampling data (namely, the discovery of new mechanisms). This complicates how results from atomistic simulations can be confidently used for direct predictions or the parametrization of higher-scale models.

I will discuss some recent efforts to quantify sampling uncertainties when system trajectories can be considered metastable, allowing a rigorous Markov chain / kinetic Monte Carlo representation[1]. Using examples of point defect diffuson in alloys and structural transformations of atomic clusters, I will show how the bounding and propagation of sampling uncertainty depends critically on both the quantity of interest and the sampling method. In particular, errors from dynamic sampling methods can be rigorously bounded[2], whilst static methods have approximate bounds that benefit from a committee approach[3]. Some of these ideas are exploited by the TAMMBER code[4], which optimally manages thousands of simulation tasks in parallel, autonomously distributing (dynamic) sampling effort such that the target uncertainty, propagated through the Markov chain, reduces maximally fast. If time allows I will also discuss how this same framework can be used to propagate and target model form uncertainty in empirical potentials.

Many-Body Approaches for Excitations In Solids—Current Limitations and Perspectives Towards Exascale Performance Claudia Draxl[1], Ronaldo Pela[1], Benedikt Maurer[1], Andris Gulans[2] and Felix Henneke[3]; [1]Humboldt-Universität zu Berlin, Germany; [2]University of Latvia, Latvia; [3]Freie Universität Berlin, Germany

The Bethe-Salpeter equation (BSE) of many-body perturbation theory (MBPT) is the state of-the-art approach to determine optical, UV, and x-ray absorption spectra of crystalline materials. Likewise, time-dependent density functional theory (TDDFT) enables the study of excitations in molecules and solids either via time propagation or by computing their response to external perturbations in the linear regime. Such high-level approaches are, however, compute-intensive, often hampering their application to complex systems. This is in particular so, if highly accurate basis sets are employed to solve the underlying DFT problem and to expand the non-local operators appearing in excited-sate methodology. In this talk, we will discuss current limitations and present various algorithms to overcome some of the bottlenecks. All this is realized in the all-electron linearized augmented planewave + local orbital (LAPW+lo) code **exciting** [1]. The first example concerns (i) an iterative solver for diagonalizing huge sparse matrices that appear when treating low-dimensional systems in codes that apply periodic boundary conditions. Making use of this method, allows us to reach microHartree precision for the energies of atoms and molecules [2]. Building on this, we are (ii) extending this approach towards the time domain in TDDFT [3]. Moreover, we make use of a (iii) recently developed algorithm for substantially speeding up the solution of the BSE [4], and (iv) demonstrate the successful implementation in **exciting** by applications to complex systems. Finally, we will discuss how to bring high-level approaches to exascale as envisioned in the European Center of Excellence NOMAD [5].

5:00 PM DS02.01.07
New Methods for the Theory of Spin-Lattice Coupling in Magnetic Materials at High Temperature Bjorn Alling; Linkoping University, Sweden

We have developed a method, the combines atomistic spin dynamics and *ab-initio* molecular dynamics (ASD-AIMD) to investigate magnetic materials at high temperature.[1] We apply the method to study the mutual coupling of spin fluctuations and lattice vibrations in paramagnetic CrN and elemental Fe. The two degrees of freedom can be dynamically coupled, and our method allows for observations of nonadiabatic effects. In CrN, those effects is found to suppress the phonon lifetimes at low temperature compared to an adiabatic, fast-magnetism approximation. The dynamic coupling identified here provides an explanation for the experimentally observed unexpected temperature dependence of the thermal conductivity of CrN and other magnetic semiconductors at and above the magnetic ordering temperature.

Our method is based on an alternating scheme of ASD and AIMD steps. In every step of AIMD, constrained non-collinear magnetic moments are used in

the density functional theory calculations. The obtained forces are used to update the atomic positions by a single-step propagation of the atoms. With the new atomic positions, new distance dependent magnetic exchange interactions are obtained and used to propagate the magnetic state for the same time-step in the ASD simulation together giving a coupled ASD-AIMD step that are repeated until convergence of studied quantaties.

The dynamics of the CrN spin system impacts atomic lattice vibrations and the quantities related to it, in particular phonon lifetimes. The magnetic state and its dynamics are influenced by the lattice vibrations. Slightly above the transition temperature (300K), the dynamical coupling, is found to significantly reduce the phonon lifetimes of the acoustic modes. In contrast, at high temperatures (1000 K) the dynamical coupling and its impact on phonon lifetimes are largely reduced.

Our ASD-AIMD method provides access to magnetic materials at high temperature with AIMD- level accuracy previously only existing for non-magnetic materials. We demonstrate its reliability by deriving the free energy differences between alpha- gamma- and delta-Fe as a function of temperature and investigate paramagnetic Fe under Earth-core conditions.

From Moiré Excitons to Charge and Energy Transfer in 2D van der Waals Heterostructures Gang Lu; California State University Northridge, United States

When 2D materials are stacked to form a van der Waals (vdW) heterostructure with a small angular and/or lattice mismatch, a moiré superlattice may appear, which could lead to novel quantum phenomena, driven by an interplay of flat energy bands and strong electron-electron interactions. In particular, the moiré superlattices comprised of 2D semiconductors, such as transition metal dichalcogenides (TMDs), could host localized, long-lived and valley-polarized moiré excitons, which are envisioned as single-photon emitters in quantum information and optoelectronic applications. In this talk, we provide an overview of our recent effort to elucidate the properties of moiré excitons in twisted 2D vdW heterostructures from first principles. We predict that moiré excitons can be formed in twisted 2D organic–inorganic halide perovskites, group IV monochalcogenides, in addition to the well-known TMD bilayers. In conjunction with localized moiré excitons, nearly flat bands are also formed in these vdW heterostructures. 1D flat bands, anisotropic and 1D moiré excitons are also predicted to emerge in some of the vdW heterostructures, specially, when defects are present. We explore how vertical electric field can be tuned to control the position, polarity, emission energy, and hybridization strength of the moiré excitons. In the second part of the talk, we will shed light on exciton dynamics in TMD vdW heterostructures. In particular, we unravel the competition of charge and energy transfer in type-II $WS_2/MoSe_2$ heterostructures. Incorporating excitonic effect in non-adiabatic electronic dynamics, our first-principles study uncovers a two-step process in ultrafast energy and charge transfer, unravel their relative efficiencies and explore the means to control their competition. The excitonic effect is revealed to drive the efficient energy and charge transfer in the heterostructures.

SESSION DS02.21: Coarse Grain Models IV
Session Chair: Ellad Tadmor
Wednesday Afternoon, December 8, 2021
DS02-Virtual

4:00 PM DS02.21.01
Investigation of Molecular Mechanism of MOF-5 Self-Assembly Using Coarse-Grained Models Fangxi Wang[1], Abhishek T. Sose[1], Praveen Thallapally[2] and Sanket Deshmukh[1]; [1]Virginia Tech, United States; [2]Pacific Northwest National Laboratory, United States

The self-assembly of porous structures including metal-organic frameworks (MOFs) is a complex process. Even though MOF-5 is one of the most widely studied structures in the literature, very little is known about its self-assembly. In this study, the growth of 3-D structure of MOF-5 is successfully investigated using coarse-grained (CG) molecular dynamics (MD) simulations by employing different growth pathways. Interactions between metal nodes, linker, and solvent molecules were developed to reproduce their structure obtained from all-atom MD simulations. These building blocks were self-assembled by employing four different pathways from which only one resulted in a 3-D MOF-5 structure that resembled experimentally reported structure. We will discuss these approaches and our results in detail. This computational approach can be used to study self-assembly of other MOFs to provide insights into their growth and self-assembly process.

4:15 PM DS02.21.02
Development of Nonbonded Interactions Between Coarse-Grained Metal and Solvents Fangxi Wang, Soumil Y. Joshi, Abhishek T. Sose and Sanket Deshmukh; Virginia Tech, United States

Metal nanoparticles (NPs) and their self-assembled functionalized hybrid structures have received huge interest due to their wide application in catalysis, sensors, and optics. In general interactions between these NP hybrids and solvents play an important role in their processing as well as in determining their self-assembled structures. To understand the role of these interactions at the molecular-level, coarse-grained (CG) molecular dynamics (MD) simulations can be employed. However, a key to generate reliable results is to use accurate and robust force-field (FF) parameters of all the components involved. In this study, we will present our methodology and FF parameters to define the interactions between CG models of metals (e.g. gold, silver, copper, etc.) with solvents (water, DMF, etc.) developed in our group. These interactions were developed to reproduce experimental (macroscopic contact angle, interfacial energies, surface tensions) and computational (binding energies) properties.

4:30 PM DS02.21.03
Development of Temperature and Solvent Transferable Coarse-Grained Polystyrene Model Fangxi Wang, Yaxin An, Soumil Y. Joshi and Sanket Deshmukh; Virginia Tech, United States

Due to its exceptional strength and compatibility with blood, polystyrene (PS) is one of the most widely used commercial polymers in the fields ranging from packaging to medical devices. Hence, understanding the structure of PS in different solvents used for its processing as well as in water becomes important to improve the quality of these products. Here, we have integrated our previous coarse-grained (CG) hydrocarbon models (J. Phys. Chem. B, 2018, 122, 7143−7153) and benzene model (J. Phys. Chem. B 2018, 122, 6, 1958–1971) to develop a new CG model of PS. The bonded interactions between hydrocarbon and benzene model were tuned such that the new PS CG model can successfully reproduce its physical properties such as density at 300 K and glass transition temperature (Tg). Then, the non-bonded interaction parameters are optimized between this new PS CG model with pure solvents (water and DMF), also developed in our group, to reproduce the radius of gyration (Rg) from all-atom molecular dynamics (MD) simulation. The conformation of PS in the DMF/water solvent mixture indicates that the globule-to-coil transition happened with the increased concentration of DMF. The radial distribution functions (RDF) analysis of PS with solvent beads suggests the water molecules are repelled far away from the PS side chains when the DMF concentration increases, which leads to the stretch of the PS chains to form a coil-like structure.

4:35 PM DS02.21.04
Permeability of Bicontinuous Nanoporous Media Chang Liu and Paulo Branicio; University of Southern California, United States

It is challenging to describe the fluid flow behavior in natural nanoporous materials due to inherent complexities of the porous network topology. In nanoporous medium, collisions and interactions between particles and walls are as important as the collisions and interactions between particles as the molecular mean free path is comparable to the characteristic length scale of the medium. In this work, we employ Many-body Dissipative Particle Dynamics (mDPD) simulations to investigate the fluid flow process through realistic bicontinuous nanoporous media, which are representative models for a wide class of nanoporous materials. Bicontinuous nanoporous models are constructed considering a defined morphology at 0.65 porosity level and varying pore sizes from 30 to 120 nm. The models provide a stochastic description of the morphology and pore size distribution and allow for a direct investigation of the dependence of permeability on average pore-size. Simulation results from fluid obtained by imposing different pressure differences on the nanoporous model by the action of two confining pistons, indicate a linear pressure drop within the nanoporous model, regardless of pore size. The steady state fluid flow through the nanoporous models is proportional to the pressure gradient applied in agreement with the Darcy's law, in spite of the complexities and different scales of the porous media considered. The predicted pore-size dependence of the permeability is well described by the Hagen-Poiseuille law considering a single shape correction factor that accounts for the flow resistance due to the complex nanoporous morphology.

4:40 PM DS02.21.05
Predicting Plasticity in 2D Model Metallic Glasses Using the Local Yield Stress and Diffusion Maps Rahul Meena[1], Michael Shields[1], Dimitris G. Giovanis[1], Michael L. Falk[1], Dihui Ruan[1], Spencer Fajardo[1], Yannis Kevrekidis[1], Thomas J. Hardin[2] and Michael E. Chandross[2]; [1]Johns Hopkins University, United States; [2]Sandia National Laboratories, United States

Shape Failure in amorphous solids arises from local rearrangements in the material's atomic configurations and how these respond to stress. To this end, the Local Yield Stress (LYS) method was recently developed to probe local regions and quantify their susceptibilities to plasticity by measuring the incremental stress required to trigger a local rearrangement. While this methodology shows great potential for enhancing predictive plastic theories, it is not a practical means for characterizing materials structure due to its computationally intensive nature. We propose a manifold learning-based framework to extract microstructural descriptors from atomistic configurations. More specifically, we deploy Diffusion Maps (a nonlinear manifold learning technique) to systematically extract the structural information features from the high-dimensional data (cartesian coordinates of local clusters of atoms and relate this structure to LYS). Due to the nature of the problem, a "point" corresponds to a geometric conformation of atoms, and thus meaningful similarity measure between configurations must be devised for capturing the actual distance between two points. Therefore, we utilize the Grassmann manifold to measure the similarity between the cluster of atoms. We start with a "proof of concept" example crystalline system where our aim is to identify known defects (vacancies and dislocation) using the machine learning approach trained to the geometric conformation of atoms before moving on to amorphous materials to demonstrate its practicability. Finally, our application is a two-dimensional binary glass-forming system, deformed with an incremental Athermal Quasistatic Shear (AQS) method.

4:45 PM DS02.21.06
Late News: (Garcia High School Student) Investigating the Atomistic Mechanism of Fibrinogen Inhibition by P12 Sophia Cai[1], LeAnn Tai[2] and Bernard Essuman[3]; [1]Barrington High School, United States; [2]Arnold O. Beckman High School, United States; [3]Stony Brook University, The State University of New York, United States

Fibrinogen is a plasma-soluble glycoprotein responsible for blood clot formation. After an injury to the blood vessels, fibrinogen molecules are polymerized into fibrin through binding and interactions at their αC domains, forming a fibrin mesh that completes a blood clot. Previous studies indicate that excessive coagulation can lead to harmful diseases and health conditions like strokes and pulmonary embolism. P12, a peptide derived from fibronectin, can mitigate fibrinogen formation and reduce thrombogenesis. In this study, we investigated the properties of the distortion of the αC domain by P12, which inhibits fibrinogen polymerization and prevents the formation of a fiber network. To test this, an in silico model of the αC domain was and potential models of the P12-αC interaction were collected from multiple docking servers. The top models from each server were further evaluated using protein-ligand affinity prediction software. The top scores were all located within residues 518 to 584, which we hypothesized to be the binding site of P12 in the αC domain. To understand the binding interactions between P12 and the αC domain, hydrogen bonding sites were mapped through Cytoscape detection. Six residues displayed hydrogen bonding with the P12 ligand, and VMD analysis indicated that two salt bridges broke due to the change in the structure of the αC domain. Furthermore, the introduction of P12 increased the overall flexibility of the αC domain complex, as indicated by higher RMSF values. The hydrophobicity of the αC domain and P12 complex was mapped using UCSF Chimera to observe the forces that keep the complex intact and determine the degree of hydrophobicity at the P12 binding sites on the αC domain. On both the P12 molecule and the αC domain, the specific sites of interaction were shown to be very hydrophobic. This research suggests that P12 is an effective inhibitor of fibrinogen polymerization due to its interactions with the αC domain.

8:00 AM DS02.02.03
Late News: Quantum Computing for New Materials and Chemistry Applications Nicolas P. Sawaya; Intel Corporation, United States

Usually when one thinks of calculating the properties of a material or molecule, the first calculation that comes to mind is electronic structure, which can be approximated on traditional computers using techniques such as density functional theory. Appropriately, most materials-related quantum algorithms developed so far have targeted electronic degrees of freedom. However, there are other types of materials simulation that would require the use of a quantum computer for accurate results. These include problems for which one is simulating vibrational, excitonic, or nuclear degrees of freedom. Though these types of simulations are relatively unexplored in the quantum computation community, they are relevant to many industrial applications. Here, we present recent work on designing quantum algorithms for important industrial applications such as microscopic energy transfer, spectroscopy, thermal properties, and analytical chemistry. We begin with an overview of general quantum computing methods for materials and chemistry simulation. Next, we discuss the design of efficient low-level quantum data structures for these applications. Metrics related to computational complexity are compared between electronic structure and these new application areas, leading us to postulate that simulating these alternative degrees of freedom will be possible before simulating electronic structure. Finally, we discuss the mathematical ways in which the problem goals are different for each application, with an eye toward guiding quantum algorithm design in these areas of materials simulation.

Bioinspired Artificial Intelligence and Protein Materials by Design Markus J. Buehler; Massachusetts Institute of Technology, United States

Nature produces a variety of materials with many functions, often out of simple and abundant materials, and at low energy. Such systems - examples of which include silk, tendon, bone, nacre or diatoms - provide broad inspiration for engineering. Here we explore the translation of biological composites to engineering applications, using a variety of tools including molecular modeling, AI and machine learning, and experimental synthesis and characterization. We review a series of studies focused on the mechanical behavior of materials, especially deformation and fracture, and how these phenomena can be modeled using a combination of molecular dynamics and machine learning, to generate a novel simulated evolutionary process that offers directed adaptation of biomaterial properties. We also present case studies of protein material optimization using genetic algorithms, applied to 3D printed composites, molecular design, and a translation of protein folding to music and back. We also review a close integration of music and materials, and review our recent research on a new bio-inspired compositional technique called materiomusic.

11:00 AM DS03.01.03
Per-Atom Magnetic Moment Prediction in Transition Metal Oxides Jaclyn Lunger, Jessica Karaguesian, Daniel Schwalbe Koda, Yang Shao-Horn and Rafael Gómez-Bombarelli; Massachusetts Institute of Technology, United States

Inorganic crystalline materials with a magnetic ground state are of interest in various applications such as spintronics, memristors, and data-storage. Even when magnetism is not the key property of interest, studying magnetic materials with Density Functional Theory requires spin-polarized calculations to find the ground state structure and energy. However, computational exploration of magnetic materials is challenging due to the complexity of their electronic and magnetic states. In particular, calculating the ground state of a magnetic material requires careful initialization because spin-polarized DFT calculations are prone to getting trapped in local minima. Previous efforts to resolve this challenge have included high-throughput workflows wherein many possible magnetic orderings are enumerated and calculated. However, this workflow is computationally intensive and requires many spin-polarized DFT optimizations to correctly identify the magnetic ground state of a single material. In this work we present a graph convolutional neural network for predicting per-atom magnetic moment magnitudes given crystal structure. This model is trained on ~ 30,000 magnetic transition metal oxides retrieved from the Materials Project and in-house calculations, and is able to estimate per-atom magnetic moment within an MAE of 0.33 bohr magnetons. We see

significant speed-ups for spin-polarized DFT calculations initialized with per-atom magnetic moments predicted by our model. Finally, we extend our model to predict collinear magnetic orderings by attaching a +/- classification to each atom. After training this extended model on the transition metal oxides that have been analyzed through a magnetic ordering workflow, we are able to predict the magnitude and sign of the magnetic moment on each atom with high accuracy and thus significantly decrease the number of calculations required to find the ordered magnetic ground state. We anticipate the use of our model to screen materials for interesting magnetic behavior and for the inverse design of novel materials with desired magnetic properties. We also propose the generalization of the presented model to predict other per-site properties—such as band structures and Bader charges—thus enabling fine-tuned exploration and design in varied materials problems.

11:15 AM DS03.01.04
Benchmarking Descriptors, Models and Systems for Many-Body Machine Learned Force Fields in Molten Transition Metals Steven B. Torrisi[1,2], Cameron J. Owen[2], Isabel Diersen[2], Lixin Sun[2], Jin Soo Lim[2], Yu Xie[2], Jonathan Vandermause[2] and Boris Kozinsky[2,3]; [1]Toyota Research Institute, United States; [2]Harvard University, United States; [3]Bosch, United States

The development of accurate and efficient molecular dynamics force fields are a crucial step in an overall materials discovery workflow that complements experiments with theoretical simulations. In order to facilitate the ongoing development of automated machine-learned force fields using tools like FLARE++ and Nequip, we have generated a benchmarking dataset of molten single-element bulk structures with a vacancy defect in order to study the interplay between many body behavior and model performance. This dataset contains ab initio molecular dynamics simulations capturing high-temperature crystalline and melted phases. We attempt to explain the difference in model performance across implementation, levels of descriptor fidelity, and individual systems based on differences in elemental properties, and using interpretable machine learning models, reveal the interplay between elemental properties and many-body character revealed by these differences in performance.

SESSION DS03.02: Machine Learning for Targeted Material Design I
Session Chairs: Sumanta Das and Christian Hoover
Tuesday Afternoon, November 30, 2021
Sheraton, 5th Floor, The Fens

1:30 PM DS03.02.01
Integrating High-Performance Computing and Machine Learning-Enabled Design of Materials Nathan Frey, Lin Li and Vijay Gadepally; Massachusetts Institute of Technology, United States

As machine learning (ML) workflows become more prevalent and computationally demanding in materials science, there is an emerging need to integrate deep domain expertise with efficient high-performance computing and appropriate ML methods. In cases where design goals require explorations of vast areas of chemical/material space, or target properties are prohibitively expensive to compute, efficient use of resources and careful choice of method enable previously inaccessible capabilities for material design. Here, we explore interactive supercomputing for applying ML to challenges in materials and chemistry. We discuss the scaling of ML methods for materials and molecular design, with respect to supercomputing resources and dataset size. We present two workflows for high-throughput virtual screening (HTVS) and ML to engineer quantum states in layered materials. An approach based on deep transfer learning, machine learning, and first-principles calculations is shown to rapidly predict key properties of point defects in 2D materials. Properties including band gap and bulk formation energy are predicted for over 4,000 2D materials using deep transfer learning. 10,000 dopant, vacancy, divacancy, and antisite defect structures are generated in 150 wide band-gap materials and more than 1,000 defect band structures are computed via first-principles methods. We identify over 100 promising, unexplored dopant defect structures in layered metal chalcogenides, hexagonal nitrides, and metal halides including GeS, h-AlN, and MgI_2. The hybrid HTVS/ML approach is also used to discover 18 transition metal oxide materials with coexisting magnetic and topological quantum orders.

Hybrid Multi-Scale and Data-Driven Models for Designing the Smart Properties of Nanocomposite Materials Atta Muhammad[1], Rajat Srivastava[1], Eliodoro Chiavazzo[1], Pietro Asinari[1,2] and Matteo Fasano[1]; [1]Politecnico di Torino, Italy; [2]Istituto Nazionale di Ricerca Metrologica, Italy

The enhanced properties of composite materials are exploited in many fields, from aerospace to electronics industries, from automotive to biomedical applications. Furthermore, smart properties (i.e. material responses influenced by external stimuli) of composites are highly desirable to design next-generation devices in a broad variety of industries. Composites are typically made of polymeric matrices reinforced with macroscopic fillers, e.g. carbon or glass fibers. Recently, nanostructured fillers have been also employed to further improve the effective and smart properties of composites. Carbon nanostructures such as graphene or carbon nanotubes are particularly suitable for that, since they show superior thermal, mechanical and electrical properties. Nevertheless, the properties of nanocomposites are determined by phenomena spanning from the nano to the macro scale and, thus, should be simulated by tailored multi-scale modelling techniques.

In this presentation, hybrid multi-scale and data-driven models to predict the properties of polymer nanocomposites reinforced with carbon nanofillers are presented and experimentally validated. Firstly, the coarse-grained interaction potentials describing some thermoset and thermoplastic polymer matrices obtained from atomistic simulations are compared between each other, to define the mesoscopic configuration more suitable to mimic the thermal-physical properties measured experimentally. Secondly, carbon nanofillers with high thermal, mechanical, and electrical properties are coarse-grained as well, and then introduced in a representative volume element of the nanocomposite to be simulated. Thirdly, sensitivity analyses are carried out by means of the coarser mesoscopic model, to identify the geometrical and physical-chemical features influencing more the thermomechanical response of the considered nanocomposites. Results are compared against both experiment and continuum simulations, to validate the proposed approach and highlight its advantages with respect to consolidated modelling strategies. Finally, data-driven algorithms based on machine learning are employed to improve the prediction capability of the multi-scale model, in order to account for the nonlinear effects in the heat transfer processes. In perspective, such hybrid data- and physics-driven methods should allow to investigate also other properties of nanocomposites, for instance electromagnetic ones.

This work has received funding from the European Union's Horizon 2020 research and innovation program SMARTFAN under grant agreement N. 760779.

2:00 PM DS03.02.03
Transforming Automated Quantum Chemistry Calculation Workflows with Machine Learning—Towards Faster and More Accurate Materials Discovery Chenru Duan and Heather J. Kulik; Massachusetts Institute of Technology, United States

Machine learning (ML) has begun to accelerate materials discovery by providing advances in efficiency needed to overcome the combinatorial challenge of computational materials design. In ML-assisted materials discovery, an automated quantum chemistry (QC) calculation workflow is used to generate datasets to train surrogate models, which serve as alternatives to rapidly explore a large space to identify candidate materials. However, current workflows with density functional theory (DFT) as workhorse leads to many attempted calculations that are doomed to fail and brings biases/inaccuracy to the training data that may be out of the domain of applicability of DFT. This includes many compelling functional materials and catalytic processes that are difficult because of their complex electronic structure, such as systems involving strained chemical bonds, open-shell radicals and diradicals, or metal-organic bonds to open-shell transition-metal centers. We address these challenges of computation efficiency and accuracy by integrating ML approaches into conventional DFT-based QC workflows.

More than half of the computational resource and time is wasted on unfruitful geometry optimizations during the transitional metal complex (TMC) design. To address this issue, we built two types of classifiers to predict the likelihood of calculation success: 1. static model prior to calculations and 2. dynamic model on-the-fly monitoring calculations. The static classifier is a near zero-cost model that rapidly filters out candidate calculations most likely to fail, while the dynamic model monitors and terminates an already running calculation if it is predicted to fail with high confidence. The prediction of the dynamic classifier is interpretable and helps reveal the failure modes in geometry optimizations. Together, these classifiers save half of the computation resources. We have also demonstrated the usefulness of these classifiers on the active learning discovery of candidate catalysts for small alkane activation.

Many interesting functional materials may have complex electronic structures difficult for DFT. We developed multiple types of classifiers to predict the presence of strong correlation, which is usually a sign of a system being out of the domain of applicability of DFT. Our models only require calculations at DFT cost and can classify which systems in a dataset will require more expensive but accurate wavefunction theory calculations, leading to overall high fidelity of the entire dataset. These models far outperform the existing unsupervised learning (i.e., clustering) methods and conventional cutoff-based approach widely used in the chemistry community in distinguishing systems that contain strong MR character. In addition, since electronic structure information is encoded as the inputs, our models are readily transferable to larger systems and systems with unseen elements. All these classifier models represent the first efforts toward autonomous workflows that move past the need for expert determination of the robustness of DFT-based materials discoveries.

2:15 PM DS03.02.04
Davis Computational Spectroscopy Workflow—From Structure to Spectra Lucas Samir Ramalho Cavalcante[1], Luke L. Daemen[2], Nir Goldman[3], Ambarish Kulkarni[1] and Adam J. Moule[1]; [1]University of California, Davis, Brazil; [2]Oak Ridge National Laboratory, United States; [3]Lawrence Livermore National Laboratory, United States

Metal-organic frameworks (MOF) hold great promise in applications on gas adsorption, catalysis, and supercapacitors because of their porous structure and modularity. Despite having a symmetrical and apparently well-organized structure formed by metal clusters connected via organic linkers, these materials have low thermal, mechanical, and chemical stability, yielding a high defect density and disorder. To overcome the stability problem, a zirconium-based MOF called UiO-66 was presented as a solution due to its high connectivity with 12 connected clusters in the face-centered-cubic topology. However, a better understanding of the nature of defects and disorder in UiO-66 MOFs is still required.

Inelastic Neutron Scattering (INS) has been proven to be a good ally in the investigation of structural and dynamic disorder but it requires detailed modeling of the system in order to characterize peak positions and intensities, and subsequently materials properties. The high computational cost of the electronic modeling has limited investigations with INS to crystalline materials, dampening the study of disordered large systems such as MOFs.

To address the trade-off between simulation cost and accuracy, we developed an automated workflow that connects various atomic simulation tools in order to investigate the relationship between material properties, lattice dynamics, and INS spectra. This workflow allows an accurate and efficient method of calculating phonon modes and the INS spectrum with the use of a broad range of quantum mechanical approximations, including density functional theory (DFT) and density functional tight-binding (DFTB). We have also implemented a machine-learned force field based on Chebyshev polynomials (Chebyshev Interaction Model for Efficient Simulation - ChIMES) to improve the accuracy of the DFTB simulations with ~100x reduction in computational expense while retaining most of the accuracy of DFT. Besides the benefits of a tool that automates the simulation and consequent analysis of the INS spectrum, our efforts expand the possibilities of investigating more complex structures that would be unfeasible with ab initio methods.

2:30 PM DS03.02.05
Materials from Fire—A New Approach to Design Material from Nature Mario Milazzo and Markus J. Buehler; Massachusetts Institute of Technology, United States

Fire has fascinated humankind since the prehistoric era and, according to different traditions, was selected as one of the four main elements that "make of all things in Nature". Science and art have both used fire as a tool and inspiration over the years. From a scientific-technological standpoint, fire is one of the fundamental agents to enable chemical reactions, and its controlled dynamics have been widely studied to optimize and control combustion processes. Another field of interest concerns fire detection and monitoring for safety purposes since an efficient control of fire since its activation has a huge impact not only on people and animal protection but also on environmental sustainability.
As for visual and music arts, fire has been used as a tool and inspiration for creating paintings but, more interestingly, has inspired composers to create melodies able to evoke its power and perpetual shape mutation without using the audible dull sounds emitted from the interaction with air.

Rooted in the interactions between sound and flames, here we report a new method to use fire for a variety of purposes, including sonification, art, and the design and manufacturing of nature-inspired materials. At the root of the work is a new method to sonify fire, thereby offering a translation from the silent nature of flames, to represent audible information, and to generate *de novo* flame images.

We use a simple setup composed of a flame from a candle whose deformation, due to an acoustic source, is recorded through a digital camera. We used the tones from an octave to create a direct mapping between the deformations of the flame and pure sounds. To encode and decode images of the flames exposed to different frequencies, we used a convolutional variational autoencoder trained on a set of 1,300 unlabeled images (100 images for each audible condition), and uses a 2-dimensional latent space vector.

This tool provides a new interactive musical instrument, which from the observation of a flame, or interaction of it with the environment – such as wind or temperature fluctuations, or different environmental gases – will result in flame shape and dynamics changes, which in turn is associated with particular sounds.

Additionally, we are able to generate *de novo* images by applying the trained deep neural network model to augment images, thus creating a deep inceptionism of fire, and use a deep convolutional variational autoencoder to realize synthetic flame shapes, including temporal sequences that resemble flickering flames.
From the materials science standpoint, we realize new materials inspired by fire by using autoencoder to generate image stacks to yield 3D geometries that are manufactured using 3D printing. This represents the first even generation of nature-inspired materials from fire, and can be a platform to be used for other natural phenomena in the quest for *de novo* architectures, geometries, and design ideas. These concepts provide a new dimension of nature-inspired design, as it yields novel image data that can be manipulated, or associated with, other forms of expression, and creates new directions in artistic and scientific research through the creative manipulation of data with structural similarities across fields. This work also underscores the fundamental importance of vibrations as a translational means to find semblances of structures across manifestations, from the invisible, to the visible, to material form.

2:45 PM DS03.02.07
Tuning Optoelectronic Properties of Semiconductors with First Principles Modeling and Machine Learning Arun Kumar Mannodi Kanakkithodi[1], Maria K. Chan[2], Xiaofeng Xiang[3], Laura Jacoby[3], Robert Biegaj[3], Rishi Kumar[4] and David P. Fenning[4]; [1]Purdue University, United States; [2]Argonne National Laboratory, United States; [3]University of Washington, United States; [4]University of California, San Diego, United States

Semiconductors with desirable electronic band structure and optical absorption are sought for solar cells, electronic devices, infrared sensors and quantum computing. Compositional manipulation via alloying at cation or anion sites, or via incorporation of point defects and impurities, can help tune the properties of semiconductors in known chemical spaces. In this work, we develop AI-based frameworks for the on-demand prediction and multi-objective optimization of the phase stability, band gap, optical absorption spectra, photovoltaic efficiency, dielectric constant, defect formation energies, and impurity energy levels in two broad classes of semiconductors, namely (a) halide perovskites with the general formula ABX_3 (where A is a large organic or inorganic monovalent cation, B is a divalent cation and X is a halogen anion), and (b) group IV, III-V and II-VI semiconductors in binary, ternary and quaternary forms. These frameworks are powered by high-throughput density functional theory (DFT) computations, unique encoding of the atom-composition-structure information, and rigorous training of advanced neural network-based predictive and optimization models.

Bayesian optimization-based active learning approaches are applied to systematically improve prediction accuracies and comprehensively traverse the compositional chemical space. Multi-fidelity learning helps to bridge the gap between (high quantities of) low accuracy calculations and (lower quantities of) high-fidelity data, constituted of either accurate, expensive computations or experimental measurements collected from the published literature. High-accuracy predictions based on modest datasets are thus accomplished for (a) band gaps and formation energies at the HSE06 level of theory utilizing PBE-level data, (b) defect and impurity energy levels with experimental accuracy utilizing PBE-level data, (c) large supercell properties utilizing smaller cell calculations, and (d) properties of all alloy compositions utilizing data from end-point and selected mixed compositions. The best predictive models are combined with two different multi-objective optimization techniques, namely, state-of-the-art genetic algorithms and variational autoencoders, to determine optimal semiconductor atom-composition-structure combinations with desired stability, optoelectronic, and defect properties. Finally, AI-based recommendations are synergistically coupled with targeted synthesis and characterization, leading to successful validation and discovery of novel compositions for improved performance in solar cells.

AI-Aided Interpretation of Electronic Transport Measurements Luca Bonaldo[1], Terry E. Stearns[1], Ilaria Siloi[2], Nicholas Mecholsky[3] and Marco Fornari[1]; [1]Central Michigan University, United States; [2]University of Southern California, United States; [3]Catholic University of America, United States

The solution of the inverse problem involves reconstructing a model from a set of observations; such a task is crucial to the majority of indirect experimental measurements, which use a variety of fitting procedures. Unfortunately, this approach often requires crude approximations and generates a misalignment between theory and experiments. A typical example is the effective mass of the charge carriers in a complex semiconductor.
To reconcile theory with experiments, we propose an innovative approach based on bi-directional training of an invertible neural network. Supported by specific domain knowledge, deep learning models are trained to correctly predict both the outcome from a set of model parameters and the parameters themselves. We will apply this approach to the electronic transport properties of materials to link the features of the band structure to conductivity, Seebeck coefficient, and carrier concentrations.
During the talk, we introduce m*2T, a code we developed to inspect the direct problem. The software involves the prediction of transport properties from band structure models which we use to efficiently generate meaningful data to train the invertible neural network. Results on the solution of the inverse problem will also be discussed.

3:15 PM DS03.02.06
***De Novo* Inverse Design of Nanoporous Materials by Machine Learning** Mathieu Bauchy; University of California, Los Angeles, United States

Although simulations excel at mapping an input material to its output property, their direct application to inverse design (i.e., mapping an input property to an optimal output material) has traditionally been limited by their high computing cost and lack of differentiability—so that simulations are often replaced by surrogate machine learning models in inverse design problems. Here, taking the example of the inverse design of a porous matrix featuring targeted sorption isotherm, we introduce a computational inverse design framework that addresses these challenges. We reformulate a lattice density functional theory of sorption in terms of a convolutional neural network with fixed hard-coded weights that leverages automated end-to-end differentiation. Thanks to its differentiability, the simulation is used to directly train a deep generative model, which outputs an optimal porous matrix based on an arbitrary input sorption isotherm curve. Importantly, this pipeline leverages for the first time the power of tensor processing units (TPU)—an emerging family of

dedicated chips, which, although they are specialized in deep learning, are flexible enough for intensive scientific simulations. This approach holds promise to accelerate inverse materials design.

4:00 PM DS03.02.09
Reconstructing Representative Dislocation Structures from XRD Measurements Through Machine Learning of Discrete Dislocation Dynamics Simulations Dylan Madisetti[1], Christopher Stiles[2,1] and Jaafar El-Awady[1]; [1]Johns Hopkins University, United States; [2]Johns Hopkins University Applied Physics Laboratory, United States

A GPU-accelerated computational modeling method for simulating X-ray diffraction (XRD) is developed and implemented to track microstructure evolution through three-dimensional (3D) discrete dislocation dynamics (DDD). This is leveraged to generate a large repository of computational XRD images, and machine learned feature vectors for processing experimental XRD images. The physics-based model implements ray-tracing techniques, Bragg-scattering theory, alloy composition, and a virtual sensor to capture micro-Laue and Debye-Scherrer images from simulated synchrotron X-ray emission. The computational speed improvement provided by this GPU-accelerated method allows for in-situ tracking of diffraction patterns over the course of a virtual experiment, and XRD image data generation from large scale 3D DDD simulations. Implementing convolutional neural networks on this data, we demonstrate that dislocation density can be tracked through time as a function of XRD peak broadening. By determining feature importance (feature attribution) within the machine learned model, the known microstructure is attributed to spreading in Laue-spots. Spreading phenomenon observed in experimental XRD patterns is then associated by similarity analysis to a microstructure in the computational repository, providing insight into the experimental sample.

4:15 PM DS03.02.10
High-Throughput Glass Transition Temperature Computations for Polymers Using Machine Learning Based Molecular Dynamics Christopher B. Kuenneth, Kuan-Hsuan Shen and Rampi Ramprasad; Georgia Institute of Technology, United States

Polymers are an important class of materials that display morphological complexity and diverse inter-atomic interactions. These two and other factors have defied large-scale and long-time quantum-accurate atomic-level simulations of polymer dynamics which are required to access many properties such as the glass transition or melting temperature. Traditional simulation methods utilize parameterized classical potentials or force fields which often lack accuracy, transferability, and versatility. To overcome these issues, here, we develop general machine learning based models for the polymer dynamics of hydrocarbons that learn from reference quantum mechanical data. Once learned, these models can emulate the parent quantum calculations in accuracy, but be about a billion orders of magnitude faster. Using our models, we perform glass transition temperature calculations of a diverse set of polymers that demonstrate a pathway towards high-throughput data generation using molecular dynamics. Challenges that remain are discussed and pathways to overcome such challenges are presented.

4:30 PM DS03.02.12
Tailoring Deep Learning Neural Networks for Atomic Column and Nanoparticle Segmentation in HR-TEM Data Matthew Helmi Leth Larsen, William Bang Lomholdt, Anders Siig Dreisig, Stig Helveg, Ole Winther, Thomas W. Hansen and Jakob Schiotz; Technical University of Denmark, Denmark

Identifying individual atoms in material samples is a challenging task in high-resolution transmission electron microscopy (HR-TEM) since the signal to noise ratio is often low to prevent that the electron beam causes irreversible changes in the sample. This is an area where machine learning can step in to assist the process.

Here we will report advancements on the tailoring of deep learning neural networks for fast detection of nanoparticles and atomic columns. This concept has previously been demonstrated for tracking gold atoms in HR-TEM image sequences [1] with an industry standard U-net architecture [2].

Training a network to distinguish between atomic species in multi-component material samples is possible by feeding the network a focal series of images. For example, providing three images of an MoS_2 sample at three different defocus settings allows a neural network to differentiate between atomic columns consisting of either 1 molybdenum, 2 sulphur, or 1 sulphur atom in HR-TEM images.

We have simulated HR-TEM images of bare MoS_2 and MoS_2 on graphene substrates in the (001) crystal direction. A training set of 10,000 images and a validation set of 500 images has been simulated applying microscopy parameter values randomly sampled from a specified range.

This work presents the superiority of the MSD-net [3], over the U-net architecture, in distinguishing between the described atomic columns in simulated HR-TEM images of MoS_2. Results show that the MSD-net achieves higher F1-scores overall for the validation set of data.

Next to identifying atomic columns, we display the ability of the MSD-net to segment entire nanoparticles and substrates, which is shown to assist in Fourier analyses by separating the nanoparticle from the substrate and providing a clarified image of the Fourier domain. This ultimately assists the process in determining crystal orientation and facet information in experimental images. The MSD-net is trained on a dataset consisting of unsupported Au nanoparticles and Au nanoparticles supported on CeO_2, both in the [110] zone axis, following a similar methodology as described for the MoS_2 datasets, but where the entire nanoparticle is labelled.

To improve the ability of the MSD-net in analyzing experimental images, we present a new method to include thermal vibrations in HR-TEM image simulations. This method consists of extracting a mean standard deviation of atomic positions dependent on their coordination number from a series of molecular dynamics simulations. These values are then used to perturb the atoms correctly by a simple translation of the positions. This is the frozen phonon approximation, but with vibrational amplitudes depending on the local structure obtained from molecular dynamics simulations. As a result, this includes thermal vibrational effects into the simulated images at a low computational cost.

In conclusion, the MSD-net is shown to outperform the U-net in identifying atomic columns in multi-component materials. This along with nanoparticle segmentation and the computationally cheap implementation of thermal vibrations presents promising applications in the future of HR-TEM image analysis and developing deep learning assisted tools for information extraction.

Machine Learning for Grain Boundary Solute Segregation Malik Wagih and Christopher Schuh; Massachusetts Institute of Technology, United States

In polycrystalline alloys, the grain boundary network has a variety of local atomic environments (site-types) that can be energetically more favorable for a solute atom to substitutionally occupy over the bulk (intra-grain) lattice. This can cause the segregation of solute atoms at the grain boundary - a well-documented phenomenon that is known to significantly impact the material properties, including, for example, mechanical, electrochemical, and magnetic properties. However, to date, there is a limited understanding of the spectrum of such atomic environments at the grain boundary, and their different affinities to solute atoms i.e. whether it promotes or prohibits solute segregation, as quantified by the segregation energy for that site-type. In this talk, we show our recently developed machine-learning framework, which can be used to predict the segregation energy of a solute atom at a grain boundary site, based solely on its unalloyed (pure solvent) local atomic environment. We also highlight the utility of the framework by using it to develop an extensive database for grain boundary solute segregation spectra for over 200 alloys.

Computational Discovery and Informatics-Assisted Classification of Double Spinel Compounds Ghanshyam Pilania, Vancho Kocevski and Blas P. Uberuaga; Los Alamos National Laboratory, United States

Spinel compounds represent an important class of technologically-relevant materials, used in diverse applications ranging from dielectrics, sensors and energy materials. While solid solutions combining two “single” spinels have been known for a long time, no ordered “double” spinel chemistries have been reported till date. Our recent computational investigations, based on a unique approach combining theory and experiments, indeed suggest presence of such distinctly-ordered double spinels for a wide range of cation chemistries.[1-2] This talk will focus on applications of informatics-based tools to understand design rules within this newly-identified double spinel chemical space.[2]

10:45 AM DS03.03.02
Ensemble Neural Network for Lithium Dendrite Growth Issei Nakamura; Michigan Technological University, United States

Lithium dendrite formation in Li-ion batteries causes fire when the dendrite continues to grow over many charge/discharge cycles and reaches the other electrode. Our recent lattice Monte Carlo (MC) simulation was based on the diffusion-limited aggregation model which accounts for metal dendrite growth in electrolytes and suggested that ionic liquids can substantially inhibit the dendrite growth and make the dendrite surface relatively uniform. However, the height and aspect ratio of the dendrite varies nonmonotonically with the ion concentrations, the model parameters, and applied voltage. Due to this complexity of the simulation results, challenges remain to identify the properties of ionic liquids for efficient dendrite inhibition. To address this issue, we have developed ensemble neural networks (NNs) that capture the MC simulation data. Our ensemble NNs outperform normal, single NNs and can learn the severe nonmonotonicity of the height and aspect ratio of the dendrite, thus enabling significant reduction in the MC simulation time.

11:00 AM DS03.03.04
A Deep Learning Augmented Genetic Algorithm Approach for 2D Fracture Discovery and Design Andrew Lew and Markus J. Buehler; Massachusetts Institute of Technology, United States

Materials fracture is a complex multiscale process in which macroscopic behavior is inexorably linked to atomic-scale interactions. While molecular dynamics (MD) simulations can provide detailed fracture behavior, it remains computationally infeasible to probe the general problems of understanding fracture mechanisms and designing fracture behavior with this method alone. Here we present a machine learning (ML) approach consisting of a convolutional neural network to predict fracture propagation in 2D materials guided by a genetic algorithm to optimize for particular behaviors of interest. By training this ML model with fracture information from MD, we are able to replace traditional MD simulations with ML predictions and treat the fracture of larger systems, in less time, with consistency to MD baselines. Our method is transferrable to multiple 2D materials and both identifies specific novel fracture mechanisms and allows us to design material structures with controlled fracture paths.

11:15 AM DS03.03.05
Multi Reward Reinforcement Learning Based Bond Order Potential to Study Strain Assisted Phase Transitions in Phosphorene Aditya Koneru[1,2], Rohit Batra[2], Sukriti Manna[1,2], Troy Loeffler[1,2], Henry Chan[1,2], Harpal Singh[3], Mathew J. Cherukara[2] and Subramanian Sankaranarayanan[1,2]; [1]University of Illinois at Chicago, United States; [2]Argonne National Laboratory, United States; [3]Sentient Science Corporation, United States

2D single sheet materials, owing to their exceptional mechanical, thermal, electrical and optical properties over their bulk counterparts, are being explored at a rapid pace. Molecular simulations remain a popular technique to explore the structure and dynamics of such materials. Accessibility to accurate and fast interatomic force-fields would promote the discovery and property evaluations of such novel materials. In this work, we introduce, design and test a machine learning workflow capable of searching the high dimensional parameter space and subsequent refining of a Tersoff type Bond Order Potential (BOP). We select Phosphorene as a representative system of interest and the parameter search is performed using a multi-reward reinforcement learning (RL) agent that has been programmed with Monte Carlo Tree Search (MCTS). The training data comprising of structure, energetics, equation of state

(EOS), elastic constants and phonon dispersions was curated from Density Functional Theory (DFT) calculations for multiple phosphorene polymorphs. We demonstrate that the new class of RL trained bond order models adequately capture all the properties of the different Phospherene polymorphs. We next perform Molecular Dynamics (MD) using parameters obtained from this approach to access the effect of strain and temperature on phase transition between black and blue phosphorene. Overall, the models are computationally cheap yet accurate and can be used to simulate dynamics and structural transformations of Phosphorene polymorphs for a wide variety of energy applications.

Graph Neural Networks for an Accurate and Interpretable Prediction of the Properties of Polycrystalline Materials Minyi Dai, Mehmet F Demirel, Yingyu Liang and Jiamian Hu; University of Wisconsin-Madison, United States

Various machine learning models have been used to predict the properties of polycrystalline materials, but none of them directly consider the physical interactions among neighboring grains despite such microscopic interactions critically determining macroscopic material properties. Here, we develop a graph neural network (GNN) model for obtaining an embedding of polycrystalline microstructure which incorporates not only the physical features of individual grains but also their interactions. The embedding is then linked to the target property using a feed-forward neural network. Using the magnetostriction of polycrystalline $Tb_{0.3}Dy_{0.7}Fe_2$ alloys as an example, we show that a single GNN model with fixed network architecture and hyperparameters allows for a low prediction error of ~10% over a group of remarkably different microstructures as well as quantifying the importance of each feature in each grain of a microstructure to its magnetostriction. Such microstructure-graph-based GNN model therefore enables an accurate and interpretable prediction of the properties of polycrystalline materials.

A Machine Learning Correction to DFTB and Its Effectiveness on Charge Transfer Salts Corina A. Magdaleno, Lucas Cavalcanté, Makena Dettmann and Karina Masalkovaité; University of California, Davis, United States

The accurate prediction of phonon modes is important for scientific progress in fields ranging from heat and electron transport in thermoelectrics to correlated disorder in metal-organic frameworks (MOFs). Density Functional Theory (DFT) is a simulation method that is highly accurate at predicting the phonon modes, but it is computationally more expensive and requires more computational hours than simulation methods such as Density Functional Tight Binding (DFTB). Recently, the Chebyshev Interaction Model for Efficient Simulation (ChIMES) was developed as an approach to correct DFTB calculations by training a machine learning model. DFTB with ChIMES was shown to be effective at improving phonon predictions in a number of small-molecule systems. However, this method has never been applied to charge-transfer salt systems, some of the most promising hole conducting materials. In this study, training sets were created for TTF-TCNQ and TCNQ systems and the models were validated by testing each training set on both systems with DFTB. The accuracy of each training set was compared against the Inelastic Neutron Scattering (INS) spectra created using DFT.

2:15 PM DS03.04.03
A Machine Learning Approach for Longitudinal Spin Fluctuation Effects in bcc Fe at T_C and Under Earth's Core Conditions Marian Arale Brännvall, Davide Gambino, Rickard Armiento and Bjorn Alling; Linköping University, Sweden

To understand the magnetism of solids at high temperature we need to study the interplay between vibrations and the magnetic degrees of freedom. The variation in magnitude of the atomic magnetic moments, the longitudinal spin fluctuations (LSF), is a degree of freedom of particular relevance in metallic magnets. The LSF energy depending on the local magnetic moment size of an atom, called the LSF energy landscape, can be calculated using density functional theory. It has been seen that, at elevated temperature, these LSF energy landscapes depend on the local environment of the atom i.e., they are influenced by both the lattice disorder caused by vibrations and the variations in the transverse orientations of neighboring moments. To simulate a magnetic material in e.g., an *ab initio* molecular dynamics simulation one needs to know how the atoms and their moments will interact with each other which, in principle, would require calculating the LSF energy landscape of each atom at every step in time. In this work we have developed a machine learning approach to predict the shapes of the energy landscapes to dramatically accelerate this process. The material used when developing this approach is bcc Fe at the Curie temperature and ambient pressure. The machine learning method used is kernel ridge regression. Two machine learning models are trained to predict the two parameters involved in determining the shape of the LSF energy landscape. As a critical test of the generality of the trained machine learning models, they are applied to predict the LSF energy landscapes of bcc Fe at temperature and pressure comparable to the conditions at the Earth's core.
Our machine learning approach is compared to other approximative methods for determining the shape of the landscapes and is shown to significantly reduce the errors. By applying the trained machine learning models in combined atomistic spin dynamics – *ab initio* molecular dynamics, the effects of LSF:s can be incorporated without having to explicitly calculate each LSF energy landscape in each time step. We perform such dynamical *ab initio* simulations for bcc Fe at both the Curie temperature and at the conditions of the Earth's core. This reveals the relevance of magnetic fluctuations on the low-density-problem of the current Earth core models.

Late News: Accelerated Prediction of Atomically Precise Cluster Structures Using On-the-Fly Machine Learning Yunzhe Wang, Shanping Liu, Peter Lile, Sam Norwood, Alberto Hernandez, Sukriti Manna and Tim Mueller; Johns Hopkins University, United States

The chemical and structural properties of nanoclusters are of great interest in numerous applications. A systematic study of structure-property relationship necessitates the knowledge of atomically precise structures of stable clusters over a variety of sizes. However, experimental characterization of the structures of these non-crystalline materials can be challenging. Computationally searching for stable structures using *ab initio* calculations is a feasible solution, but can be computationally expensive. In this work, we present a procedure that can accelerate prediction of low-energy nanocluster structures by combining genetic algorithms with interatomic potentials actively learned on-the-fly. A pool-based genetic algorithm is implemented to efficiently sample the configuration space, and moment tensor potentials are used to rapidly relax and evaluate the energies of predicted clusters. Moment tensor potentials are regularly retrained on-the-fly on density functional theory (DFT) calculations of structures that are poorly represented by existing training data and of

low-energy pool clusters. Only DFT energies of pool clusters are reported at the end to guarantee *ab initio* level of accuracy. We demonstrate an acceleration rate of ~12 times on average, comparing our procedure with genetic algorithm using purely DFT calculations. Moreover, for aluminum clusters with 21 to 55 atoms, which we used as the benchmarking systems, our genetic algorithm search identified structures with lower energy in 25 sizes than any reported clusters in the literatures, and confirmed equivalent structures for another 8 sizes. This work demonstrates a feasible way to systematically discover stable structures for large nanoclusters and provides insights into the transferability of machine-learned interatomic potentials for nanoclusters. We believe the new procedure can greatly facilitate the discovery and design of novel nanomaterials for a wide range of applications.

SESSION DS03.05: Machine Learning for Accelerating Simulations III
Session Chair: Sumanta Das
Thursday Morning, December 2, 2021

10:30 AM DS03.05.01
Active Learning of Many-Body Bayesian Potentials for Large-Scale Simulations of Phase Transformations and Thermal Transport Yu Xie[1], Jonathan Vandermause[1], Senja Ramakers[2,3], Nakib Protik[1,4], Anders Johansson[1] and Boris Kozinsky[1,5]; [1]Harvard University, United States; [2]Robert Bosch GmbH, Germany; [3]Ruhr-Universität Bochum, Germany; [4]Catalan Institute of Nanoscience and Nanotechnology (ICN2), Spain; [5]Robert Bosch LLC, United States

Machine learning interatomic potentials (MLIPs) with high efficiency and quantum accuracy are emerging as an enabling capability to simulate complex atomic level processes. To address the challenge of reliability and automated training of MLIPs, we introduced Bayesian active learning (BAL) that relies on quantified prediction uncertainty to drive an autonomous data acquisition strategy [1]. In this workflow, Bayesian MLIPs are constructed from Gaussian process (GP) based on atomic cluster expansion (ACE) descriptors. By developing a highly efficient approximation of the GP uncertainty, whose cost is independent of the training set size, we gain orders of magnitude speedup compared to inference with exact GPs.
As a demonstration, we train a MLIP for silicon carbide (SiC), a wide-gap semiconductor with diverse applications in electronics and physics. For example, point defects in SiC are promising candidates for stable controllable qubits, and an accurate description is desired of their long-time evolution. The resulting MLIP has excellent agreement with the density functional theory and outperforms previous empirical potentials in the prediction of elastic and thermal properties of pristine bulk, as well dynamics of point defects. The highly efficient active learning workflow can be extended to other systems and accelerate the discovery and understanding of materials for quantum technologies.

End to End Force Field Parametrization for Polymer Electrolytes Using Machine Learning Pablo A. Leon and Rafael Gómez-Bombarelli; Massachusetts Institute of Technology, United States

Solid polymer electrolytes (SPEs) are seen as promising alternatives to conventional liquid electrolytes in lithium battery systems due to their low density, mechanical compliance, and low flammability but are challenged by lower ionic conductivity. Molecular dynamics (MD) simulations can be used to guide the design of novel SPEs by allowing quantitative determination of separable anion and cation diffusions as well as local solvation environments. Classical potential MD simulations update molecular conformations by the net force on each atom due to bonds, angles and torsions as well as Coulomb and dispersion interactions. However, these classical potentials require the prior knowledge of materials- and local environment-specific parameters such as unique bond stiffnesses, which are often not well defined.
In this work, we explore the effects of anharmonic bonded interactions on polymer segmental motion and resulting ionic solvation and conductivity in polymer electrolyte systems. An in-house, neural network-based workflow, named AuTopology, was used to learn the interatomic potential parameters of distinct atomic environments for two different classical models from DFT forces as training data. The learned harmonic OPLS model and anharmonic PCFF+ model parameters were then used to equilibrate condensed-phase simulations at a variety of experimentally-relevant concentrations. These simulations were allowed to run for hundreds of nanoseconds to determine the individual anion and cation diffusivities and resulting conductivities. Using this framework and an in-house database of molecular conformations, we have been able to reproduce wB97XD3-level DFT forces from trained OPLS force fields to within 5.5 kcal/mol-A as well as compare the condensed phase solvation and conductivities between the OPLS and PCFF+ models for PEO and carbonate systems.

11:00 AM DS03.05.03
Development of Deep and *RF-MEAM* Potentials to Model Physical and Thermo-Mechanical Properties of Metal-Rich Carbides Tyler J. McGilvry-James[1], Bikash Timalsina[1], Andrew I. Duff[2], Nirmal Baishnab[3], Puja Adhikari[4], Saro San[4], Wai-Yim Ching[4] and Ridwan Sakidja[1]; [1]Missouri State University, United States; [2]STFC Daresbury Laboratory, United Kingdom; [3]Iowa State University, United States; [4]University of Missouri–Kansas City, United States

In the current study, we have developed Deep Learning Potentials as implemented in DeepMD code to model physical and thermo-mechanical properties of complex metal-rich carbides. These phases are critical to the creep properties of advanced Ni-based Superalloys. For this purpose, we utilized the results from a*b-initio* calculations following the Density Functional Theory approximations including the energy, forces, and virial database as generated from the Vienna Ab-initio Software Package. The efficiency and validity of the developed potentials were verified through a series of predictive molecular dynamics simulations of thermomechanical properties that are of interest to the development of advanced superalloys. In addition, we compared the Deep Learning Potentials to the analytical potentials of Reference-Free Modified Embedded Atomic Method (RF-MEAM) that we obtained by using a combined parametrization approach of Conjugate Gradient Minimization (CGM) and Genetic Algorithms as implemented in MEAMfit V2 code. The support from the National Energy Technology Laboratory (Grant No. FE0031554) is gratefully acknowledged. We also would like to thank NERSC for the supercomputer facility.

11:15 AM DS03.05.04
Accurate Prediction of Free Solvation Energy of Organic Molecules via Graph Attention Network and Message Passing Neural Network from Pairwise Atomistic Interactions Ramin Ansari[1], Amirata Ghorbani[2] and John Kieffer[1]; [1]University of Michigan, United States; [2]Stanford University, United States

Deep learning based methods have been widely applied to predict various kinds of molecular properties in the pharmaceutical industry with increasing success. The solvation free energy is an important index in the field of organic synthesis, medicinal chemistry, drug delivery, and biological processes. However, accurate experimental solvation free energy determination is a time-consuming process, and hence, methods to assess this quantity in the absence of physical samples are of interest. Here, we propose two novel models for the problem of free solvation energy predictions, based on the Graph Neural Network (GNN) architectures: Message Passing Neural Network (MPNN) and Graph Attention Network (GAT). GNNs are capable of summarizing the predictive information of a molecule as low-dimensional features directly from its graph structure, without reliance on extensive intra-molecular descriptors. Consequently, accurate predictions of the molecular properties can be made without time consuming experimental measurements. We show that our proposed models also outperform all quantum mechanical and molecular dynamics methods in addition to existing alternative machine learning based approaches in the task of solvation free energy prediction. The novelty of our neural network model is that we take pair-wise interaction of solute and solvent into consideration. We believe our proposed architecture can be used for pair-wise interactions such as solvent-solute, protein-ligand, and etc.

11:30 AM DS03.05.06
Late News: Using Machine Learning Empirical Potentials to Investigate Interdiffusion at Metal-Chalcogenide Alloy Interfaces Siddarth K. Achar[1,2], Derek Stewart[2] and Julian Schneider[3]; [1]University of Pittsburgh, United States; [2]Western Digital Corporation, United States; [3]Synopsys Inc., Denmark

Chalcogenide alloys are key materials for both selector and memory elements found in next generation non-volatile memory cells. Developing robust material stacks for memory devices is crucial for optimal device performance and long-term endurance. However, Joule heating and high electric fields during operation can often lead to atomic interdiffusion at interfaces that can degrade device performance over time. While first principles atomistic simulation can provide insight into the electronic structure and local atomic bonding configurations, due to computational constraints, this approach is limited to small atomic systems (<1000 atoms) and time scales (~10 ps). To evaluate long term device performance, we need an approach that can comfortably address complex atomic configurations at different temperatures and time scales.

While classical molecular dynamics is up for the task, the field has suffered from a lack of robust empirical potentials for materials beyond traditional semiconductors. Machine learning provides one promising approach to use *ab-initio* insight from density functional theory to inform the systematic development of new empirical potentials. In this work, we developed a robust set of machine learning potentials to examine the interaction between Ge-Se alloys and Ti electrodes. Previous experimental investigations have shown evidence for strong interfacial interaction between Ti and chalcogenide alloys[1-3]. The first principles training set draws from a range of linear combination of atomic orbitals (LCAO) DFT calculations on bulk crystal compounds, multilayer structures, and ab-initio molecular dynamic runs at different temperatures. Using this data set, we trained the empirical potentials using the moment tensor potential framework[4] implemented in QuantumATK[5]. The initial empirical potentials were also further refined by active learning which incorporates new configurations in the training dataset. The amorphous chalcogenide glasses and interface structures were intentionally not part of the training set. The machine learning empirical potentials provide accurate predictions for key material parameters in the training data (lattice constant, bulk modulus, etc). They are also able to generate reasonable atomic models for Ge-Se amorphous materials outside the training set. Long term (> 1 ns) molecular dynamic simulations[6] using these potentials shows clear evidence of interdiffusion at the Ti|Ge-Se interfaces. In this presentation, we will discuss the evolution of the composition profile over time and the impact interdiffusion will have on the electronic properties of these device structures.

Late News: (Garcia High School Student) Performance Analysis of an AI-Guided Coarse-Graining Methodology for More Efficient Protein Modeling Raaghav Malik[1], Ziji Zhang[2], Miriam Rafailovich[2], Marcia Simon[2], Yuefan Deng[2] and Peng Zhang[2]; [1]Columbus Academy, United States; [2]Stony Brook University, The State University of New York, United States

Background: For complex biological dynamics in silico studies, conventional all-atomic (AA) simulations are far too computationally expensive for large-scale systems which take up to months or even years. In the last decade, a rise in coarse-grained (CG) modeling allows for the extension of time-scales compared to the AA model, by combining atoms in larger macromolecules and leading to significant simulation speedups. Such modeling techniques hold promise, yet the most crucial part in retaining accuracy compared to all-atom models is the parameterization of CG force fields.
Methods: We evaluate two methods for parameterizing CG models for improved accuracy: a conventional iterative Boltzmann inversion (IBI) by comparing target radial distribution functions, and the CG-Net neural network model which intelligently learns the parameters from short all-atomic trajectories. CG-Net is fed inputs as Cartesian coordinates of CG particles and serves as the potential energy function from which particle forces can be computed. Network weights represent parameters of this potential energy function, and the loss function for the discrepancy between atomistic dynamics and NN-predicted CG dynamics is minimized. The molecule studied was the protein chignolin (PDB: 1UAO) at 350K (the folding transition temperature), selected to make the training time for CG-Net manageable and the ground-truth AA simulation easier to compute. After the AA equilibrium was computed using NAMD, the molecule was coarse-grained by extracting the alpha carbon atoms. After the first guess for the CG parameters was computed using VMD's CG Builder GUI, an IBI analysis was performed to iteratively generate improved parameters. Iterations are repeated until differences in RMSD values are negligible. The full AA-ground truth serves as a basis of comparison for these models.
Results: The original AA chignolin molecule used contains 138 atoms in 10 amino acid residues, with 141 bonds, 249 angles, and 369 dihedrals built using the LAMMPS topology file. After the initial apha-carbon coarse-grained model was defined, with 10 beads each representing approximately 14 atoms, both the nonbonded Lennard-Jones and bonded interaction parameters were computed using IBI. The bonded interaction parameters were tuned until the stiffness constants differed ~10% from those derived from the atomic-scale simulations. The CG model is simple, containing only 9 bonds and 8 angles built using a custom topology file and effectively reducing the degrees of freedom by 94-97%, but the IBI showed that the CG model is stable when used on chignolin due to bond lengths and angles having little alteration through successive iterations. RMSD and RDF values were also computed and compared to the all-atom simulations for validation of this method. This analysis was done both in vacuum and with chignolin solvated in TIP3P water.
Discussion and Future Work: The focus of this work was to conduct performance analysis of two different methods for parameterizing CG force fields, allowing us to accelerate the conventional AA model by 16-30 orders of magnitude. ML methods such as CG-Net show the potential for improving accuracy of CG models making it an effective technique to study large macromolecules. However, one limitation of CG-Net is the precision that is lost from modeling CG bead interactions instead of atomic interactions. Drawbacks of IBI include the inability to work with hybrid CG models and the failure to account for dihedral angles. Future work will be done to implement a combined CG model which utilizes both techniques for improved accuracy. Such

techniques can be applied in many ways to study a variety of materials, including human fibrinogen and the SARS-COV-2 spike glycoprotein.
Acknowledgment: The project is supported by the Stony Brook Garcia Center for Materials Research and the Garcia High School Program.

SESSION DS03.06: Machine Learning for Accelerating Simulations IV

1:45 PM DS03.06.03
NequIP—E(3)-Equivariant Convolutions Enable Sample-Efficient, Scalable and Highly Accurate Machine Learning Interatomic Potentials Simon L. Batzner[1], Albert Musaelian[1], Lixin Sun[1], Tess Smidt[2], Mario Geiger[3], Jonathan Mailoa[4], Mordechai Kornbluth[4], Nicola Molinari[1] and Boris Kozinsky[1]; [1]Harvard University, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]EPFL, Switzerland; [4]Robert Bosch Research and Technology Center, United States

We present Neural Equivariant Interatomic Potentials (NequIP), an E(3)-equivariant deep learning approach for learning interatomic potentials for molecular dynamics simulations. Instead of the commonly deployed invariant convolutions over scalar features, NequIP uses E(3)-equivariant convolutions over geometric tensors, better representing the symmetries of Euclidean space. The proposed model obtains state-of-the-art accuracy on a challenging set of diverse molecules and materials while at the same exhibiting remarkable sample efficiency. Interestingly, NequIP outperforms existing, invariant models with up to three orders of magnitude fewer training data and performs better than kernel methods, even on tiny data sets, thereby challenging the widely held belief that deep neural networks require massive training sets. We show results from molecular dynamics simulations using NequIP on a series of technologically relevant bulk materials as well as the folding of small proteins. The method is implemented in a scalable and highly efficient software implementation, integrated with the molecular dynamics code LAMMPS, and can be used to simulate large time- and length-scales at high accuracy and low computational cost.

2:00 PM DS03.06.02
DICE—A Linear-Scaling N-Body Interatomic Potential from E(3)-Equivariant Convolutions Simon L. Batzner, Albert Musaelian, Lixin Sun, Steven B. Torrisi and Boris Kozinsky; Harvard University, United States

Message Passing Graph Neural Networks (MPNNs) based on pairwise interactions have emerged as the leading paradigm for modeling atomistic systems by recursively propagating information along a molecular graph. While MPNNs have consistently been demonstrated to give low generalization errors, they inherently have a low level of interpretability, are not systematically improvable, and are difficult to scale to large numbers of atoms. Here, we introduce the Deep Interatomic Cluster Expansion (DICE), an equivariant neural network that leverages many-body information in a single interaction, without the need for message passing or convolutions. The method can be systematically improved by including higher-order interactions at linear cost, has physically meaningful hyperparameters, and is embarrassingly parallel. DICE builds on a novel, learnable E(3)-equivariant many-body representation that utilizes weighted tensor products of geometric features to describe N-point correlations of atoms. The proposed many-body representation overcomes the exponential scaling of a naive cluster expansion and instead scales linearly with the number of simultaneously correlated particles. We demonstrate that the use of higher-order correlations of atoms systematically improves the accuracy. We further find that DICE gives excellent performance across a wide variety of settings, outperforming both MPNNs as well as kernel-based methods on small data sets.

2:15 PM DS03.06.04
Differentiable Sampling of Molecular Geometries with Uncertainty-Based Adversarial Attacks Daniel Schwalbe Koda, Aik Rui Tan and Rafael Gómez-Bombarelli; Massachusetts Institute of Technology, United States

While neural network (NN) interatomic potentials enable fast prediction of potential energy surfaces with an accuracy matching that of the electronic structure methods, they often show volatile behaviors when extrapolating outside well-learned training domains. Domains with low prediction confidence can be identified using uncertainty quantification methods. However, arriving at such uncertainty regions requires thorough exploration of the NN phase space, often using slow atomistic simulations. Here, we exploit automatic differentiation to drive atomistic systems towards high-likelihood, high-uncertainty configurations without the need for atomistic simulations. Adversarial attacks are employed on an uncertainty metric to sample informative geometries that expand training domains of the NNs. In combination with an active learning loop, this approach provides a efficient way to bootstrap and improve NN potentials, while decreasing number of calls to the ground truth method. We demonstrate this framework on sampling of kinetic barriers, collective variables in molecules, and supramolecular chemistry. This framework can also be extended to any NN potential architecture and materials system.

2:30 PM DS03.06.05
Complex Dynamics of the CO/Pt Interaction from Bayesian Active Learning Simulations Cameron J. Owen, Lixin Sun, Jin Soo Lim, Isabel Diersen and Boris Kozinsky; Harvard University, United States

Quantitative understanding and controlling interfacial reactions between the gas-phase and solid surfaces are crucial for improving numerous catalysis and energy conversion systems. For example, the adsorption of CO on Pt surfaces is important for a variety of industrial processes (e.g., water-gas-shift reaction, PEM fuel cell catalyst poisoning). CO/Pt interaction is poorly understood but known to strongly affect the metal surface structure and dynamics. An accurate and fast reactive model could provide enormous insight into the current, and future, design of such Pt-based catalysts. Density functional theoretical (DFT) methods and existing parametric interatomic potentials have long struggled with accurately describing heterogeneous interactions. Here, we employ the FLARE framework [1] to actively learn the CO/Pt interaction, using a mapped Gaussian Process (MGP) machine-learning model, with molecular dynamics used to sample configurational space. The model accurately reproduces DFT energies, forces, and stresses as well as rigorous quantitative Bayesian uncertainties. When predictive uncertainty falls outside of the accepted tolerance, additional DFT calculations are performed to augment the training set.
We then use the MGP model to conduct large-scale MD to explore the effect of CO adsorption on various Pt-surface facets and benchmark to expected outcomes as provided by experiment.

Four Generations of Neural Network Potentials for Materials Science Jörg Behler; University of Göttingen, Germany

A lot of progress has been made in recent years in the development of machine learning (ML) potentials for atomistic simulations [1]. Neural network potentials (NNPs), which have been introduced more than two decades ago [2], are an important class of ML potentials. While the first generation of NNPs has been restricted to small molecules with only a few degrees of freedom, the second generation extended the applicability of ML potentials to high-dimensional systems containing thousands of atoms by constructing the total energy as a sum of environment-dependent atomic energies [3]. Long-range electrostatic interactions can be included in third-generation NNPs employing environment-dependent charges [4], but only recently limitations of this locality approximation could be overcome by the introduction of fourth-generation NNPs [5], which are able to describe non-local charge transfer using a global charge equilibration step in combination with an accurate short-range term. In this talk an overview about the evolution of high-dimensional neural network potentials will be given along with typical applications in large-scale atomistic simulations.

Local Gaussian Process Regression for Interatomic Potentials Spencer Hill[1], Tucker Carrington[1], Sergei Manzhos[2] and Manabu Ihara[2]; [1]Queen's University, Canada; [2]Tokyo Institute of Technology, Japan

Gaussian process regression (GPR) has gained increasing attention for the construction of interatomic potentials. In particular, GPR has been shown to produce spectroscopically accurate potential energy surfaces (PES) of molecules from fewer samples than neural networks (J Chem Phys 148 (2018) 241702). This, the absence of non-linear parameters other than a small number of hyperparameters, and the capability to compute estimates of uncertainties make GPR a promising method. GPR, however, suffers from rapidly escalating CPU cost with the number of training data. Both the cost of model training and the cost of computing the PES at points post-training increase, making calculations with more than a few tens of thousand training data not routinely feasible. The increasing cost is due to the need to calculate a matrix-vector product with the inverse of a covariance matrix matrix **K**. We explore a local version of GPR, LGPR, in which for each test point, a local covariance matrix **K'** is built, equivalent to using blocks of a permuted **K**. This approach raises the prefactor of the CPU cost but allows working with arbitrarily large training datasets. We test the approach in comparison with the classic GPR on PESs of formaldehyde and UF6 using very large test sets and property calculations and show that the size of **K'** can be considerably reduced compared to **K** with a small extra error.

8:45 AM DS03.07.03
Development of SNAP Machine Learned Interatomic Potentials for Materials in Extreme Environments Mary Alice Cusentino, Mitchell A. Wood and Aidan Thompson; Sandia National Laboratories, United States

Molecular dynamics (MD) is a widely used tool for studying materials at the atomistic scale. However, the accuracy of MD simulations is limited by the interatomic potential. This is especially true for modeling materials in extreme environments where the interatomic potential is typically utilized far from the equilibrium properties it was fitted to. Recently, machine learning has been used to develop interatomic potentials where the potential is trained on large datasets of quantum accurate data as opposed to fitting the potential to a physics based functional form. These types of machine learning interatomic potentials (MLIAPs) have been shown to have increased accuracy compared to traditional potentials [1]. One such MLIAP method, the spectral neighbor analysis potential (SNAP) [2] has been applied to a variety of materials with increased accuracy [2,3]. In this talk, we will discuss the development of SNAP potentials for molecular dynamics simulations of materials in extreme environments such as radiation or high pressure and temperature environments.

9:00 AM DS03.07.04
Machine Learning in Multiscale Mechanics of Materials Huck Beng Chew and Yue Cui; University of Illinois at Urbana-Champaign, United States

With the recent improvement of algorithms and rapid growth of computing power, machine learning is fast becoming an emerging tool for predicting and understanding material behavior across multiple length scales. With Peta-scale supercomputing resources, we are now able to generate a large number of data sets with existing deterministic material models to train the machine learning algorithms. In this technical presentation, we will discuss our recent attempts to quantify microstructural effects on material strength and fracture response at both the atomistic and the meso-scale.

The first part of the talk will discuss the utilization of machine learning to elucidate the structure-property relationship at grain boundaries of nanocrystalline metals. We now know that the strength of nanocrystalline metals is ultimately controlled by the absorption, emission, or transmission of single dislocations at the grain boundaries, which closely depend on the local atomistic stress state at the grain boundaries. Here, we develop a machine learning algorithm based on an artificial neural network (ANN) to predict the local atomistic stress (output) along [110] bicrystal symmetrical tilt Cu grain boundaries from the local atomic configuration (input). We demonstrate that successful predictions of the atomistic stress state can be achieved by ensuring

that the training set comprises of grain boundaries with both the same type and sequence of structural units. The predictive accuracy can be significantly improved by including the deformed configuration and stress state in the training dataset. This atomistic constitutive law will be used to predict the atomistic stress state from DFT calculations or HRTEM imaging, thus extending the notion of atomistic stress beyond MD domain.

The second part of this talk examines the ability of ANNs to predict the tortuous crack path in a heterogeneous microstructure, comprising of two distinct size-scales of voids which is commonplace in additively manufactured metals – the larger-scale voids represent the ~30 μm defects resulting from gas bubbles or unsintered powder in the additive manufacturing process, while the smaller ~2-10 μm background voids originate from nucleated particles or inclusions responsible for ductile fracture process in metal alloys. A small-scale yielding, modified boundary layer model with monotonic K_I-T displacement loading was used to study crack propagation through a material with local distribution of dual-scale pre-existing voids resembling AM Ti-6Al-4V. The Gurson ductile damage model was implemented to model both the background pores and the larger AM defects, and the initial porosity distribution ahead of the current crack-tip, and resulting crack propagation path was used to train an ANN. The machine learning algorithms provide critical insights into the effects of porosity distributions on the crack propagation path, supporting the notion of achieving fracture by design.

Late News: (Garcia High School Student) MR-Net—Multi-Representation Learning for Protein-Ligand Binding Affinity Prediction Emirhan Kurtulus[1], Bernard Essuman[2], Ziji Zhang[2], Miriam Rafailovich[2], Marcia Simon[2], Yuefan Deng[2] and Peng Zhang[2]; [1]Cagaloglu Anatolian High School, Turkey; [2]Stony Brook University, The State University of New York, United States

Accurately predicting binding affinities of a given protein-ligand system fast and robustly is of high importance for drug discovery and experimental microbiology simulations. Compared with deterministic models which require heavy computational workloads, deep learning models are faster yet with great generalization capabilities, providing an efficient path for knowledge discovery in molecular scientific studies.
We present MR-Net, a state-of-the-art deep learning model on PDBbind v.2019 and v.2016 datasets for protein-ligand binding affinity prediction. The proposed architecture consists of 2 transformer modules, a fully convolutional encoder and a fully convolutional decoder. To maximize the amount of extracted features from the input, 3 different representations of a given system are used: SMILES string, point cloud and atom sequence.Only the binding pocket of the system is used for the prediction. The point cloud representation is a 4D tensor of shape (length of the feature vector, x, y, z) where each atom is represented on a grid of resolution 0.5 Angstroms where the maximum distance between each atom is 30 Angstroms. The number of features in the feature vector is determined as 32. For SMILES and sequences, transformer modules are used, whereas for the point-cloud a fully convolutional encoder is proposed. The encoder is constructed with 3D depthwise separable convolution modules where skip connections are utilized to maximize the gradient flow. The transformer modules are designed with the “deeper better than larger” principle. The embedding dimension is determined as 64 and learnt from the data with additional positional encoding. The dictionary sizes are 65 and 25 for the SMILES transformer and the sequence transformer respectively. For SMILES strings, inputs longer than 2500 characters are truncated. With average pooling and convolutions with kernel size of 3, the outputs of each module are reshaped into (1, 64, 64) and concatenated along the first dimension. Then, the resulting matrix is fed into a fully convolutional decoder consisting of 2D convolutions connected to a fully connected layer. The proposed network is trained with a custom loss function aiming to minimize the Root Mean Squared Error Loss while maximizing the Pearson’s Correlation Coefficient.
For experiments on PDbbind v.2016 and v.2019 datasets containing 16,179 and 21,382 protein-ligand complexes respectively, the core set splits are used for testing purposes while the rest is used for training. During training, each sample in the input space is rotated to all the 24 combinations possible and has been added random translation to make our model center-invariant. Our experiments showed that single-headed attention performs much better than multi-head attention because of the long input sequences; hence, both used transformers are single-headed and have 6 encoder and 6 decoder layers with feed-forward dimension of 2048. To prevent overfitting, weight decay is applied. We report 1.184 Root Mean Squared Error and 0.878 Pearson’s Correlation Coefficient on PDBbind v.2016 dataset which, to our knowledge, is above the current state-of-the-art.
Our MR-Net achieves state-of-the-art performance on both PDbbind v.2016 and v.2019 datasets, greatly reducing the need for computational resources and accurately predicting the protein-ligand binding affinity. We are also planning on more optimization approaches to further extend the capability of MR-Net . Experiments with the preprocessing pipeline of our model are to be conducted for the atomic feature descriptors and grid resolution. To learn embeddings from a larger dataset, we are working on an extended version of the Word2Vec algorithm for protein-ligand complexes.
This work is supported by the Garcia High School Program. The numerical calculations reported were partially performed at TUBITAK ULAKBIM, High Performance and Grid Computing Center.

Accelerated Crystal Structure Search for Multinary Phases—Introduction to SPINNER Framework and Its Application Wonseok Jeong[1], Sungwoo Kang[1], Changho Hong[1], Seungwoo Hwang[1], Younchae Yoon[1], Youngho Kang[2] and Seungwu Han[1]; [1]Seoul National Univ, Korea (the Republic of); [2]Incheon National Univ, Korea (the Republic of)

Over the years, computational materials science has greatly contributed to novel materials search, adding to the experimental search which is inherently low-throughput compared to computational search. Computational exploration of unknown materials has two key components: crystal structure generation algorithms, and energy evaluation of the generated crystal structures. The latter is critical as the energy of the crystal structure is directly related to synthesizability. Conventionally, the energy evaluation has been carried by quantum mechanical calculations, notably density functional theory (DFT). However, when it comes to ternary or higher (multinary) phases search, DFT shows its limitation, as the size of the materials space grows exponentially with the increase of the complexity and DFT is still too slow to evaluate the immense number of crystal structures that can appear during the crystal structure search. In addition, as previous researches are more focused on crystal structure search of unary and binary phases, an efficient crystal structure generation algorithm optimized on multinary phases is still lacking.
In this presentation, we introduce SPINNER, an efficient crystal structure search framework that can carry more than 10^5 energy evaluations and has optimized crystal structure generation algorithms for multinary phases. The high efficiency of the SPINNER framework is realized by adopting machine-learning (ML) based interatomic potentials for crystal energy evaluations. ML potentials can evaluate the energy and force of given atomic structures at low computational costs while maintaining an accuracy comparable to that of DFT. With the newly developed SPINNER framework, we aim to find novel military crystals which have high Li-ion conductivity and suggest some of the promising new compounds.

10:30 AM *DS03.08.01
Data-Driven Atomistic Models for the Simulation of Material Failure James Kermode; University of Warwick, United Kingdom

The degredation and eventual failure of a specimen through fracture, fatigue or creep represents an extremely challenging test-case for atomistic materials modelling, since there is a simultaneous requirement for high accuracy in the anharmonic region near a crack tip or dislocation core where chemical bonds break, and for large length- and time-scales to correctly capture elastic relaxation associated with long-range stress fields. I will demonstrate how the Gaussian Approximation Potential (GAP) framework has been succesfully applied to this problem using models trained on *ab initio* data for silicon [1], silicon carbide [2] and diamond [3,4], as well as considering how the approach could be further leveraged in future, for example as part of QM/ML (quantum mechanics/machine learning) multiscale schemes and/or to carry out active learning [5].

Machine Learning at the Exascale for Atomistic Simulations with Improved Accuracy, Length and Time Scales Mitchell A. Wood and Aidan Thompson; Sandia National Laboratories, United States

With exascale super computers arriving in the near future, it is timely to ask whether our simulation software is capable of matching this unprecedented computing capability. While many research challenges in material physics, chemistry and biology lie just out of reach on peta-scale machines due to length and time restrictions inherent to Molecular Dynamics(MD), questions of the accuracy of our simulations will continue to linger. Simply running the same peta-scale simulations with more atoms on a larger computer (weak scaling) does not advance the accessible timescales, nor does it avoid the pitfalls of empirically developed constitutive models. This talk will overview the U.S. Department of Energy* EXAALT (EXascale Atomistics for Accuracy, Length and Time) project and our efforts to provide software tools for MD that not only scale efficiently to huge atom counts, but also enable efficient MD simulations for smaller systems too. Central to this effort are machine learned models via the Spectral Neighborhood Analysis Potential(SNAP) which demonstrate both tunable accuracy and computational cost, a highly advantageous trait for MD on exascale resources.
*This work is funded through the Exascale Computing Project (No. 17-SC-20-SC), a collaborative effort of the U.S. Department of Energy Office of Science and the National Nuclear Security Administration

11:15 AM DS03.08.04
Deep Learning Methods for Fast Prediction of Protein Vibrational Modes Darnell Granberry, Kai Guo and Markus J. Buehler; MIT Lab for Atomistic and Molecular Modeling, United States

Normal mode analysis is a powerful technique for understanding the motions of chemical and biological systems, with applications in molecular design and fingerprinting. The number of operations required to compute the normal modes of such a system scales cubically with the size of the system, making such analyses computationally intractable. In order to make this technique more accessible to the broader scientific community, prior work produced a data-driven model that relied on geometric and structural properties to predict protein normal modes with high accuracy. In this work, we experimented with creating fully end-to-end models in two ways: first, we investigated multiple architectures for predicting normal modes from amino acid sequences alone, and second, we investigated graph-based architectures. Success in this project will enable faster and more sophisticated applications in functional protein design and recognition, such as screening and inhibiting novel coronavirus spike proteins.

11:30 AM DS03.08.05
Late News: Machine Learing Accelerates Atomistic Dynamics Simulations for Single-Molecule Photodynamics and Multi-Scale Modeling of Organic Solids Patrick Reiser[1,1], Jingbai Li[2], Manuel Konrad[1], Steven Lopez[2], Wolfgang Wenzel[1] and Pascal Friederich[1,1]; [1]Karlsruhe Institute of Technology, Germany; [2]Northeastern University, United States

In many multi-scale and reactive Molecular Dynamics (MD) simulations, *ab-initio* quantum calculations such as Density Functional Theory (DFT) or post-Hartree-Fock (post-HF) methods constitute a bottleneck in simulation workflows which prevents exact predictions for long time-scales or large system sizes due to its prohibitively expensive computation costs. In the past years, machine learning has emerged as a tool to enable fast and accurate energy predictions with so-called neural network potentials [1]. A set of neural networks trained on a sufficiently large amount of quantum data offer differentiable energy predictions at constant evaluation times. Here, we adapted this methodology to develop the Python Rapid Artificial Intelligence Ab Initio Molecular Dynamics (PyRAI^{2}MD) software for photodynamics simulations investigating the cis–trans isomerization of trans-hexafluoro-2-butene and the 4π-electrocyclic ring-closing of a norbornyl hexacyclodiene [2]. The active learning approach of the neural network photodynamics simulations is capable of revealing reaction pathways like the low-yielding syn-product, which was absent in the quantum chemical trajectories, and the subsequent thermal reactions within 1 ns for the norbornyl cyclohexadiene. Additionally, we integrated the machine learning model in multi-scale simulations for organic semiconductors to compute the complete distribution of energy levels in a MD simulation to support more accurate charge transport models [3]. We find that static disorder and thus the distribution of shallow traps is highly asymmetrical for many materials, impacting the widely considered Gaussian disorder models. We furthermore analyze characteristic energy level fluctuation times and compare them to typical hopping rates to evaluate the importance of dynamic disorder for charge transport.

11:45 AM DS03.08.06
Late News: Characterizing Possible Failure Modes in Physics-Informed Neural Networks Aditi Krishnapriyan[1,2], Amir Gholami[1], Shandian Zhe[3], Robert Kirby[3] and Michael Mahoney[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]The University of Utah, United States

Recent work in scientific machine learning has developed so-called physics-informed neural network (PINN) models. The typical approach is to incorporate physical domain knowledge as soft constraints on an empirical loss function and use existing machine learning methodologies to train the model. We demonstrate that, while existing PINN methodologies can learn good models for relatively trivial problems, they can easily fail to learn relevant physical phenomena even for simple PDEs. In particular, we analyze several distinct situations of widespread physical interest, including learning differential equations with convection, reaction, and diffusion operators. We provide evidence that the soft regularization in PINNs, which involves differential operators, can introduce a number of subtle problems, including making the problem ill-conditioned. Importantly, we show that these possible failure modes are not due to the lack of expressivity in the NN architecture, but that the PINN's setup makes the loss landscape very hard to optimize. We then describe two promising solutions to address these failure modes. The first approach is to use curriculum regularization, where the PINN's loss term starts from a simple PDE regularization, and becomes progressively more complex as the NN gets trained. The second approach is to pose the problem as a sequence-to-sequence learning task, rather than learning to predict the entire space-time at once. Extensive testing shows that we can achieve up to 1-2 orders of magnitude lower error with these methods as compared to regular PINN training.

Molecular Dynamics Simulation Using Graph Neural Networks Ravinder Bhattoo, Sayan Ranu and N M Anoop Krishnan; Indian Institute of Technology Delhi, India

Molecular dynamics simulations are used to realistically simulate the material properties. The interatomic potential energy function (PEF) is critical in determining the validity of the results. We use density functional theory (DFT) to parameterize the interatomic PEF. Usually, interatomic PEF is a multi-body function whose functional form is non-trivial to determine. Therefore, estimating the functional form is very critical in determining the interatomic PEF and hence the material properties. Herein, we use a graph neural network with multi-message passing to model the interatomic PEF. Further, we use the Euler-Lagrange equation to determine the acceleration of the atomic system. Finally, we train the GNN against the simulation trajectories of unary and binary Lennard Jones (LJ) systems created from traditional molecular dynamics (MD) simulations. The trained GNN is then used to do MD simulations and demonstrate energy conservation.

Automatically Interpreting Materials Characterization Data to Model Materials Properties Using Machine Learning Jacqueline M. Cole[1,2]; [1]University of Cambridge, United Kingdom; [2]ISIS Pulsed Neutron and Muon Source, United Kingdom

Data-driven materials discovery requires the automated interpretation of large volumes of materials characterization data and its onward use in materials modeling. Thereby, materials can be designed with properties that suit a given functional application. This data-science approach is enabled by a range of methods from artificial intelligence (AI): machine learning and natural language processing. This talk will show how such AI-based methods can be employed to source materials characterization data from the academic literature, automatically interpret these data, and use them to model and predict materials properties in a molecular-engineering fashion.

4:30 PM DS03.09.02
Data-Driven Design of Switchable Nanomaterials Composed of Polarizable Nanoparticles Siva Dasetty, Igor Coropceanu, Jiyuan Li, Juan J. dePablo, Dmitri Talapin and Andrew Ferguson; The University of Chicago, United States

Homogeneous metallic nanoparticles form highly stable colloids because of the strong electrostatic repulsions. Coating with metal chalcogenide complexes and with changes to solvent polarity, the colloidal stability can be altered to result in the formation of highly ordered aggregates with diverse applications in energy storage, photonics and electronics. The structure of the self-assembled aggregates depends on the delicate interplay between the dispersion and the electrostatic interactions governed by the design parameters such as temperature, size-charge-dielectric constant of the nanoparticle and the dielectric strength of the solvent. To aid in the rational design of engineered materials composed of polarizable nanoparticles, we have established a computational and machine learning framework to efficiently screen the experimental design space, identify regimes leading to spontaneous and triggerable self-assembly, and extract microscopic design rules for engineered assembly.

We perform high-throughput virtual screening of the particle design space using a coarse-grained simulation model implementing an image-charge formalism that rigorously accounts for the many-body polarization interactions. We efficiently sample the design space and identify self-assembly phase boundaries using a data-driven active learning approach to optimally guide the deployment of computational resources. Our computational phase boundaries are in good agreement with experimental scattering measurements, and predict the structure of self-assembled aggregates become more ordered with decreasing nanoparticle size and increasing solvent dielectric constant. Finally, we use our computational models to design switchable materials systems composed of polarizable nanoparticles that are capable of triggered assembly and disassembly upon changes in temperature and solvent quality.

4:45 PM DS03.09.03
A Hierarchical Design on Bioinspired Structural Composites Using Reinforcement Learning Chi Hua Yu[1,2], Bor-Yann Tseng[3], Cheng-Che Tung[3], Zhenze Yang[2], Elena Zhao[4], Po-Yu Chen[3], Chuin-Shan Chen[5,5] and Markus J. Buehler[2]; [1]National Cheng Kung University, Taiwan; [2]Massachusetts Institute of Technology, United States; [3]National Tsing Hua University, Taiwan; [4]Deerfield Academy, United States; [5]National Taiwan University, Taiwan

Here we propose a new design method using reinforcement learning to solve bioinspired composite materials in a complex system. Biological structural materials are made by a stiff matrix and a compliance glue to exhibit extraordinary mechanical properties which synthetic materials do not possess. The reason for this excellent performance is because a particular order makes them of microstructures. To imitate the exceptional material properties of biomaterials, the idea of bioinspired structural material has been proposed. However, the number of combinations of design space is usually intractable. Therefore, we offer a new design method by using reinforcement learning to solve the problem. Here we developed a hierarchical design paradigm. The hierarchical design process starts from a design space with limited combinations. After obtaining the best design of the current system size, we expanded the design system and searched for the best design with higher resolution. We searched for the best crack resistance by using the hierarchical reinforcement

learning from a lower resolution. By comparing the design results in the two design systems, the hierarchical design can effectively increase the convergence rate. We further discussed the results obtained from each hierarchical level. It can be observed that the best structure obtained from a high-resolution design space shows a significant improvement by depressing the stress concentration at the crack tip. The best composition was examined through 3D printing. The experimental results show that there is an excellent agreement with our AI design. The design framework proposed in this research can be used as an alternative method for optimization in a complex design system with various constraints. This research can be potentially applied to bionic structural design, nanoengineering, and material design in the future.

5:00 PM DS03.09.04
Machine-learned Potential Energy Model for Extensive Sampling of the Microstructure of Complex Mixed-Ion Perovskite Hsin-An Chen and Chun-Wei Pao; Academia Sinica, Taiwan

The organic-inorganic mixed-ion perovskite materials are one of the promising active materials in the photovoltaic and optoelectronic applications because of their high absorption coefficient, high power conversion efficiency, easy processing and low fabrication cost. The microstructures of the mixed ion perovskites are vital for the device performance. However, experimental characterization of the microstructures of mixed-ion perovskites is still considered to be a challenging task; furthermore, the chemical complexity in conjunction with the huge permutation degrees of freedom makes extensive samplings over the composition space using conventional ab-initio calculations intractable. In the present study, a machine learning-enabled potential model for $MA_yFA_{1-y}Pb(Br_xI_{1-x})_3$ mixed-ion perovskite was trained for extensive exploration over both the composition and permutation space to access the energetics and microstructure properties[1]. Subsequent correlation analysis of low energy structures over the composition space allowed us to construct the process-structure-property (PSP) relationship of mixed ion perovskites, namely, to reveal the correlations among chemical compositions, ion mixing energies, chemical short-range orderings, atomic strains as well as the device performance. Our analysis suggest that the lattice distortion is the primary factor impacting material performance – in the high MA/Br concentration regime, strong lattice distortion induces high mixing energy, resulting in phase segregation and introducing defects such as domain boundaries. Hence, mitigating the lattice distortion to retain the single-phase solid solution phase is one necessary condition of the optimal composition of mixed-ion perovskite material. The present study therefore demonstrate the capability of machine-learned potential in evaluating the energetics and microstructures of mixed-ion perovskites, and can be readily extended to studying other chemically complex materials such as the high entropy materials.

5:15 PM DS03.09.05
Accelerating Lattice Thermal Conductivity Calculations with Neural Network Potentials Kyeongpung Lee, Jeong Min Choi, Wonseok Jeong, Jaehoon Kim and Seungwu Han; Seoul National University, Korea (the Republic of)

Lattice thermal conductivity is of central importance in engineering field, as insulator for silicon-on-insulator devices needs sufficiently high thermal conductivity to dissipate heat effectively during operation, for example. A fast and accurate estimation of lattice thermal conductivity can be helpful to product designers. A reliable approach for the theoretical evaluation of lattice thermal conductivity exploits ab initio calculations to decide the harmonic and anharmonic factors of Boltzmann transport equation solution. However, the anharmonic effect requires exhaustive amount of ab initio calculations, which is the most time-consuming process and hence the main bottleneck of this approach.
One of the emerging alternatives is to replace the fully ab initio approach with neural network potential (NNP), which has an accuracy comparable to ab initio calculations at a significantly reduceed computation time. In this study, we employed NNP to calculate harmonic and anharmonic factors to evaluate lattice thermal conductivity. Results were in good agreements with the ab initio results. Three types of datasets for NNP training were tested, where molecular dynamics trajectories outperformed the superposition of phonon modes and random displacements. We then discussed the framework to make this approach efficient and how to obtain reliable and high-precision results. We finally showed the total computation time compared to the fully ab initio approach.

5:30 PM DS03.09.06
Late News: Structured Gaussian Process Regression Models to Address Difficulties in Modeling Very High Dimensional Data with Product Kernels Eita Sasaki, Manabu Ihara and Sergei Manzhos; Tokyo Institute of Technology, Japan

Gaussian process regression has become increasingly popular in machine learning based materials research, quantum dynamics, and other applications. Advantages include the non-parametric nature of the method, and, by ricochet, ease of use with high-dimensional data, as increase in dimensionality does not lead to a rapid increase in the number of non-linear parameters (contrary for example to neural networks) except a small number of hyperparameters. However with very high-dimensional data, especially when some features are subject to uncertainty, commonly used product kernels (of the Matern family) can lead to a failure of the method. We will show how this phenomenon arises and propose possible solutions based on the use of high-dimensional model representations (HDMR). We will demonstrate the advantages of imposing HDMR structure on the entire function model or on the GPR kernel. In particular, we will show how the use of HDMR allows working with very sparse data and obtaining physical insight with an otherwise general ML method. Examples from modeling of kinetic energy densities, potential energy surfaces, and electricity demand prediction will be discussed.

5:45 PM DS03.09.07
Nanocrystalline Microstructure Modulation Based on Reinforcement Learning Hao Sun; Queen's University, Canada

Polycrystals are thermodynamically unstable; hence, their properties are path-dependent. Polycrystals prepared using different methods should exhibit different microstructures and properties. Although most polycrystalline metals are formed via solidification of the liquid phase, there are vast, continuous, thermal processing strategies available during solidification (temperature, cooling rates, etc.). Identifying the optimal approach to obtain a given microstructure—e.g., small average grain size, narrow grain size distribution, high density of coherent twin boundaries, and a high proportion of coincident-site-lattice boundaries—can be quite challenging. Using molecular dynamics simulations, we investigated the grain boundary properties and microstructures of nanocrystalline FCC and HCP metals formed using different strategies. Based on our simulation results, we circumvent conventional trial-and-error methods via reinforcement learning to find the most efficient pathway toward desirable microstructures and properties. Our work shows a path towards tailoring polycrystalline microstructures in a controllable and efficient manner.

SESSION DS03.10: Machine Learning for Accelerating Simulations VIII
Session Chairs: Sumanta Das, Christian Hoover and N M Anoop Krishnan

6:30 PM DS03.10.02
A Machine-Learned Potential Energy Model for Large-Scale Atomistic Simulation of 2D Ruddlesden-Popper Perovskite Material Svetozar Najman[1,2], Po Yu Yang[1] and Chun-Wei Pao[1]; [1]Research Center for Applied Sciences, Academia Sinica, Taiwan; [2]National Tsing Hua University, Taiwan

2D organic-inorganic Ruddlesden-Popper perovskite material is a promising alternative for optoelectronic and photovoltaic applications because of its long-term stability in ambient conditions relative to its 3D perovskite counterparts. Furthermore, the band gap and exciton binding energies of 2D perovskite materials are directly correlated with the number of anionic inorganic perovskite layers, indicating tunable optoelectronic properties by adjusting the proper stoichiometric ratio of the methylammonium (MA) and butylammonium (BA) spacer cations during synthesis. However, it has been shown recently that the quantum well width distribution is not uniform for selected MA to BA cation ratio[1]. Furthermore, it has been reported that 2D Ruddlesden-Popper perovskites with principle number $n > 5$ are thermodynamically unstable relative to their 3D counterparts, namely, higher 2D perovskite members would segregate into lower members and 3D like-phase[2]. Therefore, comprehensive insights into the stability and microstructure of 2D perovskite, in particular, the distribution of quantum well width are critical for enhancing the performance of 2D perovskite materials. In this work, a machine-learned potential energy model based on the Spectral Neighbor Analysis Potential (SNAP) was trained using images obtained from ab-initio molecular dynamics simulations 2D perovskite of a variety of members. The trained potential energy model possesses high fidelity in both energies and atomic forces relative to ab initio calculations, and the potential model is stable during regular molecular dynamics simulations under canonical ensemble. The potential energy model allows us to perform a series of large-scale atomistic Monte Carlo simulations of 2D perovskite slabs containing several tens of quantum wells to examine the quantum well width distribution and their impacts on the optoelectronic properties of 2D perovskites. Furthermore, this way, it is also possible to extract the properties of an active layer in a working device for the different initial stoichiometric ratio of MA and BA cations during synthesis.

6:45 PM DS03.10.03
Quantum-Accurate Machine-Learned Potential Model for Large-Scale Atomistic Simulations of Mechanical Properties Chemically Complex Alloy Po Yu Yang, Cheng-Lun Wu and Chun-Wei Pao; Academia Sinica, Taiwan

The increasing demands for developing novel chemically complex alloys have imposed a significant challenge to the modeling and simulation community. The mechanical properties of these complex alloys are essential for their applications; however, the length scale required for studying the plasticity of these alloys is beyond the reach of quantum chemistry calculations. In this study, we harnessed the power of machine learning and trained a potential model for the chemically complex Ni/Co/Ti/Zr/Hf alloy system by combining the spectral neighbor analysis potential (SNAP) model and the Bayesian optimization based on a large data set of training images labeled with energies and atomic forces computed from the density functional theory (DFT). We demonstrate that the trained potential model can predict the energies and atomic forces of this chemically complex alloy with high fidelity to the DFT calculations. A series of large-scale (over 10^5 atoms) molecular dynamics simulations were performed to examine the deformation and dislocation dynamics of both nanowires and bulk structures, and the formation of amorphous, shear band-like region following dislocation pinning was observed, which is in excellent agreement with experiments. Hence, the present study demonstrates that the machine-learned SNAP model yields quantum accuracy even for complex alloy comprised of five constituents, allowing for investigating the plasticity deformation of chemically complex alloys with atomistic insights.

7:00 PM DS03.10.04
Development of Coarse-Grained Models of Carbohydrates Parisa Farzeen, Soumil Y. Joshi and Sanket Deshmukh; Virginia Tech, United States

Over the last few years, coarse-grained (CG) molecular dynamics (MD) has emerged as a way to accurately simulate large and complex systems in an efficient and inexpensive manner due to its lowered resolution, faster dynamics, and larger time steps. Although several CG models for proteins and soft materials are available in literature, few models for carbohydrates can be found. Carbohydrates, due to their nature, open up the possibility of a large variety of sequences, linkages and structures, which makes CG model development arduous. Replicating α and β configurations of monosaccharides separately and capturing their ring structures also remain challenging. Here, we will discuss our machine learning (ML) accelerated approach and results on the development of a CG model for monosaccharide units which captures the aforementioned intricacies in their structures. In this study we use a bottom-up approach to map CG beads onto monosaccharides, while capturing the differences in orientation of the hydroxyl groups with respect to the aromatic rings. The force-field parameters for these CG models are optimized using the artificial neural network (ANN)-assisted particle swarm optimization (PSO) method. These models have further potential to simulate larger systems consisting of oligo- and polysaccharides.

7:15 PM DS03.10.06
Machine Learned Interatomic Potentials for the Calculation of the Detonation State of Energetic Materials with Quantum Accuracy Cong Huy Pham, Nir Goldman and Laurence Fried; Lawrence Livermore National Laboratory, United States

In this work, we present the development and application of the Chebyshev Interaction Model for Efficient Simulations (ChIMES) to the study of hydrazoic acid (HN_3) under detonation. Computational study of HN_3 is challenging due to its ultrafast detonation, i.e. the chemical decomposition to stable products is complete in less than 10 ps, and the system evolves through multiple thermodynamics (ambient and extreme conditions) and electronic (metal and insulator) states. We show that ChIMES, a generalized many-body reactive force field machine-learned to density-functional theory molecular dynamics (DFT-MD) trajectories, is able to retain the accuracy of DFT simulation in describing structural properties and chemistry for a wide range of unreactive and decomposition conditions of liquid HN_3 while increasing orders of magnitude in computational efficiency. The techniques and recipes for MD model creation here allow for direct simulation of nanosecond shock compression experiments and calculation of the detonation properties of materials with the accuracy of Kohn-Sham DFT.
This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

Low-Dimensional Manifolds Underpin the Atomic Structure of Glassy Materials Thomas J. Hardin[1], Mark Wilson[1] and Michael Shields[2]; [1]Sandia National Laboratories, United States; [2]Johns Hopkins University, United States

The atomic structure of glassy materials lacks long-range order; glassy materials do, however, possess short- and medium-range order imposed by nature's thermodynamic drive towards an energetic minimum. So, while the space of local atomic configurations that appear in a glass is in some sense "larger" than one would find in a crystalline material, that space is nonetheless constrained to a manifold by energetics, with the details of that manifold depending on the chemistry of the glass. We generated molecular dynamics samples of a silicate glass and a generic binary metallic glass, extracted the local atomic environments from each, and applied diffusion maps and an autoencoder architecture to identify the low-dimensional manifold underpinning the local structure of both exemplar materials. The resulting structural parameterizations are partially interpretable in terms of intuitive physical quantities, and enable identification of both outliers and reoccurring structural motifs. Comparison of the structural parameterizations between the covalent glass and the metallic glass illuminates the relative local structural complexity of these materials, reflecting the inflexibility of bonds in the covalent glass compared to bonds in the metallic glass. This presentation will cover our methods and analysis, and will look forward to applications of our structural parameterizations in computational statistical mechanics and as structural state variables in mesoscale and continuum models.
Sandia National Laboratories is a multimission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC., a wholly owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525 (SAND2021-7304 A).

SESSION DS03.11: Machine Learning for Targeted Material Design III

Computational Materials Modeling with Integrated Machine Learning Michele Ceriotti; EPFL, Switzerland

When modeling materials at the atomic scale, achieving a realistic level of complexity and making quantitative predictions are usually conflicting goals. Data-driven techniques have made great strides towards enabling simulations of materials in realistic conditions with uncompromising accuracy.
In this talk I will summarize the core concepts that have driven the extraordinarily fast progress of the field and discuss some of the most promising modeling techniques that combine physics-inspired and data-driven paradigms. I will focus in particular on "integrated" models that combine a prediction of the interatomic potential and that of functional properties, that open up a new dimension to the simulation of materials in realistic conditions. I will present several compelling examples ranging from water to semiconductors and from metals to molecular solids, and indicate the most pressing open challenges in the field

8:30 AM DS03.11.02
A Machine Learning-Based 3D Battery Design Method Kaito Miyamoto[1,2], Scott Broderick[1] and Krishna Rajan[1]; [1]University at Buffalo, The State University of New York, United States; [2]Toyota Research Institute of North America, United States

To power microelectronics of IoT (internet-of-things) applications, high-performance microbatteries are critically important. Given their limited size, the three-dimensional design of microbatteries is key to maximize their performance. To design the 3D microbattery architecture following the power-sources requirements of a variety of IoT devices, a computational strategy to identify the target battery architecture is vital. In this talk, we propose a 3D battery optimization system which consists of the automatic geometry generator [1] and highly accurate machine-learning (ML) based performance simulators that utilize a small number of performance data obtained from the continuum simulations. As the ML-based performance simulators evaluate the energies of the 3D battery with much smaller computational cost and with comparable accuracy, as compared with the continuum simulations, it is possible to find the best geometries from a huge number of randomly generated 3D battery geometries. We demonstrate the effectiveness of our approach by designing a set of microbatteries having higher energy than the simplest 3D battery (i.e., an interdigitated plates configuration which is characterized by the shortest ion-transport distance) without reducing the power. Compared with the simplest geometry, one of the designed geometries displayed 1.4 times higher energy at low current density and the other showed 6.5 times higher energy at high current density. The best geometry changes with the applied current, indicating that there exists a particular optimal geometry for each electronic device. This work is an important first step toward the realization of such a tailor-made 3D microbattery design.

8:45 AM DS03.11.03
PSP—A Toolkit for Efficient Generation of 3D Atomic-Level Polymer Models Harikrishna Sahu[1], Huan Tran[1], Kuan-Hsuan Shen[1], Joseph H. Montoya[2] and Ramamurthy Ramprasad[1]; [1]Georgia Institute of Technology, USA, United States; [2]Toyota Research Institute, United States

Typically, 3D atomic models are required for physics-based simulations of materials. Within the specific area of polymer science, an automatic engine for generating such polymer models is needed. We have developed a python toolkit named Polymer Structure Predictor (PSP) for suggesting a hierarchy of polymer models, ranging from oligomer/infinite polymer chains to sophisticated amorphous models[1], which can be used downstream in physics-based simulations. The only input of PSP is the simplified molecular-input line-entry system (SMILES) string of the repeat unit of a polymer. The performance of PSP was tested by comparing the generated models with the known experimental data of several polymers. The output files can be directly used with several computational software, such as VASP, ORCA, LAMMPS, and GAMESS, allowing automation for computing properties. PSP has already been used in the polymer version of computational autonomy for materials discovery (CAMD) [2], establishing extensive databases for polymer bandgap and charge injection barriers that power the Polymer Genome platform (www.polymergenome.org).

PSP is expected to benefit a wide number of academic and industrial research activities, realizing automation in polymer discovery. In the context of the emerging polymer informatics ecosystem, this toolkit will substantially reduce efforts to develop extensive databases of computed polymer properties. Besides, simpler visual models of polymeric materials would likely aid in polymer synthesis research, benefiting experimental polymer scientists.

9:00 AM DS03.11.04
Inverse Design of Two-Dimensional Materials with Invertible Neural Networks Victor Fung[1], Jiaxin Zhang[1], Guoxiang Hu[2], Panchapakesan Ganesh[1] and Bobby Sumpter[1]; [1]Oak Ridge National Laboratory, United States; [2]The City University of New York, United States

The ability to readily design novel materials with chosen functional properties on-demand represents a next frontier in materials discovery. However, thoroughly and efficiently sampling the entire design space in a computationally tractable manner remains a highly challenging task. To tackle this problem, we propose an inverse design framework (MatDesINNe) utilizing invertible neural networks which can map both forward and reverse processes between the design space and target property. This approach can be used to generate materials candidates for a designated property, thereby satisfying the highly sought-after goal of inverse design. We then apply this framework to the task of band gap engineering in two-dimensional materials, starting with MoS_2. We show the framework can generate novel, high fidelity, and diverse candidates with near-chemical accuracy. We extend this generative capability further to provide insights regarding metal-insulator transition, important for memristive neuromorphic applications among others, in MoS_2 which is not otherwise possible with brute force screening. This approach is general and can be directly extended to other materials and their corresponding design spaces and target properties.

9:15 AM DS03.11.05
Gaussian Process Regression Acceleration of Mechanism and Transition Rate Calculations Hannes Jonsson; University of Iceland, Iceland

The task of finding the mechanism and estimating the rate of an atomic rearrangement in a material typically involves finding a minimum energy path and first order saddle point on the energy surface. When such calculations are combined with electronic structure calculations, the computational effort can be large. Furthermore, in order to carry out simulations of long time scale dynamics, all relevant saddle points on the energy rim surrounding a given initial state minimum need to be found, a significant challenge when electronic structure calculations are involved. Machine learning using Gaussian process regression can accelerate these tasks and reduce the computational effort by an order of magnitude [1,2]. An approximate energy surface is generated and most of the iterations in the path optimization and saddle point searches are carried on this faster, approximate surface, which is updated when new electronic structure calculations have been perormed. By using a kernel based on pairwise distances between atoms and introducing a length scale or each type of atom pair, and working with inverse distances in a non-stationary kernel, a robust algorithm has been developed for rate calculations and long time scale simulations [3,4]. Examples of diffusion in and on the surface of solids, as well as reactions at solids surfaces will be presented as examples of such calculations where density functional theory is used to evaluate the atomic forces.

Late News: Analogical Materials Discovery—An Unsupervised Learning Approach for Inverse Design of Disordered Perovskite Materials Achintha A. Ihalage and Yang Hao; Queen Mary University of London, United Kingdom

While compositional disorder can generate exciting properties in perovskites, it is often challenging to predict the formability of such materials using *ab initio* methods such as density functional theory (DFT). Target-driven discovery of disordered perovskite materials can be accelerated by applying experimental data powered machine learning methods. Here, we demonstrate that an unsupervised deep learning strategy can find fingerprints of disordered materials that embed perovskite formability and underlying crystal structure information by learning only from the chemical composition, manifested in $(A_{1-x}A'_x)BO_3$ and $A(B_{1-x}B'_x)O_3$ formulae. The unsupervised model learns the crystal system of disordered solid solutions at a 72% success rate even though no information on the crystal structures was originally supplied to the model. Material fingerprints extracted by the model facilitates inverse exploration of promising perovskites based on similarity investigation with known materials, identified as analogical materials discovery. Quantifying materials analogies can further provide insights on possible phase transitions and significantly reduce the computational time required by DFT in predicting the properties of disordered materials. We demonstrate analogical materials discovery can also assist in finding a plausible experimental geometry required to initialise DFT computations by modelling six novel lead-free perovskites.

9:45 AM DS03.02.11
Machine Learning Models to Predict Defect Properties in High Entropy Alloys Gaurav Arora, Anus Manzoor and Dilpuneet S. Aidhy; University of Wyoming, United States

The presence of multiple elements in large proportions poses a major computational challenge to understand and predict defect properties in high entropy alloys (HEAs) using conventional atomistic methods. To overcome this challenge, we have developed a machine learning (ML) model to predict the defect properties such as vacancy formation energies, migration energies, and stacking fault energy (SFE) in HEAs. Using the support vector machine model and local nearest-neighbor information of only the binary constituents' alloys, we predict the defect energies in ternary, quaternary, and quinary alloys with high level of accuracy. Similarly, using linear regression and bond lengths, we predict SFEs in HEAs. Our scheme utilizes density functional theory and atomistic simulations database of binary alloys fed to ML models. The relative importance of various descriptors, both electronic and atomic, and the accuracy of various algorithms are discussed. The work is performed in Ni-based HEAs towards the development of high-temperature materials for extreme environments. A key benefit of this approach is that once the binary database is built and the model is trained, defect energies can be predicted with little computational expense thereby bypassing a large number of calculations that would be otherwise needed every time a new composition is discovered in the HEA phase space.

1:00 PM *DS03.12.01
AI-Enabled Nanoscale Imaging Mathew J. Cherukara; Argonne National Laboratory, United States

Gaining transformative insight into dynamic materials processes at the nanoscale is extremely desirable but has largely remained elusive. Emerging characterization techniques such as coherent imaging methods (e.g. Ptychography), nano-CT and Lorentz TEM are providing an unprecedented view of materials structure and properties at the nanoscale. However, these methods that rely on algorithmic inversion of measured data are not typically suited to *in-situ* or *operando* imaging. This is because the successful inversion of raw data requires enormous online computing power which is projected to increase even more with faster detectors and next generation x-ray and electron sources (> PFLOPS). I will describe our work in applying AI to both accelerate current methods and create new imaging modalities from various X-ray and electron imaging techniques. Our AI-enabled methods are hundreds of times faster than traditional algorithms used for image reconstruction, opening up the prospect of real-time 3D imaging at the nanoscale.

1:30 PM DS03.12.02
Deep Learning Model to Predict Complex Stress and Strain Fields in Hierarchical Composites Zhenze Yang, Chi Hua Yu and Markus J. Buehler; Massachusetts Institute of Technology, United States

Materials-by-design is new paradigm to develop novel high-performance materials. However, finding materials with superior properties is often computationally or experimentally intractable because of the astronomical number of possible combinations in the design space. Especially for composite materials, the heterogeneity and structural complexity really hinder us from calculating materials properties and searching for optimal designs at low costs. Fortunately, with the recent advances in artificial intelligence (AI) or machine learning (ML), new approaches and perspectives are provided to solve the puzzles. This study is proposed to leverage deep learning methods to bridge the gap between a material's microstructure – the design space – and the physical performance. Specifically, it will answer research questions about how to use AI for fast predictions on physical fields of composite materials like stress or strain directly from the input materials geometry. Using a game-theory based conditional generative adversarial networks (cGANs), an end-to-end deep learning approach are developed to give accurate predictions on not only physical fields data but also derivative global properties such as modulus and recoverability. Furthermore, the proposed approach offers extensibility by predicting complex materials behaviors regardless of component shapes, boundary conditions and geometrical hierarchy, providing new perspectives of performing physical modeling and simulations. The method outperforms some conventional numerical methods such as finite element analysis (FEA) and is able to vastly improves the efficiency of evaluating physical properties of hierarchical materials directly from the geometry of its structural makeup. In addition, the idea of geometry-to-field translation can also be applied to other areas in the sciences, such as density functional theory fields, fluid mechanical fields, or electromagnetism.

1:45 PM DS03.12.04
A Deep Learning Approach to the Inverse Problem of Modulus Identification in Elasticity Bo Ni[1,2] and Huajian Gao[3]; [1]Brown University, United States; [2]Massachusetts Institute of Technology, United States; [3]Nanyang Technological University, Singapore

The inverse elasticity problem of identifying elastic modulus distribution based on measured displacement/strain fields plays a key role in various non-destructive evaluation (NDE) techniques used in geological exploration, quality control and medical diagnosis (e.g., elastography). Conventional methods in this field are often computationally costly and cannot meet the increasing demand for real-time and high-throughput solutions for advanced manufacturing and clinical practices. Here, we propose a deep learning (DL) approach to address this challenge. By constructing representative sampling spaces of shear modulus distribution and adopting a conditional generative adversarial net (cGAN), we demonstrate that the DL model can learn the high-dimensional mapping between strain and modulus via training over a limited portion of the sampling space. The proposed DL approach bypasses the costly iterative solver in conventional methods and can be rapidly deployed with high accuracy, making it particularly suitable for applications such as real-time elastography and high-throughput NDE techniques.

2:00 PM DS03.12.05
Predicting Properties of BCC Refractory Multicomponent Alloys Using Physics Informed Statistical Learning Yong-Jie Hu[1,2] and Liang Qi[1]; [1]Univ of Michigan, United States; [2]Drexel University, United States

Body-centered cubic (bcc) refractory multicomponent alloys are of great interest due to their remarkable strength at high temperatures. Optimizing the chemical compositions of these alloys to achieve a combination of high strength and room-temperature ductility remains challenging. We first analyzed the electronic structures of crystalline defects in BCC refractory alloys. The interactions between solute atoms and crystalline defects such as vacancies, dislocations, and grain boundaries are essential in determining alloy properties. Here we present a general linear correlation between two descriptors of local electronic structures and the solute-defect interaction energies in binary alloys of body-centered-cubic (bcc) refractory metals (such as W and Ta) with transition-metal substitutional solutes. One electronic descriptor is the bimodality of the d-orbital local density of states for a matrix atom at the substitutional site, and the other is related to the hybridization strength between the valance sp- and d-bands for the same matrix atom. For a particular pair of solute-matrix elements, this linear correlation is valid independent of types of defects and the locations of substitutional sites. These results provide the possibility to apply local electronic descriptors for quantitative and efficient predictions on the solute-defect interactions and defect properties in alloys. At the second step, with these local/global electronic descriptors and a simple bond-counting model, we developed regression models to accurately and efficiently predict the unstable stacking fault energy (γ_{usf}) and surface energy (γ_{surf}) for refractory multicomponent alloys. We performed first-principles calculations with the special quasi-random structure (SQS) method to predict γ_{usf} and γ_{surf} for 106 individual binary, ternary and quaternary bcc solid-solution alloys with constituent elements among Ti, Zr, Hf, V, Nb, Ta, Mo, W, Re, and Ru. Then we developed surrogate models based on statistical regression to accurately and efficiently predict γ_{usf} and γ_{surf} for refractory multicomponent alloys in the 10-element compositional space. Building upon binary and ternary data, the surrogate models show outstanding predictive capability in the high-order multicomponent systems. The ratio between γ_{usf} and γ_{surf} can be used to populate a model of intrinsic ductility based on the Rice model of crack-tip deformation. Therefore, using the surrogate models, we performed a systematic screening of γ_{usf}, γ_{surf}, and their ratio over 112,378 alloy compositions to search for alloy candidates that may have enhanced strength-ductility synergies. Search results were also validated by additional first-principles calculations and reported experimental results.

2:15 PM *DS03.12.06
Data-Driven Insights into Materials Design Abhishek K. Singh; Indian Institute of Science, India

Data driven machine learning methods in materials science are emerging as one of the promising tools for expanding the discovery domain of materials to

unravel useful knowledge. The power of these methods will be illustrated by covering three major aspects, namely, development of prediction models, establishment of hidden connections and scope of new algorithmic developments. For the first aspect, we have developed accurate prediction models for various computationally expensive physical properties such as band gap, band edges and lattice thermal conductivity. The prediction model for band gap and band edges are developed on 2D family of materials -MXene, which are very promising for a wide range of electronic to energy applications, which rely on accurate estimation of band gap and band edges. These models are developed with GW level accuracy, and hence can accelerate the screening of desired materials. For the lattice thermal conductivity prediction model, an exhaustive database of bulk materials is prepared. By employing the high-throughput approach, several ultra-low and ultra-high lattice thermal conductivity compounds are predicted. The property map is generated from the high-throughput approach and four simple features directly related to the physics of lattice thermal conductivity are proposed. For the second aspect, we have connected the otherwise independent electronic and thermal transport properties. The role of bonding attributes in establishing this relationship is unraveled by machine learning. An accurate machine learning model for thermal transport properties is proposed, where electronic transport and bonding characteristics are employed as descriptors. In the third aspect, we have proposed a new algorithm to develop highly transferable prediction models. The approach is named as guided patchwork kriging, which is applied for prediction of lattice thermal conductivity.
Ref: **Chem. Mater. 31, 14, 5145 (2019), J. Mater. Chem. A, 8, 8716 (2020), Chem. Mater. 32, 15, 6507 (2020)**

2:45 PM DS03.06.01
Predicting Ground State and Metastable Crystal Structures Using Elemental and Phonon Mode Descriptors Aria Mansouri Tehrani, Bastien Grosso, Ramon Frey and Nicola Spaldin; ETH Zurich, Switzerland

We present two methods to predict the crystal structure, given the chemical composition, by combining machine learning and high-throughput density functional theory (DFT) methods.
In our work, initially, a classification model predicts the point groups of the given stoichiometries. Based on the predicted point group, a series of high-throughput DFT calculations determine the ground state of non-centrosymmetric crystal structures. Using this framework, we also extended our analysis to predict new ferroelectric compounds. In addition to the ground state structure, identifying metastable polymorphs that might get stabilized by controlling the synthetic conditions is of great importance as they can exhibit different functionalities. Then, using the example of bismuth ferrite, we illustrate how crystal structure, decomposed into distortion modes, can be implemented as a feature to explore the energy surface leading to the identification of metastable polymorphs. Therefore, we studied $BiFeO_3$ as a multifunctional compound with a rich low-energy phase space. A training set is constructed by mapping the phase space based on possible distortion modes starting from the cubic perovskite structure. A machine learning model is built using the generated training set predicting new metastable phases of $BiFeO_3$.

9:00 PM *DS03.13.01
Graph-Based Neural ODEs for Learning Dynamical Systems Yizhou Sun, Zijie Huang and Wei Wang; University of California, Los Angeles, United States

Many real-world systems, such as moving planets, can be considered as multi agent dynamical systems, where objects interact with each other and co-evolve along with the time. Such dynamics is usually difficult to capture. Understanding and predicting the dynamics based on observed trajectories of objects become a critical research problem in many domains. In this talk, we propose to treat dynamical systems as evolving graphs, and design graph neural network (GNN)-based ODEs to approximate system dynamics via the observed signals. In particular, we provide solutions to two challenging scenarios. First, we propose to learn system dynamics from irregularly-sampled partial observations with underlying graph structure. To tackle the above challenge, we present LG-ODE, a latent ordinary differential equation generative model for modeling multi-agent dynamical system with known graph structure, which is the first Graph ODE model in this direction. Second, we propose to learn system dynamics where both node features and edges are evolving. We present a dual Graph ODE, CG-ODE, where both node and edge dynamics are modeled. Experiments on motion capture, spring system, charged particle datasets, COVID-19, and simulated social dynamical systems demonstrate the effectiveness of our approaches.

9:30 PM DS03.13.02
Development of a Realistic 3D Model of Multicrystalline Si Structure Using Image Processing and Machine Learning of Optical Images and Finite Element Stress Analysis on the Model Kenta Yamakoshi[1], Kentaro Kutsukake[2], Takuto Kojima[1], Hiroaki Kudo[1] and Noritaka Usami[1]; [1]Nagoya University, Japan; [2]RIKEN, Japan

Multicrystalline Si (mc-Si) is widely used as a material for solar cells. Mc-Si can be usually produced at a low cost by the directional solidification (DS) method. However, many crystal defects exist in mc-Si ingot and among them, especially the dislocation cluster leads to lower solar cell efficiency than that of monocrystalline Si solar cells. For the growth of multicrystalline materials, the mechanism of crystal defect generation has not yet been elucidated due to the complexity of the structure caused by the diversity of crystal orientations and grain boundaries. We aim to elucidate the universal mechanism by combining experiments, theories, simulations, and machine learning using realistic data-driven models collected from actual multicrystals. In this study, a realistic 3D mc-Si model including the dislocation cluster generation region was created by image processing and machine learning on a large amount of PL and optical images collected from actual mc-Si ingots. In addition, finite element stress analysis was performed on the model to investigate the effect of stress on dislocation cluster generation.
We used high-performance (HP) mc-Si in this research. The ingot was sliced into 729 wafers of 156 mm x 156 mm x 180μm. First, Photo Luminescence (PL) images of the sequentially numbered as-slice wafers on the top of the ingot were taken. From the PL image, the distribution of dislocation clusters in HP mc-Si ingot is obtained [1], and taking a look at this distribution, we determined the 9.18 mm×9.18 mm×3.60 mm region to be modeled, in which a dislocation cluster is generated. Then, the wafers were alkali etched and taken their optical images. By taking the optical images while changing the position of the light source, a vector reflecting the crystal orientation can be obtained for each pixel. These vectors were used to analyze crystal orientation by originally developed crystal orientation estimation model using machine learning [2], and crystal grain segmentation at the region by Mean Shift Clustering. Finally, the mc-Si model for finite element stress analysis was then created by stacking sequentially numbered sections with corrections. The model consists of 53816 nodes and 48373 hexahedral elements, and each grain is given the orientation of a representative point obtained by orientation prediction. Then, finite element stress analysis was performed on this model. From the distribution of dislocation clusters, we expect that dislocation clusters are generated during crystal growth, not in the cooling process. So the conditions for the analysis were the temperature and stress that reproduced

the inside of the ingot during crystal growth by the DS method.
As a result, finite element stress analysis was successfully performed on the realistic model which reproduces the mc-Si structure well, and we could obtain the stress tensor at each node in this model. From these tensors, various analysis results can be obtained, such as the distribution of Mises equivalent stress. From the distribution of Mises equivalent stress, it was found that the stresses were concentrated at grain boundaries and grain boundary triple points as expected. On the other hand, there is no stress concentration near the dislocation cluster generation point. Therefore, the Mises equivalent stress is not likely to contribute to dislocation cluster generation. In the future, the stress tensors obtained from the analysis results should be used to investigate the resolved shear stress at the slip plane, which has a large impact on dislocation generation and to discuss its effect on the generation of dislocation clusters.

9:45 PM DS03.13.03
Chemical Hardness-Driven Interpretable Machine Learning Approach for Rapid Search of Photocatalysts Ritesh Kumar; Indian Institute of Science, India

Strategies combining high-throughput (HT) and machine learning (ML) to accelerate the discovery of promising new materials have garnered immense attention in recent years. The knowledge of new guiding principles is usually scarce in such studies, essentially due to the “black-box” nature of the ML models. Therefore, we devised an intuitive method of interpreting such opaque ML models through SHapley Additive exPlanations (SHAP) values and coupling them with the HT approach for finding efficient two-dimensional (2D) water splitting photocatalysts. We developed a new database of 3099 2D materials consisting of metals of various oxidation states connected to six ligands in an octahedral geometry, termed the 2DO database. The first tier of the HT scheme screened 2DO materials with high thermodynamic and dynamic stabilities. The ML models were constructed using a combination of composition and chemical hardness-based features to gain insights into the thermodynamic and overall stabilities. Most importantly, it distinguished the target properties of the isocompositional 2DO materials differing in bond connectivities, since it combines the advantages of both elemental and structural features. The interpretable ML regression, classification, and data analysis lead to a new hypothesis that the highly stable 2DO materials follow the hard and soft acids and bases (HSAB) principle. The most stable 2DO materials were further screened based on suitable band gaps lying within the visible region and band alignments with respect to standard redox potentials using the GW method, resulting in 21 potential candidates. Moreover, $HfSe_2$ and $ZrSe_2$ were found to have high solar-to-hydrogen efficiencies reaching their theoretical limits. The proposed methodology will enable materials scientists and engineers to formulate predictive models, which will be accurate, physically interpretable, transferable, and computationally tractable.

10:00 PM DS03.13.04
Prediction of Toughness in Heterogeneous Materials Using Machine Learning A. N. S. Sadi and Zubaer M. Hossain; University of Delaware, United States

Composites or heterogeneous materials have a wide range of applications in the fields of aerospace, structural materials, biomedical, energy conversion devices, high-temperature materials, etc. But the effective properties of composites, in particular, toughness and strength are hard to predict as a function of their constituent properties. By definition, heterogeneous materials contain different shapes, sizes, compositions, and material or phase distributions at different length scales, making iterative experiments inefficient, time-consuming, and expensive to use for this purpose. In this work, the toughness of heterogeneous brittle material is investigated using a combination of continuum scale simulations and machine learning techniques. Our goal is to predict the configurations (or different structural and material parameters) of the composite that optimize its effective toughness. The continuum simulations are based on the variational phase-field modeling of fracture, and we applied the novel surfing boundary condition, which allows adequate time for the crack to propagate, enabling evaluation of the critical energy release rate or toughness. In particular, we focus on understanding the criteria for deflection vs. penetration for a number of composite configurations and identify the structural or material descriptors that define the criteria. Using the descriptors, we develop supervised machine learning models for predicting the toughness of the composite. The models are trained using data sets, collected from continuum simulations and are used to ascertain the toughness-structure correlation for a number of unexplored variants of the configurations. This talk will discuss the findings and highlight the need for applying machine learning tools to predict the toughness of a composite, for an arbitrary choice of structural and material parameters.

10:15 PM DS03.13.05
Late News: Development of Machine-Learning Force Fields for Complex Materials Systems in Energy Applications Kwangnam Kim[1], Aniruddha Dive[1], Andrew Grieder[1,2], Nicole Adelstein[2], ShinYoung Kang[1], Liwen Wan[1] and Brandon Wood[1]; [1]Lawrence Livermore National Laboratory, United States; [2]San Francisco State University, United States

There are increasing interests in using machine-learning (ML) interatomic potentials in molecular dynamics (MD) simulations to explore local structure and chemistry that governs key physical and chemical properties of materials for energy applications. A number of methodologies has been developed to train ML potentials (e.g., neural network potential, Gaussian approximation potential, etc.) using local atomic environments in structure data as feature inputs and energies, forces, and/or virial tensors of the structures as outputs. The training data are often collected from highly accurate ab-initio simulation and therefore the trained and validated ML potentials are capable of performing simulations with quantum-level accuracy while achieving thousands of times faster computational speed than ab-initio calculations. In this talk, we will discuss our recent development of ML interatomic potentials based on artificial neural network[1,2] to study ion transport phenomena in highly-disordered, garnet-type LLZO solid-electrolyte and establishment of local correlation between Li-ion transport kinetics and the structural and chemical features of disordered LLZO. The training data was collected from AIMD simulations at a wide range of temperatures and our developed ML potentials are able to predict energies and forces for both crystalline and amorphous LLZO with DFT level of accuracy. Our predicted elastic properties, ion diffusivities, radial distribution functions, and vibrational characteristics of atoms also show excellent agreement with those calculated by ab-initio simulations. Based on similar methodology, we will briefly discuss the development of ML force field for the LLZO/$LiCoO_2$ interfaces that are relevant for all-solid-state battery technologies, and illustrate how the ML force field can be applied to understand Li-ion transport at the interfaces and to probe the structural and chemical instabilities at the interfaces.

Differentiable Simulations and Deep Learning for Materials Design Ekin D. Cubuk; Google, United States

Materials informatics datasets and computational resources are growing rapidly. While machine learning offers a promising set of generic tools for extracting insight from large volumes of data, these tools are not inherently good at generalizing to new data. For this reason, tools that enable a seamless integration of physically informed priors with machine learning are crucial for building data-driven models that generalize in a useful way. I will talk about our recent work in this direction where we combine differentiable atomistic simulations with graph neural networks and meta-learning, with applications to materials modelling, optimization, and discovery.

Improved Air Processability of Organic Photovoltaics by Using a Stabilizing Antioxidant to Prevent Thermal Oxidation Marc Steinberger, Hans Joachim Egelhaaf, Andreas Distler and Christoph J. Brabec; I-Meet Institute Materials for Electronics and Energy Technology, Germany

During the production of organic solar cells, the exposure of constituting materials and resulting devices to light, heat, oxygen and water is a potential source of degradation. We show that thermo-oxidation of the active materials occurs upon annealing the active layer or upon stirring the active materials solutions in air at elevated temperatures. By comparing various blends of donor polymers with fullerene or non-fullerene acceptors, the fullerene is identified to be the most susceptible component to thermal oxidation in both film and solution, while the polymer remains unaffected. In both cases, the effect on the photovoltaic device performance consists predominantly in a decreased short-circuit current (J_{SC}), suggesting that the underlying degradation mechanism is the same in the solid state and in solution. Thermo-oxidation of the active layer during annealing of the device can be decelerated by blending nickel(II) dibutyldithiocarbamate ($Ni(dtc)_2$) as antioxidant additive into the active layer. While small concentrations of additive stabilize the J_{SC} and therefore the power conversion efficiency, higher contents negatively affect device performance. Thermo-oxidation of the active materials in solution during stirring in air at elevated temperatures can be avoided for several hours by adding as little as 0.5% of $Ni(dtc)_2$. The observation that the antioxidant is consumed during stabilization of the active materials suggests a sacrificial protection mechanism.

Recycling of Rare-Earth Magnets and Lithium Batteries Without Toxic Byproducts Valery Kaplan[1], Ellen Wachtel[1], Kyoung-Tae Park[2] and Igor Lubomirsky[1]; [1]Weizmann Institute of Science, Israel; [2]Korean Institute of Industrial Technology, Korea (the Republic of)

Sustainable technological development requires recycling of materials, particularly those essential for energy generation and storage, such as the lanthanides and lithium (Li). Recycling of these metals is currently not performed on a large scale, but with growth in demand, one may foresee serious shortages already by the end of the current decade.
High energy density magnets, based on alloys of Nd(+/-Pr +/-Dy)–Fe–B (Nd-alloy), are critical components of a variety of electromechanical and electronic devices. During the last decade, consumption of lanthanide (*a.k.a.* "rare earth", RE, element) has risen annually by ≈30%(!!!), primarily due to increased production of hybrid and electric vehicles. Since a standard hybrid/electric automobile requires ≈5-10 kg of RE, while ≈ 40 wt % of the Nd-alloy is lost as scrap during the manufacturing process, large-scale recycling of RE has become an urgent necessity. However, recovery of RE from manufacturing scrap, and especially from end-of-life magnets, poses a difficult technical challenge. The latter requires removing the magnets from the used device, demagnetization, crushing/milling, and applying chemical processes to separate the RE from the Fe component. Demagnetization, by heating *in vacuo*, and crushing/milling are both costly procedures and the latter may introduce unwanted contamination. Strong acids/bases and/or corrosive melts are currently employed to extract the RE metals. Both routes produce toxic waste, for which the cost of neutralization often exceeds the value of the recovered RE. *Instead*, we developed an economically and ecologically friendly RE recycling process. Pulverization (decrepitation) into ~ 45mm particles is achieved by introducing atomic hydrogen into the used magnets, without the necessity for prior demagnetization, *via* room temperature electrolysis in a diluted NaOH solution. Separation of Fe from the RE is achieved by chlorination of the fine powder at ~ 673K, which results in sublimation of chlorides of Fe and B, leaving pure RE chloride. Chlorine gas from non-RE sublimates is recycled, while the RE chlorides may be reduced to metal *via* moderate temperature eutectic melt electrolysis.
Although Li-batteries initially emerged as a power source for portable devices, incorporation of Li-batteries in vehicles and industrial power banks, led to an exponential growth in the demand for lithium and cobalt. While lithium production is almost exclusively oriented towards batteries, cobalt is also an essential component of high-strength alloys and magnets, with demand for batteries beginning to compete with these traditional applications. Recovery of Li and Co from spent Li-batteries poses technical challenges. In addition to the fact that opening and crushing spent batteries may result in self-ignition, current technologies aim at Co extraction only. Many of these technologies require sequential treatment with acids and bases, producing toxic waste, or involve dumping of crushed batteries into Co-smelting ovens. In both cases, lithium ends up in compounds from which it cannot be readily recovered. We have developed an economical procedure that recovers metallic Co and Ni, and Li in carbonate form. This process is based on treating crushed, spent batteries with natural gas in a rotating kiln at 973K. Following treatment, Co and Ni may be extracted with a magnetic separator and Li_2CO_3 can be leached out with water, leaving all other components, *e.g.*, compounds of Cu, Mn and Al, for further recycling. Since the proposed process does not use or produce

toxic substances, runs at relatively low temperature, yields high recovery for both Co and Li and can be run with simple equipment, it may be considered as suitable for immediate scaling-up and industrial implementation.

2:00 PM EN01.02.02
Printable and Recyclable Carbon Electronics Using Crystalline Nanocellulose Dielectrics Nicholas Williams, George Bullard, Nathaniel Brooke, Michael Therien and Aaron D. Franklin; Duke University, United States

Electronic waste (e-waste) is a global concern, adding millions of tons of refuse that frequently contains environmental and biological toxins to landfills on a yearly basis. Efforts to extend the life of electronics through right to repair advocacy have thus far not been successful to curb the accumulation of e-waste. Recyclable electronics offers a promising solution to prevent this environmental disaster; however, demonstrations to date often evince recyclability or environmental compatibility through simple, single component demonstrations that focus on re-capturing conductive components. While these reports make pivotal progress towards green electronics, further investigations are required to create a truly revolutionary technology to thoroughly address the e-waste concerns—namely the accumulation of all components of an electronic device. Hence, a completely recyclable electrical device is desperately needed.

Through the use of nanocellulose as a dielectric, we report the creation of the first fully recyclable transistor device with a paper substrate, conductive graphene contacts, and a semiconducting carbon nanotubes channel. To further address environmental concerns associated with energy usage during device manufacturing, these electrical devices are printed almost entirely in a “print-in-place” fabrication procedure at room temperature with only a single toluene rinse at 80 °C. With the addition of a small concentration of table salt to the nanocellulose dielectric ink, these transistors have among the highest area specific on-currents and lowest subthreshold swings of any printed transistor (regardless of substrate) and maintain their performance over 6 months storage in air. Finally, after these devices complete their utility, they can be controllably broken down to their base components and the environmentally damaging nanomaterial inks (graphene and carbon nanotubes) can be recaptured for the later printing of new recyclable transistors with similar performance. The realization of fully recyclable electronics on a broad scale has the potential to be the watershed forestalling the environmental disaster that will inevitably result from the continued accumulation of electronic waste.

2:15 PM EN01.02.03
Microstructure Transition at the LTCC-Wafer Interface of Electronic Carrier Substrates That are Designed by *SiCer* Technology Hannes Engelhardt[1], Clemens Motzkus[1], Katharina Freiberg[2], Beate Capraro[1], Arno L. Görne[1] and Markus Rettenmayr[2]; [1]Fraunhofer IKTS, Germany; [2]Friedrich-Schiller-Universität Jena, Germany

The combination of semiconductor technologies with micro-electro-mechanical systems (MEMS) as sensors and actuators has been developed in recent years. This technology combines a silicon wafer and a multilayer low-temperature cofired ceramic (LTCC) carrier and is named *SiCer*. Several design concepts were established and this innovative substrate technology is gaining importance in sensor integration (Stehr et al. 2019). The elaborated LTCC is adopted to the thermal properties of the silicon wafer and the bonding at the silicon-LTCC interface is the key to the versatility and robustness of the *SiCer* technology. This contribution focuses on the investigation of the microstructure transition at the bonding interface between silicon and LTCC. High resolution transmission electron microscopy investigations including a highly sensitive EDS for elemental analysis reveals phase transformations that take place during the combined bonding and sintering process of *SiCer* substrates. The observed phase evolution is discussed by means of thermodynamic considerations and conclusions on the bonding mechanism are proposed. The influence of the initial wafer surface including oxidic thin films is interpreted with regard to desirable *SiCer* substrate properties.

Stehr et al. 2019:
Stehr, Uwe; Hagelauer, Amelie; Hein, Matthias A. (2019): SiCer: Meeting the Challenges of Tomorrow's Complex Electronic Systems [From the Guest Editors' Desk]. In: *IEEE Microwave* 20 (10), S. 26–92. DOI: 10.1109/MMM.2019.2928614.

2:30 PM EN01.02.04
Towards a Sustainable Preparation of Hybrid PVDF-$CoFe_2O_4$ Self-Standing Films for Magnetoelectric Applications—Seeking For a Substitute of N,N-Dimethylformamide Fayna Mammeri[1,2,3], Raphaël Hanemian[1,2,3], Ulises Acevedo-Salas[4,2] and Hakeim Talleb[4,2]; [1]Université de Paris, France; [2]Centre National de la Recherche Scientifique, France; [3]Labex SEAM, France; [4]Sorbonne Université, France

Multiferroic materials have the potential for many applications such as actuators, sensors, or memory devices, thanks to their magnetoelectric effect (ME). Such effect was first observed in inorganic single crystals but due to their low Curie temperature and their weak ME coupling coefficient, they were seldom integrated into devices. To overcome these limitations, the composite material strategy offers the opportunity to tune the ferromagnetic and ferroelectric properties of the two phases acting on the hybrid interface. In this context, we developed new flexible multiferroic composite materials through (i) smart tailoring of the hybrid interface between a ferroelectric and *piezoelectric* fluoropolymer, PVDF, crystallized in its β-polymorph to present suitable properties, and inorganic ferrimagnetic and *magnetostrictive* nanoparticles (NPs), cobalt ferrite ($CoFe_2O_4$), and (ii) effective control of NPs size [1] and surface chemistry [2].

To the best of our knowledge, up to now, there is no paper dealing with the sustainable preparation of hybrid $CoFe_2O_4$-PVDF films for magnetoelectric applications: Dimethylformamide (DMF) is still the most used solvent to prepare these materials since it is considered the best solvent to induce the crystallization of PVDF in its β-polymorph. However, it is now well-known that solvents with high polarity tend to induce the crystallization of β-PVDF [3]. Hence, the question raised is now: new solvents are doubtless required to improve the sustainability of the synthesis of PVDF-based films but will they be as efficient as DMF to induce the crystallization of β-PVDF in presence of 13 nm $CoFe_2O_4$ nanoparticles?
We present here our first studies on the synthesis of $CoFe_2O_4$-PVDF magnetoelectric thin films using less toxic solvents and their resulting properties. A comparison with the first series prepared in DMF is presented too.

Informing Availability and Recycling Potential in Metals Elsa Olivetti; Massachusetts Institute of Technology, United States

As product complexity in electronics increases, our consideration of the manufacturing, end of life processes and materials supply chains required to produce these electronics must keep apace of that complexity. Metrics that only cover technical performance miss opportunities to drive towards more sustainable approaches to design and processing. This presentation will discuss work in understanding materials availability and the potential for materials

recovery to improve the sustainability of electronics. We will also describe materials market modeling work to understand limits on metals recycling policy to reduce primary mining for copper and other electronics-prevalent materials.

Nanoscale Grain Growth Suppression in Metal Oxide Nanoribbons at High Temperature Hyeuk Jin Han[1], Gyu Rac Lee[2], Yujun Xie[1], Hanhwi Jang[2], David Hynek[1], Eugene Cho[2], Ye Ji Kim[2], Yeon Sik Jung[2] and Judy Cha[1]; [1]Yale University, United States; [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Nano-grained metal oxides can significantly improve the physical and chemical properties of the metal oxides for diverse applications that utilize a large surface area, such as gas sensors and catalysts. However, the inherent thermal instability of nanoscale grains is a major challenge and hinders technological applications that are operated at elevated temperatures. Thus, controlling the temperature-stability of nano-grained structures represents both a scientifically interesting problem as well as a major technological advancement to enable widespread applications of metal oxides.
Here, we report highly effective grain growth suppression in metal oxide nanoribbons to demonstrate the high-temperature stability of nanoscale grains. By controlling the metal to oxygen ratio and the nanoscale dimension of the initial amorphous metal oxide nanoribbons, we show that the average grain size was maintained at ~ 6 nm, despite high annealing temperatures up to 900°C for 6 hours. We find that excess oxygen in the initial amorphous metal oxide nanoribbons prevents the merging of small grains during crystallization, leading to suppressed growth of the small grains. This was verified by *in situ* transmission electron microscopy experiments, during which we directly observed crystallization of the nanoribbons. As an exemplary application that exploits nanoscale grains, we demonstrate a gas sensor using grain growth suppressed tin oxide nanoribbons, which exhibited both high sensitivity and unusual long-term operation stability due to the thermodynamically stable nanoscale grains. Our findings provide a new pathway to simultaneously achieve high performance and excellent thermal stability in nano-grained metal oxides, which will be useful for various device applications.

4:15 PM EN01.03.02
Bioresorbable Primary Battery Anodes Built on Core−Double-Shell Zinc Microparticle Networks Yutao Dong and Xudong Wang; University of Wisconsin-Madison, United States

Bioresorbable electronics, which decomposed in the physiological environment after a designed period of stable function and corresponding byproducts are resorbed and vanish, have gained increasing interests in state-of-the-art biomedical implants for pre-diagnosis, monitoring and treatment of diseases, drug delivery which only requires the function for a certain period of time. Compared to other transient power supplies, such as piezoelectric nanogenerators, supercapacitors, bioresorbable batteries are promising power source with higher energy density and continuous output which typically are composed of bioresorbable material that degrade into non-toxic contents in physiological environment during and/or after discharge. State-of-the-art bioresorbable batteries are built upon Mg or Zn metal-based galvanic cells due to their good biosafety and electrochemical activity. Due to extreme high chemical activity of Mg, current Mg-based bioresorbable batteries all exhibited fluctuating voltage output and rapid output drops without a controllable lifetime, which cannot meet the requirements of an implantable power supply. Additionally, the fast degradation rate could induce localized releasing of concentrated hydroxyl ions, leading to inflammation or other harmful effects. Compared to Mg, Zn metal has moderate degradation rate which can circumvent undesirable local pH increase and minimize gaseous hydrogen evolution. Furthermore, in bioresorbable metal-based galvanic cell systems, although both the anode and cathode are needed, it is the metal anode that dissolves in the electrolyte and primarily determines battery lifetime and power output. Nevertheless, almost all current models were built on bulky foils or plates, where their degradation occurred naturally on the metal surface. Therefore, there was no control over the degradation rate, direction and sequence, and thus all showed a poor controllability on the battery output and lifetime, which further limits their practical applications. In this work, we report a bioresorbable zinc primary battery anode filament built on Zn micro-particles (MPs) coated with chitosan and Al_2O_3 nano-films. This battery filament exhibited a well-controlled dissolution direction and rate due to the mesoscale MP assembly, and the protective coatings. When discharged in 0.9% NaCl saline, single Zn MP filament with a 0.17 x 2 mm cross-section exhibited a stable voltage output of 0.55 V at a current of 0.01 mA, where the current and voltage output could be simply designed by integration of the battery filaments in parallel or in series, respectively. The operational time could be directly adjusted by the length of filament. A stable 200-hour discharging time was achieved by a 15 mm Zn MP filament. By increasing the filament cross-sectional area, higher current output can be achieved at the same discharging voltage, raising the output power. The final discharging byproducts, mostly $ZnO/Zn(OH)_2$, could slowly dissolve in biofluids, making this composite filament completely degradable. This complete bioresorbable primary battery showed a full level of control of output and lifetime, providing a promising solution to in vivo powering transient bioelectronics.

4:30 PM EN01.03.05
Study of Competing Effect of In-Plane and Out-of-Plane Anisotropies on the Overall Properties of Magnetic Tunnel Junction-Based Molecular Spintronics Device (MTJMSD) Properties Bishnu R. Dahal, Marzieh Savadkoohi, Eva Mutunga, Andrew Grizzle, Christopher D'Angelo and Pawan Tyagi; University of the District of Columbia, United States

Molecular spintronics is gaining attraction because molecules possess weak scattering mechanism. As a result, molecules retain spin information over a long time. Molecular Spintronics devices (MSD) are also considered crucial for futuristic quantum computing technology [1]. The major challenge of MSD is making robust and mass-producible spintronic devices at the nanoscale. To overcome this issue, we have designed a magnetic tunnel junction-based molecular spintronics device (MTJMSD). MTJMSD is fabricated by bridging paramagnetic molecules across the edges of the ferromagnetic electrodes. These molecules form dominant conducting channels over tunneling conduction between two ferromagnetic electrodes of an MTJ. MTJMSD enables the utilization of ferromagnetic electrodes with a wide range of magnetic anisotropies. Here, we are analyzing the magnetic switching mechanism, hysteresis loop (M-H Curve), and the overall magnetic properties of MTJMD as a function of anisotropies along with constant Heisenberg couplings.
In this paper, we report a theoretical Monte Carlo Simulation (MCS) study to explain the impact of anisotropies on the MTJMSD equilibrium properties. We also investigate theoretically how the nature of magnetic hysteresis changes as we apply the in-plane, out-of-plane, and in-plane and out-of-plane at the same time on the same ferromagnetic electrode. The application of anisotropy creates multiple magnetic phases of opposite magnetic spins on the same ferromagnetic electrode. When in-plane and out-of-plane anisotropies are applied on an electrode simultaneously, the magnetic moment of the electrodes

possessed its maximum value. The MTJMSD possessed its maximum value since the competing effect of anisotropies wiped out the multiple magnetic phases.
In this study, we also investigated the effect of anisotropies on the nature of the hysteresis curves generated computationally using MCS. We applied the in-plane and out-of-plane magnetic anisotropies on the same ferromagnetic electrode of an MTJ. The effect of the in-plane anisotropy transformed the regular magnetic hysteresis of MTJMSD into a “wasp-waisted” -like hysteresis curve[2]. The “wasp-waisted” -like hysteresis curve is hypothesized due to the presence of multiple magnetic phases on the ferromagnetic electrodes caused by strong magnetic anisotropy. The application of equal magnitude of in-plane and out-of-plane anisotropies brings back the M-H curve into a regular hysteresis curve but with nearly zero coercivity. The zero coercive hysteresis closely agree with the experimentally measured M-H curves under the same situations. In this paper, we will also present the overall properties of MTJMSD when the spin fluctuations option is incorporated in the MCS code.

This research is supported by National Science Foundation-CREST Award (Contract # HRD- 1914751), Department of Energy/ National Nuclear Security Agency (DE-FOA-0003945).

4:45 PM EN01.03.06
Investigation of Spin Fluctuation, Thermal Energy and Exchange Coupling Effect on Magnetic Tunnel Junction-Based Molecular Spintronic Devices (MTJMSD) Marzieh Savadkoohi, Bishnu R. Dahal, Andrew Grizzle, Christopher D'Angelo and Pawan Tyagi; University of District of Columbia, United States

Molecular spintronics is an emerging field that takes advantage of both spin properties and molecular electronics. The conjugation of spin degrees of freedom with molecular magnetic properties results in novel electronic devices with several advantages. The spin carriers carry and encode information in their spin state which allows development of efficient memory and logic devices [1]. Molecules have also unlimited passive and active magnetic properties that can be tailored with spin properties of atoms. Combination of spintronics with molecular electronics is an attractive method of making nanoscale devices with improved performance and functionality. Using organic molecules as conducting bridges between ferromagnetic electrodes has been a fascinating way of manipulating spin properties. However, the conventional techniques struggle with various challenges such as mass-producibility, endurability, and reliability of fabricated devices. In this work, we have proposed, and simulated a cross-junction shaped spintronic device called magnetic tunnel junction based molecular spintronic device (MTJMSD) using Monte Carlo Simulation (MCS) to investigate spin-dependent charge transport phenomenon. MTJMSD is made of two ferromagnetic electrodes (FME) separated by a few nanometer-thick tunneling barrier. Unlike previous methods, magnetic molecules are attached on the exposed edges of the FM electrodes in the outer world [2-4].
The interaction between magnetic molecules and FM electrodes, strengths and nature of couplings, molecules and electrodes’ type, thermal energy, and several other factors play important role in defining MTJMSD ultimate properties. In this work, we have computationally investigated few parameters (e.g., Heisenberg exchange coupling, electrodes’ size, thermal energy, spin fluctuation) that affect MTJMSD’s magnetic properties. Our results show that the magnetic couplings between molecules and FM-electrodes have a dominant role in dictating MTJMSD’s magnetic moment and spin orientation. Antiferromagnetic and ferromagnetic molecule-FME couplings forced the FM electrodes to take antiparallel and parallel spin states with respect to each other respectively at room temperature. Our results also showed that despite significant increase in time evolution of magnetic moment, stability is not achieved at higher temperatures. The electrodes’ size (length and thickness) affected molecules’ ability to induce magnetic properties in FM electrodes to some extent. However, the nature of coupling between FMEs is still dictated by molecules at stronger Heisenberg exchange coupling values. Spin fluctuation increased equilibrium energy and temporal evolution of magnetic moment compared to the non-spin fluctuation case. It also introduced some stripe-shaped spin orientation within electrodes. The current MCS studies complement our ongoing experimental research which investigates the effect of organometallic molecules on MTJ’s hysteresis loop and saturated magnetic moments.

ZnO Nanobrush Electrodes for Enhanced Photoelectrochemical Water Splitting Young-Min Kim and Yun-Mo Sung; Korea Univ, Korea (the Republic of)

ZnO has been highlighted as one of the most attractive candidates for water splitting due to its high oxidation power, chemical stability, non-toxicity, and low production cost. Despite its superior intrinsic properties, there exist a few reports on photoelectrochemical (PEC) water splitting with pure and monolithic ZnO. Due to the large energy band gap (3.2 eV) ZnO can be activated only under the ultra-violet light irradiation, which seriously limits its broad applications to water splitting. Thus, to overcome this drawback most researches on PEC water splitting with ZnO have been focused on the impurity doping for energy band gap modification, the noble metal decoration for the plasmon resonance energy transfer (PRET), and the type II heterojunction

formation with other semiconductors for visible light absorption.
Here, we report the breakthrough for the water splitting of pure ZnO photoelectrodes. First, we developed the growth method of high-density and faceted ZnO micro-rod (MR) structures on a conductive substrate. Subsequently, nano-branches were grown all over the facets of ZnO MRs using a dip coating followed by hydrothermal synthesis to realize ZnO nanobrush (NB) structures. The ZnO NB electrodes (NBEs) revealed the photocurrent density of 1.687 mA/cm^2 at 1.23 V_{RHE} and 0.48% conversion efficiency (ABPE) at 0.81 V_{RHE}, which is as far as we know the highest conversion efficiency value among monolithic ZnO photoelectrodes. The length of nano-branches could be precisely controlled by the solvothermal reaction time. As-synthesized ZnO NBEs exhibited photocurrent density ~1.36 times higher than that of bare micro-rod electrodes (MREs). The role of nano-branches in the photocurrent density increase was verified by the open-circuit potential and Nyquist plot analyses. The extra space charge region (SCR) occurring by introducing nano-branches on the surfaces of ZnO MRs was for the first time proposed as a mechanism for the increased photocurrent density in the ZnO NB structures.

Tunable Redox-Active Materials for Sustainable Electrochemically-Mediated Separations Kai-Jher Tan and T. A. Hatton; Massachusetts Institute of Technology, United States

Separation processes are ubiquitously employed for purification purposes in chemical production, as well as potable water generation and environmental remediation. The rising intensity of global issues such as the growing world population, low water security, and worsening industrial pollution all necessitate further advancement in the discovery, development, and application of materials for separations. Electrochemical approaches are an attractive alternative due to the innate propensities of redox-active species for modular design, molecular recognition, reversible operation, and lower energetic requirements, all of which can be realized via only electrochemical stimuli without any chemical additives. The current state-of-the-art for sustainable electrochemical separation technologies was delineated in a recent review,[1] and include electrochemically-mediated techniques at its forefront. In this work, the focused design of redox-active materials for imparting specific functionalities to electrosorption processes are discussed.

Redox-active composite materials have been developed from four different classes of electroactive species in order to enable redox-mediated ion detection and removal in water, with designed controllability over their pseudocapacitance, stability, analyte selectivity, and energetics. Anion separation was achieved using an organometallic ferrocene co-polymer whose electrochemical activity in different electrolyte solutions can be manipulated based on its co-monomer.[2,3] Through principles of hydrophobicity, the metallopolymer can be engineered to activate in the presence of hydrophilic anions instead of hydrophobic ones, for subsequent application in the stable and seven-fold selective electrochemical extraction of perrhenate over nitrate. The ferrocene macromolecule motif was also extended to the generation of zwitterionic polyelectrolytes that possess pH-sensitive electrochemical behavior in both homogeneous and heterogeneous environments.[4] Cation separation was facilitated through the preparation of pH-dependent quinone and electronically-tunable crystalline hexacyanoferrate-based conductive electrodes, which were paired together with polymeric ferrocenes to produce asymmetric redox-active systems that could reduce the extent of anode fouling by preventing parasitic water reduction, offer optimizable separation energies, allow for the enhanced and simultaneous recovery of transition metal compounds without altering their bulk oxidation state, and enable continuous operation under flow conditions.[2,3] Lastly, redox-active components were incorporated into a particulate scaffold instead of an electrode framework with the purpose of further improving their potential for ion separation through heightened maneuverability and phase contact provided in part by the judicious variation of material hydrophilicity.[5] Polypyrrole and polyferrocene-containing magnetic composites were synthesized through a facile multi-step procedure, and exhibit strong adsorption capacities for both inorganic and organic contaminants.

Introduction of TiO_2 as a New Potential Alternate Electron Transport Layer in Kesterite Solar Cells—Energy Band Alignment and Nanoscale Probing of CZTS/TiO_2 Heterojunction Nisika Nisika and Mukesh Kumar; Indian Institute of Technology Ropar, India

Kesterite-based Cu-Zn-Sn-S (CZTS) solar cells with layer stacking of Al/Al:ZnO/ZnO/CdS/CZTS/Mo are attracting attention in last few years, owing to less toxic and more abundant elements [1-2]. However, the current efficiency of CZTS champion solar cell is 11.01% that shows high disparity from its counterpart, Cu–In– Ga–Se (CIGS) solar cell [3]. High voltage deficit in CZTS solar cells is one of the primary cause of low efficiency. The lower performance of CZTS solar cells is mainly attributed to high open circuit voltage deficit due to increased interface recombination. Therefore, absorber-buffer interface engineering is essential and deserves more investigation to understand the charge dynamics at the interface. Here, we report wide band gap (3.8 eV) TiO_2 as a potential candidate to substitute conventional CdS buffer layer with low-band gap (2.4 eV) and toxic in nature. The surface and interface of CZTS-TiO_2 layer was investigated using X-ray photoelectron spectroscopy (XPS) and ultraviolet photoelectron spectroscopy (UPS). The result reveals favourable "spike"-like conformation at CZTS-TiO_2 interface with conduction band offset (CBO) value of 0.17 eV. The nanoscale probing of interface by Kelvin Probe Force Microscopy (KPFM) across CZTS-TiO_2 layers show a higher potential barrier for interface recombination at CZTS-TiO_2 in contrast to conventional CZTS-CdS interface. Finally, the fast decay response and lower persistent photoconductivity (PPC) of photogenerated carriers for CZTS-TiO_2 heterojunction based photodetector, further validate our results. Carrier management via interface engineering using emerging materials will help to obtain high efficiencies in CZTS solar cells.

8:30 AM EN01.05.03
Evolution of Structure, Composition and Optical Properties of ZnO Nanocrystals Films Co-Doped with Ga and In Donor-Like Impurities Brahim El Filali[1], Tetyana V. Torchynska[2], Georgiy Polupan[3], Jorge L. Ramirez Garcia[3] and Lyudmyla Shcherbyna[4]; [1]Instituto Politecnico Nacional, UPIITA, Mexico; [2]Instituto Politecnico Nacional, ESFM, Mexico; [3]Instituto Politecnico Nacional, ESIME, Mexico; [4]V. Lashkaryov Institute of Semiconductor Physics at NASU, Ukraine

The impact of double donor doping on the crystal structure, morphology, film compositions, emission and electrical properties has been studied in the ZnO:Ga:In nanocrystal films. The films were deposited by ultrasonic spray pyrolysis on silicon substrates heated to 400°C. To the study of double donor doping, two groups of samples were prepared. In the first group the In content was of 1at%, but the Ga contents were varied in the range 0.5-3.0at.%. In the second group the In content was of 2at% and the Ga contents were changed in the range 0.5-2.5at%. To stimulate the film crystallization, all samples were annealed at 400 °C for 4h in a nitrogen flow (5L/min).
The variation non monotonous of the crystal lattice parameters, compositions, the PL intensities, and electrical resistivity has been detected in the ZnO nanocrystal (NC) films. The high-quality NC films with the wurtzite-type crystal structure, planar morphology, bright near band edge (NBE) emission and the small intensity of defect related PL bands have been obtained. The reasons for parameter varying non monotonically and the optimal concentrations for the Ga/In double donor doping of ZnO NC films have been analyzed and discussed.

8:45 AM EN01.05.04
Pb Sequestration to Safeguard Using Halide Perovskite-Based Devices Rene D. Mendez Lopez[1], David Cahen[1,2] and Barry Breen[3]; [1]Bar Ilan University, Israel; [2]Weizmann Institute of Science, Israel; [3]3GSolar Photovoltaics Ltd., Israel

We aim at providing functionalized encapsulation of Halide Perovskites (HaPs) to prevent Pb from reaching the environment, especially the groundwater, in case of module device damage/breakage and subsequent exposure to the elements. HaPs are widely explored in research and development, specifically for optoelectronic devices, including large-scale outdoors employment in solar cell panels, due to their outstanding properties as light-absorbing materials. The most efficient devices use a Pb-based HaP. PbI_2 and $PbBr_2$, together possibly with oxides/hydroxides, are the most likely decomposition products if devices are broken and the HaP is exposed to the ambient. As these Pb dihalides are soluble, albeit sparingly, in water, exposure to rain can release Pb ions that may reach the groundwater.
Such a scenario carries obvious environmental and public health risks. We show here how to mitigate and even eliminate this scenario by efficient sequestering of Pb ions. A scheme of ligands is presented for sequestration as part of an encapsulation, using commercial materials and methods, reaching, till now, 90% lead retention in a commercially viable process.

9:00 AM EN01.05.06
Opto-Electronic Properties of Al_2O_3/ZnO Multilayer Heterostructure as a Transparent Conductor Krishan Ghosh[1,2], Bishwajite Karmakar[1] and Ariful Haque[2]; [1]Missouri State University, United States; [2]Texas State University, United States

Transparent conductors (TC) have great importance in day-to-day life and state of the art high-tech applications. For instance, they are used in light-emitting diodes, solar cells, transparent thin film resistors, display devices, and many others due to their good electrical conductivity and high transmittance in the visible region. However, current materials used for the TC are very costly. Current research interest is to develop low-cost TC with better electrical conductivity and high optical transmittance. The objective of this work is to tune the electrical and optical properties of low cost Al_2O_3/ZnO multilayer heterostructure on quartz substrates through anion as well as cation doping in ZnO and find out a better TC. All the heterostructures were made using pulsed laser deposition technique through varying growth parameters such as oxygen pressure, substrate temperature, and number of laser shots. The initial sample was a pristine ZnO layer, followed by a 95/5 ZnO/Al_2O_3 superlattice, then 90/10, and 80/20. To enhance electrical conductivity with minimum reduction in transmittance, the samples were annealed under forming gas (96% Ar and 4% H_2). The structure of the heterostructures was characterized via X-ray diffraction (XRD), Raman spectroscopy, photoluminescence (PL), and scanning electron microscopy. The electrical conductivity of the samples was determined via four probe electrical measurements, and the optical transmittance was determined by UV-VIS spectroscopy. XRD and Raman spectroscopy data confirm the presence of Al-doped ZnO and Al_2O_3 in the sample. The PL spectroscopy indicates the presence of oxygen as well as other point defects in the samples and specially, the number of oxygen vacancies increases with annealing. The optical measurements show that the transmittance of the superlattice oxide thin film decreases from 90 to 80 % with annealing. However, the electrical conductivity increases 4-6 order of magnitude with annealing. The resistivity decreases from 2 Ohm-cm to 6.2 E-03 Ohm-cm for the optimum sample. This multilayer heterostructure oxides can be useful for developing low-cost TC for optoelectronic applications.

9:15 AM EN01.05.07
Effect on the Ferromagnetic Property in Q-Carbon as a Function of Size Nayna Khosla[1], Jagdish Narayan[1], Kaushik Sarkar[1] and Dhananjay Kumar[2]; [1]North Carolina State University, United States; [2]North Carolina Agricultural and Technical State University, United States

The recent discovery of Q – carbon has opened ways for the fabrication of fascinating heterostructures using the non-equilibrium technique of nanosecond pulse laser annealing. Q- carbon is reportedly the densely packed metastable state phase of carbon with about 80% sp^3 content. The pure Q- carbon exhibits extraordinary hall effect and room temperature ferromagnetism whereas the Boron doped Q- carbon shows superconductivity. In Q carbon films which we have grown on sapphire, we observed that these magnetic and electrical properties can be attributed to the abundant unpaired electrons near the fermi energy level. This talk will put a light on the ferromagnetic properties as a function of size. With the increase in the size, we observe that the ferromagnetism increases up to a critical size. It is very interesting to see how does the magnetism changes with the size and what is this critical size. This will be an interesting lead in the magnetic and electron transport properties of Q- carbon which will enhance the functionalities of the fabricated devices and its application in carbon based spintronics.

Late News: Multifunctional Coatings for Textiles Based on Functional Particles Derived from Sustainable Sources Jagadeshvaran P L and Suryasarathi Bose; Indian Institute of Science, India

Recently, there is an increased demand for the development of multifunctional materials and hence they have allured enormous interest in every other application possible. With the threat of escalating electromagnetic (EM) pollution, there is a strong need to develop materials and strategies to curb it. Textiles have been used as promising candidates for electromagnetic waves, particularly in the microwave frequency ranges, owing to their numerous advantages like flexibility, lightweight and conformability. In addition, it is beneficial in creating multiple interfaces for microwave attenuation on textiles

with functional coatings. Herein, we report for the first time, the preparation of a multifunctional coating that is based on iron titanate (FT) and multiwalled carbon nanotubes (CNT) which can shield both microwaves and UV radiations. The iron titanate used here is sourced from a sustainable precursor – the ilmenite sand, while the CNT is commercially sourced. In order to demonstrate the contribution of FT in EMI shielding, another particle was also used – this was synthesized in the same protocol as that of FT with copper ions incorporated (CuFT). On comparison, it was found that FT tends to interact with and attenuate EM radiation along with CNT – much better than CuFT. The coated fabrics show an EMI shielding effectiveness of -30 dB for a stack of four layers in the broadbands viz. X and Ku – translating to a 99.9% attenuation of the incident EM signals. Further, there is a jump in conductivity of around four orders in magnitude for the coated fabric in comparison to the neat fabric. It is worth to note that the coating confers an ability to block 99.9% of the UV radiation over the wavelength ranging 200-400 nm. Furthermore, the prepared coatings significantly improve the flame retarding properties of the neat fabric. With such remarkable properties, these coatings have the huge potential to significantly enhance the commercial value of cotton fabrics without adding much to its cost.

1:15 PM EN01.06.02
Late News: Controlling H2 Production in Si Etching while Utilizing Advanced Chemical Concentration Ismail Kashkoush, Tyler Webber, Dennis Nemeth, Darian Waugh and Steven McKinley; NAURA-Akrion, United States

Anisotropic etching of silicon is usually performed using alkaline etchants such as aqueous KOH, TMAH and other hydroxides like NaOH. A large variety of silicon structures can be fabricated in a highly controllable and reproducible manner with the strong correlation of the etch rate due to the orientation of the crystal structure, etchant concentration and temperature. Therefore, anisotropic etching of <100> silicon has been a key process in common MEMS based technologies for realizing 3-D structures. These structures include V-grooves for transistors, small holes for ink jets and diaphragms for MEMS pressure sensors. The actual reaction mechanism has not been well understood and comprehensive physical and chemical models for the process have not yet been developed. With increasing numbers of MEMS applications, interest has grown in recent years for process modelling, simulation, and software tools useful for the prediction of etched surface profiles [1-4]. Utilizing near infrared spectrometry (NIR) technology allows TMAH/KOH concentration to be controlled effectively while monitoring the silicate concentration within the bath during the silicon etching process. This technique allows for higher uniformity and longer continuous etching times without interrupting the wafer process within the tank. While maintaining the Si concentration, the system will partially drain the tank bath mixture and replenish it with fresh chemical of each component at the desired concentration [5]. This was effective to a specific number of wafers to be processed in one lot batches, however with this new application the number of wafers processed per lot has been increased two-fold. In the present study, controlling the production of the H_2 byproduct from the etching reaction with TMAH/KOH while monitoring the bath concentration increases the overall throughput. The chemical solution travels through a new application which allows the hydrogen gas to be released from the solution and transferred to the top of the tank effectively removing from the solution. The now H_2 gas removed solution then re-enters the tank, with minimal H_2 in the solution, removing the chances of any contamination blocking the Si wafer and decreasing the uniformity or etching. The results show that the number of wafers per lot have been increased via controlled chemical replenishment while mitigating the hydrogen gas by-product. With this new application the process can run higher throughput, even with long etch processing times for Si.

Energy Efficient Computing and Memory-Storage Devices Stuart Parkin; Max Planck Institute of Microstructure Physics, Germany

Energy efficient computing and memory-storage devices are key to further increases in high performance computing that is essential to today's data centric world. We discuss, on the one hand, Magnetic Racetrack Memory[1, 2] that promises a high capacity, high performance, non-volatile, memory-storage device that could supplant magnetic disk drives and solid-state FLASH, and, on the other hand an extremely energy-efficient memcapacitor device[3] that could allow for massive neuromorphic computing systems.

Late News: Recyclate-Based Additive Manufacturing for Functional Materials in Green ICT Sebastian Klemenz[1], Jürgen Gassmann[1] and Anke Weidenkaff[1,2]; [1]Fraunhofer-Einrichtung für Wertstoffkreisläufe und Ressourcenstrategie IWKS Hanau, Germany; [2]Technische Universität Darmstadt, Germany

The future in functional materials manufacturing has to have the challenge of resource criticality in mind. Ways to address this issue include providing resource efficient material manufacturing methods (e.g. additive manufacturing of functional materials) and reducing the use of critical materials by providing alternative materials or resources such as efficient recycling processes. While additive manufacturing has advantages to more energy demanding and waste producing methods, this method has to be adjusted for the use of sustainable printing materials and the production of functional materials for sustainable technologies such as green ICT. This would reduce not only the energy demand of ICT systems, but also increase their materials sustainability. Our activities on recyclate-based additive manufacturing is based on materials flow analysis and electronic waste recycling. The goal is a versatile process for recyclate powder production to provide sustainable printing materials for additive manufacturing of functional materials in high-tech technologies. We present our plan for the close connection of efficient recycling and powder production techniques, our technical capability at Fraunhofer IWKS and give an overview of the research questions we are working on.

2:15 PM EN01.06.05
Late News: Advancing Green Resilient Materials for Sustainable Housing Alexis Smith and Lilian P. Davila; University of California, Merced, United States

Researchers have been using different approaches to address challenges in the fabrication of sustainable building materials such as reproducibility, reliability, and using renewable materials while preserving properties. Despite these efforts, there are still fundamental limitations in the current fabrication methods of such materials. To solve those challenges, investigators have been studying recently wood-based insulating material, in combination with

ceramic binding agents, to create novel green materials for housing applications. This new material can lead to fully capable load-bearing house components (e.g. wall systems) with high-insulation high-strength properties, where burning is not required in the molding process of the sample preparation. In this study, we have investigated the properties and ecological traits of the new green material by calculating composition-dependent properties and life-cycle assessment (LCA) via physics-based modeling. Using eco-audit data and materials design software, we have conducted systematic analyses of several housing siding samples and evaluated traits including mechanical properties, price, energy, and CO_2 footprint. We evaluated the role of material composition, binder type, and the environmental impact of potential house sidings made of cedarwood, fiber cement, pine-magnesia, and flame block-oriented strand board (OSB). Results indicate the most impactful material for house sidings is Flame block OSB. The effect of resins (painting, enamel baked coating, polymer powder coating) was also evaluated and LCA results show that OSB with polymer powder coating is the least eco-friendly in the manufacturing stage. The hypothesis is that by modifying the siding's composition and binder type, the impact on the environment could be further decreased. Overall results from this study were found to be in good agreement with recent experiments reported elsewhere independently, and mechanical properties together with LCA data of the new green material are significant in determining sustainable alternatives compared to other counterparts. This research contributes to improving material discovery by the combination of design, predictive modeling, and LCA evaluation which allows researchers to determine the technical and commercial feasibility of new sustainable house components.

Steep-Slope Transistors with Subthreshold Swing < 10 mV/dec Using Organic Memory Devices, Threshold Switching Devices and Schottky Diodes Jamal Aziz, Honggyun Kim, Shania Rehman and Deok-kee Kim; Sejong University, Korea (the Republic of)

With the rapid development of transparent integrated circuits, the requirement of transistors with lower subthreshold swing (SS) is becoming necessary. Here, we fabricate three device structures showing abrupt switching and make their series connection with conventional field effect transistors (FET) to lower the SS value. Firstly, we demonstrate an environmentally friendly, disposable, and transparent conductive bridge random access memory (CBRAM) device, composed of 99.3 vol.% nanocellulose fiber. Our CBRAM consists of silver (Ag) electrochemically active electrode and nanocellulose fiber (ca. 15 nm) based switching layer on FTO coated glass substrates. Devices with CBRAM can enable the FET with lowest SS slope by switching the metallic filament between ON and OFF. Niobium oxide (NbO_2) based threshold switching devices and zinc oxide (ZnO) based transparent and flexible Schottky diodes with electrical breakdown were also stacked with FET giving the SS < 10 mV/dec. Comparatively, the transistor plus CBRAM stack can significantly improve the SS slope with lowest leakage current compared to the other series stack, showing the great potential to boost the development of the future generation workhorse transistors.

8:15 AM EN01.07.02
Late News: Novel Stabilization Mechanism on Polar Oxide Surface Jinho Byun[1], Zhipeng Wang[2], Sangho Oh[2] and Jaekwang Lee[1]; [1]Pusan National University, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of)

The stability of polar oxide surfaces has long been an interesting topic in surface science. Since the electrostatic potential diverges with increasing polar oxide thickness, various screening processes involve such as surface reconstruction, charge transfer, and adsorption of foreign charged species. Here, combining the density functional theory calculations and molecular dynamic simulations, we report that the vicinal surface steps can completely stabilize the polar oxide surface without introducing defects and excess charge. The evolution of steps at the vicinal surface, and resulting stabilized polar surface will be discussed and associated underlying mechanism will be introduced along with atomic-scale scanning transmission electron microscopy images.

8:30 AM EN01.07.03
Late News: On the Origin of the Dark Current and Its Relationship with the Electronic Noise Current in Organic Photodiodes Canek Fuentes[1,2], Wen-Fang Chou[2] and Bernard Kippelen[2]; [1]Northeastern University, United States; [2]Georgia Institute of Technology, United States

Organic photodiodes (OPDs) are expected to play an important role in the development of sustainable electronics since they can be used for photovoltaic or photodetector applications and be fabricated in biodegradable susbtrates, such as those based on nanocellulosic materials, and be easily recycled [1]. To optimize the properties of organic semiconductors used in such devices for photodetector applications, it is critical to develop an improved understanding of the electronic noise characteristics of OPDs. In the dark, the electronic noise current of a photodetector such as an OPD determines the lowest detectable optical power [2]. Yet the physical origin of the electronic noise current and its relationship with the dark current measured in steady state is rarely studied through direct measurements and consequently remains poorly understood [2,3,4].
Using detailed temperature- and optical power-dependent studies of the electrical characteristics of OPDs, we demonstrate that grounded in thermodynamic principles, the steady-state optoelectronic properties of OPDs can be described using an equivalent circuit approach to derive the reverse saturation current, ideality factor and shunt resistance values as a function of temperature.
These detailed studies reveal that the reverse saturation current is thermally activated with a barrier height that is equal to the transport bandgap divided by the ideality factor. The value of the ideality factor is well-approximated as the inverse of the recombination order of the limiting recombination process in the dark, yielding a value between 1 and 2 for most common recombination mechanisms, such as band-to-band recombination and trap-assisted recombination, either through mid-gap states or through an exponential trap distribution (Urbach tail).
Derivation of these parameters and its thermal dependence enables an accurate description of the current density in OPDs in the dark as a function of voltage and temperature and under illumination conditions varying over nine orders of magnitude. Furthermore, thermodynamically consistent expressions for the shot and thermal noise contributions using the reverse saturation current and shunt resistance values derived experimentally, are used to estimate the white noise electronic noise current. This analysis shows that at the low measurement bandwidth values typically used to characterize OPDs, the electronic noise is limited by flicker noise even in OPDs showing electronic noise current values in the tens of femtoampere. Critically, we show that the electronic noise at low measurement bandwidth values does not scale with the steady-state dark current density, as it is often assumed in the literature.
These findings, have important implications for the accurate characterization of OPDs, but also, reveal the critical role that trap-assisted charge recombination and the width of the transport bandwidth play in determining their steady-state dark current characteristics. Although these material properties play a critical role in determining the magnitude of the white noise, our results suggest that they may play a secondary role in determining the magnitude of the electronic noise in OPDs at low measurement bandwidth values.

Late News: Tellurium Oxide as a Back-Contact Layer for Long Lasting CdTe Solar Cells Camden Kasik, Ramesh Pandey and James Sites; Colorado State University, United States

The formation of a passivating and selective back contact is necessary for constructing CdTe solar cells with an open circuit voltage greater than 1 volt. Recombination at the back surface and a large back-contact barrier are widely recognized as major problems limiting CdTe solar-cell performance. Other solar cell technologies have demonstrated the use of metal oxides to help passivate the back contact. We explore the use of tellurium oxide as a passivating buffer layer to improve device performance. In these experiments we study the effect tellurium oxide's () thickness, treatment, and process gas composition have on device performance. The large bandgap of also has implications for electron reflectors, to reduce recombination at the surface, and bifacial applications. The effects of on device performance are characterized by current-voltage and quantum-efficiency measurements, showing efficiencies and open-circuit voltages up to 17.5% and 849 mV. Admittance and capacitance voltage measurements are used to study the depletion width and carrier concentration, while time resolved photoluminescence measurements are used to explore the effects on recombination. We found cells with carrier densities up to 1e15 carriers per cubic centimeter and carrier lifetimes up to 160 ns. Our results demonstrate the viability of as a buffer layer to improve passivation and performance in CdTe solar cells. An added benefit of is the ability to utilize an undoped absorber, which is crucial to reduce degradation in CdTe solar cells.

9:00 AM EN01.07.05
One-Pot Synthesis of Nitrogen-Doped Hierarchical Porous Carbon Using Combustion Waves for High-Performance Supercapacitor Electrodes Seonghyun Park, Seo Byungseok and Wonjoon Choi; Korea University, Korea (the Republic of)

Supercapacitors have attracted tremendous interests due to their long-term stability and high power density derived from fast charge/discharge rate. Among them, heteroatom-doped porous carbon materials have been extensively explored and synthesized for industrial applications. However, their complex and time-consuming synthesis routes impede scalable fabrication. Herein, we report a facile one-pot synthesis strategy of nitrogen-doped hierarchical porous carbon void shell (N-HPCVS) using combustion waves. Free-standing films were prepared by mixing recrystallized sodium chloride particles with collodion, which is a nitrocellulose solution, where the particles and the nitrocellulose could act as templates and fuel covering the precursors, respectively. When a heat source, enabled by a joule-heated nichrome wire applied to the film, the combustion wave appeared as an instant thermochemical processing and propagated along the whole film within ten seconds. Owing to the rapid combustion waves involving the functional reaction of the NaCl particles, which could manipulate the thermodynamic transition, the incomplete combustion naturally occurred, and the carbon residue around the templates remained as resulting materials. Since the nitrocellulose comprises cellulose with nitro-group, the remaining carbon spontaneously includes nitrogen dopants. Through simple rinsing with DI water, the NaCl templates were removed and N-HPCVS were finally obtained. Owing to the thermal decomposition of NaCl templates and sudden evaporation of gases during the propagation of combustion waves, the hierarchical porous structure of N-HPVCS comprising of macro and meso-/micro-pores was completed.. Furthermore, the tunable physicochemical characteristics of N-HPVCS could be achieved by only optimizing initial fuel loading. Based on screening the processing conditions of combustion waves, the properly adjusted N-HPCVS30 which was prepared with 500 mg of NaCl and 30 g of collodion, exhibited outstanding specific capacitance (305 F/g at 0.5 A/g) and long-term cycling stability (116% retained after 10,000 cycles). Furthermore, the symmetric two-electrode cell employing the N-HPVCS presented remarkable power and energy density (25 kW/kg and 18.8 Wh/kg), as well as long-term cycling retention (98.25 % after 10,000 cycles). The rational fabrication strategy of N-doped hierarchical porous carbon using the combustion waves will inspire fascinating hybrid electrodes and catalysts which cannot be achieved through conventional synthesis methods.

9:15 AM EN01.07.06
Defect Formation Energies and Charge Transition Levels of Gold-Related Defects in Silicon via Semilocal and Hybrid Density Functional Theory Naheed Ferdous; University of Illinois at Urbana-Champaign, United States

Reconciling results from conventional and hybrid density functional theory is important to establish the level of accuracy achievable and best practices in first-principles simulations of defects in semiconductors. We present a case study to assess the extent to which calculations performed with (i) Perdew, Burke, and Ernzerhof (PBE) combined with systematic band edge shifts and (ii) Heyd, Scuseria, and Ernzerhof hybrid HSE06 can reproduce experimental results for gold-related defects in silicon. Substitutional Au_{Si}, substitutional dimers Au_{Si}--Au_{Si}, and tetrahedral interstitials Au_i are considered in detail.

***Ab Initio* Study of Structural, Electronic and Optical Properties of $Cu_2NiSnSe_4$** J. El Hamdaoui[1], L. M. Pérez[2], D. Laroze[2], M. EL- Yadri[1], El Mustapha Feddi[1] and Gen Long[3]; [1]Mohammed V University in Rabat, Morocco; [2]Universidad de Tarapacá, Chile; [3]Saint John's University, United States

In this manuscript, we report a recent investigation of the structural, electronic and optical properties of the new quaternary chalcogenide $Cu_2NiSnSe_4$ (CNTSe). Our calculations were done using the first principle approach. We have employed the full-potential linearized augmented plan-wave (FP-LAPW) method implemented in wien2k code. To treat the exchange and correlation effect of our numerical calculations we used the Tran-Blaha modified Becke-Johnson potential combined
with the Hubbard potential U (mBJ+U). Our numerical calculations showed that CNTSe exhibit high absorption and direct bandgap. We also determined the real and imaginary parts of the dielectric function, the reflectivity, and the refraction index.

Synthesis and Characterization of Biomass-Derived Charge-Transfer Salts Using Asymmetric Donor Molecules with Tetrathiafulvalene

Structure Masaru Ide[1], Eiji Masai[2], Yuichiro Otsuka[3], Masaya Nakamura[3] and Hironori Ogata[1]; [1]Hosei University, Japan; [2]Nagaoka University of Technology, Japan; [3]Forest Research and Management Organization, Japan

Lignin, which is contained in woody biomass at 20 to 30%, is a polymer with a three-dimensional network structure in which complex aromatic molecules are bonded. It was abandoned. If useful applications can be established by converting lignin into high value-added organic materials, it can be expected to greatly contribute to the formation of a recycling society. In 2006, a technology for producing 2-pyrone-4,6-dicarboxylic acid (PDC), which is an intermediate metabolite of lignin, was developed using the lignin metabolism system of the bacterial SYK-6. Focusing on the high electron acceptability of PDCs, we have developed various charge transfer salts based on PDCs and investigated their structures and electrical properties. Therefore, we have focused on tetrathiafulvalene(TTF) derivatives as electron donors, and have synthesized charge-transfer salts with PDC using these molecules by electrolytic method and clarified their various physical properties.
In this study, we expanded our research to asymmetric electron donors with the TTF molecular framework. we have synthesized the several kinds of charge-transfer salts with asymmetric TTF derivatives by taking advantage of the low crystallinity based on the asymmetry.
In this study, we report the results of systematic investigation of these crystal morphologies, crystal structures, electronic properties and magnetic properties, as well as the differences in structure and properties of charge-transfer salts with symmetric TTF derivatives.

Towards Circular Economy in Electro Mobility Oliver Gutfleisch[1,2], Jürgen Gassmann[1], Mario Schönfeldt[1], Konrad Opelt[2], Eva Brouwer[1], Oliver Diehl[1], Urban Rohrmann[1], Jörg Zimmermann[1] and Anke Weidenkaff[1,2]; [1]Fraunhofer-Einrichtung IWKS, Germany; [2]Technische Universität Darmstadt, Germany

The current transformation in the mobility sector is accompanied by a change in the materials needed for the new key components. Rechargeable batteries are one imperative in electro mobility. The same holds for their usage in mobile devices, power tools and stationary energy storage devices. Equally important for electro mobility, but also for the other named devices, are the high performance permanent magnets, which are used in motors with the highest efficiency, lowest weight and volume. Every battery in a modern electric vehicle needs a magnet; the more efficient the magnet the less battery is needed, the longer the driving range. Batteries as well as motors contain valuable and resource critical metals elements such as neodymium, dysprosium, cobalt, lithium, and copper. The mining of these elements is intense in energy and chemical consumption. Furthermore, they also contain substances that would endanger our environment and health if disposed of improperly. Effective recycling of end-of life products is therefore of great relevance from both an economic and an ecologic point of view. Using the technosphere will also yield some leverage from the monopolistic supply situation for primary strategic metals.

We will highlight first in this talk the *Center for Dismantling and Recycling for Electromobility*, which is build up at Fraunhofer IWKS in Hanau. Here, the robot assisted dismantling and recycling of key components of electric vehicles like batteries, fuel cells, electric motors and power electronics are in the focus. For traction motors in electric vehicles, permanent magnets based on rare earth elements (REE) like Nd-Fe-B and Sm-Co are used due to their outstanding magnetic performance in a wide temperature range. The global demand for REE will increase drastically in the near future. To meet this demand and to secure the supply for other magnet applications several recycling techniques for permanent magnets are highlighted. The recycled magnets show a low environmental footprint and compete well with those made from primary materials in terms of magnetic properties and cost.

In a second part, we will focus on secondary properties of permanent magnets. The driving force for R&D has been the demand for superior primary magnetic properties. Now, the increasing number of applications using Nd-Fe-B permanent magnets in more severe conditions leads to extended requirements for the magnets. In fly wheel energy storages or electric motors for example, high rotational speeds are used. The resulting high forces on the magnets and can lead to a magnet failure due to the high intrinsic brittleness of Nd-Fe-B intermetallic compound. Concepts for Nd-Fe-B based magnets with high fracture strength are introduced.

11:20 AM *EN01.08.04
Achieving a Circular Economy Bill Tumas, David S. Ginley and Nancy Haegel; National Renewable Energy Laboratory, United States

Based on a definition of the MacArthur Foundation a circular economy is “Looking beyond the current take-make-waste extractive industrial model, a circular economy aims to redefine growth, focusing on positive society-wide benefits. It entails gradually decoupling economic activity from the consumption of finite resources, and designing waste out of the system. Underpinned by a transition to renewable energy sources, the circular model builds economic, natural, and social capital. It is based on three principles:
Design out waste and pollution
Keep products and materials in use
Regenerate natural systems”
NREL has initated a comprehensive program to examine a number of supply chains from raw materials to end of life and recycling. Key observations are that you can design even complicated systems to have nearly zero environmental impact and lead to true sustainability. An important element of this is to develop materials systems that are not only reusable but are also self healing and self restoring. A true circular economy incorporated te concepts of increased use of renewable electrons for many processes and improved approaches to grid and storage utilization.
We will discuss practical examples of this approach including: approaches to solar energy conversion with earth abundant non-toxic elements, lifecycle extension of materials in PV, Wind, and energy storage. A key element of a long term strategy can be illustrated in the polymer and composites area where materials are designed for easy end of life reuse and where self-healing materials can extent initial lifetimes substantially. This is especially true as we move to the “electrification of everything”. We will discuss new approaches to materials design for longevity, self healing and ultimate recycling where these approaches are ultimately enabling for a true circular economy.

Modeling of the Potential Distribution and the Electrical Double Layer in Solid-State Batteries Yue Qi[1,2], Michael Swift[2,3], Harsh D. Jagad[1] and James W. Swift[4]; [1]Brown University, United States; [2]Michigan State University, United States; [3]US Naval Research Laboratory, United States; [4]Northern Arizona University, United States

The electrical double layer (EDL) is a key feature of all electrochemical interfaces, controlling the kinetics and thermodynamics of both electron transfer and ion transfer reactions, and therefore the performance of solid-state batteries (SSB). Unlike in a liquid electrolyte with an EDL made of solvated ions, the EDL in a solid electrolyte is made up of charged point defects. Thus, the well-known Poisson-Boltzmann equation at electrode/liquid-electrolyte interfaces no longer holds in SSBs. This problem is even more challenging, as ion insertion and/or reaction with the electrode alters the material and thus band alignments at the electrode/solid-electrolyte interfaces.
In this talk, a density functional theory (DFT)-informed theoretical framework was established to predict the interface potential profiles. We first assumed the electrochemical potential for Li^+ ions reached a constant at the open circuit equilibrium condition, then derived the relationship among the electrostatic potential, the lithium chemical potential, Fermi level, ionization potential, and the work function. This relationship yielded quantitative profiles of the electrostatic potential and electronic energy level alignments across the entire solid-state batteries. It was predicted the electrostatic potential inside the solid electrolyte can be either flat or sloped due to the point defect chemistry in the different solid electrolyte materials. The electrostatic potential jump at the electrode/electrolyte interface creates intrinsic barriers for Li^+ transport across the interface. The model prediction over a range of solid-state battery systems can be used to explain multiple experimental impedance observations at solid-electrolyte/cathode interfaces. To obtain the electrostatic potential variation as a function of the distance to the interface, a more general model for the EDL at a solid-state electrochemical interface based on the Poisson-Fermi-Dirac equation was developed. The EDL structure is presented in various materials that are thermodynamically stable in contact with a lithium metal anode. The model further allows designing the optimum interlayer thicknesses to stabilize the interface without introducing additional electrostatic barriers for lithium ion transport at relevant solid-state battery interfaces.

11:00 AM EN02.01.02
Compressive Stress in Solid–State Electrolyte by Ion Implantation—A Molecular Dynamics Case Study for LLZO Harsh D. Jagad[1], Stephen J. Harris[2], Chunmei Ban[3] and Yue Qi[1]; [1]Brown University, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]University of Colorado Boulder, United States

Cracks and Fracture in solid state electrolytes such as LLZO enables Li dendrites to penetrate in the form of dendrites. These dendrites pierce through the solid-state electrolyte and eventually cause an electrical short between the anode and the cathode. One method to slow down this process is to increase the fracture resistance of the glass / ceramic type solid electrolyte via ion exchange, where, for example, large iso-valent cation exchanges with a primary cation in the glass thus increasing the residual compressive stress, and hence increasing its toughness. This technique is used commercially, for example, to make crack-resistant glass for cell phones (Gorilla Glass) where Na+ ions in the glass are exchanged with larger iso-valent K+ ions. In this work we use quantum calculations combined with molecular dynamics modelling to explore the residual stress situation for the case when Li+ ions are exchanged with the larger K+ ions in LLZO. Increasing the fraction of Li+ ions exchanged increases the residual compressive stress. Unfortunately, if too many Li+ are exchanged, the Li+ conductivity is reduced. Another concern is the diffusion of K should be negligible compared to Li, thus ensuring that the compressive zone remains stable. We explore how to optimize these tradeoffs in order to make a solid-state electrolyte that has both high resistance to fracture and high Li+ ion conductivity.

11:15 AM EN02.01.03
Modeling of the Effects of Interface and Compressive Stress in Maintaining a Flat Li Surface During the Stripping Process Min Feng[1], Chi-Ta Yang[2] and Yue Qi[1]; [1]Brown University, United States; [2]Michigan State University, United States

The Li metal is a good candidate for the anode in the solid-state batteries due to its high specific capacity (3860 mAh/g), but the Li dendrites formed due to nonuniform Li deposition usually cause short-circuiting, impeding the commercial application of the Li metal-based solid-state batteries. The non-uniform Li deposition is the result of an uneven distribution of current density on the inhomogeneous Li surface, where Li atoms tend to deposit on the surface protrusions and further promote the dendrite growth. Since the stripping process generates vacancies when removing Li, which may accumulate as voids and lead to uneven distribution of current density and dendrite growth, understanding how vacancies evolve near the Li/solid electrolyte (SE) interface is critical to help maintain a smooth Li surface during the stripping process and contribute to a uniform Li deposition in subsequent cycling.

In this work, a density functional theory (DFT) - kinetic Monte Carlo (KMC) multiscale simulation scheme is developed to simulate the Li vacancy evolution at two representative interfaces: Li/LiF (lithiophobic) and Li/Li_2O (lithiophilic). As the compressive stress is usually applied during the battery operation, the stress induced Li creep effects are considered given the low melting point of Li. Specifically, the DFT calculations are utilized to get the optimized atomic interface structure, calculate the Li vacancy formation energy and the Li forward (towards the interface) and backward (towards the bulk) hopping barriers. The KMC simulation is then used to simulate the evolution of Li vacancies near the interface by taking various Li hopping rates based on the DFT as inputs. To incorporate the creep behavior under a mechanical bias (E_p) into the hopping events, the DFT-calculated forward (backward) hopping barrier is decreased (increased) by half of E_p, which leads to a net Li flux rate corresponding to the creep strain rate imposed by the compressive stress (σ) on a given Li foil thickness (L).
It was found that at room temperature, without the creep effects, few vacancies at the Li/LiF interface migrate to the bulk Li, while at the Li/Li_2O interface, vacancies submerge into the bulk quickly. When the creep effect is considered, although vacancies at the Li/Li_2O interface more readily travel into deeper regions in the bulk Li, a large portion of vacancies at the Li/LiF interface migrate into the bulk as well. Thus, the interfacial properties (lithiophilic or lithiophobic) determine the vacancy hopping behavior with no creep effects but have weaker impacts on the vacancy evolution under compressive stress. Over the typical range of the product of L and strain rate in Li metal batteries spanning over 6 orders of magnitude, vacancies in Li/LiF can always form a uniform distribution in the Li metal and show little dependence on L×strain rate values, suggesting the importance of applying the compressive stress during Li stripping.

11:30 AM EN02.01.04
Guiding Principles to Find Fast Li-Ion Conductors KyuJung Jun[1], Yan E. Wang[2], Yihan Xiao[1] and Gerbrand Ceder[1]; [1]University of California, Berkeley, United States; [2]Samsung Research America, United States

Solids with high lithium-ion conductivity are of great importance for the realization of solid-state batteries. So far thiophosphates have been reported to exhibit the highest lithium ionic conductivity. However, they pose several intrinsic problems such as their narrow thermodynamic window[2] and H_2S gas evolution from the oxidation of the sulfide solid electrolyte.[3] This has led to a shift of interest towards oxide superionic conductors. The discovery of novel fast Li-ion conductors within an oxide anion framework has been challenging due to the less effective screening of cation interactions by the oxygen anions.[4] Most of the work so far has been limited to the compositional and structural modification within the frameworks of the known superionic conductors such as garnet[5] or the lithium analogue of the Na-superionic conductors (NASICON).[6]

In this talk, we will discuss our recent findings on the relation between the topology of the crystal structure and fast Li-ion transport by utilizing first principles modeling based on density functional theory. We find that there are well-defined features of crystal structures that promote fast Li-ion conduction. In some cases, these crystallographic features provide a highly distorted lithium environment which reduces the barrier for Li hopping by several hundreds of meVs. Using these features we performed high-throughput ab-initio molecular dynamics on the Materials Project database to search for novel oxide superionic conductors and discover 10 novel oxide frameworks that are predicted to exhibit high ionic conductivity exceeding 0.1 mS/cm at room temperature. This study provides new insights on the structural origin of fast diffusion in oxide superionic conductors and can be applied as a general guideline to discover novel frameworks that can be designed to enable fast lithium diffusion.

Thermodynamic Modeling of Cycling-Induced Damage in Lithium-Ion Battery Fuqian Yang; Univ of Kentucky, United States

One of the obstacles hindering the development of lithium-ion battery of high quality is the cycling-induced structural damage/degradation, which contributes to the capacity fade. In this work, we bring out the important role of the structural damage/degradation in the deformation analysis of active material in lithium-ion battery during charging and discharging. Following the approach in damage mechanics, we introduce a scalar state variable in thermodynamic potentials to describe the evolution of the structural damage/degradation. The scalar state variable is dependent on chemical reaction, enthalpy change, dilatation and strain energy during electrochemical cycling. A constitutive relation is developed, in which the elastic properties and the molar volume of the active material are implicit functions of the scalar state variable. Using the constitutive relation, we incorporate the lithiation-induced damage in the analysis of the lithiation-induced deflection of an electrode beam. The numerical results show the relaxation of the lithiation-bending moment induced by the lithiation-induced damage. The method developed in this work provides an approach to incorporate cycling-induced structural damage/damage in the deformation analysis of lithium-ion battery.

SESSION EN02.02: Solid Electrolytes I
Session Chairs: Fudong Han and Yue Qi
Tuesday Afternoon, November 30, 2021
Hynes, Level 3, Ballroom C

1:30 PM *EN02.02.01
Computational Materials Design for Solid-State Li and Na Ionic Conductors Yan E. Wang[1,2]; [1]Samsung Advanced Institute of Technology, United States; [2]Samsung Semiconductor, Inc., United States

Solid-state batteries have attracted tremendous academic and industrial attention as the likely successor to lithium ion batteries. The key component of solid-state batteries is the solid-state electrolytes with high ionic conductivity [1] and great interfacial stability against battery electrodes [2]. While many sulfide and halide ionic conductors are reported with high conductivity, the chemical instability in the air of these materials inhibits their practical usage in batteries. Due to their stability and non-toxicity, oxides are the preferred choice for solid-electrolyte materials, but only a handful of oxide Li-ion conductors have been experimentally discovered with high conductivity.

Computational modeling based on density-functional-theory methods has been used to accurately predict the intrinsic properties of solid electrolyte materials. Such predictive power has made computational modeling a critical tool to efficiently design and discover new materials with desired properties, such as low cost, high ionic conductivity, great phase and electrochemical stability, accelerating the development of all-solid-state batteries [3].

In this talk, I will present our new discoveries in the physical and chemical design principles for solid-state electrolyte materials using computational modeling. More specifically, I will discuss crystallographic descriptors in solid-state ionic conductors which would enable fast ionic transport. I will report our recent progress in using high-throughput screening for computational design and experimental discovery of novel lithium and sodium solid-state electrolytes.

2:00 PM EN02.02.03
Rate-Dependent Deformation in Amorphous Sulfide Glass Electrolytes Christos E. Athanasiou[1], Xing Liu[1], Eugene Nimon[2], Steve Visco[2], Nitin P. Padture[1], Huajian Gao[3] and Brian W. Sheldon[1]; [1]Brown University, United States; [2]Polyplus Battery Company, United States; [3]Nanyang Technological University, Singapore

Amorphous sulfide electrolytes exhibit exceptionally high Li-ion conductivity near room temperature. A key concern, however, is their mechanical stability in the presence of strains in the adjacent electrode materials accompanying reversible Li storage. Detailed understanding of elastoplastic and fracture properties is lacking, mainly due to the difficulties associated with characterizing such highly moist-sensitive materials. In this talk, we will present our experimental results showing that the mechanical behavior of amorphous sulfide electrolytes is rate-dependent, i.e., they exhibit viscous characteristics when undergoing deformation. We will further demonstrate through careful instrumented indentation experiments, that the material behaves in a viscoplastic manner at short timescales of ~ 1 min. Finally, we will discuss the implications of these findings for understanding and improving the contact of the sulfide electrolytes with Li-metal anodes.

2:15 PM EN02.02.04
Temperature Dependent Anion Rotational Dynamics Correlated to Cation Transport in Cluster Ion Anti-Perovskites Sunil Mair[1], Ping-Chun Tsai[2,1], Yiliang Li[1], Kwangnam Kim[3], Alex Chien[4], Jeffrey Smith[3], David Halat[5], Liang Yin[6], Duhan Zhang[1], Jue Liu[4], Saul Lapidus[6], Nitash Balsara[5], Jeffrey Reimer[5], Donald Siegel[3] and Yet-Ming Chiang[1]; [1]Massachusetts Institute of Technology, United States; [2]National Taiwan University of Science and Technology, Taiwan; [3]University of Michigan–Ann Arbor, United States; [4]Oak Ridge National Laboratory, United States; [5]Lawrence Berkeley National Laboratory, United States; [6]Argonne National Laboratory, United States

As fast-ion conductors, cluster-ion anti-perovskites (APs) are attractive for potential new mechanisms of conduction whereby cation and anion motion is highly correlated [1, 2]. Cluster-ion APs, like perovskites, have a framework that accommodates diverse atomic substitutions. Furthermore, the potential for cluster-ion substitution onto one or both anion sites (A and B in X_3AB) provides additional compositional degrees of freedom. We have synthesized and characterized a series of compositions $Na_{3-x}(NH_2)_xO_{1-x}(BH_4)$, a unique sodium ion conductor with two chemically distinct cluster anions, in order to further understand the correlation between anion rotation and cation translation. We are particularly interested in the x = 1 composition which shows a significant positive deviation from conductivity trends as predicted by a vacancy diffusion model. This presentation will discuss the synthesis and characterization of $Na_2(NH_2)(BH_4)$ via XRD, neutron diffraction, NMR, and AIMD, aimed at understanding the temperature dependent rotational dynamics of the cluster anions and their effects on cation transport.

This work was supported as part of the Joint Center for Energy Storage Research, an Energy Innovation Hub funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences.

2:30 PM EN02.02.05
Polymorphism in the Solid Electrolyte $Na_4P_2S_6$: Phase Formation through Synthetic Control and Superionic Sodium-Ion Conduction Christian Schneider[1], Tanja Scholz[1], Maxwell W. Terban[1], Zeyu Deng[2], Roland Eger[1], Viola Duppel[1], Igor Moudrakovski[1], Armin Schulz[1], Jürgen Nuss[1], Pieremanuele Canepa[2] and Bettina V. Lotsch[1,3]; [1]Max Planck Institute for Solid State Research, Germany; [2]National University of Singapore, Singapore; [3]Ludwig Maximilian University, Germany

The search for fast new sodium-ion solid electrolytes remains intense to eventually realize all-solid-state sodium batteries for scalable energy storage solutions in the future. In the pursuit of extraordinary performing electrolytes, candidate materials are currently often designed from scratch while drawing on chemical intuition to improve the ionic conductivity.
For the sodium hexathiohypodiphosphate $Na_4P_2S_6$ a complementary strategy will be showcased, namely, how synthetic control and post-synthetic treatment impact this material's properties, even though structural differences are minute.[1] Two different synthesis methods are compared: a solid-state reaction[2] and a precipitation route from aqueous solution[3]. Combined investigations using powder X-ray diffraction (PXRD), precession electron diffraction (PED), differential scanning calorimetry (DSC), solid-state nuclear magnetic resonance spectroscopy (ssNMR), and Raman spectroscopy reveal that the solid-state synthesized material is characterized by a Na^+ and vacancy disorder-driven enantiotropic phase transition at 160 °C (α- to β-$Na_4P_2S_6$), which is accompanied by a symmetry change of the $P_2S_6^{4-}$ anion. Precipitated $Na_4P_2S_6$ already crystallizes in a β-like polymorph at room temperature, likely assisted by inter- and intralayer defects. Bond-valence and nudged elastic band (NEB) calculations are employed to identify a low energy, 2D conduction network in β-$Na_4P_2S_6$, suggesting facile 2D long-range Na^+ diffusion. Electrochemical impedance spectroscopy reveals a higher ionic conductivity at room temperature in precipitated β-like $Na_4P_2S_6$ (2×10^{-6} S cm^{-1}) compared to the solid-state α polymorph (7×10^{-7} S cm^{-1}). The activation energy is around 0.4 eV for both materials.
Independent of the synthetic protocol, $Na_4P_2S_6$ exhibits another high-temperature polymorph (γ). A structural analysis spanning local and long-range length scales enables the elucidation of the complex structure. The anion and cation arrangement facilitates 3D superionic Na^+ conduction, which we confirm with *ab initio* molecular dynamic (MD) simulations.

Scalable LLZO Solid Electrolyte Processing for Solid-State Batteries Arno L. Görne, Juliane Hüttl, Martin Drüe, Michael Arnold, Kristian Nikolowski and Mareike Wolter; Fraunhofer Institute for Ceramic Technologies and Systems (IKTS), Germany

The substitution of liquid electrolytes with solid ionic conductors is a promising strategy for a new generation of safer batteries with higher energy densities. In terms of developing components for All Solid-State Batteries, plenty of research focused on optimization of solid electrolyte properties. Garnet materials, especially doped $Li_7La_3Zr_2O_{12}$ (LLZO), are considered a very promising class of solid electrolytes due to their high lithium-ion conductivity in the range of 10^{-4} S/cm[1,2], as well as their compatibility with metallic lithium as anode. Recently, the combination of inorganic electrolytes with conducting polymers to form hybrid materials has also come into focus.[3,4]

Scientific research mainly addresses material properties and characterization, but less manufacturing methods and cell assembly. Fraunhofer IKTS is investigating different scalable manufacturing processes for All Solid-State Batteries[5] in several projects. We have developed a process chain for freestanding LLZO separator sheets with high ion conductivity, and we have started the processing of LLZO inks for rapid printing of electrolytes or as conductive additives. This talk will give an overview about the material's synthesis, slurry preparation, tape casting, lamination, and sintering, as well as ink development and printing. Some of the challenges encountered during the development will be included, too.

The properties of the obtained LLZO were evaluated using XRD, scanning electron microscopy and electrochemical methods, especially impedance spectroscopy. The morphological and electrochemical properties of the cast and sintered LLZO sheets or printed LLZO were compared to sintered pellets of the same powder.

Development of Materials for All-Solid-State Lithium-Sulfur Batteries Donghai Wang; The Pennsylvania State University, United States

All-solid-state Lithium-Sulfur battery technology is the most promising candidate for next-generation batteries due to its high energy density, long cycle life, and superior safety. However, it faces many challenges, such as unstable lithium/solid-state electrolyte (SSE) interface, lithium dendrite penetration, and poor sulfur utilization of the cathode, which hinder its practical application. In this talk, first, I will present a novel approach based on the use of organic-inorganic nanocomposite interphase to construct stable lithium/$Li_{10}GePS_{12}$ (LGPS) interface. The nanocomposite is formed in situ on Li by the electrochemical decomposition of a liquid electrolyte, thus having excellent chemical and electrochemical stability, an affinity for Li and LGPS, and limited interfacial resistance. And stable Li electrodeposition over 200 cycles for a full cell was achieved. Second, a sulfur vapor deposition (SVD) method for fabricating sulfur-carbon composite with a high sulfur content of 71.4-83.3 wt% will be present for all-solid-state lithium-sulfur batteries. By creating better interfacial contact at the carbon-sulfur interface and confining sulfur within porous carbon, the electronic transport within the sulfur cathode is improved. Enhanced discharge specific capacities, rate performance, and cycling stability of sulfur cathode were demonstrated using the SVD method compared with conventional sulfur-carbon preparation approaches. Last, I will present the development of solid-state-electrolyte with high conductivity to significantly enhance sulfur utilization to enable solid-state Li-S to achieve high energy density.

4:30 PM EN02.03.02
4 V Room-Temperature All-Solid-State Sodium Battery Enabled by a Passivating Cathode/Hydroborate Solid Electrolyte Interface Ryo Asakura[1,2], David Reber[1], Léo Duchêne[1], Seyedhosein Payandeh[1], Arndt Remhof[1], Hans R. Hagemann[2] and Corsin Battaglia[1]; [1]Empa-Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]University of Geneva, Switzerland

Room-temperature operation of high-voltage all-solid-state batteries requires solid electrolytes that combine high cation conductivity (≥1 mS cm^{-1}), compatibility with lithium or sodium metal anodes and high-voltage cathodes, and intimate electrode/solid electrolyte interfaces. However, none of the solid electrolytes has fulfilled these material properties so far. Hydroborates, a yet underexplored class of solid electrolytes,[1,2] are highly conductive at room temperature and compatible with lithium and sodium metal anodes. However, the cell voltage was limited up to 3 V in previous reports,[3–6] mainly due to the limited electrochemical oxidative stability of the solid electrolytes.[7]
Here we show that a hydroborate solid electrolyte, consisting of two kinds of hydroborate anions with different oxidative stability limits, can be effectively stabilized in contact with a 4 V-class cathode.[8] At high voltage, the less stable anions tend to form a passivating interphase layer upon electrochemical oxidation at the cathode/solid electrolyte interface, while the more stable anions remain intact in the interphase layer, maintaining cation conduction. The self-passivating interphase enables the first stable cycling of a 4 V-class hydroborate-based all-solid-state battery employing a sodium metal anode and a cobalt-free, high-voltage cathode. The cells exhibit a discharge capacity of 100 mAh g^{-1} at C/5 and an excellent capacity (78 %) and energy (76 %) retention after >800 cycles at room temperature. Applying external pressure enables a discharge capacity of >110 mAh g^{-1} at C/10 with a high areal capacity close to 1.0 mAh cm^{-2}. This work records the highest discharge cell voltage and specific energy at the active material level among all reported all-solid-state sodium batteries, demonstrating the attractive material properties and potential of hydroborates that surpass intensively investigated oxides and

sulfides as solid electrolytes for high-voltage all-solid-state batteries.

Keynote: New Perspectives on Materials Challenges in Li Metal and Solid–State Batteries Y. Shirley Meng; University of California, San Diego, United States

Lithium (Li) metal has been considered as an ideal anode for high-energy rechargeable Li batteries while Li nucleation and growth at the nano scale remains mysterious as to achieving reversible stripping and deposition. A few decades of research have been dedicated to this topic and we have seen breakthroughs in novel electrolytes in the last few years, where the efficiency of lithium deposition is exceeding 99%. Here, cryogenic-transmission electron microscopy (Cryo-TEM/Cryo-FIB) was used to reveal the evolving nanostructure of Li deposits at various transient states in the nucleation and growth process, in which a disorder-order phase transition was observed as a function of current density and deposition time. More importantly, the complementary techniques such as titration gas chromatography (TGC) reveals the important insights about the phase fraction of solid electrolyte interphases (SEI) and electrochemical deposited Li (EDLi). While cryo-EM has made significant contributions to enabling lithium metal anodes for batteries, its applications in the area of solid state electrolytes, thick cathodes are still in its infancy, I hope to showcase how innovative characterization for solid state batteries can be designed to probe buried interphases. Last but not least, I will discuss a few new perspectives about how future cryogenic imaging and spectroscopic techniques can accelerate the innovation of novel energy storage materials and architectures.

Flame Assisted Spray Pyrolysis of $LiAlO_2$ Thin–Film Electrolytes for All-Solid-State Batteries Valerie L. Muldoon, Jianan Zhang and Sili Deng; Massachusetts Institute of Technology, United States

As the demand for lithium-ion batteries with improved safety and energy density increases, all-solid-state batteries (ASSBs) have become a promising option for a wide variety of applications due to the elimination of the flammable liquid electrolyte. In particular, oxide-based solid electrolytes are advantageous because of their exceptional chemical stability against many high voltage cathode materials and lithium metal. However, oxide-based solid electrolytes generally have a lower ionic conductivity than that of liquid electrolytes and sulfide-based solid electrolytes, thereby necessitating the use of a thin, dense film to shorten the ionic diffusion path and ensure a good rate performance. Many current methods used to synthesize oxides produce aggregated powders with wide size distributions and therefore cannot be used to make thin, dense, defect-free films. Furthermore, gas-phase deposition techniques, such as atomic layer deposition, can produce high quality thin films, but are severely limited by their high cost and low production rate. We investigated using flame assisted spray pyrolysis, an inexpensive, scalable method that produces loosely agglomerated nanoparticles with controlled morphology, combined with conventional tape casting to produce thin film solid-state electrolytes. $LiAlO_2$ was specifically chosen as the solid-state electrolyte due to its impressive chemical stability that has recently made it a promising choice for electrode coatings in both conventional batteries and ASSBs. The morphology and ionic conductivity of the as-synthesized $LiAlO_2$ films as well as the cycling performance of a battery with $LiAlO_2$ films, a lithium metal anode, and a $Li(Ni_{0.8}Co_{0.1}Mn_{0.1})O_2$ cathode were characterized and discussed.

EN02.05.04
Fabrication of High-Quality Thin Solid-State Electrolyte Films Assisted by Machine Learning Yu-Ting Chen[1], Marc Duquesnoy[2,3,4], Darren H. S. Tan[1], Jean-Marie Doux[1], Hedi Yang[1], Grayson Deysher[1], Phillip Ridley[1], Alejandro A. Franco[2,3,4], Y. Shirley Meng[1] and Zheng Chen[1]; [1]University of California, San Diego, United States; [2]Laboratoire de Réactivité et Chimie des Solides (LRCS), Université de Picardie Jules Verne UMR CNRS 7314, France; [3]Réseau sur le Stockage Electrochimique de l'Energie (RS2E), France; [4]Alistore-ERI European Research Institute, France

Solid-state electrolytes (SSEs) are promising candidates to circumvent flammability concerns of liquid-based batteries. However, attaining high energy densities requires thinning down SSE layers remains challenging as scalable coating processes are needed. Manufacturing parameters, including binder type, binder ratio, liquid to solid ratio, and cosolvent among others, have a significant influence on the performance of SSE films. While previous studies have reported the fabrication of thin and flexible SSEs, only ionic conductivity was considered for performance evaluation, and no systematic research on the effects of manufacturing conditions on the quality of the SSE films was performed. Here, both uniformity and ionic conductivity are considered for evaluating the SSE films under the guidance of machine learning (ML). Unsupervised ML algorithms, Principal Component Analysis and *k*-

Means clustering, associated to Support Vector Machine, are employed to decipher the interdependencies between manufacturing conditions and film performance. Guided by ML models, an SSE film with a thickness of 40 µm was fabricated and used to construct a $LiNi_{0.8}Co_{0.1}Mn_{0.1}O_2$ || Li_6PS_5Cl || LiIn cell, leveraging its high ionic conductivity and good uniformity to achieve stable cycling performance. This study presents a ML-assisted experimental approach as an efficient strategy to optimize SSE films, paving the way towards mass production of all-solid-state batteries.

EN02.05.05
Improved Ionic Conductivity and Battery Function in a Lithium Iodide Solid Electrolyte via Particle Size Modification Mikaela Dunkin[1], Steven King[1], Kenneth Takeuchi[1,2], Esther S. Takeuchi[1,2], Lei Wang[2] and Amy Marschilok[1,2]; [1]Stony Brook University, United States; [2]Brookhaven National Laboratory, United States

In high energy density batteries, solid electrolytes (SEs) are a safe and promising alternative to liquid electrolytes, but challenges such as low ionic conductivity and dendrite formation, remain. Recent work by others has determined that dendrite formation within $Li_7La_3Zr_2O_{12}$ and Li_3PS_4 SEs is due to their non-negligible electronic conductivity. Thus, research must re-focus its efforts to keep electronic conductivity low. Notably, solid LiI has negligible electronic conductivity, making LiI a good candidate for SE development. In our previous work, we utilized LiI SE with a conductive additive to create a composite SE capable of forming a Li/I_2 rechargeable battery *in situ*. Additional work demonstrated interfacial modification with either lithium or gold contacts, can effectively lower the cell impedance and improve coulombic efficiency (CE).
In this work, a LiI SE was improved by reducing particle size via processing. Several processing methods were examined; grinding (G), sonicating (C-S), and grinding with sonicating (G-S), and compared to a control (C) sample of LiI that underwent no processing. To control for LiI hydration effects, which results in increased conductivity via increased defect density, LiI monohydrate content was controlled among samples. With further processing, particle size was reduced from 5 ± 1 µm to 2.0 ± 0.2 µm for the C and G-S samples. Each sample was utilized with a 1:2 lithium iodide:3-hydroxypropionitrile ($LiI(HPN)_2$)) conductive additive, creating a 80/20 $LiI/LiI(HPN)_2$ SE composites. Reducing particle size resulted in a significant increase in ionic conductivity, from 7.7×10^{-8} to 6.1×10^{-7} S cm^{-1}, at room temperature. This improvement is attributed to an increase in the number of grain boundaries and defects, enabling better mixing with the electrolyte additive, $LiI(HPN)_2$ and an overall improvement in ion transport. 3D confocal Raman spectroscopy with non-negative matrix factorization (NMF) analysis determined aggregation of HPN within the composites was lessened in the sample with smallest particle size. When utilized in a self-forming Li/I_2 battery, reduced particle size (improved conductivity) led to significantly reduced overpotential, enabling the coulombic efficiency to reach 100% in the first cycle. Additionally, the cells with G-S composite electrolyte (smallest LiI particle size) exhibited improved electrochemical function at higher cycling rates compared with the other electrolyte types. This work demonstrates the effect(s) of decreasing solid electrolyte particle size in a self-forming, self-healing, all solid-state battery.

EN02.05.06
Characterization Study on Deposited $Li_{1+x}Al_xTi_{2-x}(PO_4)_3$ Thin Films for All–Solid-State Li-Ion Battery Applications Marie Francoise C. Millares, Christopher Ajiduah, Latika Susheel, Kevin Shah, Seiichiro Higashiya, Hassaram Bakhru, Devendra Kumar and Haralabos Efstathiadis; SUNY Polytechnic Institute, United States

All solid-state Li-ion batteries hold the promise of safety, lower cost, and improvements concerning specific energy, specific power, and cycle performance compared to traditional liquid Li-ion batteries. However, there has been little work done on the fabrication of solid electrolyte via plasma vapor deposition (PVD) technique. Our goal is to deposit and characterize solid electrolyte thin film using a NASICON-like, lithium aluminum titanium, phosphate ($Li_{1+x}Al_xTi_{2-x}(PO_4)_3$, (LATP)) solid compound and fabricate microbatteries using lithography. LATP is the interest in this study due to its high ionic conductivity of ~$3x10^{-3}$S cm^{-1} and reported stability. They are deposited through RF-magnetron sputtering of a 99.9% pure single LATP target onto a thermal silicon oxide substrate. The films' structural and compositional properties were characterized using multiple techniques such as scanning electron microscopy (SEM) and X-ray diffraction while the lithium depth profile on pristine and cycled devised was measured by secondary ion mass spectroscopy (SIMS) and nuclear reaction analysis (NRA). SIMS and NRA data were combined to depict a lithium depth profile of 0.1 atomic % ^{7}Li in the electrolyte. SIMS and NRA will also be used to correlated the atomic % of ^{7}Li in the electrolyte and quantify the Li trapped in the electrodes after cycling to the battery performance.

EN02.05.07
Spatially-Resolved *Operando* Structural Analysis of Sulfur-Based All–Solid–State Lithium Batteries Using EDXRD Alyssa Stavola, Xiao Sun, Andrea Bruck, Daxian Cao, Hongli Zhu and Joshua Gallaway; Northeastern University, United States

All solid-state lithium batteries (ASSBs) offer higher power and energy density than traditional lithium-ion batteries and are inherently safer due to solid-state electrolytes (SSEs) replacing flammable organic liquid electrolytes. Due to their high room temperature ionic conductivity and malleability allowing for good contact at the electrodes, sulfide-based SSEs are promising candidates for ASSBs. However, thiophosphate based SSEs face two main challenges for commercialization: the narrow voltage window where the electrolyte is electrochemically stable, and its reactivity with NMC and Li metal active materials. Pairing sulfide SSEs with compatible cathodes is crucial to designing high energy dense ASSBs.

An FeS_2 metal sulfide cathode offers a high theoretical capacity (894 mAh/g) and excellent compatibility with sulfide SSEs without additional interface engineering. ASSBs based on $Li_{6.6}Ge_{0.6}Sb_{0.4}S_5I$ (LGSSI) and FeS_2 exhibit an initial capacity of 715 mAh/g at C/10 and are stable for 220 cycles with a capacity retention of 84.5% at room temperature. The structural stabilities of $Li_{6.6}Ge_{0.6}Sb_{0.4}S_5I$ (LGSSI) during cycling are characterized by operando energy dispersive X-ray diffraction (EDXRD), which allows rapid collection of spatially-resolved structural data without redesigning or disassembling the sealed cells and risking contamination by air (Figure 1a). The electrochemical stability is assessed, and an operating voltage window from 0.7-2.4 V (vs. In–Li) is confirmed. Initial EDXRD of a carbon/In-Li half cell is shown in Figure 1b, with the primary reflection of LGSSI observed near a photon energy of 86 keV. During a negative potential sweep (shown in Figure 1c) LGSSI reflections located in the carbon cathode shifted to lower energy, indicating a locally higher d-spacing. This demonstrated that contact with conductive carbon caused a structural instability in the LGSSI.

Layered Li-Ni $_{1/3}Mn_{1/3}Co_{1/3}O_2$ (NMC111) is a widely used cathode material due to its high working potential (>3.6V), and high capacity of 160 mAh/g. However it is proposed that sulfide SSE decomposes where it contacts the NMC cathode particles, causing ionically insulating interfaces to form and hindering the transport of lithium ions. This decomposition of active materials causes a large capacity loss in the first cycle, and the reactivity of NMC and the SSE has prevented this battery from achieving high energy density. A 120 µm thick NMC111 cathode was paired with electrolyte Li_6PS_5Cl as the SSE and operando EDXRD was utilized to determine the time-dependent lithiation gradient during the first two cycles. This structural analysis of the cathode reveals information about the current distribution and its time evolution; vital information to increasing the energy density of sulfide based ASSBs.

EN02.05.08
Nano Additives Having Low Interfacial Energy to Sulfur That Enable Stable Reactions of Sulfur Cathode in Solid-State Batteries Jong Ho Won; Kookmin University, Korea (the Republic of)

With the use of energy storage devices rather than generators in larger and harsher environments, the demand for new energy storage devices with superior performance and reliability is increasing. The ideal structure proposed to meet this requirement is in the form of using lithium metal for the positive electrode, sulfur for the negative electrode, and placing a solid electrolyte between the two electrodes. The sulfur electrode has a theoretical capacity of at least five times higher than that of the conventional cathode, so it is expected to improve the performance of energy storage devices. However, the actual capacity of sulfur electrode varies depending on the state of the solid electrolyte. If a solid electrolyte with high crystallinity and high rigidity is used, the interfacial compatibility with sulfur is low, so that only a small part of the theoretical capacity of sulfur can be utilized. Therefore, for high capacity, a gel-type solid electrolyte with low crystallinity should be used to increase the interfacial properties of sulfur and electrolyte. However, in a gel-type solid electrolyte with a low crystallinity that sulfur exhibits theoretical performance, the sulfur electrode is combined with lithium and causes a shuttle effect that can't be easily controlled and reversed, just like a liquid electrolyte, and the sulfur diffuses to all parts of the battery. When lithium is removed from sulfur, sulfur with low conductivity is irregularly precipitated in the cell, seriously impeding repeated charge/discharge and stable operation. In this study, nano-additives were used to increase the stability when using a gel-type solid electrolyte and a sulfur electrode. The use of nano-additives significantly improved the performance of the sulfur electrode while maintaining the properties of the solid electrolyte. Nanoadditives have been materials with highly controlled internal structures and high surface areas, such as graphene pomegranate pockets and nitrogen-rich carbon nanotubes. For example, graphene pomegranate sacs provide conductivity to the sulfur electrode and make the sulfur stable around it because of its low interfacial energy with sulfur. In addition, when lithium is removed from the sulfur electrode, sulfur is precipitated around the graphene pomegranate bag, leading to a stable reaction. In addition, in the case of nitrogen-rich carbon nanotubes, excellent conductivity was provided by uniformly stacking structures extending in one direction, and sulfur was accommodated in a large internal space. In addition, the low interfacial energy with sulfur allowed sulfur to stay near the nanotubes with sufficient nitrogen, leading to structurally reversible reactions during charging and discharging. We accurately revealed the interfacial energy between nano-additives, sulfur electrodes, and electrolytes based on experiments, and through electrochemical tests, stability was verified through more than 3,000 charge/discharge reactions, and close to theoretical capacity were achieved. As a result, nano additives with similar surface energy to sulfur stabilize the unstable behavior of sulfur through low interfacial energy and control the irreversible reaction of sulfur in solid electrolytes.

EN02.05.09
Fast Lithium–Ion Conduction in the Perovskite-Type Solid Electrolyte Jaejin Hwang and Jaekwang Lee; Pusan National University, United States

Solid electrolytes with a fast ion conduction are crucial for all solid batteries. The perovskite type lithium lanthanum titanate (LLTO) solid electrolytes have been known as one of promising next-generation lithium-ion batteries because they provide high-energy density and superior cyclic stability. However, in spite of these advantages, their practical application is plagued by low ionic conductivity at room temperature.
Here, the LLTO solid electrolyte optimized at the temperature of 1380°C are found to exhibit high lithium ion conductivity of 2.55×10^{-4} S/cm, which was more than 100 times higher than that of the solid electrolyte stabilized at 1200°C. In addition, periodic lattice shrink/expansion was observed in the LLTO optimized at 1380°C. Using the first-principles density functional theory calculations, we find that the oxygen vacancies play critical rules in expanding the lattice parameter normal to the lithium migration path, which greatly enhance lithium ion conductivity. Relevant structure reconstructions and underlying mechanism will be discussed in detail at the atomic scale.

EN02.05.10
Late News: Efforts to Increase the Ionic Conductivity of Lithium Carbonphosphonitride Thermosets Andrew Purdy, Brian L. Chaloux, Megan B. Sassin, Christopher A. Klug and Daniel M. Fragiadakis; Naval Research Laboratory, United States

Lithium dicyanamide ($LiN(CN)_2$) reacts with phosphorus cyanide ($P(CN)_3$) in a 2:1 or greater mole ratio in any anhydrous non-protic mutual solvent to form a resin. The resin solution is used to coat metal coupons or to impregnate silica fiber paper, which are then cured at temperatures of 200-300 °C, forming adherent, ion conducting films. When fully cured, those films have a low ionic conductivity, probably due to rigid crosslinking of the thermoset. We will report our efforts to increase that ionic conductivity by introducing various additives to the system. We have explored (1) adding cations of different sizes, (2) increasing the Li concentration by adding lithium cyanide, (3) introducing $RP(CN)_2$ components to reduce the crosslink density, (4) adding non-volatile, Li-coordinating organic plasticizers to increase ion mobility. The ionic conductivity and chain motions of these films were characterized by impedance and dielectric relaxation spectroscopy. Additionally, reactions in solution were followed by NMR and bulk thermoset material was analyzed by solid state NMR. We evaluated how the composition and conductivities of these materials depends on conditions of preparation.

EN02.05.11
Late News: A study on the Improvement of Atmospheric Stability of LLZTO Solid Electrolyte for All-Solid-State Batteries Jong Woo Kim, Young Ah Park, Su Hyeong Kim, Jisu Na and Young Soo Yoon; Gachon University, Korea (the Republic of)

To recognize the autonomous driving of electric vehicles in real-time, large-capacity batteries should be installed in the vehicle. Liquid electrolyte-based lithium-ion batteries (LIBs) have limited battery capacity expansion due to their liquid electrolytes and have an explosion risk during driving. To resolve the LIB's limitations, solid-state electrolytes (SEs) are promising to considerable research attention. However, SEs are low ion conductivity than liquid electrolytes and make the dendrite during the working process. Garnet structure solid electrolytes were known that have high ion conductivity at room temperature, among solid electrolytes.
In this study, we studied the characteristics of the garnet structure-based Li-La-Zr-Ta-O (LLZTO) according to atmospheric exposure time after the solid-state synthesis method. LLZTO's morphology characteristic according to the synthetic environment was analyzed using the XRD (X-ray Diffraction) and SEM (Scanning electron microscopy). To analysis electrochemistry properties such as ion conductivity and activation energy, impedance analysis was performed. LLZTO's impedance data is comparing was compared the commercial LLZTO's ion conductivity. To compare the LLZTO's ionic conductivity reduction ratio according to the atmospheric exposure time, we compared synthetic LLZTO and commercial LLZTO with atmospheric exposure time. As a result, we found that the ionic conductivity reduction ratio of synthetic solid electrolytes is smaller than commercial LLZTO.

EN02.05.12
Late News: Optimization of Lithium Ceramic - Poly(vinylidenefluoride-co-hexafluoropropylene) (PVDF-HFP) Composite Separator for Lithium Metal Batteries Lara Dienemann, Lily Geller, Anil Saigal and Michael A. Zimmerman; Tufts University, United States

Lithium metal batteries are more energy-dense than commercial lithium-ion batteries; however, unstable and non-uniform plating and stripping at the lithium metal anode can lead to short circuiting if the structures, known as dendrites, breach the gap between anode and cathode. To mitigate this problem, inorganic-organic hybrid films have been placed at the lithium metal anode to encourage uniform deposition arguably through the robust mechanics and diffusion mechanisms of the composite. This study aims to optimize the design of these films by focusing on poly(vinylidenefluoride-co-hexafluoropropylene) (PVDF-HFP) composite films, quantifying the relationship between concentration of LiF and $Li_{6.4}La_3Zr_{1.4}Ta_{0.6}O_{12}$ (Ta-doped LLZO) ceramic fillers to mechanics and conductivity of the separator as well as to plating and stripping uniformity at the lithium metal anode after cycling. The hybrid separators demonstrate high modulus, yield stress, and ductility in uniaxial tension experiments as both pristine and swollen with electrolyte. Additionally, long term cycling validates the composite as electrochemically compatible in a lithium metal system through *postmortem* surface analysis of

the lithium metal electrodes.

EN02.05.13
Late News: (Garcia High School Student) Modeling Ion Transport and Dendrite Formation in All-Solid-State Lithium-Ion Batteries Jack Kugler[1], Aishik Dhori[2], Satvik Lolla[3], Neha Basu[4], Anirudh Bharadwaj[5], Zhuolin Xia[6] and Dilip Gersappe[6]; [1]Philips Exeter Academy, United States; [2]Munster High School, United States; [3]Poolesville High School, United States; [4]BASIS Scottsdale, United States; [5]Lynbrook High School, United States; [6]SUNY-Stony Brook, United States

All-Solid-state Lithium-Ion batteries(ASSLIBs) are considered as more efficient and safer alternatives to traditional lithium-ion batteries with liquid electrolytes. Among the candidate solid electrolyte materials, Lithium Phosphorus Sulfide (LPS) has attracted the attention of researchers due to its high Lithium ion conductivity. However, major challenges arise due to LPS having complicated porous geometries and multiple phases with different ion transport abilities. Additionally, suppressing dendrite growth at the anode surface is needed for high energy density solid state batteries using Li metal as anode. Our goal is to identify the electrolyte that best promotes ion transport and the interface morphology that best suppresses dendrite growth.

In this study, we used the Lattice Boltzmann Method (LBM) to simulate half-cells with a Li working electrode, virtual Li counter electrode, and LPS solid electrolyte. In order to investigate the ion transport process, we tested the electrolyte with various porosities, diffusivities, and phases with different ion conductivities. In our ion-transport simulations, we simulated Li-ion transport through solid-state electrolytes by measuring flux at the electrolyte-electrode interface . The results show that flux at the electrolyte-electrode interface increases as porosity decreases or diffusivity increases. Our multiphase simulations were conducted with a single porous electrolyte with less conductive secondary phases. The simulation indicated that lower percentage of the second phase resulted in higher Li-ion flux. To investigate dendrite formation, we studied three interface morphologies: rough with no micropattern, rough with micropattern, and smooth with micropattern. For each system, we varied charge current, surface roughness, and micropattern hole size. Our results reveal that dendrite formation at the anode/electrolyte interface is favored in the rough systems and is inhibited in micropattern systems. Our study demonstrates the effects of factors on the performances of ASSLIBs in order to provide information for finding high-performing and commercially-viable candidate systems.

EN02.05.14
Highly Stable $LiNi_{0.8}Mn_{0.1}Co_{0.1}O_2$ with LiOH Coating in Thiophosphate-Based All-Solid-State Batteries Xiao Sun[1], Yubin Zhang[2], Yan Wang[2] and Hongli Zhu[1]; [1]Northeastern University, United States; [2]Worcester Polytechnic Institute, United States

Nickle-rich LiNi0.8Co0.1Mn0.1O2 (NMC 811) exhibits outstanding properties in high energy density and low cost, making it promising as the cathode material in all-solid-state lithium batteries (ASSLBs). In various solid-state electrolytes (SEs), thiophosphate-based eletrolyes own superior ionic conductivity and processbility. However, NMC 811 suffers from severe surface electrochemical, chemical, and voltage incompatibility towards thiophosphate-based electrolytes. Diverse interface engineerings have been reported to solve this issue, whereas they are typically cumbersome and expensive. Therefore, finding a coating strategy that satisfied all the requirements of cost-efficiency, stability, uniformity, scalability, and easy-achieving is necessary. In this work, we fabricated a highly stable NMC 811 coated with a ~10 nm of LiOH-based layer through a time-and cost-effective one-step sintering process. Compared with conventional coating strategies, this method made a conformally coating in the NMC 811 lithiation process without extra processes. Meanwhile, LiOH interfacial coating layer only conducts ions but not electrons resulting suppressed decomposition of sulfide electrolyte. As a result, the ASLBs exhibited remarkable cycling stability for 600 cycles with a capacity of 130 mAh g^{-1} on average at C/10 at a wide electrochemical window of 2.50−4.20 V (vs. Li-In) and satisfactory rate capability (119.4 mAh g–1 at 1C).

EN02.05.15
High Performance Stretchable Spiral Lithium-Ion Battery Banafsheh Hekmatnia, Hamidreza Fallahtafti, Alamgir Karim and Haleh Ardebili; University of Houston, United States

Recently, there has been a great attention toward stretchable and flexible lithium-ion batteries (LIBs) that are safe, leakage-proof, low cost, and electrochemically and mechanically stable. These stretchable batteries must provide long cycle life and show high electrochemical and mechanical performance for a wide variety of applications such as wearable electronics, biomedical sensors and portable devices.
Due to this accelerated demand, in this study, a thin-film stretchable lithium-ion battery has been fabricated, tested and optimized. The lithium-ion cell is fabricated in a spiral configuration with the thickness of less than 0.8 mm and provides out-of-plane stretchability. In addition, comprehensive tests including electrochemical and mechanical cycling, and electrochemical impedance spectroscopy (EIS) has been conducted to evaluate and optimize the performance of the stretchable batteries. Results show that high areal discharge capacity of 1 mAh/cm^2 after 100 electrochemical cycles is achieved for spiral stretchable batteries. Moreover, electrochemical performance, EIS and voltage of the stretchable batteries have been measured simultaneously in both flat and stretched states. Results reveal that the spiral battery can be stretched up to 500% without any significant change in its electrochemical performance. Furthermore, scanning electron microscopy (SEM) images of the battery confirm stable interfaces and structural integrity throughout cycling and stable specific capacity up to 200 cycles has been demonstrated. In comparison with the previous work on stretchable batteries, a significant enhancement has been achieved with respect to specific capacity, energy density, performance stability in stretched state and during long cycles.

SESSION EN02.06: Metal Anodes I
Session Chair: Fudong Han
Wednesday Morning, December 1, 2021
Hynes, Level 3, Ballroom C

10:30 AM *EN02.06.01
Interfacial Dynamics in Anode-Free Solid-State Batteries Neil P. Dasgupta; University of Michigan, United States

Solid-state batteries (SSBs) have seen a dramatic increase in research in recent years because of their ability to address safety challenges associated with flammable liquid electrolytes, and the potential to enable Li metal anodes. Recently there has been an increase in attention paid to anode-free SSB configurations, where all of the lithium inventory in the battery is supplied from the cathode. Accordingly, Li metal is plated out at the interface between a solid electrolyte and a metallic current collector. This enables a N:P ratio of 1, representing a significant increase in the theoretical energy density compared to cells with excess Li metal in the anode. The anode-free configuration results in unique physical phenomena with regards to chemo-mechanics at the interface, and also represents a valuable platform to quantify the stability and reversibility of Li plating and stripping at solid-solid interfaces.

To probe the dynamic evolution of anode-free solid-state batteries, in this talk, I will present results using a complimentary set of *in situ/operando* methodologies. First, we will explore quantify the impacts of electrochemical cycling conditions and external variables on the voltage signatures and reversibility of anode formation. Comparisons will be made between anode-free cells using state-of-the-art metal oxide and sulfide solid electrolytes. *Operando* video microscopy will be used to study the morphological evolution of the interface, including 3-dimensional analysis using focus variation microscopy. The chemical evolution of SEI formation during the initial anode formation cycle will be explored using *operando* x-ray photoelectron spectroscopy (XPS). The results of these investigations point towards unique processes that occur in anode-free SSBs, including transitions in reaction pathways between SEI formation and Li plating, as well as mechanical evolution of both the Li metal and current collector during nucleation and growth.

11:00 AM EN02.06.02
Lithium Deposition-Induced Fracture of Carbon Nanotubules. Measurement of Hydrostatic Stress in Plated Li Stephen J. Harris[1], Yongfu Tang[2], Sulin Zhang[3], Feng Ding[4] and Jianyu Huang[2,5]; [1]Lawrence Berkeley National Laboratory, United States; [2]Yanshan University, China; [3]The Pennsylvania State University, United States; [4]Ulsan National Institute of Science and Technology, Korea (the Republic of); [5]Xiangtan University, China

The increasing demand for safe and dense energy storage has shifted research focus from liquid electrolyte-based Li-ion batteries towards solid-state batteries (SSBs). However, the application of SSBs is impeded by uncontrollable Li dendrite growth and short circuiting, whose mechanism remains elusive. Herein we conceptualize a scheme to visualize Li deposition in the confined space inside carbon nanotubules (CNTs) to mimic Li deposition dynamics inside solid electrolyte (SE) cracks, where the high-strength CNT walls mimic the mechanically strong SEs. We observed that the deposited Li propagates as a creeping solid in the CNTs, presenting an effective pathway for stress relaxation. When the stress-relaxation pathway is blocked, Li deposition-induced stress reaches GPa level and causes CNT fracture. Mechanics analysis suggests that interfacial lithiophilicity critically governs Li deposition dynamics and stress relaxation. Our study offers critical strategies for suppressing Li dendritic growth and constructing high energy density, electrochemically and mechanically robust SSBs.

Ultra-High Areal Capacity Li Electrodeposition at Metal-Solid Electrolyte Interfaces Under Minimal Stack Pressures Enabled by Interfacial Na-K Liquids Richard Park, Cole D. Fincher, Andres Badel, Michael Wang, W. C. Carter and Yet-Ming Chiang; Massachusetts Institute of Technology, United States

The need for higher energy density rechargeable batteries has generated interest in metallic electrodes paired with solid electrolytes. However, impedance growth at the Li metal-solid electrolytes interface due to void formation during cycling at practical current densities and areal capacities, e.g., greater than 0.5 mA cm^{-2} and 1.5 mAh cm^{-2} respectively, remains a significant barrier. Here, we show that introducing a wetting interfacial film of Na-K liquid between Li metal and $Li_{6.75}La_3Zr_{1.75}Ta_{0.25}O_{12}$ (LLZTO) solid electrolyte permits reversible stripping and plating of up to 150μm of Li (30 $mAhcm^{-2}$), approximately ten times the areal capacity of today's lithium-ion batteries, at current densities above 0.5 mA cm^{-2} and stack pressures below 75 kPa, all with minimal changes in cell impedance. We further show that this increase in the accessible areal capacity at high stripping current densities is due to the presence of Na-K liquid at the Li stripping interface; this performance improvement is not enabled in the absence of the Na-K liquid. This design approach holds promise for overcoming interfacial stability issues that have heretofore limited performance of solid-state metal batteries.

11:30 AM EN02.06.04
An Investigation of Chemo-Mechanical Phenomena in All-Solid-State Lithium Metal Batteries Using *In* Situ Curvature Measurements Jung Hwi Cho[1], Kunjoong Kim[2], Srinath Chakravarthy[3], Xingcheng Xiao[4], Jennifer L. Rupp[2] and Brian W. Sheldon[1]; [1]Brown University, United States; [2]Massachusetts Institute of Technology, United States; [3]Samsung Advanced Institute of Technology, United States; [4]General Motors, United States

Lithium metal penetration through garnet based LLZO solid electrolytes (SEs) have been identified as a critical failure process. At critical current density, LLZO SE has been known to short-circuiting, and can even result in fracturing of the SE. The combined chemo-mechanical phenomena- which can significantly affect the performance in all solid-state batteries, requires detailed investigation of several related phenomena. Characterizing the dynamical mechanical evolution that occurs in the electrode-SE is challenging. Investigation of the mechanical driving forces of lithium metal penetration through the SE is a particularly important challenge. To probe the chemo-mechanical phenomena that occur during lithium plating, this study reports in-situ curvature measurements that were designed to evaluate the stresses that evolve in LLZO during lithium plating. The experimental configuration created for this work provides data which was analyzed with a detailed Finite Element Model (FEM) to quantitatively evaluate stress evolution in the solid electrolyte. The results show that Li metal plating within a surface flaw can produce stress build-up prior to short-circuiting. The combined results from both the experiments and the FEM suggest that it is critical to minimize surface defects and flaws during manufacturing processes.

11:45 AM EN02.06.05
Measurements and Maps to Understand the Mechanical Behavior of Lithium, Sodium and Potassium Metal Cole D. Fincher[1], Yuwei Zhang[2], Jungho Shin[2], George Pharr[2] and Matt Pharr[2]; [1]Massachusetts Institute of Technology, United States; [2]Texas A&M University, United States

Pure metals (i.e., Li, Na, K) are attractive battery anodes because they possess large theoretical capacities for their respective systems. However, pairing metal anodes with solid electrolytes produces a rigid interface with fundamental mechanical issues: stress buildup can lead to electrolyte fracture and metal penetration, while a lack of sufficient pressure leads to a loss of anode-electrolyte contact. The anode's mechanical properties govern both stress buildup and relaxation, but such properties (e.g., the yield stress) are highly sensitive, varying by orders of magnitude with temperature, rate, and size. In this work, we systematically survey the mechanical behavior of lithium, sodium, and potassium at bulk scales for temperatures from 0 C to 45 C and strain rates from 10^{-2} to 10^{-4} s^{-1}, while using micro- and nano-indentation measurements to delineate the size-dependence of mechanical behavior. Temperature dependent and (separately) size dependent deformation mechanism maps emerge from these measurements, allowing the prediction of flow stress for alkali metals under a broad variety of conditions. Towards illustrating the utility of the deformation mechanism maps, we outline the implications for stress buildup within metallic protrusions at the solid-state electrolyte / anode interface. Furthermore, both deformation maps and mechanical measurements demonstrate that Na and K metal are far softer than Li metal under equivalent conditions, and may provide more conformal interfaces than Li metal during operation of fast-charging solid-state batteries. Overall, the results presented herein will provide important guidance in designing solid-state batteries with persistent interfacial contact

SESSION EN02.07: Metal Anodes II

Dynamic Operation of Solid–State–Batteries Kelsey B. Hatzell and Wahid Zaman; Princeton University, United States

Garnet solid-state electrolyte $Li_7La_3Zr_2O_{12}$ (LLZO) are promising candidates for the development of all solid-state batteries, owing to their high ionic conductivity and chemical stability in contact with Lithium metal. However, insufficient interfacial contacts in LLZO-based solid-state batteries leads to high area-specific resistance (ASR), gradual void formation and dendrite-induced shorting during electrochemical cycling[2]. By applying external pressure to symmetric / full cells, proper interfacial contact can be achieved. However, excessive stack pressure can be detrimental to Li-LLZO kinetics and stability, which affects the overall cell performance[3]. In this study, we systematically evaluated the combined effect of stack pressure (5-30 MPa) and temperature (25-70C) in Li stripping/plating behavior (symmetric cells).The morphological changes at Li-LLZO interfaces under pressure and temperature are complex in nature. Improper contact points lead to void formation and inhomogeneous plating, which result to rise in constriction resistance. The contact issues can be eliminated completely under extreme confinement. But stress-induced Li dissolution along grain boundaries or surface flaws of LLZO can still cause shorting. Through critical current density (CCD) and long-term Li-stripping measurements on Li\LLZO\Li cells, an optimum pressure range of 10-20 MPa is observed for stable operation at room temperature up to 0.5 mA/cm^2. The cell shorting scenarios at high current densities are different. At low pressure (5 MPa) cells encounter a void-induced shorting, whereas at high pressure (20 MPa), stress-induced shorting is evident. Increasing the temperature at the optimum pressure range shows a significant increment of current density (> 1.3 mA/cm^2). Combined effect of pressure and temperature in full cell performance and stability was also investigated by employing composite $LiFePO_4$ electrodes.

Cooperative Role of Concentration and Electric Field for Dendritic Growth in Rechargeable Batteries Asghar Aryanfar[1,2] and Sajed Medlej[1]; [1]American University of Beirut, Lebanon; [2]California Institute of Technology, United States

We develop a real-time framework for computing the concentration and electric fields in one dimensional battery cell. Subsequently we calculate the kinetics of dendritic growth using asynchronous evolution in the concentration of anions and cations and the cell voltage. Consequently, we develop a phase field model for the initiation and growth process of the dendritic microstructures which is highly dependent to the computed three variables. The main focus in the phase field model is the variation in the charge density ρ and the value of the computed electric potential V for determining the ultimate energy functional ΔG . The results are useful for determining the design strategy for controlling the microstructures particularly for the effect of the original concentration C_0, the potential difference V_0 and the inter-electrode separation l.

2:15 PM EN02.07.03
Mechanistic Understanding of Lithium Dendrite Formation in Solid Electrolytes Fudong Han; Rensselaer Polytechnic Institute, United States

The successful integration of Li metal anode with solid electrolytes seems to be a must for a high-energy-density solid-state battery. However, Li dendrites tend to form in solid electrolytes during plating and eventually lead to the short circuit of the cell. The formation of dendrites has been observed in solid electrolytes with various crystal structures from glass, glass-ceramic, poly-crystalline to single-crystalline, but the mechanism of such an unexpected dendrite growth remains elusive. In this presentation, I will introduce our recent understandings of lithium dendrite formation in solid electrolytes based on neutron depth profiling characterizations and electrochemical measurements on typical solid electrolytes. We highlight the important role of the electronic conductivity of solid electrolytes in the formation of isolating dendrites inside solid electrolytes. We will also discuss corresponding dendrite prevention strategies.

Structural and Mechanical Characterization of NaSICON Solid Electrolytes Upon Cycling in Molten Sodium Ryan C. Hill[1], Martha M. Gross[2], Amanda Peretti[2], Leo J. Small[2], Erik D. Spoerke[2] and Yang-Tse Cheng[1]; [1]University of Kentucky, United States; [2]Sandia National Laboratories, United States

The ever-growing demand for robust, long-duration energy storage has driven research into emerging technologies, such as sodium-based batteries. Solid sodium electrolytes are a key component to the successful implementation of molten sodium, solid-state, and sodium-ion batteries for large-scale and long-duration energy storage. The sodium (Na) Super Ion CONductor (NaSICON) is a promising candidate solid electrolyte, due to its high conductivity and chemical stability against molten sodium. At high current densities or after extended use, however, potential changes in the material properties of NaSICON may lead to various forms of degradation. In-situ deterioration of NaSICON stands to potentially decrease the performance, lifetime, and safety of sodium batteries. Characterizing potential degradation mechanisms is critical to widespread NaSICON utilization, but these processes have not been studied extensively. In this presentation, the microstructural, mechanical, and electrochemical properties of NaSICON before and after exposure to sodium battery environments are investigated. Structural characterization by x-ray diffraction, atomic force microscopy, and scanning electron microscopy is combined with mechanical and electrochemical measurements, such as nanoindentation and electrochemical impedance spectroscopy. We have found that critical properties, such as elastic modulus, of NaSICON are altered after exposure to electrochemical cycling. These changes, coupled with high current density, can lead to localized failure in the form of microcracking or dendrite formation and propagation. The degradation and failure of these electrolytes may be further exacerbated by the presence of microstructural ceramic defects, such as porosity, from the fabrication process. Understanding these mechanisms will be used to guide improved design and formulation of NaSICON for use in sodium batteries.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

Late News: Creep and Anisotropy of Free-Standing Lithium Metal Foils in an Industrial Dry Room Lara Dienemann, Anil Saigal and Michael A. Zimmerman; Tufts University, United States

Commercialization of energy-dense lithium metal batteries relies on stable and uniform plating and stripping on the lithium metal anode. In electrochemical-mechanical modeling of solid-state batteries, there is a lack of consideration of specific mechanical properties of battery-grade lithium metal. Defining these characteristics is crucial for understanding how lithium ions plate on the lithium metal anode, how plating and stripping affect

deformation of the anode and its interfacing material, and whether dendrites are suppressed. Recent experiments show that the dominant mode of deformation of lithium metal is creep. This study measures the time and temperature-dependent mechanics of two thicknesses of commercial lithium anodes inside an industrial dry room, where battery cells are manufactured at high volume. Furthermore, a directional study examines the anisotropic microstructure of 100 μm thick lithium anodes and its effect on bulk creep mechanics. It is shown that these lithium anodes undergo plastic creep as soon as a coin cell is manufactured at a pressure of 0.30 MPa, and achieving thinner lithium foils, a critical goal for solid-state lithium batteries, is correlated to anisotropy in both lithium's microstructure and mechanical properties.

4:15 PM EN02.07.06
Late News: Tracking Li Microstructure Growth in Solid-State Batteries with Lithium Anode Observed with Non-Invasive *In Situ* Three-Dimensional 7Li MRI Haoyu Liu[1], Po-Hsiu Chien[1], Ghoncheh Amouzandeh[1], Jens T. Rosenberg[2], Samuel C. Grant[2] and Yan-Yan Hu[1,2]; [1]Florida State University, United States; [2]National High Magnetic Field Lab, United States

Dendrite formation is one major cause of battery failure and associated safety hazards. The emergent solid-state batteries using lithium anodes remain victim to dendrite growth, which hinders its commercial viability. The mechanism of dendrite formation and propagation in solid electrolytes is largely different from that in liquid systems, yet the challenges in non-invasively and directly tracking the process in real-time leave the exact mechanism elusive. Herein, we demonstrate for the first time to track the kinetics of lithium dendrite growth at both the interface and bulk of different depths in Li/ $Li_7La_3Zr_2O_{12}$ (LLZO) /Li solid cells using three-dimensional in-situ and ex-situ nuclear magnetic resonance imaging (MRI) non-invasively. We show that the accumulation of Li microstructure kicks off from the surface of LLZO before hard shorting the Li/LLZO/Li cell. More importantly, we identified Li evolution originated both from the interface and from the bulk LLZO electrolyte. The techniques developed and demonstrated herein can also be applied to other related fields in materials research.

4:30 PM EN02.07.07
Monolithically Printed All–Solid–State Lithium Metal Micro-Battery from Liquid Dispersions Ahmed Abdelaziz, Anthony S. Childress and Ahmed Busnaina; Northeastern university, United States

Recent demands for very small electronic devices generated a need for miniaturized energy-storage devices that can provide the power and energy needed for various applications such as wearable gadgets, medical devices and wireless sensor networks. Rechargeable micro-batteries have been investigated as a reliable route for achieving this target. However, in order to reach reliable performance of such micro-batteries while reducing the size and minimizing the fabrication cost, more sophisticated architectures need to be developed. Here, we introduce a novel approach to fabricate an all solid-state Li metal micro-battery based on directed fluidic assembly-based printing. This unique approach facilitated the assembly of all battery components including cathode, anode, and electrolyte at micro-scale dimensions, without the need of implementing costly fabrication techniques or utilizing complicated sacrificial templates as in the case of traditional micro-battery fabrication methods. Moreover, the porous cathode framework attained using this approach provided enough space for the polymer electrolyte to infiltrate the porous cathode leading to a cathode-supported electrolyte membrane. This drastically enhanced the battery performance through combining superior ionic transport and low interfacial resistance between the electrolyte and the cathode, as well as providing excellent electronic pathways through the cathode scaffoldings. Results shows that the as-printed $LiFePO_4$/Li solid state battery has an outstanding performance with discharge capacity of 157 mA h g^{-1} at 0.1C, and a long-term cycling stability of 99.6% coulombic efficiency with a capacity retention of 89 .5 % after 200 cycles. The EIS measurements also showed a lower interfacial resistance of the cathode-supported electrolyte micro-battery compared to its separated membrane counterpart. We believe that this unique approach will pave the way for mass production of high performance all solid-state micro batteries based on Li metal anodes as miniaturized energy devices.

4:45 PM EN02.07.08
Late News: Interrupted Anion Sublattice for Fast Li+-ion Conduction in Li_3PO_4–LiI Sawankumar V. Patel[1], Haoyu Liu[1], Erica Truong[1], Yan E. Wang[2], Lincoln Miara[2], Valentina Lacivita[2], Ryounghee Kim[2] and Yan-Yan Hu[1]; [1]Florida State University, United States; [2]Samsung Advanced Institute of Technology, United States

Rational design and synthesis of solid electrolytes using cost-effective precursors for fast ion conduction is an effective approach for producing solid electrolytes for mass production at a low-cost. In this study, we demonstrate how the ionic conductivity in a poor Li^+-ion conductor-Li_3PO_4-can be tuned to a fast Li^+-ion conductor by interrupting the PO_4^{3-} anion sublattice via diversifying the anion species. This is achieved by first introducing a highly polarizable I^- anion in the vicinity of PO_4^{-3} which results in a frustrated Li-anion interaction, thereby encouraging fast hopping around the interrupted anion framework. An ionic conductivity of 0.15 mS/cm at room temperature was achieved for the composition $1.4Li_3PO_4$ – LiI, a 10^{10}-fold enhancement compared with the ionic conductivity of Li3PO4, 10^{-14} mS/cm. Phase analysis from multinuclear solid-state NMR revealed a large fraction of amorphous phases $Li_{3+y}PO_4I_y$ and Li_4PO_4I, in addition to the residual crystalline LiI and $LiI{\cdot}H_2O$ phases. The formation of $Li_{3+y}PO_4I_y$ and Li_4PO_4I phases was determined to be the reason for achieving high Li^+-ion conduction which was confirmed by AIMD. ^{7}Li NMR relaxometry revealed fast-Li^+-ion mobility because of the incorporation of iodide anions that resulted in the interruption of the PO_4^{3-} sublattice. ^{6}Li tracer-exchange NMR showed Li_4PO_4I to be more conductive than the $Li_{3+y}PO_4I_y$. Overall, this study demonstrates that interruption of anion frameworks by introducing large polarizable anion in an amorphous matrix is powerful strategy to enhance Li^+-ion conduction.

5:00 PM EN02.07.09
Late News: Unraveling the Enhanced Ion Dynamics and Structural Disorder in Li5.3PS4.3Cl1.7-xBrx Pengbo Wang[1], Sawankumar V. Patel[1], Haoyu Liu[1], Po-Hsiu Chien[1], Lina Gao[1], Xuyong Feng[1], Jue Liu[2] and Yan-Yan Hu[1]; [1]Florida State University, United States; [2]Oak Ridge National Laboratory, United States

Fast ion conductors with high conductivity and stability are key to realizing high-performance all-solid-state batteries for next-generation energy storage. Lithium argyrodites have demonstrated tunable conductivity via anion doping. However, Li deficiency and anion mixing coexist in previously studied halogen-doped argyrodite compounds, and both of them impact Li^+ conduction.[1-3] To investigate the effects of anion mixing, we synthesized novel argyrodites $Li_{5.3}PS_{4.3}Cl_{1.7-x}Br_x$ ($0 \le x \le 1.7$) with fixed Li content. The highest room-temperature conductivity around 26 mS/cm is achieved in $Li_{5.3}PS_{4.3}Cl_{0.7}Br$, with an exceptionally low activation energy of 0.16 eV for Li^+ transport. To characterize the long- and short-range structural order and to discover the origin of fast Li^+ conduction, X-ray diffraction and nuclear magnetic resonance are utilized. It shows that a diversified anion sublattice is formed via S/Cl/Br mixing at Wyckoff 4d sites. While the long-range structure is maintained, the introduction of Br^- in the structure displaces Cl to off-center positions from 4a/4d sites. The effects of the observed anion disorder on the mobility of Li^+ and anions are investigated using NMR relaxometry. It reveals that Br^- incorporation slows down Li^+ motion but increases PS_4^{3-} rotation, and overall leads to lower energy barriers for Li^+ transport.

Multidimensional Diagnostics of Solid-State Lithium Batteries Yan Yao; University of Houston, United States

The complex origins of solid-state battery failure call for multidimensional diagnostics utilizing not one but a combination of tools that can quantify the void and dendrite formation, identify the chemical and mechanical natures of the Li dendrites and electrolyte decomposition products, and *in situ* monitor the evolution of the processes. However, there is lack of tools that connect multiple techniques with desirable length scale, resolution and sensitivity for characterizing solid-state batteries. The objective of this work is to develop an air-free vessel with an in-situ cell test platform connecting FIB-SEM tomography, ToF-SIMS, and in-SEM nanoindentation for structural, chemical, and mechanical characterizations of solid-state Li batteries. We fabricated solid-state thin-cells (less than 100 μm) and micro-cells with electrochemical performance on par with their bulk-type counterparts. Electrochemical tests with precise temperature control, external pressure, and pressure monitoring of thin solid-state cells were demonstrated with structural, chemical and mechanical characterizations. We hope the consolidated diagnostic platform presented here will allow us to effectively predict and optimize the physical and chemical changes of components within solid-state Li batteries during charge and discharge.

Imaging Interfaces and Interphases in All-Solid-State Batteries at the Nanoscale Ece Deniz[1], Elliot J. Fuller[2], A. A. Talin[2] and Marina Leite[1]; [1]University of California, Davis, United States; [2]Sandia National Laboratories, United States

To date, a primary challenge for the further development of all-solid-state batteries is resolving and controlling the Li-ion distribution within their interfaces and interphases. Therefore, spatially determining where Li^+ favorably accumulates upon device cycling can reveal how to mitigate the chemical reactions that lead to capacity fade. Here, we implement nanoscale-resolved secondary ion mass spectroscopy (SIMS) in an oxygen-free environment to elucidate the spatial distribution of Li^+ ions in energy-storage devices composed by Si/LiPON/$LiCoO_2$ in a thin film configuration, an ideal model system with >90% capacity retention after 100 cycles and 98% of Coulombic efficiency. We acquire the ionic depth profile and 3D map of Li^+ for both pristine and cycled devices, revealing a Li^+ enrichment at the electrolyte layer upon cycling. This 3D tomography of Li^+ spatial distribution indicates enrichment of Li^+ at the LiPON electrolyte. As an independent technique to tomographical studies, we will also discuss the surface potential distribution in both in-plane and cross-section modes, from nanoscale maps acquired with environmental Kelvin-probe force microscopy (KPFM), performed under Ar and with no air exposure. Our KPFM measurements enable access to all relevant interfaces in full devices under various environmental conditions, such as temperature and humidity. The complementary imaging methods employed in our work represent a useful platform for screening Li-ions and can be extended to 3D designs and to other types of batteries, such as Na-ion devices.

SESSION EN02.09: Polymer and Composite Electrolytes

1:30 PM EN02.09.01
Wood-Derived Solid Electrolyte for Li-Metal Batteries—Atomic Structure and Fast Ion Transport Mechanism Qisheng Wu[1], Chunpeng Yang[2], Liangbing Hu[2] and Yue Qi[1]; [1]Brown University, United States; [2]University of Maryland, United States

Solid-state batteries with lithium metal anodes are attractive for next-generation energy-storage systems with high energy density and safety. But the realization of these promises largely depends on the development of superior ion conductors for the solid-state electrolyte as well as ion-conducting additives for the cathode materials. A research group led by Prof. Liangbing Hu at the University of Maryland, College Park demonstrated that molecule-engineered cellulose nanofibrils through the insertion of copper and lithium ions can be used as a high-performance solid polymer electrolyte that presents record-high ionic conductivity, wide electrochemical stability window, low activation energy, and scalability. The new system, namely Li-Cu-CNF, has the benefit of low cost since the main material sources are wood fibers. In addition, the one-dimensional structure of Li-Cu-CNF also makes it an effective ion-conducting binder for the cathode, and its effective ionic percolation allowed us to fabricate the thickest $LiFePO_4$ solid-state cathode ever reported, suggesting the material's potential for increasing battery energy density.
Despite the experimental discovery, the origin of the high Li-ion conductivity in the Li-Cu-CNF system remained a mystery. We have developed both quantum and atomistic models to uncover the accurate atomic structures of the Li-Cu-CNF system and the lithium-ion conduction mechanism therein. These understandings cannot be obtained by any currently available experimental techniques. We have unveiled the atomic structures of Li-Cu-CNF very quickly with input from experiments. Through comprehensive density functional theory calculations, classical molecular dynamics simulations, and x-ray absorption spectroscopy modeling, we clearly showed how copper ions connect the cellulose chains and open the channels, which are preconditions for insertion and effective transport of lithium ions in Li-Cu-CNF. More than that, we have proposed that the abundant oxygen-containing functional groups and bound water in the cellulose molecular channels lead to a lithium-ion hopping mechanism that is decoupled from the polymer segmental motion, which is the most fundamental reason that Li-Cu-CNF can deliver the highest lithium-ion conductivity among all the solid polymer electrolytes ever reported

during the last four decades. Using molecular dynamics simulations, we have pointed out that the conduction mechanism can also be generalized to cellulose-based sodium-ion and potassium-ion batteries.

Li-Salt Doped Single-Ion Conducting Polymer Electrolytes Laura C. Loaiza[1] and Patrik Johansson[1,2]; [1]Chalmers University of Technology, Sweden; [2]Alistore-ERI (CNRS FR 3104), France

Traditional solid polymer electrolytes (SPEs) aiming at lithium battery application are made by simply dissolving a Li-salt in a suitable polymer matrix, rendering both Li^+ cations and anions mobile. As a result, since most of the lithium batteries chemistries involve the intercalation/deintercalation of the Li^+ cation, concentration gradients and cell polarization develop, causing premature cell failures. Another polymer electrolyte design is to graft the anion onto the polymer backbone, whereby single-ion conductors (SICs) with the Li^+ cation as the sole mobile species can be created. SICs both provide the safety, the mechanical stability, and the flexibility of SPEs, and circumvent the problematic issues connected with cycling, but their ionic conductivities remain low at room temperature, due to the rigidity of the polymer matrix and the dense electrostatic interactions from the attached ionic group.[1,2]
Herein we suggest and explore an intermediate and synergetic design; by using a SIC, LiPSTFSI (poly[(4-styrenesulfonyl) (trifluoromethanesulfonyl) imide]), doped with the LiTFSI salt. The aim is to improve the ion transport mechanism by both increasing the Li^+ concentration and the flexibility of the polymer matrix – as TFSI is a plasticizing anion.[3,4]
We have explored different doping degrees, from 1 to 90 wt%, and how they induce changes in the glass transition temperatures, the mechanical properties, and the charge carrier speciation. With a rather high doping degree, 50-70 wt% LiTFSI, we find considerable improvements in the Li^+ dynamics and the ionic conductivity. A deeper analysis of the conduction mechanism reveals an Arrhenius behavior, with possibilities for strong trade-offs/synergies between ion transport by hopping between ionic clusters, a different speciation, an increased charge carrier concentration, and an increased free volume.

2:00 PM EN02.09.03
Polyborane-Based Electrolytes for Solid–State, Lithium-Ion Batteries Fernando Villafuerte, William Wolf, Jeongmin Kim, Quan Gan, Stephen Munoz, Julia R. Greer, Robert H. Grubbs, Thomas F. Miller, III and Simon C. Jones; California Institute of Technology, United States

Lithium-ion batteries (LIBs) are the primary candidates for advancing energy storage needs, but their function is hampered by the liquid, organic-solvent-based electrolytes that shuttle lithium cations between electrodes during charging and discharging. These electrolytes, e.g. $LiPF_6$ in EC:DEC, can combust if a battery's operating constraints are exceeded. Solid polymer electrolytes (SPEs) offer a promising alternative: they are more thermodynamically stable than their liquid counterparts, and are stable when in contact with Li metal, which could substantially increase a battery's capacity. Polyethylene oxide (PEO), noted for its ability to dissolve lithium salts and conduct lithium ions, has been the focus of SPE research since the 70's. Its primary drawback is the strong coordination of Li^+ relative to loosely coordinated anions, which translates into a low cationic transference number. In addition, ionic conduction occurs only in amorphous domains of the bulk polymer matrix, which renders ionic conductivity suboptimal at ambient conditions, approaching the benchmark of 10^{-3} S/cm only at 80°C.

The persistent issues with PEO and PEO-based architectures are low ionic conductivity and transference number. Recent computational work by Savoie et al.[1] suggests that using Lewis-acidic boron moieties in the polymer backbone, as opposed to the Lewis-basic ether oxygen, can invert the solvation mechanism and increase Li^+ cation mobility relative to that of the anion. It has been experimentally demonstrated that including boron-containing moieties in polymer electrolyte materials provides an anion trapping site which improves Li^+ transference.[2,3]

We present the synthesis of a novel, single-ion conducting, polymer electrolyte and its preliminary electrochemical and material characterization. The electrolyte is accessible through the modification of a simple and abundant polyolefin, polybutadiene, by the introduction of dialkylborane moieties to the backbone through hydroboration. We create an ionically conductive polymer film by first drop casting the synthesized polyborane onto stainless steel discs, and then adding butyllithium to it. This electrolyte exhibits geometry-normalized conductivities approaching 10^{-7} S/cm at 50°C. Further electrochemical and material characterization, in addition to molecular dynamics simulations, provide insight into the mechanism of ionic conduction in these polymer films and allow for further optimization.

Structural Investigation of LAGP/PEO Composite for Solid–State Batteries Using Vibrational and Nuclear Magnetic Resonance Spectroscopies L. J. Deiner[1], Kalle Levon[2], David Clarkson[3,4], Mounesha Garaga[3] and Steven G. Greenbaum[3,4]; [1]NYC College of Technology, United States; [2]NYU Tandon School of Engineering, United States; [3]Hunter College-CUNY, United States; [4]CUNY Graduate Center, United States

Solid state lithium ion batteries have the potential to meet increasingly stringent safety and power density requirements in the transportation and consumer electronics sectors. Realizing the promise of solid state lithium ion batteries will require development of composite solid electrolytes that combine the compliance and processability of polymers with the ruggedness, temperature flexibility, and ionic conductivity of ceramics. In this work, we present a simple one-pot method for preparation of a high inorganics composite comprised of lithium aluminum germanium phosphate (LAGP) and polyethylene oxide (PEO). This is the first step toward development of composite materials more readily compatible with a broad range of battery fabrication techniques. Fourier transform infrared (FTIR) analysis of the polymer/ceramic product shows perturbations in the P-O stretching region (800 cm^{-1} to 1250 cm^{-1}) of the LAGP spectrum, consistent with specific surface interaction between the LAGP and the PEO. Solid state multinuclear magnetic resonance (^7Li, ^{27}Al, ^{31}P), which is sensitive to even small changes in short-range structure of the bulk phase, reveals little difference between LAGP and the LAGP/PEO composite, suggesting that the polymer-ceramic interaction is confined to a thin surface region. Results obtained for other composite

preparation schemes, including sheer vs. impact milling and pre-treatment activation of the LAGP surface will be presented.

Safety Impacts of Liquid Electrolyte Inclusion in Solid State Batteries Alex Bates[1], Yuliya Preger[1], Loraine Torres Castro[1], Katharine L. Harrison[1], Stephen J. Harris[2] and John Hewson[1]; [1]Sandia National Laboratories, United States; [2]Lawrence Berkeley National Laboratory, United States

Solid-state battery (SSB) technology is racing toward commercialization due to its perceived inherent safety and high energy density, both key metrics for the electric vehicle market. To that end, high interfacial resistance between solid electrolyte (SE) and cathode is a critical challenge that must be overcome. The addition of liquid electrolyte (LE) at the SE and cathode interface has been shown to substantially reduce interfacial resistance. However, the inclusion of LE has also led to safety concerns and an emphasis on all-solid-state batteries (ASSBs). In this presentation we quantify the potential thermal consequences of various failure modes, to inform the safety-performance trade-off associated with the potential inclusion of LE in SSBs.

Thermodynamic modeling of a SSB allowing for addition of LE will be presented for the first time, alongside analysis of an ASSB and Li-ion battery (LIB). Three failure scenarios were considered; thermal runaway from external heating, internal short circuit, and catastrophic mechanical failure of the SE. Thermal runaway from external heating included cathode decomposition, LE reaction with the resulting O_2, and LE reaction with the lithiated anode. Internal short circuit considered the complete conversion of stored electrochemical energy to heat, without other reactions. Catastrophic mechanical failure allowed for thermal runaway combined with cathode-generated O_2 reacting with the Li anode through a broken SE. The volume of LE in SSB and LIB was varied, and the resulting potential heat release compared. Heat release and potential temperature rise was analyzed for different ASSB, SSB, and LIB formats of increasing energy density. The results show that the addition of small quantities of LE at the cathode in SSBs has modest safety consequences and may be a relevant pathway to commercialization. For small quantities of LE, the potential temperature rise of the typical thermal runaway reactions are small relative to the release of stored energy, highlighting the importance of the overall energy density in assessing safety. The results allow safety concerns to be integrated with interfacial resistance performance challenges to better inform SSB designs.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology and Engineering Solutions of Sandia LLC, a wholly owned subsidiary of Honeywell International Inc. for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

Low Temperature Preparation of Thin–Film Lithium Battery Cathodes Wyatt E. Tenhaeff, Zhuo LI and Fei Hu; University of Rochester, United States

Solid-state lithium thin-film batteries (TFBs) offer exceptional energy storage performance with high energy density, long cycle life, and enhanced safety. Fabrication of thin film cathodes typically involves high temperature depositions or a thermal annealing step to crystallize the thin film cathodes into the desired crystallographic phases. For example, state-of-the-art sputter deposited $LiCoO_2$ (LCO) must be annealed at >500°C to achieve a maximum charge storage capacity of 67 µAh cm^{-2} $µm^{-1}$ (equivalent to 135 mAh g^{-1}). These high temperatures place significant constraints on the materials of construction and processing of solid-state thin film batteries. In this talk, our efforts to develop low temperature cathode fabrication approaches to mitigate these constraints and expand the potential applications of thin film batteries will be discussed.

The first project utilizes polymeric charge-transfer complexes. These complexes are formed through vapor phase infiltration of I_2 or ICl into poly(4-vinylpyridine) (P4VP) films prepared by initiated chemical vapor deposition (iCVD). iCVD enables room-temperature synthesis of well-defined films directly on the surface of Pt current collectors. After infiltration with I_2 or ICl, the cathodes are coated nominally with 1 mm of lithium phosphorous oxynitride (LiPON) electrolyte and an evaporated Li metal anode. Discharging at 70°C, the P4VP-I_2 and P4VP-ICl deliver capacities of 8.7 and 36.2 µAh cm^{-2} $µm^{-1}$, respectively, with an average voltage of 2.2V and 3.15V. The cathodes appear to be irreversible under normal operating conditions, limiting their application to primary electrochemical cells. However, it has been shown that these cathodes are readily prepared on flexible, temperature sensitive substrates, as well as complex, three dimensional architectures, which should allow them to be readily integrated into wearable, low cost devices and enable additional energy-intensive applications.

In the second project, a class of lithium metal oxide cathode materials are prepared by RF magnetron sputtering and incorporated into solid state thin film batteries consisting of LiPON electrolyte and Li metal anode. Charged to 4V vs. Li/Li^+, specific capacities in excess of 110 mAh cm^{-2} mm^{-1} have been achieved, which is 64% larger than state-of-the-art LCO cathodes. When cycled at a rate of 0.6C (100 minutes for charge/discharge), 83% of the maximum capacity is retained. Moreover, the cathodes are highly reversible with coulombic efficiencies in excess of 99.8%, resulting in greater than 94.7% capacity retention over 100 galvanostatic charge/discharge cycles. Efforts to further enhance rate performance and cycle lives will be discussed, in addition to demonstrations of these cathodes on flexible, polymeric (temperature sensitive) substrates.

Facile Solution Synthesis of Lithium Thiophosphate Solid Electrolyte with High Room-Temperature Ionic Conductivity Daiwei Wang, Li-Ji Jhang and Donghai Wang; The Pennsylvania State University, United States

All-solid-state lithium battery technology is one of the most promising candidates for next-generation batteries due to the high energy density, long cycle life and superior safety. To realize the technology in practical application, solid electrolyte (SE) is the key. The family of thiophosphate SEs is receiving much attention due to the high ionic conductivity at room temperature (> 1 mS cm^{-1}) which could even exceed conventional liquid electrolytes. However, most of the thiophosphate SEs were prepared through solid-state-reaction route by high-energy ball milling and post high-temperature treatment at above 300 °C which is energy consuming and not suitable for large-scale production. Here, we will demonstrate the synthesis of argyrodite-type SEs through facile solution-based method with low annealing temperature below 200 °C. The synthesized SE demonstrated a high ionic conductivity of ~ 4.01 mS cm^{-}

[1] at room temperature and superior stability against lithium metal anode. At room temperature, Li|SE|Li symmetric cell demonstrated a high critical current density of 1 mA cm^{-2} and low areal interfacial resistance of 6 ~ 7 Ω cm^2. The demonstration of the synthesis of argyrodite-type SEs extend the family of solution-synthesized sulfide-based SEs.

Prediction of the Electrochemical Stability and Reaction Mechanisms of Solid–State Electrolytes Marnix Wagemaker, Tammo K. Schwietert and Alexandros Vasileiadis; Delft Univ of Technology, Netherlands

Solid-state batteries have significant advantages over conventional liquid batteries, providing improved safety, design freedom, and potentially reaching higher power and energy densities. One of the major obstacle in the commercial realization of solid-state batteries is the high resistance at the interfaces. Essential for overcoming this bottleneck is to achieve in-depth fundamental understanding of the crucial electrochemical processes at the interface. Conventional electrochemical stability calculations for solid electrolytes, determining the formation energy towards the energetically favourable decomposition products, often underestimate the stability window because kinetics are not included. Here we discuss a computational scheme that takes the redox-activity of the solid electrolytes into account in calculating the electrochemical stability, which in many cases appears to dictate decomposition route and thus the electrochemical stability. This methodology is applied to different chemical and structural classes of solid electrolytes, exhibiting goodagreement with experimentally observed electrochemical stability. Several examples will be discussed, and compared to experimental observations. These results suggest that the electrochemical stability of solid electrolytes is not always determined by the stability of the decomposition products but often originates from the intrinsic stability of the material itself. The processes occurring outside the stability window can lead towards phase separation or solid-solution depending on the reaction mechanism of the material. These newly gained insights provide better predictions of the practical voltage ranges and structural stabilities of solid electrolytes, which may be valuable for material and interface design of solid-state batteries.

How Disorder and Particle Size Affects Solid Ionic Conduction and Solid–State Batteries Wolfgang Zeier; University of Muenster, Germany

The advent of solid-state batteries has spawned a recent increase in interest in lithium conducting solid electrolytes, especially in the lithium thiophosphates. However, many open questions remain when trying to optimize electrolytes and understand solid state battery chemistries.

In this presentation, we will show how an understanding of the structure-transport properties of the lithium argyrodites Li_6PS_5X can help tailor the ionic conductivity. We show that an anion site-disorder and anionic charge inhomogeneities are important and that and that tailoring dis disorder leads to improvements of the conductivity.

Further, we will show that it is not only important to find fast ionic conductors, but that fast ionic conduction is paramount within solid state battery composites. Measuring the effective ionic transport in cathode composites provides an avenue to explore transport and stability limitations that in turn provide better criteria for solid state battery performance.

Lastly, we will show how tailoring particle size distributions can help create solid-state battery cells with conversion-type active materials.

11:30 AM EN02.11.03
Exploring Aliovalent Substitutions in the Lithium Halide Superionic Conductor $Li_{3-x}In_{1-x}Zr_xCl_6$ ($0 \leq x \leq 0.5$) Bianca Helm[1], Roman Schlem[1], Bjoern Wankmiller[1], Ananya Banik[1], Ajay Gautam[2], Justine Ruhl[2], Cheng Li[3], Michael R. Hansen[1] and Wolfgang Zeier[1]; [1]University of Muenster, Germany; [2]Justus-Liebig-Universität Giessen, Germany; [3]Oak Ridge National Laboratory, United States

Solid-state batteries enable safer energy storage than common liquid ion batteries due to the use of a solid electrolyte. To compete with liquid ion batteries the solid electrolytes need to be structurally tailored to provide comparable conductivities.[1,2] In recent years, the ternary halides Li_3MX_6 (M = Y, Er, In; X = Cl, Br, I) have garnered the interest of researchers due to their high ionic conductivities. Iso- or aliovalent substitutions within this material class are scarce preventing a deeper understanding of structure-property relationships. In this work, we investigate the impact of Zr substitution on the structure and ionic conductivity of Li_3InCl_6 ($Li_{3-x}In_{1-x}Zr_xCl_6$ with $0 \leq x \leq 0.5$) using a combination of neutron diffraction, nuclear magnetic resonance and impedance spectroscopy. Analysis of high-resolution neutron diffraction data suggests a cation site-disorder and a tetrahedrally coordinated Li^+ site, which has not been reported in Li_3InCl_6 yet. In combination, all here-found Li^+ positions form a three-dimensional polyhedral network enabling 3D diffusion. The Zr^{4+} substitution in Li_3InCl_6 induces non-uniform volume changes and increases the number of vacancies in the structure, all of which lead to an increasing ionic conductivity in this series of solid solutions. This investigation highlights the importance of understanding the solid electrolyte structure-property relationships to further improve not just the materials themselves but also for the utilization in solid-state batteries.

Consequences of Br/S Site-Exchange on the Properties of Li6PS5Br Argyrodites Marcel Sadowski and Karsten Albe; Technical University of Darmstadt, Germany

Li6PS5Br argyrodites have been identified as promising solid electrolytes due to high ionic conductivities. Although it is known that the material can be

synthesized with anion site-disorder among Br and S the exact effect on its properties has not been clear so far. In line with experimental investigations we show in this contribution how systematic density functional theory calculations have been applied to understand the intricate interplay between the underlying Br/S site-exchange and the materials properties.
The lattice constant of Li6PS5Br was found to depend on the degree of Br/S site-exchange and shows a minimum at 50% site-exchange. Also energetically a relationship is found and the most stable structures are obtained for the ordered material, i.e., at 0% site-exchange. At 50% the least stable structures are found and the energy difference amounts to 125 meV/f.u. on average. The assessment of the configurational entropy due to Br/S site-exchange itself and the vibrational entropy cannot explain the experimentally observed dependence between temperature and equilibrium site-exchange. We therefore conclude that a substantial part of the entropy needs to stem from the highly mobile Li ions.
Indeed, the Br/S site-exchange is key for favorable transport properties of Li6PS5Br. In the absence of any site-exchange only local Li motion within Li "cages" around the S ions is observed. Even at 700 K such intracage jumps dominate the simulations. Temperatures of 800 K or higher are need to initiate intercage jumps that are needed for true long range transport within reasonable simulation times. The introduction of Br/S site-exchange changes the situation drastically: At 50% site-exchange long-range transport is observed already at 500 K. In order to understand the diffusion mechanism we analyzed the individual anion exchanges. According to our simulations the main reason for improved transport properties is due to Br ions on S sites. These defects mainly cause for the generation of Li Frenkel pairs whose interstitial is rather mobile and travels among the neighboring Li cages via interstitial and interstitialcy mechanisms. The Li vacancy, on the other hand, seems to be strongly bound to the anion defect.
At last we focused on grain boundaries in Li6PS5Br. Admittedly, their resistances to the ionic conductivity seem to be of little concern experimentally but the reasons for this circumstance have not been elucidated, yet. To this end we prepared simple tilt and twist grain boundaries and analyzed their influence on the Li diffusion. We find that again the Br/S site-exchange plays a delicate role in this context: At 0% site-exchange grain boundaries seem to improve the transport properties because they locally disrupt the strict cage ordering. At 50%, however, Li transport is slightly deteriorated compared to the bulk phase.

Structure-Composition-Conductivity Relationships of Glass-Ceramic Lithium Thiophosphates Electrolytes Haoyue Guo, Qian Wang, Alexander Urban and Nongnuch Artrith; Columbia University, United States

Lithium thiophosphates (LPS), with the general composition $(Li_2S)_x(P_2S_5)_{1-x}$, are one of the most promising classes of prospective electrolyte materials in solid-state batteries (SSBs), owing to their superionic conductivity at room temperature ($>10^{-3}$ S cm^{-1}), soft mechanical properties, and low grain boundary resistance. So far, several glass-ceramic (*gc*) LPS compositions have been synthesized and characterized experimentally. The ionic conductivity of the *gc*-LPS materials is significantly influenced by the glassy phases, and the relationship between structures and conductivity remains unclear due to the limitation of experimental techniques in characterizing amorphous phases. To resolve the atomic structures of *gc*-LPS with varying compositions, we mapped the phase diagram by integrating density functional theory (DFT), artificial neural network (ANN) potentials as implemented in the atomic energy network package (ænet), genetic-algorithm (GA) sampling, and *ab initio* molecular dynamics (AIMD) simulations. The thermodynamic stability and ionic conductivity of glassy/ceramic phases was correlated with the local structural motifs in the known LPS crystal structures. Structure-composition-conductivity relationships of *gc*-LPS were demonstrated. With machine learning accelerated sampling and AIMD simulations, a candidate solid-state electrolyte composition with high ionic conductivity ($>10^{-2}$ S cm^{-1}) was identified, which could provide a design strategy for optimized LPS materials with enhanced conductivity and stability.

Exploring the Synthesis of Alkali-Metal Anti-Perovskites Kwangnam Kim[1,2], Yiliang Li[3], Ping-Chun Tsai[3,4], Fei Wang[3], Seoung-Bum Son[5], Yet-Ming Chiang[3] and Donald Siegel[1]; [1]University of Michigan, United States; [2]Lawrence Livermore National Laboratory, United States; [3]Massachusetts Institute of Technology, United States; [4]National Taiwan University of Science and Technology, Taiwan; [5]Argonne National Laboratory, United States

The development of solid-state batteries has been slowed by limited understanding of the features that control ion mobility in solid electrolytes (SE). In the case of anti-perovskite (AP) SE, lattice distortions have been proposed as one such controlling factor: APs that exhibit distortions of the octahedral building blocks are predicted to exhibit enhanced ionic mobility. Nevertheless, large distortions come at a cost to stability, implying a tradeoff between stability and ionic mobility. The present study combines theory and experiments to explore the synthesizability of several marginally-stable APs predicted to exhibit high mobility for Li^+, Na^+, and K^+. Density functional theory calculations, in combination with the quasi-harmonic approximation, were used to predict the free energy change, $\Delta G_r(T)$, for synthesis reactions involving 36 alkali-metal-based APs, X_3AZ (X = Li, Na, or K; A = O, S, or Se; Z = F, Cl, Br, or I). A linear correlation is observed between the degree of lattice distortion and the stabilization temperature, at which $\Delta G_r(T) = 0$. Hence, APs with the highest ionic mobility generally require the highest synthesis temperatures. These data were used to guide experimental synthesis efforts of APs by estimating the temperatures above which a given AP is expected to be thermodynamically stable. Attempts were made to synthesize several AP compositions; overall, good agreement is obtained with the computational predictions. These data suggest that a compound’s zero Kelvin decomposition energy is an efficient descriptor for predicting the ease and likelihood of synthesizing new SEs.

Halide-Based Solid-State Batteries—Electrolyte, Stability, Interface and Electrode Xueliang A. Sun; University of Western Ontario, Canada

All-state-state lithium batteries (ASSLBs) have gained worldwide attention because of intrinsic safety and increased energy density. Compared with other types of solid-state electrolytes including oxide-based, polymer-based and sulfide-based electrolytes, recently-developed halide-based solid-state electrolytes (SSEs) have garnered considerable attention for all-solid-state lithium batteries (ASSLBs) due to the high ionic conductivity, high oxidation voltage and good stability toward oxide cathode materials [1]. However, there are still many challenges in halide-based solid-state electrolytes for ASSLBs including controllable and mass-production synthesis, achieving high humidity tolerance and demonstrate high-performance of ASSLBs; in particular,

increased understanding of mechanisms during synthesis and tuning their properties of the electrolytes as well as interface with electrode materials[1].

In this talk, **(i)** I will demonstrate synthesis strategy [2-3], in particular, new and salable water-mediated synthesis method [2]. **(ii)** I will report a systematic study on the correlations among structural evolution, Li^+ migration properties, and humidity stability resulting of the halide-based electrolytes, along with in-situ characterization for understanding of the mechanisms [4], **(iii)** Full cell battery performance will be optimized [5], and **(iv)** humidity ability [6]. In the end, energy densities of ASSLBs using different solid-state electrolytes in ASSLBs will be discussed [7].

Development of PEO-Based Polymer-In-Salt Electrolytes for High-Voltage Lithium Metal Batteries Haiping Wu, Peiyuan Gao, Hao Jia, Ji-Guang Zhang and Wu Xu; Pacific Northwest National Laboratory, United States

Rechargeable lithium (Li) metal batteries are regarded as the next-generation power sources due to their high energy density that can potentially reach 500 Wh kg^{-1} at cell level. The success of high energy-density Li metal batteries largely depends on the development of electrolytes because the electrolyte should be chemically and electrochemically stable on both Li metal anode and high-voltage cathode, suppress the growth of mossy/dendritic Li morphology and prevent the penetration of Li dendrites. Currently, the liquid electrolytes have achieved much progress, reaching a high Li Coulombic efficiency (CE) about 99.5% and a high voltage stability up to 4.5 V. However, the Li CE is still not high enough to ensure the long cycle life and the mossy/dendritic Li formation during repeated cycling would cause safety concerns. The solid-state inorganic electrolytes face more challenges, in either low ionic conductivity, high interfacial resistance with electrodes, poor stability with Li metal or high voltage cathode, unable to prevent Li penetration, or low mechanical strength, etc. The third approach is to use polymer or polymer composite electrolytes, which may mitigate the above issues related to liquid electrolytes and solid-state inorganic electrolytes. Polyethylene oxide (PEO) is the most widely studied polymer in polymer electrolytes and batteries. However, the conventional PEO-based electrolytes have low room-temperature ionic conductivity and low oxidative stability (< 4 V vs. Li/Li^+), thus their applications must be set at high temperatures and limited to 4 V-class cathode materials, resulting in a low energy density of the batteries. Therefore, to develop high-voltage PEO-based electrolytes for Li metal batteries is of high significance. In this talk, we will report the efforts at PNNL to develop PEO-based polymer-in-salt electrolytes that are stable up to 4.3 V. More details will be discussed during the presentation at the meeting.

Ionic Conductivity Transitions in Sodium Antiperovskite Ionic Conductors Yiliang Li[1], Ping-Chun Tsai[1], Fei Wang[1], Sunil Mair[1], Duhan Zhang[1], Liang Yin[2], Saul Lapidus[2] and Yet-Ming Chiang[1]; [1]Massachusetts Institute of Technology, United States; [2]Argonne National Laboratory, United States

Anti-perovskites materials have recently attracted great interest as a family of solid state electrolytes with high ionic conduction.[1] Typical solid-state ionic conductors have temperature-dependent ionic conductivity following Arrhenius behavior over a substantial range of temperature, corresponding to a constant activation energy E_a. In the Na_3OCl antiperovskite, there are regimes of Arrhenius behavior separated by broad transitions, all while the structure remains cubic . Such non-Arrhenius ionic conductivity of Na_3OCl has been observed in previous literature. [2][3] However, there is no clear explanation for this non-Arrhenius transition. Differential scanning calorimetry shows thermal transitions in the vicinity of these conductivity transitions. Reitveld refinement on temperature dependent synchrotron XRD of Na_3OCl suggests changes in the B_{eq} and anisotropic U_{33} of Na around 305ºC, which is consistent with the conductivity jump temperature. Meanwhile, the octahedral tilts observed at low temperature becomes much less above the transition temperature. We explain this as the activation of octahedra fluctuation[1] above the transition temperature as the time-averaged synchrotron fitted structure becomes closer to cubics . In this work, we use multiple temperature-resolved characterization methods including synchrotron XRD, transport measurements, and calorimetry, and modeling by AIMD and DFT, to understand this behavior and to gain insight into tuning antiperovskites for high ionic conductivity.

This work was supported as part of the Joint Center for Energy Storage Research, an Energy Innovation Hub funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences.

2:00 PM EN02.12.05

Visualizing the Morphology Variation of CuS-Based SSBs by 3D Tomography Katherine A. Mazzio[1,2], Zhenggang Zhang[2], Kang Dong[1], Ingo Manke[1] and Philipp Adelhelm[2,1]; [1]Helmholtz-Zentrum Berlin, Germany; [2]Humboldt-Universität zu Berlin, Germany

Solid state batteries (SSBs), especially those utilizing conversion-type active materials (C-AMs), are one of the most promising future energy storage devices.[1] However, the volume variation of C-AMs upon electrochemical cycling are a great challenge for the mechanical stability of SSBs. The periodic volume variation is known to deteriorate the physical contact between the AMs and solid electrolytes (SEs), and emphasizes the necessity of achieving robust mechanical properties.[2] Although considerable progress already made by choice of materials, modulation of their interfaces, or even adopting new

battery concepts,[3] there is still a long way to go in order to realize practical SSBs.

Obtaining a better understanding of SSBs is highly desirable, but appropriate methods are often limited by their shallow penetration depth alongside design aspects of the cells. Compared with other technologies, 3D tomography is able to penetrate solid-state samples and detect details of the bulk by virtue of utilizing high energy X-Rays, making 3D tomography a powerful technology for visualizing SSBs during operation.[4] CuS is a well-studied conversion material with high electronic and ionic conductivity that exhibits a volume expansion of 75% after being fully lithiated. It also shows good cycling stability and is known to react with lithium in a manner that produces a macro-scale displacement of Cu in SSBs.[5] While known to occur in standard cells, this type of displacement reaction in metal sulfides has not yet been studied in SSBs.

Herein, a model SSB with Li/β-Li_3PS_4/μm-CuS structure was investigated by 3D tomography to study the macro-scale displacement reaction and its accompanying morphological and volume variations. We found that the applied mechanical field can seriously affect the reaction, where the reduced Cu particles and cracks clearly demonstrate growth in preferred orientations. While Cu reduction is reversible, nearly 50% of cracks are maintained within the electrodes after the 1st delithiation. This results in disruption of the ionic and electronic transport pathways, as supported by a higher transfer resistance and the observation of more "dead" materials produced in the electrodes.

Crystal Structure and Structure-Property Relationship of New Halide Li-Ion Conductors as Solid Electrolyte for All-Solid-State Batteries Zhantao Liu[1], Jue Liu[2] and Hailong Chen[1]; [1]Georgia Institute of Technology, United States; [2]Oak Ridge National Laboratory, United States

Solid electrolyte is the key component for all-solid-state batteries. Extensive research attentions are being attracted to the design and development of high performance solid electrolytes with high ionic conductivity and low diffusion energy barriers. Recently halides with general formula Li_3MX_6 (M=metals such as Y, In and Sc; X=Cl or Br) have attracted a lot of attention from both industry and academia because the halide Li-ion conductors are potentially more all-around candidates for all-solid-state batteries than existing sulfides and oxides. They showed higher ionic conductivities than those of oxides (such as LLZO and variants) and better chemical and electrochemical stabilities than sulfides (such as LGPS and argyrodite materials). However, many detailed features in their crystal structure are yet to be clearly described and the key factors that govern the ionic conductivity are yet to be revealed. Here we report our recent findings in design, synthesis, electrochemical testing and particularly crystal structure characterizations of novel halide compounds. The long range structure and the thermodynamic stability are investigated with using ex situ and in situ synchrotron X-ray diffraction. The Li sublattice, local ordering and stacking faults are characterized with using neutron diffraction and pair distribution function analysis. The relation between these structural features and the ionic conductivity and diffusion energy barriers are revealed and discussed.

4:00 PM *EN02.13.01
A Solid Transformation of Energy Storage Eric D. Wachsman; University of Maryland, United States

Solid-state Li-batteries (SSLiBs) have the potential to be a transformational and intrinsically safe energy storage solution. However, their progress has been limited by high solid-solid interfacial impedance and numerous reports of Li-dendrites and a corresponding "critical current density". By first modifying the garnet surface to enable Li-metal to wet it and then fabricating garnet-electrolytes into tailored tri-layer microstructures to form electrode supported dense thin-film (~10μm) solid-state electrolytes we have been able to overcome these limitations. The microstrucurally tailored porous garnet scaffold support increases electrode/electrolyte interfacial area, overcoming the high impedance typical of planar geometry SSLiBs resulting in an area specific resistance (ASR) of only ~2 to 7 Ωcm^{-2} at room temperature. The unique garnet scaffold/electrolyte/scaffold structure further allows for charge/discharge of the Li-metal anode and cathode scaffolds by pore-filling, thus providing high depth of discharge ability without mechanical cycling fatigue seen with typical electrodes. Moreover, these scalable multilayer ceramic fabrication techniques, without need for dry rooms or vacuum equipment, provide for dramatically reduced manufacturing cost.

The fabrication of supported dense thin-film garnet electrolytes, their ability to cycle Li-metal at high current densities with no dendrite formation, and results for Li-metal anode/garnet-electrolyte based batteries with a number of different cathode chemistries will be presented.

4:30 PM *EN02.13.02
Solid State BaSeries—From Interfaces to High Energy Density Jihui Yang; University of Washington, United States

Room temperature lithium ion conductors have been intensively studied in an attempt to develop solid state batteries that can be deployed for high energy applications. In recent years, promising solid lithium ion conductors with competitive ionic conductivity to those of liquid electrolytes have been demonstrated. The integration of highly conductive solid electrolytes into the battery system is, however, still very challenging mainly due to the high impedance existing at different interfaces throughout the battery structure.

In this talk, I will highlight our recent work on the understanding of interfaces between the solid electrolytes and anode & cathode, providing new insights into enabling future all solid-state batteries. I will also show that high energy and long cycle life can be achieved in solid state batteries via optimizing the

interfacial thermodynamics.

5:00 PM EN02.13.03
Strategies to Enhance the Performance of All-Solid-State Sodium Batteries Yang Li, William Arnold, Selim Halacoglu and Hui Wang; University of Louisville, United States

All-solid-state sodium (Na) batteries (ASSSBs) attract increasing attention due to the use of high-capacity Na metal anode and solid electrolytes (SEs) with high safety. Recently, significant research achievements have been made in developing Na-ion conductors. In particular, sulfide SEs generally offer higher ionic conductivity (10^{-4}–10^{-3} S cm^{-1} at room temperature) and lower grain boundary resistance. However, the practical applications of sulfide-based ASSSBs are significantly hampered by the challenges originating from (1) significant reactions at SE/Na interface; (2) poor solid-solid contact between SE and electrodes. To solve these issues and enhance the electrochemical performance of sulfide-based ASSSBs, here, we design and demonstrate several strategies including elements doping in sulfide SEs and interface modifications between sulfide SEs and electrodes. As a result, long-term cycling stability was achieved due to 1) the formation of stable interface to prevent the sever interfacial reactions; 2) the creation of intimate contact between sulfide SEs and electrodes. These methods provide effective strategies to address the challenges between sulfide SEs and Na metal, enabling the successful utilization of Na metal and sulfide SEs in ASSSBs towards next-generation safe and high-energy density energy storage systems.

5:15 PM EN02.13.04
Enabling a Long Lasting Sodium All-Solid-State Battery Swastika Banerjee and Shyue Ping Ong; University of California, San Diego, United States

Sodium all solid-state batteries (Na-ASSBs) offer a combination of improved safety and lowered costs due to the use of non-flammable solid-state electrolytes (SSEs) and naturally abundant Na-based raw materials. However, a fundamentally different approach is necessary to achieve a simultaneous leap in multiple SSE properties – ionic conductivity, (electro) chemical stability and processibility. Our recent work has demonstrated long cycle performance of a Na-ASSB enabled by a new class of halide-based SSE, achieving a capacity retention of approximately 90% after 1000 cycles at a rate of 1C, representing one of the best Na-based battery performances in the literature till date. This was made possible through a joint computational and experimental exploration of novel halide-based Na SSEs. In this talk, I will discuss computational strategies based on ab initio and the machine learning interatomic potential, that has proven to be highly effective to report the discovery of moderate ionic conductivity of 6.6 x 10^{-5} S cm^{-1} at ambient temperature for $Na_{3-x}Y_{1-x}Zr_xCl_6$ (NYZC) several orders of magnitude higher than oxide coatings. Enhanced Na-conductivity in NYZC is attributed to abundant Na vacancies and cooperative MCl_6 rotation resulting non-Arrhenius behavior.

5:30 PM EN02.13.05
Shedding Light on the Sulfide Electrolytes/Electrode Interphases in Solid–State Batteries via Integrated Computation and Spectroscopy Chuntian Cao[1], Sizhan Liu[1], Yonghua Du[1], Nongnuch Artrith[2], Alexander Urban[2], Deyu Lu[1], Shinjae Yoo[1] and Feng Wang[1]; [1]Brookhaven National Laboratory, United States; [2]Columbia University, United States

Solid-state batteries (SSBs) have been recognized as promising next-generation rechargeable batteries because of their potential to push energy density limits and ensure safety. Sulfide-based solid electrolytes (SEs) are promising candidates for solid-state batteries (SSBs) because of their high ionic conductivity and good malleability. Like conventional liquid electrolytes, SE decomposes at the electrode-electrolyte interface when the potential is outside its electrochemical stability window, forming a solid-solid interphase (SSI) layer. SSI's properties and the dynamic evolution of its structure are crucial for the stability and performance of SSBs. For example, some decomposition products may have high ionic resistance, which is detrimental to the cell performance; some redox processes are reversible and participate in the electrochemical cycle with the active electrode materials. Understanding the dynamic structure of the SSI and its impact to transport properties is essential for incorporating sulfide SE into commercial batteries.

Modelling the inherent complexity and the dynamic evolution of the SSIs is very challenging with first-principles methods, such as density functional theory, because of the computational hurdle associated with the large system size (*e.g.*, more than one thousand atoms) and time scale. Herein, we develop an integrated approach that combines high-performance computing and machine learning tools with state-of-the-art synchrotron X-ray absorption spectroscopy (XAS)/electron energy-loss spectroscopy (EELS), to tackle the complex SSIs. *Ex situ* and *in situ* XAS/EELS are applied to characterize SSIs' chemical structure and dynamic evolutions upon formation and during electrochemical cycling. We focus on two types of sulfide SEs, the baseline glass/ceramic Li_2S-P_2S_5 (LPS), and the more advanced argyrodite Li_6PS_5Cl (LPSCl) which has higher ionic conductivity and is promising for commercial use. Our results reveal the reaction mechanism at the interface of sulfide-based SEs and provide a fundamental understanding of the current material limitations. This study can help identify key material parameters to optimize cell performance, thus providing a basis for the design and optimization of SEs for SSBs.

5:45 PM EN02.13.06
Rational Design of Cathode Interface for Wide Temperature All-Solid-State Batteries Sixu Deng, Changhong Wang and Xueliang A. Sun; Western University, Canada

Inorganic all-solid-state lithium-ion batteries (ASSLIBs) are considered as a promising candidate for next-generation energy storage devices that can meet the safety requirements of electric vehicles by utilizing nonflammable solid-state electrolytes (SSEs).[1, 2] However, the poor interfacial compatibility in composite cathodes (SSE/cathode/carbon/current collector) is challenging the stable delivery of electrochemical performance.[3, 4] Our research mainly focuses on the development of interfacial engineering strategies to address the challenges at the internal and external interfaces in the composite cathodes targeting high-performance ASSLIBs. [5-7] In this talk, three parts will be included. Firstly, I will review our previous studies. For example, at the SE/cathode interface, we designed a dual-functional Li3PO4 (LPO) modification to suppress both the side-reactions and contact loss at the SSE/cathode interface.[8] We also developed a surface-cleaning strategy to investigate the underlying degradation mechanism at SSE/cathode interface.[9] At the SSE/carbon interface, a poly(3,4-ethylenedioxythiophene) (PEDOT) modification is designed as a semiconductive additive for composite cathodes.[10] The modified ASSLIB demonstrates a competitive rate capacity, which is 10 times greater than that of the bare cathode. Secondly, I will introduce our recent work, focusing on the current collector interface. Our study found that the interfacial stability at the current collector interface is highly dependent on the temperatures. At the end of this talk, I will introduce our work on low-temperature inorganic ASSLIBs. Our study revealed that manipulating the electronic conductivity in the composite cathodes is the key factor that determines the electrochemical performance at low temperatures.

SESSION EN02.14: Solid State Batteries I
Session Chairs: Fudong Han and Huilin Pan
Monday Afternoon, December 6, 2021
EN02-Virtual

6:30 PM *EN02.14.01
Stablized Interface in Li-Ion Batteries via *In Situ* Solidification Jiaze Lu[1], Rusong Chen[1], Xiqian Yu[1] and Hong Li[1,2]; [1]Institute of Physics, Chinese Academy of Sciences, China; [2]Beijing Welion New Energy Technology Co., Ltd., China

Thermal runaway of nonaqueous Li-ion batteries starts from decomposition of the solid electrolyte interphase (SEI). Introduction of solid electrolyte has been considered as a promising solution to improve the safety and achieving high energy density. However, it is quite challenging for the construction well-conducted and thermal stable interfaces. Our previous research indicates the thermal stability between metallic lithium and inorganic solid-state electrolytes is not always under controlled. Herein, we proposed that the *in-situ* solidification strategy is a comprehensive methodology for the pathway toward practical solid state batteries. For example, the *in-situ* solidification strategy is applied to generate artificial solid electrolyte interface (SEI) between electrodes (both cathode and anode) and electrolytes. The *in-situ* built SEI not only promotes the electrochemical stability, but also shows great potential for the promotion on the thermal stability of SSBs. Thus, the *in-situ* solidification could make the thermal property of SEI well-designed and controllable, which means the thermal stability of the battery could be improved significantly.

7:00 PM *EN02.14.02
Sulfide Electrolyte for All-Solid-State Rechargeable Batteries Xiayin Yao, Hongli Wan, Gaozhan Liu and Zhihua Zhang; Ningbo Institute of Materials Technology and Engineering, Chinese Academy of Sciences, China

Sulfide electrolytes have been considered as one of the most promising ion conductors for all-solid-state lithium batteries due to the breakthrough in ionic conductivity, low particle-boundary resistance and excellent ductility.[1] Different type sulfide electrolytes with room temperature ionic conductivity of $10^{-3} \sim 10^{-2}$ S/cm have been successfully synthesized. The electrochemical stability and compatibility with lithium can be improved with oxide or halogen doping[2] as well as densified solid electrolyte with flat surface[3]. Based on the high ionic conductive sulfide electrolyte powder, thin film were obtained by wet chemical surface modification method[4] or dry film approach[5]. The obtained $Li_{5.4}PS_{4.4}Cl_{1.6}$ sulfide electrolyte membrane possesses a high ionic conductivity of 8.4 mS cm^{-1} with a thin thickness of 30 μm, which is crucial to realize high energy density all-solid-state rechargeable batteries.[5] Compared with lithium transition metal oxide cathodes, sulfur based materials, especially transition metal sufides, show much better interface compatibility with sulfide electrolytes. A series of transition metal sulfides or sulfur-based materials are employed as electrodes for all-solid-state rechargeable batteries, such as MoS_3[6] FeS_2[7], VS_4[8] or sulfur[9]. The intimate contact interface can be realized by coating sulfide electrolytes evenly on the surface of active materials, which enables the battery to withstand the large stresses/strains during repeated charging/discharging, leading to significant improvements in energy density and cycle life.[10] Besides, in order to improve electronic conductions, highly conductive carbonaceous materials were employed as hosts for nanosized sulfur based materials to form active material/electrom additive nanocomposites. Although different reaction mechanisms, all these nanocomposites employed as cathodes in all-solid-state ltihum batteris show enhanced electrochemical performances[6, 9]. Furthermore, coating sulfide electrolyte on active material/electron additive nanocomposites can simultaneously realize three-dimensional electronic/ionic conduction networks at the triple solid-solid contact interface[8, 11]. For example, 10%rGO-VS_4@$Li_7P_3S_{11}$ nanocomposites with multi-channel continuous electronic/ionic conductive network can be prepared by a facile liquid-phase deposition reaction and further employed as an alternative material for sulfur cathode in all-solid-state room temperature lithium batteries, exhibiting improved rate capability and cycling stability. [8]
Clearly, all-solid-state lithium batteries with sulfur-based cathodes and sulfide electrolytes are promising next generation high energy density batteries. More attentions should be concerned in the dendrite formation, interfacial contact, reducing the electrolyte thickness as well as high specific areal capacity with high current density.

7:30 PM EN02.14.03
Exploration of Li-Rich Inorganic Compounds with Inverse Ruddlesden-Popper-Type Structure by First-Principles DFT Calculations for Solid Electrolyte Application in All-Solid-State Batteries Randy Jalem[1], Yoshitaka Tateyama[1], Kazunori Takada[1] and Masanobu Nakayama[2]; [1]NIMS-GREEN, Japan; [2]Nagoya Institute of Technology, Japan

The all-solid-state Li-ion battery (Li-ASSB) is expected as one of the next-generation energy conversion and storage devices that could potentially become widespread in use owing to a number of its promising features such as high energy density (with the use of Li metal/alloy as anode), high working capacity (with the use of high-voltage cathodes), and high safety in contrast to conventional batteries with organic and liquid components (i.e., organic/liquid electrolytes). These aforementioned features are closely linked to the inorganic solid electrolyte (SE) component in Li-ASSB. Thus, novel high-performance SE design and optimization has become one of the the highly active areas in battery research.
Recently, electronically-inverted Li-rich perovskites have attracted great interest for SE use. In here, using density functional theory (DFT) calculations, an in-silico-generated chemical space of more than 500 inorganic compounds with an inverse Ruddlesden-Popper-type structure ($Li_4(X_{1-a}X'_a)(Z_{1-b}Z'_b)_2$, where X, X' = {$O^{2-}$, S^{2-}, Se^{2-}, Te^{2-}} and Z, Z' = {F^-, Cl^-, Br^-, I^-}, $0 \leq a, b \leq 1$) was explored in order to find novel solid electrolyte candidates. Based from DFT thermodynamic convex hull results, about 167 compounds were determined to be (meta)stable, at least 20 novel compounds were found to belong to the $Li_4O(Cl_{1-b}Br_b)_2$ series and O/S/I-bearing compositions. Representative compounds were further evaluated using: i) phase diagram approach for (electro)chemical stability analysis, ii) slab modelling for surface properties and ii) DFT molecular dynamics method for characterizing Li^+ ion conductivity and transport mechanism. Computationally cheap, yet useful, material descriptors were also determined based from correlation analysis of the accumulated DFT dataset. These descriptors can be useful in future solid electrolyte design/screening, such as for thermodynamic phase stability, electronic property, and Li^+ ion conduction properties.

Mechanochemical Synthesis and Characterization of Hexagonal Li_4SnS_4-Based Solid Electrolytes Misae Otoyama, Kentaro Kuratani and Hironori Kobayashi; National Institute of Advanced Industrial Science and Technology (AIST), Japan

Sulfide solid electrolytes (SEs) have attracted much attention because of their high ionic conductivity and deformability. However, sulfide SEs have an issue of low air-stability. They generate H_2S gas when exposed to air. Sahu *et al* reported that stability of sulfide SEs against moisture in air can be explained by hard and soft acids and bases theory.[1] Based on the theory, Sn-based SEs such as Li_4SnS_4 show higher air-stability than argyrodite type SEs and Li_2S–P_2S_5 type SEs, which have P–S bonds.[2,3] However, Li_4SnS_4 showed lower ionic conductivity of ~10^{-5} S cm^{-1} 25 °C than the conventional SEs (10^{-3}–10^{-4} S cm^{-1}). Kanazawa *et al* reported that the hexagonal Li_4SnS_4 prepared by mechanochemical treatment showed higher ionic conductivity than orthorhombic Li_4SnS_4 prepared by solid phase synthesis.[3] In this study, LiI and Li_3PS_4 were added to hexagonal Li_4SnS_4 to increase ionic conductivity of Li_4SnS_4-based SEs. Furthermore, air-stability of them was compared.
The XRD patterns of LiI-added Li_4SnS_4 showed the diffraction peaks of hexagonal Li_4SnS_4 shifted to the lower angle, suggesting that the lattice volume increased due to the I^- ion with large ionic radius. The sample with x = 0.43 in xLiI●(1−x)Li_4SnS_4 showed the higher ionic conductivity of 1.6×10^{-4} S cm^{-1} at 25 °C than that with x = 0 (4.5×10^{-5} S cm^{-1}). Furthermore, XRD patterns of as-milled samples of LiI–Li_4SnS_4–Li_3PS_4 systems exhibited halo patterns, indicating that they became amorphous state due to the multicomponent. The sample of 37LiI●38Li_4SnS_4●25Li_3PS_4 (mol%) showed the ionic conductivity of 4.5×10^{-4} S cm^{-1} at 25 °C. These samples are decomposed by heat-treatment at more than 240 °C, suggesting that they are thermally metastable. The prepared Li_4SnS_4-based SEs showed similar air-stability to hexagonal Li_4SnS_4 and generated smaller amount of H_2S gas than the argyrodite type SEs.

Molecular Dynamics Study of Peculiarly High Li-Ion Conductivity in Li{$N(SO_2F)_2$}{$NCCH_2CH_2CN)_2$ Molecular Crystal Ryoma Sasaki[1,2], Makoto Moriya[3,3], Yuki Watanabe[1], Kazunori Nishio[1], Taro Hitosugi[1] and Yoshitaka Tateyama[1,2]; [1]Tokyo Institute of Technology, Japan; [2]National Institute for Materials Science, Japan; [3]Shizuoka University, Japan

All-solid-state battery (ASSB) has attracted great attention for future energy storage with safety and high-energy density. The practical application of ASSBs requires solid-state electrolytes (SSEs) which are not only highly conductive but also flexible for good interfacial contant between SSEs and electrodes. Recently, Li{$N(SO_2F)_2$}{$NCCH_2CH_2CN)_2$ (Li(FSA)$(SN)_2$) organic flexible molecular crystal has been experimentally reported as a promising SSE with high Li-ion conductivity of ca. 10^{-4} S cm^{-1} at room temperature and exceptionally low activation energy (E_a) of 28 kJ mol^{-1} [K. Tanaka *et*

al., *Nano Lett.*, 2020, **20**, 8200-8204]. However, the fast conduction mechanism remains unexplained because all the Li-ions are held in the crystal framework, and the distances between the constituent Li-ions are too long for hopping. Herein, molecular dynamics (MD) simulations were performed to clarify the mechanism of the extraordinarily fast Li-ion conduction in the succinonitrile (SN)-based molecular crystal. Atomistic MD revealed that Li-ion vacancies can exist stably in $Li(FSA)(SN)_2$ crystal and give rise to the one-dimensional Li-ion hopping pathway contrary to the conventional scenario in which the fast conduction is attributed to the three-dimensional pathway. The calculated E_a of 34 kJ mol^{-1} is in good agreement with the experimental value, which substantially supports the one-dimensional conduction. The low E_a is intimately connected with the motion of the SN molecules. Two SN molecules at the vacancy site change their conformation, following which one of the SN molecules creates an electronegative region, while the other one carries the adjacent Li-ion to the electronegative region by the swing motion. The insights on the behavior of organic moieties and Li-ion conduction obtained from this study enable to propose a novel design principle for the fast ion-conductive molecular crystals.

Universal Liquid-Phase Synthesis of Sulfide Solid Electrolyte for All-Solid-State Batteries Yoon Seok Jung; Yonsei University, Korea (the Republic of)

For addressing the requirements of better safety and higher energy density of lithium-ion batteries targeting for the electric vehicle application, solidification of electrolytes using nonflammable superionic conductors has been rigorously investigated. Owing to their high ionic conductivities reaching maximum 10^{-2} S cm^{-1} at room temperature and the mechanically-sinterable property, sulfide solid electrolyte (SE) materials are considered as the key to the success of all-solid-state batteries. Moreover, wet-chemical syntheses and/or processes of sulfide SEs have been developed. The wet-chemical synthesis, such as using tetrahydrofuran, proceeds in a suspension, and provides opportunities in multiple aspects including particle size control and the reduction of mixing energy. For several compositions of sulfide materials, it has been shown that SEs could be fully dissolved into specific solvents, such as ethanol and methanol, and then the original SEs could be precipitated via the removal of solvent and subsequent heat treatment. This is referred to as the solution process. The solution processability of sulfide SEs offers direct SE coatings on active materials and infiltration of the conventional electrodes used for lithium-ion batteries. Both of which allow for intimate ionic contacts between active materials and SEs.
In this presentation, we report on a new universal liquid-phase synthesis of sulfide solid electrolytes, which takes the combined advantages of the wet-chemical synthesis and the solution process. It is demonstrated that SE precursors including not only conventional Li_2S, P_2S_5, and LiX but also metal sulfides are fully dissolved in a solvent, forming a homogeneous solution. Via the universal liquid-phase synthesis, promising electrochemical performances are demonstrated for Li- and Na-ion all-solid-state batteries.

Tailoring Slurries Using Cosolvents and Li Salt for Contact Engineering for All-Solid-State Batteries Kyu Tae Kim[1], Dae Yang Oh[1], Tae Young Kwon[1,2] and Yoon Seok Jung[1]; [1]Yonsei University, Korea (the Republic of); [2]Hanyang University, Korea (the Republic of)

All-solid-state Li or Li-ion batteries (ASLBs) using inorganic solid electrolytes (SEs) have promising opportunities in terms of better safety and higher energy density. The cut-off score of Li^+ conductivities of 10^{-3} S cm^{-1} for room-temperature operable ASLBs severely narrows the SE materials to several classes of materials, including sulfides, closo-borates, and halides. Thanks to mechanical sinterability, cost, and density, sulfide SEs are highly competitive, however, they suffer from poor chemical stability when preparing wet-slurries. They are dissolved in conventional polar organic solvents and conventional polymers such as PVDF are thus not available. Furthermore, the polymeric binders impedes Li^+ ion transport. This could be relieved by employing liquid electrolytes or gel polymer electrolyte binders but at the expense of the ASLB's thermal stability.[1]
In this study, we reports on our recent development of dry polymer electrolyte (DPE) binders for practical ASLBs.[2] Furthermore, the use of cosolvents and Li salt offers the engineering ability to control ionic contacts and Li^+-conductivity, respectively. Remarkable enhancements in utilizing electrode active materials and their outstanding thermal stability, enabled by the contact and Li^+-conductivity engineerable DPE-based binders, will be presented.

Development of New Ionic Electrolytes by Tailoring the Cation, Anion and Molecular Structure. Jenny Pringle, Faezeh Makhlooghiazad and Colin Kang; Deakin University, Australia

Organic ionic plastic crystals (OIPCs) have shown increasing promise as solid state electrolytes for energy devices such as lithium or sodium batteries, DSSCs and fuel cells. OIPCs are crystalline phases found in many of the same organic salt families as ionic liquids but these materials have elevated melting points and exhibit various forms of disorder, which is the origin of their plastic mechanical properties. This intrinsic disorder is fundamentally responsible for the fast ion conduction of introduced target ions, such as lithium or sodium, and core to their efficient performance as solid-state electrolytes. However, how different cation, anion and molecular structures impact the phase behaviour, disorder and ion transport in the electrolytes is still not well understood.
Key to the development of plastic crystal electrolytes is expanding the range of cations and anions available, and understanding the resulting structure and dynamics. Here we discuss our development of new plastic crystal-based materials for energy applications, in particular lithium metal batteries. We also discuss our recent research into novel zwitterion-based electrolytes. Insights into the relationships between the different cations, anions and zwitterionic

structures and the physical, thermal and electrochemical properties of the resultant solid electrolytes are presented.

10:00 PM EN02.15.04
Fabrication and Characterization of Solid-State Li Batteries Using $Li\{N(SO_2F)_2\}(NCCH_2CH_2CN)_2$ Molecular Crystalline Electrolyte and $LiCoO_2$ Thin-Film Electrode Yuki Watanabe[1], Kenjiro Tanaka[2], Kazunori Nishio[1], Ryo Nakayama[1], Ryota Shimizu[1,3], Makoto Moriya[2] and Taro Hitosugi[1]; [1]Tokyo Institute of Technology, Japan; [2]Shizuoka University, Japan; [3]Japan Science and Technology Agency, Japan

Solid-state Li batteries have the potential for the increased power density. For this aim, it is crucial to understand the structural, chemical, and mechanical properties of interfaces between electrolyte and electrode. A molecular crystalline solid electrolyte is a candidate for better mechanical contact with the electrode due to its physical flexibility [1]. Among a variety of molecular crystals, we selected $Li(FSA)(SN)_2$ composed of lithium bis(fluorosulfonyl)amide (FSA: $Li\{N(SO_2F)_2\}$) and succinonitrile (SN: $NCCH_2CH_2CN$) [2]. Although $Li(FSA)(SN)_2$ exhibits a high Li-ion conductivity of ~10^{-4} S cm^{-1} at 30 ºC, the battery operation using this electrolyte has yet been tested. In this study, we fabricated solid-state batteries using $Li(FSA)(SN)_2$ molecular crystals and $LiCoO_2$ thin-film electrodes. The cyclic voltammogram showed redox current peaks at around 3.9 V vs. Li/Li^+, being in good agreement with the redox voltages of $Co^{3+/4+}$ for $LiCoO_2$ positive electrode. When the battery was charged and discharged at the current density of 1 µA cm^{-2} in 3.0–4.0 V vs. Li/Li^+, the discharge capacity after 100 cycles maintained 90% of the 1st discharge capacity (50 mAh g^{-1}) and the Coulombic efficiency in each cycle was approximately 95%. These results indicate the high cycle stability and efficiency in solid-state Li batteries using $Li(FSA)(SN)_2$ molecular crystals [2].

Chemically-Modified Binders with Improved Mechanical Strength for Sheet-Type Electrodes of All-Solid-State Batteries Tae Young Kwon[1,2], Kyu Tae Kim[1], Dae Yang Oh[1], Seunggoo Jun[1], Yong Bae Song[1] and Yoon Seok Jung[1]; [1]Yonsei University, Korea (the Republic of); [2]Hanyang University, Korea (the Republic of)

Despite the increased demand of high-energy density lithium-ion batteries (LIBs), safety issues caused by the use of flammable organic electrolytes hinder their market expansion. In this regard, all-solid-state lithium batteries (ASLBs) using nonflammable inorganic solid electrolytes (SEs) are considered a promising alternative to conventional LIBs.[1] In particular, high Li-ion conductivity and deformable property of sulfide SEs are important advantages for high-performance practical ASLBs. However, there has been much room for improvement of performances of ASLBs using sulfide SEs. Specifically, the chemo-mechanical issues of crack propagation occurring at electrode active materials and interfaces are attributed to the severe deterioration of the performance.[2,3] Thus, the adhesion property of polymeric binders that provides the mechanical integrity of ASLBs is important.
In this presentation, we report on our recent development of polymeric binders whose mechanical strength are improved via chemical method during slurry fabrication process. Promising electrochemical performances of ASLBs using the chemically-modified binders will be presented

Tuning Schottky Barrier Height at the Interface of Metal and Mixed Conductor Kazunori Nishio[1], Tetsuroh Shirasawa[2], Koji Shimizu[3], Naoto Nakamura[1], Ryota Shimizu[1], Satoshi Watanabe[3] and Taro Hitosugi[1]; [1]Tokyo Institute of Technology, Japan; [2]National Institute of Advanced Industrial Science and Technology (AIST), Japan; [3]The University of Tokyo, Japan

Understanding electronic and ionic transport across interfaces is critical for designing high-performance electronic and ionic devices. However, the electronic structures at the interfaces of metals and mixed conductors, which conduct both electrons and ions, remain poorly understood. To quantitatively address the issue, we fabricated thin-film batteries using epitaxial thin films through an in-vacuo process [1]. This study reveals that a Schottky barrier is present at the interface of a Nb-doped $SrTiO_3$ metal (current collector) and a $LiCoO_2$ mixed conductor (positive electrode) and that the interfacial resistance can be tuned by inserting an electric dipole layer. Furthermore, the interfacial resistance significantly decreased by more than 5 orders of magnitude upon the insertion of a 1 nm-thick insulating $LaAlO_3$ layer at the interface [2]. We apply these techniques to solid-state lithium batteries and demonstrate that tuning the electronic energy band alignment by interfacial engineering is applicable to the interface of metals and mixed conductors. These results highlight the importance of designing positive electrode and current collector interfaces for solid-state lithium batteries with high power density.

The Synthesis of Core-Shell Particles for Lithium-Ion Batteries by Chemical Solution Deposition Dries De Sloovere[1,2], Fulya Ulu Okudur[1,2], Satish Kumar Mylavarapu[1,2], Marlies Van Bael[1,2] and An Hardy[1,2]; [1]UHasselt, Belgium; [2]EnergyVille, Belgium

Lithium-ion batteries (LIBs) are the most common energy storage technology for portable electronics and electric vehicles. Their performance may be further improved by the synthesis of core-shell particles, where an active material core is coated with a shell consisting of a material with high conductivity. As such, the shell may enhance the energy and power density of batteries containing a liquid electrolyte by creating a network for electron and ion transport. The shell materials may also act as protective coatings for an improved electrochemical stability, e.g. by preventing the dissolution of transition metals, particularly manganese.
This presentation will provide an overview of our recent research on the preparation of core-shell particles for use as positive electrode materials in LIBs. The synthesis of these materials relied on chemical solution deposition (CSD) as coating technique, where the shell material is formed from a solution. By careful control of the hydrolysis and condensation of a titanium precursor dissolved in ethanol, an amorphous TiO_x layer was formed on the surface of $LiNi_{0.5}Mn_{1.5}O_4$ (LNMO) particles.[1] Subsequent annealing caused the diffusion of Ti ions into the LNMO surface and the formation of a 2-4 nm thick Ti-rich spinel surface. Ti surface doping suppressed the dissolution of Ni and Mn and thereby increased LNMO's electrochemical stability and rate capability. In another instance, LNMO core particles were coated with amorphous $Li_4Ti_5O_{12}$ (LTO) using a solution-gel synthesis route.[2] In this technique, aqueous precursor solutions containing the metal ions are made and mixed in stoichiometric ratios. The LNMO particles are dispersed in the precursor mixture, after which the water is dried off and the resulting material is annealed. The amorphous LTO coating improved LNMO's rate capability and acted as a HF scavenger, increasing the electrochemical stability.

Similar coating techniques were also employed for the coating of titanium oxide layers on $LiNi_{0.6}Mn_{0.2}Co_{0.2}O_2$ (NMC-622) particles.[3] NMC-622 can offer a high energy density owing to its high theoretical capacity. However, increasing the upper cut-off potential to further increase the energy density has a negative impact on its electrochemical stability. Applying a TiO_x coating on the NMC-622 surface was found to have a positive influence on the electrochemical stability of NMC-622/$Li_4Ti_5O_{12}$ full cells. In half cells, TiO_x coated NMC-622 showcased an improved rate capability compared to the uncoated material. The rate capability of NMC-622 could also be improved by coating it with $LiNbO_3$ using a solution-gel coating technique.
In summary, CSD routes were developed for the synthesis of core-shell materials, consisting of a core of an active material for LIBs, and a shell that provides conductivity and electrochemical stability. The CSD routes are versatile and may be extended to numerous shell and core materials, providing exciting opportunities to improve the latter's performance in various applications.

Atomistic Insights into Oxide and Oxyhalide Solid Electrolyte Materials Saiful Islam; University of Bath, United Kingdom

In the critical area of sustainable energy storage, solid-state batteries are attracting considerable attention due to their potential safety, energy-density and cycle-life benefits [1]. A complete understanding of solid electrolyte materials for lithium- and sodium-ion batteries requires greater fundamental knowledge of their structural, ion transport and interface properties. For example, the impact of aliovalent doping, defect clustering and grain boundaries on Li- and Na-ion conduction properties are often not fully understood on the atomic-scale. This talk will highlight recent studies [2-4] on ion conduction mechanisms, doping effects and grain boundary structures in oxide and oxyhalide anti-perovskite based solid electrolyte materials.

11:00 AM *EN02.16.02
Understanding Bulk and Interfacial Li-Ion Transport in $Li_7La_3Zr_2O_{12}$ Garnets and Composite Solid Electrolytes Using Atomistic Simulations Javier Carrasco[1], Maurico R. Bonilla[2], Fabian A. Garcia Daza[3], Pierre Ranque[1], Frederic Aguesse[1] and Elena Akhmatskaya[2,4]; [1]CIC energiGUNE, Spain; [2]Basque Center for Applied Mathematics, Spain; [3]The University of Manchester, United Kingdom; [4]Basque Foundation for Science, Spain

Garnet $Li_7La_3Zr_2O_{12}$ is a promising solid electrolyte candidate for solid-state Li-ion batteries. However, sufficiently fast Li-ion mobility required for battery applications only emerges at high temperatures, upon a phase transition to cubic structure. A well-known strategy to stabilize the cubic phase at room temperature relies on aliovalent substitution; in particular, the partial replacement of Li^+ by Al^{3+} and Ga^{3+} ions. Yet, fundamental aspects regarding this aliovalent substitution remain poorly understood. Here we present some exciting examples of our most recent theoretical work in this area [1-2] and, with the aid of experiments, also expand our simulation capabilities towards understanding interfacial Li-ion transport in composite materials comprising a conductive, flexible polymer matrix embedding $Li_7La_3Zr_2O_{12}$ filler particles [3].

We first examine why, despite having the same formal charge, Ga^{3+} substitution yields higher conductivities (10^{-3} S/cm) than Al^{3+} (10^{-4} S/cm). To answer this long-standing question, we combined for the first time molecular dynamic simulations and advanced hybrid Monte Carlo sampling techniques to precisely unveil the atomistic origin of this phenomenon explicitly performing simulations at room temperature [1]. Our results show that Li^+ vacancies generated by Al^{3+} and Ga^{3+} substitution remain adjacent to Ga^{3+} and Al^{3+} ions, without contributing to the promotion of Li^+ mobility. However, while Ga^{3+} ions tend to allow limited Li^+ diffusion within their immediate surroundings, the less repulsive interactions associated with Al^{3+} ions lead to a complete blockage of neighboring Li^+ diffusion paths. This effect is magnified at lower temperatures and explains the higher conductivities observed for Ga-substituted systems.

In addition, we thoroughly compared the room temperature Li-ion diffusion in tetragonal and cubic Al-substituted $Li_7La_3Zr_2O_{12}$ [2]. Combining the conductivities of individual phases through an effective medium approximation allowed us to estimate the conductivities of cubic/tetragonal phase mixtures that are in good agreement with those reported in several experimental works. This suggests that phase coexistence (due to phase equilibrium or gradients in Al content within a sample) could have a significant impact on the conductivity of Al-substituted $Li_7La_3Zr_2O_{12}$, particularly at low Al contents.

Finally, we investigate interfacial Li-ion transport in a composite solid-state electrolyte integrating polyethylene oxide (PEO) plus lithium bis(trifluoromethanesulfonyl) imide (LiTFSI) and Ga-doped $Li_7La_3Zr_2O_{12}$ fillers [3]. Our simulations automatically produce the interfacial Li-ion distribution assumed in previous space-charge models and, for the first time, a long-range impact of the garnet surface on the Li-ion diffusivity is unveiled. Based on our calculations and tensile strength and conductivity experimental measurements, we are also able to explain a previously reported drop in conductivity at a critical filler fraction well below the theoretical percolation threshold.

Overall, by making a thorough comparison with reported experimental data, our theoretical studies and simulations advance the current understanding of Li-ion mobility in $Li_7La_3Zr_2O_{12}$ garnets and their interfaces with polymer matrices in composite electrolytes. These fundamental insights might guide future in-depth characterization experiments of these relevant energy storage materials.

Electric Potential Distribution and Interface Impedances in a Solid-State Battery Elliot J. Fuller[1], Evgheni Strelcov[2], Jamie Weaver[2], Michael W. Swift[3], Joshua Sugar[1], Andrei Kolmakov[2], Nikolai Zhitenev[2], Jabez McClelland[2], Yue Qi[4], Joseph Dura[2] and A. A. Talin[1]; [1]Sandia National Laboratories, United States; [2]National Institute of standards and technology, United States; [3]U.S. Naval Research Laboratory, United States; [4]Brown University, United States

Measuring and predicting potential distributions within solid-state batteries is key to understanding and controlling the mechanisms that limit their performance. We combine Kelvin probe force microscopy (KPFM) and neutron depth profiling (NDP) to map the contact electric potential difference and the corresponding Li distributions within operating Si-LiPON-LiCoO2 solid-state batteries under open circuit, low current and high current conditions. We observe the largest drop in potential at the anode-electrolyte interface with a smaller drop at the cathode electrolyte interface and a shallow gradient within the bulk of the electrolyte. Cycling at high current irreversibly increases the potential drop at the electrolyte/anode interface, a change that is also observed in impedance spectra collected in situ. We deconvolve the contributions from ions, electrons, and interfaces to the measured potential distributions by correlating KPFM and NDP profiles and by comparisons with a first principles-informed energy 'band' model for ions and electrons.

11:45 AM EN02.16.05
Effect of Polymer Architecture on Microstructure, Segmental Dynamics and Ionic Conductivity in PEO-PMMA Based Solid Polymer Electrolytes Recep Bakar and Erkan Senses; Koc University, Turkey

Poly(ethylene oxide) based solid polymer electrolytes (SPEs) have been increasingly popular due to its fast segmental dynamics, high conductivity, and the ability of solving a wide range of different lithium salts. However, downsides of using PEO are its semi-crystalline nature and poor mechanical performance. The primary challenge for this electrolyte system is to increase the mechanical strength without decreasing ionic conductivity. To achieve this, one technique is to blend PEO with another polymer that can provide mechanical rigidity and eliminate crystallinity. In this sense, a high (T_g) polymer poly(methyl methacrylate) (PMMA) is commonly used. Incorporation of PMMA into PEO significantly increased the mechanical strength and efficiently decreased PEO crystallization. However, there was a major drawback: PEO segmental dynamics decreased dramatically. To overcome this, using various PEO architectures as linear and non-linear ones including stars, hyper-branched and bottlebrushes could be a promising way. Neat non-linear PEOs were reported to have less crystallization and more free volume due to branching compared to linear counterparts. Moreover, there would be fewer contact sites and interpenetration between PEO and PMMA due to topological constraints, which will suppress the decrease in PEO segmental dynamics. To these hypotheses, we used PMMA in blends with varying PEO architectures (linear, stars, hyper-branched and bottlebrushes) and then doped with lithium bis(trifluoromethane-sulfonyl)-imide (LiTFSI) salt to form novel SPEs. XRD results revealed that room temperature miscibility of these polymers can be strikingly expanded over 50 % using non-linear PEO (PEO:PMMA). Temperature modulated DSC results showed two distinct effective glass transition temperatures which could be tuned from linear to non-linear structures with increased number of branching. Broadband dielectric spectroscopy (BDS) measurements have unveiled PMMA segmental dynamics known as α relaxation have increased less for the non-linear PEO/PMMA blends in comparison to their linear counterparts because of less contact sites and interpenetration between PMMA and PEO introduced by the topological changes, suggesting that faster PEO segmental dynamics would be possible and promote ionic conductivity in these systems. The PEO/PMMA blend based electrolytes consisting of 20%wt PEO showed that the ionic conductivity for the bottlebrush PEO architecture was five times greater than the linear counterpart at around room temperature while other non-linear topologies have similar ionic conductivities when compared to linear PEO architecture. Furthermore, extending PEO content over 50wt% PEO in these linear and non-linear PEO/PMMA based solid polymer electrolytes resulted in a significant increase reaching up to $3.6*10^{-4}$ S/cm , as high as one order of magnitude at room temperature and three times higher at higher temperatures up to in the ionic conductivities when compared to ionic conductivities of pure PEO based electrolytes usually ranged between 10^{-5}-10^{-4} S/cm. Thus, this study indicates promising results such that non-linear PEO/PMMA based solid polymer electrolytes with faster segmental dynamics and higher PEO content could potentially lead higher ionic conductivities required for the application standpoint of the PEO based solid polymer electrolytes. Eventually, room temperature mechanical characteristics for PEO/PMMA blends will be also discussed.

11:50 AM EN02.16.06
Computation Discovery and Design of Chloride Lithium-Ion Conductors Yunsheng Liu, Shuo Wang, Adelaide Nolan and Yifei Mo; University of Maryland, United States

All-solid-state Li-ion batteries require Li-ion conductors as solid electrolytes (SEs). Li-containing halides are emerging as a promising class of lithium-ion conductors with good electrochemical stability and other properties needed for SEs in all-solid-state batteries. Compared to oxides and sulfides, Li-ion diffusion mechanisms in Li-containing halides are less well understood, in particular regarding the effects of Li content and cation sublattices, which can be tailored for improving Li-ion conduction. Using first-principles computation, a systematic study is performed on the Li-ion conduction of known Li-containing chlorides with close-packed anion frameworks and a wide range of their doped compounds. A dozen potential chloride Li-ion conductors are predicted with increased Li-ion conductivities, and it is revealed that the Li-ion migration is greatly impacted by the cation configuration and concentrations. By analyzing a large set of materials data, it is proposed that low Li content, low cation concentration, and sparse cation distribution increase Li-ion conduction in chlorides, and these principles are demonstrated in designing new chloride Li-ion conductors. This study provides insights into the effects of the cation sublattice on Li-ion diffusion, highlights potential chloride Li superionic conductors, and proposes design principles to further develop halide Li-ion conductors.

Analyzing Microstructural Implications on Fast Charge Behavior of Solid-State Batteries Bairav Sabarish Vishnugopi and Partha Mukherjee; Purdue University, United States

Solid-state batteries (SSBs) that pair an inflammable solid electrolyte with a lithium metal anode can potentially improve the energy density, power density and safety of current lithium-ion batteries. Designing a composite cathode with sufficient ionic/electronic transport pathways and active interfacial area is pivotal to achieve optimal rate performance in SSBs. Electrode microstructure-coupled transport and kinetic interactions affect the evolution of internal resistive pathways, utilization of active material and the electrochemical reaction distribution within these systems. In this work, we analyze the mesoscale underpinnings of electrode microstructure on the underlying kinetic-transport mechanisms, thermo-electrochemical interplay, and the resulting influence on cell performance. Design criteria including the fraction of conductive additives and particle sizes required to achieve fast charge/discharge rates in SSBs are discussed.

Impact of Protonation on the Electrochemical Performance of $Li_7La_3Zr_2O_{12}$ Garnets Rabeb Grissa, Seyedhosein Payandeh, Meike Heinz and Corsin Battaglia; Empa-Swiss Federal Laboratories for Materials Science and Technology, Switzerland

$Li_7La_3Zr_2O_{12}$ (LLZO) garnet ceramics are promising electrolytes for all-solid-state lithium-metal batteries with high energy density. However, these electrolytes are prone to Li^+/H^+ exchange, that is, protonation, resulting in degradation of their Li-ion conductivity. Here, we identify how common processing steps, such as surface cleaning in alcohol or acetone, trigger LLZO partial protonation[1]. We deconvolute the contributions to the electrochemical impedance spectra of both the protonated LLZO phase (HLLZO) and its decomposition products forming upon annealing. While the mixed conduction of H^+/Li^+ ions in HLLZO decreases the contribution of the electrolyte to the overall impedance, it deteriorates the transport of Li^+ ions across the LLZO/Li interface. This is also the case after thermal decomposition of HLLZO, which occurs at significantly lower temperature than that for pristine LLZO. As a result, symmetric Li/LLZO/Li cells suffer from inhomogeneous lithium electrodeposition within the first three cycles when stripping and plating a capacity of 1 mAh/cm^2 per half-cycle at 0.1 mA/cm^2. We demonstrate that LLZO protonation is avoided when applying solvents with very low acidity, such as hexane. Such Li/LLZO/Li cells provide stable cycling over more than 300 h, demonstrating the importance of selecting an appropriate solvent for LLZO processing to prevent dendrites formation.

12:03 PM EN02.16.10
Molecular Dynamics Simulations of Hydroxide Diffusion in Polymer Electrolytes Young C. Kim, Michelle D. Johannes, Brian L. Chaloux and Megan B. Sassin; U.S. Naval Research Laboratory, United States

Many factors affect the conduction of ions through polyelectrolyte membranes including: water and ion content, glass transition (Tg) of the polymer, dielectric constant of the medium, and microstructure (e.g. aggregation, microphase separation). Determining the effects that chemical changes to a polymer will have on the conductivity of the resulting ion exchange materials requires characterizing and deconvoluting the many different properties that depend upon polymer chemistry. Molecular dynamics (MD) simulations can be applied to rapidly screen whether candidate changes to a polyelectrolyte's structure will have the desired effect on ion transport.
Poly(dimethylaminomethyl styrene) (pDMAMS) is a structurally simple polymer capable of hydroxide conduction after quaternization with CH¬3I and OH- exchange. The effects of changing ion content on OH- ion diffusivity in anhydrous, quaternized pDMAMS are studied using MD simulations on linear co-polymers of 4-dimethylaminomethylstyrene (4-DMAMS) and 4-butylstyrene, selected for its similar Tg to pDMAMS. Molecular dynamics is utilized to characterize truly anhydrous systems, whereas most experimental materials would contain a non-negligible amount of tightly bound water. Increasing content of neutral 4-butylstyrene over methylated 4-DMAMS results in a tradeoff between increased polymer flexibility and decreased dielectric strength and ion content. MD simulations are performed on co-polymers with 4-butylstyrene content from 0% to 75%. At 300 K, MD simulations yield an OH- self-diffusion coefficient of ~ 0.05 μm2/s in pure methylated pDMAMS (0% 4-butylstrene). As the 4-butylstyrene content of co-polymers increases up to 50%, OH- diffusivity decreases by a factor of two, but at 75% 4-butylstyrene content, the OH- diffusion constant increases by a factor of two compared to that of 100% methylated pDMAMS. The glass transition temperature of the co-polymers decreases as the 4-butylstyrene content increases, from ~800 K at 0% 4-butylstyrene to ~500 K at 75%, thus providing a more mobile platform for OH- at high 4-butylstyrene content. The dramatic decrease in Tg with increasing 4-butylstyrene but minimum OH- diffusivity at ~50% 4-butylstyrene shows that there are competing factors affecting hydroxide conduction in these materials. Simulations of alternating and random co-polymers show that the patterning of co-polymers has little effect on the OH- diffusivity. This study presents a computational framework to understand fundamental principles regarding hydroxide conduction in polymer electrolytes.

Lithiophobic-Lithiophilic Gradient Interlayer Enabled Solid–State Lithium Metal Batteries Chunsheng Wang and Hongli Wan; University of Maryland, United States

A low Li plating/stripping Coulombic efficiency and continuous lithium dendrite growth are two critical challenges for all-solid-state batteries. Here, we address both challenges by inserting a mix-conductive interlayer between electrolyte and Li anode. The lithiophilic side of interlayer promotes the uniform deposition of lithium, while lithiophobic layer inhibits the Li plating on electrolyte surface and prevents the lithium dendrite growth. The mixed ionic/electronic conductive interlayer enable enables Li anode to achieve a high Coulombic efficiency (CE) of 99.6%, which is the highest CE reported. The electrochemical performance of solid state Li/LiCoO2 full cells weas also investigated.

1:30 PM *EN02.17.02
Solid-State Batteries with High-Capacity Anodes—Interface Evolution and Chemo-Mechanics Matthew T. McDowell; Georgia Institute of Technology, United States

Solid-state batteries offer the promise of improved energy density and safety characteristics compared to lithium-ion batteries, but electro-chemo-mechanical evolution and degradation of materials and interfaces can play an outsized role in limiting their performance due to the all-solid nature of these systems. Here, I will present my group's recent work using *in situ* and *operando* experiments to understand interfacial evolution and stress changes in solid-state batteries with lithium metal and alloy anodes. *Operando* X-ray tomography is used to reveal interfacial dynamics in solid-state batteries with Li metal anodes. Segmentation and detailed image analysis enable correlation of interfacial contact loss to electrochemical behavior of symmetric cells, and the loss of interfacial contact area at the Li metal interface is found to cause current constriction and cell failure. The effects of interphase formation on mechanical degradation, stress evolution, and contact area loss are also discussed. Finally, stack pressure evolution during cycling of full solid-state batteries is measured *in situ* and correlated with fundamental processes within electrode materials and the properties of composite electrode structures. Cells with alloy-based anodes are found to exhibit large (megapascal-level) changes in stack pressure during cycling in a constant volume cell casing, with stable capacity and stress changes over long-term cycling. Together, these findings show the importance of controlling chemo-mechanics and interfaces in solid-state batteries.

Analysis of Interphase Formation between Metal Ion Containing Solid Electrolytes and the Lithium Metal Anode in Solid-State Batteries Luise Riegger[1,2], Svenja-Katharina Otto[1,2], Sven Jovanovic[3], Steffen Merz[3], Marcel Sadowski[4], Olaf Kötz[1,2], Roman Schlem[5], Sascha Harm[6,7], Robert Calaminus[7,6], Simon Burkhardt[1,2], Felix Richter[1,2], Joachim Sann[1,2], Wolfgang Zeier[5], Bettina V. Lotsch[7,6], Karsten Albe[4], Josef Granwehr[3] and Jürgen Janek[1,2]; [1]Justus Liebig University, Germany; [2]Center for Materials Research (LaMa), Germany; [3]Forschungszentrum Jülich GmbH, Germany; [4]Technische Universität Darmstadt, Germany; [5]University of Muenster, Germany; [6]Ludwig-Maximilians-Universität München, Germany; [7]Max Planck Institute for Solid State Research, Germany

Solid electrolytes (SEs) containing metal ions such as Li_3InCl_6 or Li_7SiPS_8 have gained interest for applications in solid-state batteries (SSBs) in recent years due to their high ionic conductivities. However, there are still some challenges to overcome, such as their inherent reduction instability, which impedes the application with a lithium metal anode (LMA) [1].
If the decomposition layer formed upon contact of a SE with lithium metal contains electronically conducting compounds like metals, the decomposition layer can form a mixed conducting interphase (MCI) that continues to grow until either lithium is depleted or the SE is completely reduced. As a result of the metal dispersed in the MCI, the electronic conductivity of the cell should increase, which in turn decreases the internal cell resistance and leads to short circuits [2]. However, this is not the case for all metal ion containing SEs. The resistance of a Li|Li_3InCl_6|Li cell, for example, constantly increases during the decomposition. Despite the fact that indium metal is among the formed decomposition products the interphase behaves like a Solid Electrolyte Interphase with a low interphase conductivity [3]. Therefore, knowledge about the composition of the interphase between lithium metal and SEs as well as the temporal evolution of the cell resistance is crucial.

Here, we report our latest findings on the stability of a variety of metal ion containing SEs in contact with lithium metal. We further cover the kinetics of the heterogeneous solid-state reaction and the chemical composition of the resulting interphase. Impedance spectroscopy measurements were conducted to investigate the temporal evolution of the interphase resistance between the lithium metal anode and the SE. *In situ*-sputter-deposition of lithium metal onto the surface of the SE pellets and subsequent X-ray photoelectron spectroscopy measurements were performed to study the chemical composition upon contact. Multiple repetitions of these steps allow a detailed characterization and identification of the decomposition products within the forming interphase. By additionally employing time-of-flight secondary ion mass spectrometry, we were able to categorize the interphase and estimate its spatial extension. Combining the results allows a detailed distinction between possible interphases of metal ion containing electrolytes and thereby promotes the understanding of the SE stability toward LMAs.

Building Li Free Anodes for Solid–State Batteries Kevin Guo; Ford Motor Company, United States

Solid state batteries (SSB) offer potential advantages over traditional lithium ion batteries in energy density, safety and battery packing. Much of the prior work has focused on the development of solid electrolytes but the anodes and cathodes are also key to delivering the potential benefits of a SSB. The anode of a SSB could use several different choices of active material, such as graphite, silicon, graphite/silicon, and Li metal, which is generally considered as the ultimate choice for a SSB due to its high specific capacity. However, since in principle the cathode provides all Li needed in the battery operation, there is technically no need to put extra Li in the anode to achieve an operating cell.

Various concepts for a Li-free anode have been studied, but there are many challenges to implement this concept. Particularly when the anode only consists of current collector, inducing Li to plate and strip at the interface between LLZO and current collector has proven difficult. We start with approaches to directly reduce the interfacial resistance between LLZO and the current collector by sputtering a thin film of metal directly onto the LLZO separator. A simple test cell is used with a Li metal foil on one side of a LLZO separator which has a metal film and current collector on other side. At the beginning of performance testing, the cell requires an “initialization” by plating a small amount of Li onto the current collector. This initial charging conditions the interface between the metallized LLZO and the current collector and the quality of new interface affects the performance of cell in terms of the critical current density and cycling behavior. In this work, two type of metallization(Au or Cu) are used to explore this approach. The impact of initial Li plating for various values of current and total deposited capacity is described. In addition, the impact of operating temperature is investigated.

On the Cause of Pore Formation and the Limitation of Pore Annihilation at Lithium Metal/Solid electrolyte Interfaces Lisette Haarmann[1], Stefanie Frick[1], Shreyas Ramachandran[2], Jochen Rohrer[1] and Karsten Albe[1]; [1]Technische Universität Darmstadt, Germany; [2]Birla Institute of Technology & Science, India

Pore formation at the lithium metal anode (LMA) | solid electrolyte (SE) interface is a key obstacle in the path to utilizing LMAs in solid state batteries (SSB) at the industrial level.
Oftentimes it is theorized that this pore formation would occur due to an insufficient vacancy diffusion within the LMA. Recently, however, it has been shown that the interfacial work of adhesion between the LMA and the SE is a key factor in determining if vacancy agglomeration at the LMA | SE interface is thermodynamically favored. [1]
In order to computationally address the kinetics of this system at finite temperature, kinetic Monte Carlo (KMC) simulations based on a nearest neighbour bond counting approach are applied in this work. As SE, differently treated garnet Li7La3Zr2O12 (LLZO) were considered [2].
It was found that neither the formation, nor the annihilation of pores are a result of slow vacancy diffusion. The pore formation, on the one hand, is mainly influenced by the interface thermodynamics between the LMA and the SE. The pore annihilation, on the other hand, is limited by the stripping of vacancies from the pore surface.
Within the implemented setup, an analytical expression for the anodic critical current density, beyond whichthe interface becomes morphologically unstable, was defined. The results are in accordance with values determined experimentally by electrochemical impedance spectroscopy (EIS) measurements and reveal an order of magnitude variation depending on the interface thermodynamics. Likewise, the time until full contact loss, t0, strongly depends on the interaction strength between the LMA and the SE. For a given LMA|SE interaction energy, the experimentally observed square root dependence between t0 and the applied stripping current density was reproduced [3].
The analysis of pore dissolution in a lithium metal bulk cell showed that the healing time (until a pore is completely dissolved) can be described by an

analytical model of precipitate shrinkage if the curvature of the pore surface is taken into account. Moreover, it was concluded that the transfer of vacancies into the bulk is the limiting step of pore dissolution, which is in accordance with activation barriers determined by Density Functional Theory (DFT) calculations.
Finally, a proposed method to attenuate and/or compensate pore formation at the LMA | SE interface, namely the introduction of a thin ionic liquid interlayer (IL) [4], is incorporated within the KMC model. The experimentally observed increase in the time until contact loss is reproduced and attributed to a suppression of vacancy kinetics at the interface due to an instantaneous adjustment of the IL until its maximal volume expansion is reached.

Soybean Oil Derived Solid-State Electrolytes for Lithium Batteries Ashish Raj[1], Satyannarayana Panchireddy[1], Bruno Grignard[2], Christophe Detrembleur[2] and Jean-Francois Gohy[1]; [1]Université Catholique de Louvain, Belgium; [2]University of Liège, Belgium

The solid-state battery has drawn a huge interest with its motive to overcome the issues and challenges faced by batteries using conventional liquid electrolytes. The novel idea of using green approaches or bio-based sources for lithium batteries excites many researchers due to their eco-friendly, less carbon footprint in its synthesis and recycling at the end. In this work, we report a full bio-based solid-state electrolyte based on functionalized carbonated soybean oil (CSBO) obtained from the naturally occurring epoxidised soybean oil (ESBO) using CO_2 and biomass. CSBO shows remarkable adhesive properties as characterized by rheological measurements owing to its bigger chains bearing multifunctional cyclic carbonates. LiTFSI salt reinforced CSBO was characterized following standard electrochemical measurements exhibiting ionic conductivity to ~10^{-3} S cm^{-1} at 100 ºC and 10^{-5} S cm^{-1} at room temperature. The electrochemical window for this electrolyte was obtained to be 4.8 V (*vs.* Li/Li^+) and transference number up to 0.31, allowing it to be explored for high voltage cathodes. CBSO shows stable stripping and plating behaviour for longer cycles making it a good candidate for higher coloumbic efficiency electrolyte batteries. We also demonstrated the galvanostatic charge-discharge of $LiFePO_4$ (Lithium Ferrrophosphate, LFP) with CSBO electrolytes delivering the gravimetric capacity of 124 $mAhg^{-1}$ and 150 $mAhg^{-1}$ appx. at ambient room and higher temperature respectively. Therefore, our study provides a promising direction of developing bio-based solid electrolytes to facilitate progress in sustainability, cost-effective and safe manner to create a solid-state lithium-ion battery for global utilization.

Fabrication of LLZO Powder and Fibres and Their Application in PEO-LLZO Composite Solid Electrolytes Tor Olav O. Sunde, Laure Guironnet, Maria Teresa Guzman Gutierrez, Roberto Scipioni, Marius Sandru, Peter Molesworth, Nils Wagner and Anita H. Reksten; SINTEF Industry, Norway

The dramatic possible effects of climate change are becoming clearer day by day. Batteries are a key technology to reach the UN Sustainable Development Goals, by accelerating the shift to zero-emission transportation and providing energy storage to allow for an increased proportion of intermittent renewable energy sources. However, today's conventional lithium-ion batteries with a liquid electrolyte are steadily reaching the limit of their physiochemical energy density, while safety issues related to the flammable liquid electrolyte remain a challenge. Solid state batteries, on the other hand, offers the potential of high safety, high energy density and high power density. There are many classes of solid electrolytes, each with their own advantages and disadvantages. Hybrid composite electrolytes, with ceramic fillers in a solid polymer electrolyte, offers the potential to overcome the disadvantages related to both ceramic and polymeric electrolytes alone.

Here, we present a detailed investigation of the fabrication and performance of solid poly (ethylene oxide) (PEO) - $Li_{6.25}Al_{0.25}La_3Zr_2O_{12}$ (Al-doped LLZO) composite electrolytes. LLZO powder and fibres were prepared, by solid state reaction and needleless electrospinning, respectively. Both fabrication routes were chosen due to their scalability. For the powder, the effect of the calcination temperature and ball milling on the phase purity and particle size of the LLZO powder was investigated. The preparation of solutions for needleless electrospinning is more challenging than for conventional electrospinning. Here, the conductivity and viscosity to prepare spinnable solutions for needleless electrospinning was investigated, as well as the effect of the calcination temperature on the phase purity. The solid electrolytes were prepared by casting composites of the ceramic fillers in PEO with lithium bis(trifluoromethanesulfonyl)imide (LiTFSI). The effect of ceramic filler content, particle size and morphology and dopamine functionalization on the solid electrolyte performance was investigated. While there are several reports of these effects studied individually, a detailed understanding of their combined effects appears to still be lacking, which is necessary for composite electrolytes to successfully reach their potential.

Towards Low-Cost Solid State Li-S Batteries Jianbin Zhou, Shen Wang, Charles Soulen and Ping Liu; University of California, San Diego, United States

Li-S batteries promise high energy density, low cost, and free of resource constraints of transition metals. Solid state Li-S also in principle circumvents the soluble sulfur species involved in its liquid electrolyte counterpart, resulting in longer cycle life. However, the volume change of both Li and S cathode, the insulating nature of S, and the tendency of Li dendrite-related cell shorting have continued to plague the technology. In this talk, we will report our recent effort towards building a long-life solid state Li-S cell. To stabilize the Li anode, we employ porous carbon as a mixed-conducting 3D host for Li metal. This reduces the effective current density acting on the electrolyte layer, increases the apparent critical current and mitigates cell shorting. To reduce the thickness and enhance the mechanical stability of the electrolyte, we use in-situ polymerization to form nanoscopic composites of sulfide-based solid electrolytes. Finally, we engineer sulfur cathodes with intrinsic electronic conductivities and limited volume changes to extend cycle life. With

advancements on all components of the cell, we will fully realize a long-life, low-cost solid state Li-S technology.

Thin-Film Glassy Solid Electrolytes Enabling High Energy Density Li and Na Batteries Steve W. Martin; Iowa State University, United States

Fast ion conducting glasses have long been considered as alternatives to flammable liquid electrolytes in Li and Na batteries. However, for such glassy solid electrolytes (GSEs) studied so far, they have lacked the unique combination of required electrochemical properties for use as a solid electrolyte with the equally important requirements of viscoelastic behavior to form them into thin films suitable for high ion conductivity separators. Indeed, to date, most GSEs are considered as "invert" glasses where the high viscosity promoting glass formers in the compositions, such as SiO_2, B_2O_3, or P_2O_5 are not the dominant component, but rather are the minor component and the alkali salt, such as Li_2O or Na_2O is the majority component. This has led to the general observation that such high alkali content invert glasses are rather poor glasses formers that crystallize rapidly upon heating above their glass transition temperature into the viscoelastic supercooled liquid regime. This has forced most workers in this field to consider only fully crystallized polycrystalline ceramic versions of these compositions or at most glass ceramics where the crystalline phase is dominant, > 90 v/v%. In this first ever report of thin film fast ion conducting glasses made by viscoelastic deformation processing of redrawing glass preforms, we report new compositions where we have broken this long standing paradigm of high conductivity combined with high alkali salt concentration but poor glass formability and will summarize our efforts to produce thin films of Li and Na ion conducting glasses and test in them in symmetric and asymmetric cells.

5:00 PM EN02.18.03
Safe Flexible Rechargeable Batteries with Subzero-Temperature Operation and Self-Charging Capabilities Ying Wang; Louisiana State University, United States

Flexible solid-state batteries are designed to be conformal, lightweight, and can be rolled without any loss of energy. They are needed for powering wearable electronics, smart packaging, and medical devices, etc. Most of them target at room temperature applications, as the sluggish ionic transport in the solid-state electrolytes degrades even faster at lower temperature. Though organic electrolytes allow for a wide working temperature window, most organic electrolytes require expensive, tedious, and toxic synthesis processes. Recently, rechargeable batteries based on aqueous electrolytes have shown high potential attributed to their low cost and intrinsic safety. For instance, the zinc ion battery (ZIB) is attractive owing to its stable zinc anode from abundant sources, features of multivalent charge transfer, a superb theoretical capacity and low redox potential of the zinc anode. Another appealing choice is an aqueous battery using non-metal ions as charge carriers, such as NH_4^+ with a lighter molecular weight (18 g mol^{-1}) than metal ions above and a small hydrated ionic size of 3.31 Å, leading to faster ion diffusion in the electrolyte. However, the use of aqueous electrolytes poses a challenge due to its freezing at sub-zero temperature.
In this work, concentrated hydrogel electrolytes are employed to construct flexible zinc ion batteries and ammonium ion batteries that can operate at subzero temperature with better safety and lower cost, while maintaining high energy/power and long cycling life. The quasi-solid-state electrolyte is simply synthesized via using respective salt, water, and hydrophilic polymer (e.g., biodegradable edible xanthan gum). The composition of the electrolyte is optimized to maximize the battery performance. A flexible ZIB is assembled using the hydrogel electrolyte sandwiched between a vanadate cathode and a zinc anode, while a flexible ammonium ion battery consists of the electrolyte between a vanadate cathode and a polyaniline anode. For example, the flexible ZIB exhibits a very high capacity of 239 and 83 mAh g^{-1} under 0.2 A g^{-1} at -20 degreeC and -40 degreeC, respectively. Additionally, chemically self-charging flexible batteries are fabricated, which are different from conventional self-charging systems relying on energy sources. Notably, the ZIB can be chemically self-charged by the oxidation reaction between the cathode and the oxygen in air. The flexible ZIB delivers a specific discharge capacity of 179 mAh g^{-1} after the cathode is exposed to air and oxidized for 12 hours at room temperature, exhibiting a decent self-recharging ability. As such, this study sheds new light on the utilization of concentrated hydrogel electrolytes in flexible batteries with new capabilities, for developments of next-generation electrochemical energy storage technology with high safety and low cost.

5:15 PM EN02.18.04
***In Situ* FIB as a Method to Prepare and Characterize Solid–State–Batteries** Yevheniy Pivak, Christian Deen-van Rossum and Hugo H. Pérez Garza; Denssolutions, Netherlands

In situ biasing Transmission Electron Microscopy technique is a powerful tool to reveal morphological and structural changes in solid state battery samples at the nanoscale during charge and discharge cycles. It has an advantage over other methods like X-ray or Neutron Diffration as it provides a direct observation on the dynamic evolution of crystal and electronic structures and can uncover intrinsic mechanisms behind it. The former one is especailly important as it accounts for the performance of batteries.

One of the main limitations in the application of in situ biasing TEM to study solid state batteries is FIB lamella sample preparation process. It's not only complicated, but it also possess a very low success rate and as a result, very time consuming. In general, preparing a clean and electrically connected biasing sample without electrical short circuit is a challenging task. There are a lot of pitfalls when preparing FIB lamellas for electrical experiments. Often the preparation process needs to be repeated several times after unsuccessful TEM experiments due to sample's bad electrical quality. These repetitions cost additional FIB and TEM time.

In this work we would like to present a new method of preparing and preliminary characterizing sold state battery samples in a dual beam microscope - an in situ FIB. This method is based on MEMS Nano-Chips designed for biasing and heating and biasing TEM experiments. The method uses a modified SEM stub, e.g. FIB stub with electrical connections to the outside world. The stub is specifically designed to prepare the FIB lamella on the MEMS chip in one go (without breaking the vacuum). During the preparation, the sample can be biased to check for short circuits and for proper electrical connection to the sample, ensuring the good quality of the lamella. We will also discuss how the tool can be employed to do further characterization of the sample inside FIB/SEM and its correlation with the in situ TEM technique.

5:30 PM EN02.18.05
Utilizing iCVD to Polymerize Thin, Conformal Electrolytes for Alkaline Batteries Megan B. Sassin, Brian L. Chaloux, Jeffrey Long, Joel Miller and Debra R. Rolison; U.S. Naval Research Laboratory, United States

Polymer electrolytes can provide several advantages over liquid electrolytes in alkaline battery architectures. Mechanically robust polymer separators such as Celgard membranes inhibit dendrite growth and can be made exceptionally thin, which increases current density by minimizing IR losses. However, preparing ionically conductive, submicron-thick polyelectrolyte films on nonplanar electrode geometries remains a challenge for solution and melt polymer processing methods.
We use free radical–initiated chemical vapor deposition (iCVD) of styrenic monomers to grow 100 nm – 1 μm thick films on a variety of metallic and insulating substrates and then convert the polymer into anion-conductive polyelectrolytes. By judicious choice of quaternization and ion-exchange conditions, the thin-film polymer survives conversion from hydrophobic insulator to high ion-exchange capacity (IEC up to 3 mEq g^{-1}) polyelectrolyte

without delamination or pinhole formation. The single-ion conductivity of bicarbonate (HCO_3^-), the equilibrium anionic species, is measured by impedance spectroscopy of the films on interdigitated electrodes as a function of relative humidity; the films exhibit modest conductivity even when equilibrated at low relative humidity.
The chemical structure of these thin films is characterized using surface overlayer enhanced ATR-IR spectroscopy and X-ray photoelectron spectroscopy to determine their similarity to previously reported iCVD-grown polymer and bulk materials polymerized using the same monomer and initiator. Solid-state magic-angle spinning ^1H and ^{13}C NMR spectroscopy performed on films grown on high surface–area substrates allows us to contrast chemical structure in the supported thin-film expression with their bulk-polymerized counterparts.

5:35 PM EN02.18.06
Lithium Vanadium Oxide Made by Co-Sputtering as a Cathode Material for Solid-State Batteries Victoria Castagna Ferrari, Nam Soo Kim, Sang Bok Lee, Gary Rubloff and David Stewart; University of Maryland, College Park, United States

Solid-state batteries (SSBs) are emerging as the next devices to substitute conventional lithium-ion batteries. Besides improved safety and reliability, the capability of thin film processing to design devices in novel form factors creates new opportunities in energy storage. Nevertheless, the most common cathode material used in thin film batteries is lithium cobalt oxide (LCO), which is only electrochemically active in a particular phase formed at 500 °C, and there are many reports of Li deficiency in the films after annealing. In pursuit of a low temperature alternative which will also address the Li deficiency, we have studied a new process to deposit lithiated vanadium oxide (LVO) thin films as a promising cathode material for application in SSBs. Vanadium oxide (V_2O_5) has a layered structure that can be preserved with the insertion of up to 2 lithium ions, giving it a higher theoretical capacity when compared to LCO. Herein, the lithium content of the cathode is controlled simultaneously with the deposition of the vanadium oxide host on a silicon wafer substrate using a co-sputtering process, where two targets – vanadium oxide (V_2O_5) and lithium oxide (Li_2O) – are run at the same time to produce the films.
The LVO co-sputtering process was studied and analyzed, including structural characterization and electrochemical evaluation using a conventional liquid cell. A SSB employing the LVO as a cathode was successfully fabricated, and presented electrochemical activity with good reversibility at different electrochemical conditions, which proves that the LVO is a good candidate as a cathode material for SSBs. The power of the V_2O_5 target was fixed at ~150 W while the Li_2O target power was varied to change the amount of lithium in the LVO films to have a desirable capacity during charge and discharge. The effect of a post-deposition annealing at 300 °C was also studied in comparison to LVO samples produced at ambient temperature. To the best of our knowledge, this is the first time that a successful co-sputtered lithiated vanadium oxide material is fabricated and tested in a SSB.
Raman spectroscopy indicates that some peaks correspond to vibrations which are found in crystalline V_2O_5 films, but it suggests that the LVO has its own characteristic peaks. A post-deposition annealing step did not dramatically alter the Raman spectrum, but the vibrational modes were better preserved after electrochemically cycling when the LVO is post-annealed at 300 °C under a nitrogen atmosphere. Surface analysis obtained from XPS confirmed a lithiated V_2O_5 composition up to 3 lithium ions per vanadium oxide. The best LVO film held ~70 % of the theoretical capacity (1 lithium per V_2O_5) as calibrated by liquid cell testing, and less when used in a SSB, but showed excellent reversibility in early cycling and a higher voltage than bulk V_2O_5. The use of co-sputtered LVO in SSBs will still be further investigated, but the preliminary results indicate the developed LVO is an excellent candidate for a cathode material. The use of a relatively low post-annealing temperature to produce an electrochemically active material, and the possibility to apply the developed co-sputtering process with different ion species, like magnesium or sodium, reveal the potential use of this work for a broader range of solid-state devices.

5:40 PM EN02.18.07
Lithium Cyanophosphine Sol-Gels as Polyelectrolyte Matrices for Li^+ Conduction Brian L. Chaloux, Megan B. Sassin, Andrew Purdy and Albert Epshteyn; Naval Research Laboratory, United States

A primary hazard associated with lithium ion batteries is the combustibility of the liquid electrolyte, which is a key component for conduction of Li^+ between anode and cathode. Polymer electrolytes can nominally improve safety by reducing the quantity and volatility of organic species. However, their poor room-temperature conductivity (10–100× lower in plasticized PEO than in pure propylene carbonate) and propensity to pyrolyze into volatile, flammable species at sufficiently elevated temperature makes them less-than-ideal electrolytes for lithium-ion batteries.
Lithium dicyanamide – $LiN(CN)_2$, itself a lithium salt explored for battery electrolytes – is shown to react with cyanophosphines (e.g. $P(CN)_3$, $RP(CN)_2$ where R is an aromatic moiety) in up to a 2:1 mole ratio, resulting in cross-linked sol-gel networks that fully incorporate both monomers. The high phosphorus and low hydrocarbon content of the resulting lithium cyanophosphine yields a material that is thermo-oxidatively stable, while simultaneously providing a high density of labile Li^+ (up to 5 mEq g^{-1}).
Pulsed field gradient (PFG) ^1H, ^7Li, and ^{13}C NMR spectroscopies were utilized to demonstrate that: a) Oligomerization of both dicyanamide and cyanophosphine definitively occurs prior to gelation; b) Negligible amounts of either monomer remain unreacted; and c) Lithium remains effectively coordinated by the solvent, diffusing in concert with solvent instead of the oligomeric cyanophosphine polyanions. The resulting sol-gels exhibit a Li^+ transference number near unity when used as an electrolyte between lithium foils, in accordance with NMR data showing negligible polyanion diffusivity under these conditions. Application of the measured Li^+–solvent complex diffusion coefficients as the reaction mixture approaches gelation also allows estimation of Li^+ mobility and, by proxy, the fraction of mobile Li^+ in the system.

5:45 PM EN02.18.08
Lithium Ion Mobility in Oligomerized and Polymerized Lithium Dicyanamide Christopher A. Klug, Daniel M. Fragiadakis and Andrew Purdy; Naval Research Laboratory, United States

Lithium dicyanamide ($LiN(CN)_2$) can trimerize, oligomerize, or polymerize through thermal treatment, and the product of this polymerization is dependent on both impurities and conditions of heating. We have thermally treated LiC_2N_3 containing small amounts of various additives such as halide, NaC_2N_3, LiCN, and other materials as pressed pellets under vacuum, and characterized the products by both solution and solid state NMR, and by dielectric relaxation spectroscopy. Direct detection of ^{13}C NMR spectra for the solid products was used to the relative amounts triazine and C≡N. The relative intensities and widths of the triazine peaks reflected variations in the reaction completion. Variable temperature ^7Li NMR was particularly useful for determining the correlation times and activation energies of the lithium ion motion in these materials as a function of preparation conditions and thermal history.

Highly Conductive Solid–State Electrolytes Based on *closo* Borates Compounds Hiroko Kuwata, Oscar Tutusaus and Rana Mohtadi; Toyota Motor North America, Inc, United States

All solid-state batteries (ASSB) are receiving increased attention for a variety of reasons that include elimination of the volatile solvents and support of faster battery charging compared with typical liquid-type systems [1]. One of most important components in the ASSB is the solid state electrolyte. To enable fast battery charging, it is necessary that the electrolytes have high ionic conductivities. Several families of solid state electrolytes currently exit and

include sulfides, halides, oxides and boron-hydrogen salts. *Closo* borate materials are promising candidates owing to their high ionic conductivity (> 6 mS cm^{-1} in Li system [2] and > 30 mS cm^{-1} in Na system [3,4] and wide electrochemical window. Our group has demonstrated that these anions have high compatibility with active metals such as magnesium making these salts highly attractive for utilization as solid state electrolytes [4,5,6] . Herein, we will assess the potential of these solid state electrolytes and discuss our recent efforts towards understanding and improving the Li^+ and Na^+ ionic mobilities in these electrolytes.

Solid-Electrolyte Interphase Progressive Growth Towards the Si Interior Yang He[1], Lin Jiang[2] and Chongmin N. Wang[3]; [1]University of Science and Technology Beijing, China; [2]Thermo Fisher Scientific, United States; [3]Pacific Northwest National Laboratory, United States

Solid-electrolyte interphase (SEI), a layer formed on the electrode surface, is essential for electrochemical reactions in batteries and critically governs the battery stability. Active materials, especially those with extremely high energy density, such as silicon (Si), often inevitably undergo large volume swing upon ion insertion and extraction, raising a critical question as how the SEI interactively responds to and evolves with the material and consequently controls the cycling stability of the battery. Here, by integrating sensitive elemental tomography, advanced algorithm and cryogenic scanning transmission electron microscopy, we unveil, in three-dimension, a correlated structural and chemical evolution of Si and SEI. Corroborated with a chemomechanical model, we demonstrate progressive electrolyte permeation and SEI growth along the percolation channel of the nanovoids due to vacancy injection and condensation during the delithiation process. Consequently, the Si-SEI spatial configuration evolves from the classic “core-shell” structure in the first few cycles to a “plum-pudding” structure following extended cycling, featuring the engulfing of Si domains by the SEI, which leads to the disruption of electron conduction pathways and formation of dead Si, contributing to capacity loss. The spatially coupled interactive evolution model of SEI and active materials, in principle, applies to a broad class of high-capacity electrode materials, leading to a critical insight for remedying the fading of high-capacity electrodes.

Lithium Nitride Coating Layer Deposited Using Magnetron Sputtering on Sulfide Solid-State Electrolyte Zhifei Li and Andriy Zakutayev; National Renewable Energy Laboratory, United States

Lithium containing materials have been of great interest for coating development, due to the rapid development of lithium-ion batteries. Among these materials, lithium nitride has received much attention recently due to its high lithium-ion conductivity and low electric conductivity, which together are beneficial for coating layers at the interface between lithium metal anodes and sulfide electrolytes in solid-state lithium batteries. Previously reported lithium nitride coatings were prepared by the reaction between lithium metal and nitrogen atmosphere at elevated temperature, which makes it challenging to precisely control the thickness of the resulting lithium nitride layer. The thickness of the coating layer is important for the performance of the obtained batteries, because too thick coating introduces unnecessary interfacial impedance, and too thin coating does not improve the stability.
In this study, we prepared lithium nitride via magnetron sputtering for the first time, using Li metal target in Ar/N_2 gas atmosphere, with deliberate preparation of the Li target surface to avoid oxide contamination, and careful control of the sputtering power to avoid melting of the Li target. The polycrystalline Li_3N formed on the target surface and the amorphous coating on the glass substrate were measured by x-ray diffraction and other characterization methods. The thickness of the obtained lithium nitride coating can be controlled by varying the sputtering time. We applied the resulting lithium nitride coating on the sulfide electrolyte as an interfacial layer to stabilize the sulfide electrolyte in contact with Li metal. After cell assembly protocol was systematically optimized, the obtained coated sulfide solid-state electrolyte showed a slightly increased impedance and a significantly improved cycling performance in a spring-loaded lithium metal symmetric cell. These results demonstrate the feasibility of sputtering Li_3N binary and related ternary lithium nitride coatings as interfacial layers in solid-state batteries.

EN02-Virtual

10:30 AM EN02.19.01
Overscreening and Underscreening in Solid-Electrolyte Grain Boundary Space-Charge Layers Jacob M. Dean[1,2], Samuel W. Coles[1,2], William Saunders[1], Andrew McCluskey[3,1], Matthew Wolf[1], Alison Walker[1] and Benjamin J. Morgan[1,2]; [1]University of Bath, United Kingdom; [2]The Faraday Institution, United Kingdom; [3]Data Management and Software Centre, European Spallation Source, Denmark

Polycrystalline solids can exhibit material properties that differ significantly from those of equivalent single-crystal samples, in part, because of a spontaneous redistribution of mobile point defects into so-called space-charge regions adjacent to grain boundaries. The general analytical form of these space-charge regions is known only in the dilute limit, where defect-defect correlations can be neglected. Using kinetic Monte Carlo simulations of a three-dimensional Coulomb lattice gas, we show that grain-boundary space-charge regions in non-dilute solid electrolytes exhibit overscreening -- damped oscillatory space-charge profiles -- and underscreening -- decay lengths that are longer than the corresponding Debye length and that increase with increasing defect-defect interaction strength. Overscreening and underscreening are known phenomena in concentrated liquid electrolytes, and the observation of functionally analogous behaviour in solid electrolyte space-charge regions suggests that the same underlying physics drives behaviour in both classes of systems. We therefore expect theoretical approaches developed to study non-dilute liquid electrolytes to be equally applicable to future studies of solid electrolytes.

Thin and Robust LATP Solid Electrolytes with Close-to-Bulk Ionic Conductivity and Its Integration in Solid-State Architectures Juan Carlos

Gonzalez-Rosillo[1], Valerie Siller[1], Marc Nuñez Eroles[1], Raul Arenal[2,3,4], Juan Miguel Lopez del Amo[5], Alex Morata[1] and Albert Tarancon[1,6]; [1]Catalonia Institute of Energy Research, Spain; [2]Instituto de Nanociencia y Materiales de Aragón, Spain; [3]Universidad de Zaragoza, Spain; [4]Fundación ARAID, Spain; [5]CIC energiGUNE, Spain; [6]Catalan Institution for Research and Advanced Studies, Spain

Glassy-type solid state electrolytes such as state-of-the-art LiPON avoid grain boundaries and prevent Li-dendrite propagation leading to extremely good cyclability and the commercialization of planar thin-film LiPON-based microbatteries. However, its reduced ionic conductivity (~1 μS/cm) limits its performance at high/discharge rates and the severe degradation of its electrochemical and structural properties upon their exposure to ambient conditions and high temperatures (> 300 °C) hinders scalability and manufacturability. Among the next generation solid-state electrolytes, NASICON superionic solid electrolyte $Li_{(1+x)}Al_xTi_{(2-x)}(PO_4)_3$ (LATP) with $0.3 \leq x \leq 0.5$ remains one of the most promising solid electrolytes thanks to its good ionic conductivity (~0.5 - 1 mS●cm^{-1}) and outstanding stability in ambient air. Despite the intensive research for bulk systems, there are only very few studies of LATP in thin film form. In particular, the only successful reports of relatively high ionic conduction (~10^{-5} S●cm^{-1}) have been achieved through amorphous sputtered films.

In this talk, we will explore the properties of high performance LATP thin films fabricated by Large-Area Pulsed Laser Deposition. The as-deposited thin films exhibit an ionic conductivity around 0.5 μS●cm^{-1} at room temperature (comparable to the state-of-the-art of LiPON) which increases to remarkably high values of 0.1 mS●cm^{-1} after an additional annealing at 800 °C. We will discuss the formation of a glassy, intergranular phase connecting highly conducting LATP grains as a possible cause for the significant enhancement in ionic conductivity by two orders of magnitude. The performance of both as-deposited and annealed LATP films makes them suitable as solid electrolytes, which opens the path to a new family of stable and highly performing thin solid-electrolytes. We will discuss its integration with other battery components, with special attention to interfacial coatings matching the electrochemical window at low potentials.

11:00 AM EN02.19.03
Synthesis and Characterization of Li_3PO_4-Coated $LiMn_{1.5}Ni_{0.5}O_4$ Spinel as Positive Electrode for High Voltage Li-Ion Batteries Jon Serrano-Sevillano[1,2], Montserrat Casas-Cabanas[1] and Dany Carlier[2]; [1]CIC EnergiGUNE, Spain; [2]Institut de Chimie de la Matière Condensée de Bordeaux, France

$LiMn_{1.5}Ni_{0.5}O_4$ (LNMO) spinel material, is being thoroughly studied as a cathode candidate for lithium ion battery. LNMO can crystallize either with an ordered structure ($P4_332$ space group), where the manganese and the nickel atoms are located in specific sites, or with a disordered structure (Fd-3m space group), where the manganese and the nickel are randomly distributed. Synthesis parameters are key to control the degree of ordering in LNMO and the electrochemical performance is highly affected by it. In particular, the disordered structure is found to have better performances, especially at high rates. The ordering can be studied using several techniques such as neutron powder diffraction (NPD), Raman or solid state magic angle spinning nuclear magnetic resonance (NMR). In particular, ^{7}Li NMR spectra shows a single peak for the fully ordered structure, while a larger number of signals is found for the disordered one. In the first part of this study, we propose a signal assignment of the NMR signals using DFT calculations, which has helped to understand how each different lithium local environment modifies the Fermi contact shift.
Some of the main advantages of LNMO are that they have good performance at high rates due to their 3D structure, and their ability to store large energy density as their work at high voltage. However, cycling at high voltage has as well some drawbacks, especially in terms of structural and chemical stability. Electrolyte degradation and manganese dissolution in the electrolyte are two of the main problems this material faces. Coating the LNMO with a protective layer is regarded as an effective approach to stabilize the electrode/electrolyte interface. Li_3PO_4 was calculated to have a good compatibility [1] and it has been experimentally found to avoid chemical attacks from the electrolyte [2]. One of the main issues in the study of the coating refers to their characterization. This is often challenging and can cast doubts on their goodness. By instance, HRTEM images can only provide local information, so the combination of different techniques is required. In this work, ^{7}Li and ^{31}P MAS NMR is used, in combination with X-ray diffraction (XRD) and scanning and transition electron microscopies (SEM and TEM), to provide a trustworthy characterization of Li_3PO_4-coated LNMO prepared by different routes. In particular, the closeness of diamagnetic compounds (such as Li_3PO_4) to paramagnetic ones (such as LNMO) have strong influence on the NMR spectra, [3] so NMR can be a useful technique to have an overall idea on the goodness of the coating. In addition, ^{7}Li MAS NMR allows to characterize as well, whether the coating process does modify the Ni/Mn distribution in the spinel phase.

Understanding Metal Deposition in Solid Electrolytes Due to Mixed Ionic-Electronic Conduction Qingsong Tu[1], Tan Shi[1], Srinath Chakravarthy[2] and Gerbrand Ceder[1]; [1]University of California, Berkeley, United States; [2]Samsung Research America, United States

Among the alternatives to conventional Li-ion batteries, solid-state batteries (SSBs) have the potential for high energy density as they may enable the use of a metal anode. However, the penetration of metal filaments into a solid electrolyte (SE) and resulting shorting is an obstacle to the commercialization of metal-anode SSBs. This work utilizes continuum modeling to study the mechanism of metal deposition within the SE due to the electronic conductivity of the SE. We show that metal deposition can happen in isolated micro-size voids within the SE and we specify the conditions under which it causes failure due to SE fracture. The vulnerability to metal deposition in the SE is investigated by controllable parameters (such as the cell voltage, applied current density, and etc.), and suppression strategies of metal deposition are proposed. These findings provide a deeper understanding of the Li penetration in the SE in order to eventually overcome the challenge in solid-state batteries. In addition, our work shows that metal propagation through the electronic can be overcome with a few focused strategies.

11:30 AM EN02.19.05
***In Situ* Transmission Electron Microscopy Characterization of Electro-Chemo-Mechanics at Interface Beteween Solid Electrolyte and Lithium Anode** Akihiro Kushima; University of Central Florida, United States

All-solid-state lithium battery is attracting attention as one of the promising candidates for a next generation energy storage technology. The solid electrolyte (SE) with much higher modulus than lithium is expected to prevent lithium dendrite penetrations and contributes to improved safety while increasing the energy density. However, there are many cases where lithium dendrite penetrates the solid electrolyte leading to a short circuit and premature failure of the battery. The interaction between the growing lithium dendrites and the solid electrolyte involves complex interplay of electrochemistry and mechanics. This can become even more complicated when the size-scale of the dendrites are in nano-scale, particularly at the initial state of the nucleation and growth, since the mechanical properties deviates from the bulk. Here in situ transmission electron microscopy (TEM) plays an important role in directly observing the growth behavior of the dendrites and how it is affected by the mechanical stress at the SE/Li interface. We developed a quantitative in situ TEM technique that can measure the force imposed on the lithium dendrite as it grows from the solid electrolyte.

The method was applied to evaluate the critical force that changes growth direction of the dendrite from vertical to horizontal with respect to the SE surface. Since the size of the dendrite was in nano-scale it sustained much higher stress than the bulk yield stress. Furthermore, the method successfully captured the change in the mechanical behavior of the dendrite at different growth rate indicating higher stress can be imposed to the SE at faster growth rate. In addition to the mechanical response of the dendrite growth, the crack propagation of the SE was characterized. It revealed that the lithium dendrite, during it growth process, can cause the crack to propagate in the SE from the surface defect. The in situ TEM observation clearly showed the crack growth and opening behavior, and the force associated with the process was precisely evaluated. The in situ TEM provides fundamental insights to the electro-chemo-mechanics of the lithium dendrite and solid electrolytes, and the information obtained in this work can be used as essential parameters to design all-solid-state lithium batteries with improved performance.

11:45 AM EN02.19.06
Anionic Polyelectrolyte Coating as Artificial Solid Electrolyte Interface for Zinc Anode Phonnapha Tangthuam and Soorathep Kheawhom; Chulalongkorn University, Thailand

Zinc (Zn) anode has good promise for energy storage application due to its excellent intrinsic properties such as high stability, high volumetric capacity, abundance, and low cost. Its relatively high electrode potential of -0.76 V vs. standard hydrogen electrode is ideal for neutral or mildly acidic aqueous electrolytes. Further, its polarization is much lower than other multivalent metal anodes such as magnesium and aluminum. However, its significantly high self-corrosion, hydrogen evolution reaction during the charging process, dendrite growth, and nonuniform stripping/plating of the Zn over long-term cycling restrict its practical application. These issues can lead to the migration of Zn during the plating/stripping processes and even cause battery failure. Artificial solid electrolyte interface (ASEI) applied on the surface of Zn anode has been suggested as a promising approach to address these issues. ASEI regulates the initial nucleation and manipulates Zn ion distribution in the surroundings of the anode surface. Nonetheless, only a few studies have investigated ASEI prepared using anionic polyelectrolyte.
In this study, we report the observation of ASEI on a Zn-carbon composite anode, based on ultra-thin layers of carboxymethyl cellulose (CMC), which is an anionic polyelectrolyte. The Zn anode having ASEI enables reversible and dendrite-free zinc plating/stripping even at high current densities, endowed by the fast ion migration coupled with cationic modulation. The ASEI is highly permeable for Zn ions and avoids excessive Zn utilization by hindering the access of water molecules and electrons. The ASEI can effectively suppress corrosion and regulate Zn plating/stripping behavior as confirmed via electrochemical characterization. Electrochemical impedance spectroscopy studies confirm that the anode having ASEI exhibits reduced charge transfer resistance and enhanced Zn ions absorption/desorption. As confirmed by X-ray tomography, during the charging and discharging cycle, no evidence for dendrite growth and zinc migration are observed. A mechanistic investigation of the role of CMC as ASEI is presented, along with data showing that the CMC coating layer can enhance the cycling stability of the Zn anode in aqueous Zn-ion batteries. This technique can be also applied in other Zn-based batteries having aqueous electrolytes.

Late News: Lithiophilic Thin Films on Li2CO3-Free Garnet Solid Electrolytes—A Double Approach to Improve the Interface Stability with Lithium Marco Siniscalchi, Susannah Speller and Chris Grovenor; University of Oxford, United Kingdom

The interfacial impedance between lithium metal and garnet solid electrolytes (e.g. LLZO) is usually dominated by poor solid-solid contact. This can lead to current constriction spots at the interface and to the rapid growth of lithium filaments through the LLZO, eventually short-circuiting the cell at small nominal current densities. Different approaches have proven effective to decrease such interfacial impedance, for example the removal of the lithio-phobic Li_2CO_3 layer which can form on the LLZO surface during glovebox storage. Alternatively, lithio-philic thin films like amorphous Al_2O_3 can be deposited at the Li|LLZO interface. Both approaches show similar interfacial impedances before cycling, but the difference in the long-term effect on the interface stability is unclear. Also, whether lithio-philic thin films can provide a mechanical and/or electronic-insulating barrier hindering the propagation of lithium filaments, or whether their role is simply to improve the lithium wettability on the LLZO surface to avoid current constrictions, remains an open question. In this study, we deposit amorphous Al_2O_3 and LiPON thin films via magnetron sputtering on Li_2CO_3-free LLZO solid electrolytes obtained via a rapid acid treatment. We assess the performance of such thin films through potential step chronoamperometry and in-operando impedance spectroscopy, and we use scanning electron microscopy to investigate the morphological stability of the modified Li|LLZO interface. Our findings provide a better understanding of the effect of interfacial ceramic thin films on improving the cycle life of a lithium metal cell. We also assess the most useful properties of the interfacial thin films which prevent the propagation of lithium filaments through the solid electrolyte.

***In Situ* Precipitation of LATP in PEO-Matrix Composite to Form Strong Interphase-Conducting Solid Electrolyte** Guangyu Wang and John Kieffer; University of Michigan–Ann Arbor, United States

A novel water based in-situ precipitation method is devised for the fabrication of polymer matrix composite solid electrolytes, achieving effective spatial dispersion of $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$ (LATP) nanoparticles up to particle loadings of 30 wt% (15 vol%). Amorphous LATP nanoparticles precipitate in ostensibly random locations within the poly(ethylene) oxide (PEO) matrix. The highest 20°C ionic conductivity of 3.8×10^{-4} S/cm, observed at 13 vol% LATP and EO/Li = 10, which exceeds that of the polymer matrix by 2 orders of magnitude. This result is consistent with earlier predictions based on our tri-phase model, both in composition and magnitude. Accordingly, the most highly conductive region is the interphase into which the polymer surrounding the LATP particles is transformed. Minimizing particle agglomeration permits expansion of the interphase into a larger fraction of the bulk polymer. Detailed analyses of our data provide new insights into the nature of the interphase and the transport mechanisms in these systems.(NSF-DMR 1610742)

8:00 AM EN02.05.02
Performance Analysis of Li-Ion Battery for Low-Temperature Space Applications Amani Alhammadi, Amarsingh Bhabu Kanagaraj and Daniel Choi; Khalifa University, United Arab Emirates

The main challenge that hinders the use of lithium (Li)-ion batteries in space applications is their low performance at low temperatures from -30 to 20 °C. Such low performance is mostly due to the low ionic conductivity and freezing of the non-solid electrolyte leading to a significant loss in the battery's capacity. In this research, the behavior of Li-ion batteries is investigated by employing electrochemical characterization techniques to study their

performance at low temperatures. The findings of this research indicate that the capacity of Li-ion batteries is decreased greatly at subzero temperature. Cyclic voltammetry profiles show that the peak separation increases with decreasing the temperature while the current decreases. The charge transfer resistance increases due to the freezing of the non-solid electrolyte, which leads to unstable Solid Electrolyte Interphase (SEI) film formation and weak permeation of electrolyte into the active material. The capacity decreases due to a significant decrease in the diffusivity of lithium ions and substantially increased charge-transfer resistance. The cell retains nearly 50% of its room-temperature capacity at 0 °C. This can be ascribed to the low diffusivity of lithium ions which affects the interface stability between the cathode and the electrolyte. Material characterization methods such as x-ray photoelectron spectroscopy (XPS) and X-ray diffractions (XRD) are used to examine the change in the material of the electrodes and the electrolyte to determine the reasons behind the performance degradation. This study contributes to the development of Li-ion batteries for low temperature and space applications by understanding the electrochemical behavior of Li-ion batteries.

8:05 AM EN02.17.06
A Spreadable Interlayer Enables Highly Stable NASICON Solid Electrolyte/Li Metal Interface Shizhao Xiong and Aleksandar Matic; Chalmers University of Technology, Sweden

The solid-state lithium metal battery (SSLMB) has been considered as a promising candidate for safe high-energy-density storage systems as it can deliver superior safety, cycling life, energy density and cell design. Despite considerable advantages, the advance of SSLMB-technology is still hindered by a highly resistive and unstable interface between the Li-metal anode and the solid electrolyte leading to decreased practical capacity and continuous side reactions [1, 2].

To achieve good interface compatibility between the solid electrolyte and Li anode, interlayers have been proposed to stabilize the interface through improved physical contact between the solid electrolyte and Li anode and increased chemical/electrochemical stability. During the past decades several years, several strategies have been considered which can be summarized as top-down approaches (magnetron sputtering, spark plasma sintering, electron-beam evaporation, pulsed laser deposition, solvent casting, spin coating), and bottom-up approaches (sol–gel derived synthesis, atomic layer deposition, chemical vapor deposition, electrochemical-assisted synthesis)[3-5]. However, most of those strategies are not capable of building an interface that can fulfil the demands of high conductivity, good physical contact, and chemical stability at the same time.

In this contribution we demonstrate an approach, based on a tailored multifunctional interlayer between the NASICON solid electrolyte ($Li_{1.5}Al_{0.5}Ge_{1.5}(PO_4)_3$, LAGP) and Li anode, that successfully addresses the interfacial issues[6]. This interlayer is designed by creating a quasi-solid-state paste in which the functionalities of LAGP nanoparticles and an ionic liquid electrolyte (IL) are combined. In the solid-sate cell, the LAGP-IL interlayer separates the Li metal from bulk LAGP electrolyte and creates a chemically stable interface with low resistance (~5 Ohm cm^2) and efficiently prevents thermal runaway at elevated temperatures (300 ºC). We show that solid-state cells designed with this interlayer can operate at high current densities, 2 mA cm^{-2} (an order of magnitude higher than that previously reported) and deliver high energy density, high-rate capability, and increased safety. The same strategy can also be applied to the SSLMB based on other classes of solid electrolytes for future energy storage technologies to meet the demand of high energy density.

Four-Phonon Scattering—A Critical Process Determining Thermal and Radiative Properties Tianli Feng; The University of Utah, United States

Phonon scattering plays a central role in the quantum theory of phonon linewidth, which in turn governs important properties including infrared spectra, Raman spectra, lattice thermal conductivity, thermal radiative properties, and also significantly affects other important processes such as hot electron relaxation. Since Maradudin and Fein's classic work in 1962, three-phonon scattering had been considered as the dominant intrinsic phonon scattering mechanism and has seen tremendous advances. However, the role of four-phonon scattering had been persistently unclear and so was ignored. The tremendous complexity of the formalism and computational challenges stood in the way, prohibiting the direct and quantitative treatment of four-phonon scattering. In 2016, a rigorous four-phonon scattering formalism was developed, and the prediction was realized using empirical potentials. In 2017, the method was extended using first-principles calculated force constants, and the thermal conductivities of boron arsenides (BAs), Si and diamond were predicted. The predictions for BAs were later confirmed by several independent experiments. Four-phonon scattering has since been investigated in a range of materials and established as an important intrinsic scattering mechanism for thermal transport and radiative properties. After this tutorial, the audience is expected to (1) be familiar with the background of three- and four-phonon scattering and their roles in thermal and radiative properties of materials, (2) understand the various characteristics of four-phonon scattering mechanism in different systems and scenarios, (3) understand the broad impact of four-phonon scattering on thermal transport and radiative properties in various materials, (4) be able to tell in which types of materials and scenarios will four-phonon scattering be critical, (5) be able to use the open-source code Four-Phonon together with Sheng BTE to calculate four-phonon scattering rates (linewidth) and thermal conductivities for materials.

Relationships Between Molecular Structure and Thermal Conductivity of Epoxy Resins David Cahill; University of Illinois, United States

High and low thermal conductivities in polymers are needed for new materials for thermal management. While the thermal conductivity of simple inorganic crystals can be calculated from first principles with good accuracy, a predictive understanding of the relationship between the thermal conductivity and the molecular structure of polymers is not yet established. We recently embarked on an extensive experimental study of the molecular structure/thermal-conductivity relationships within the class of materials known as epoxy thermosets, i.e., mixtures of epoxide monomers and amine hardeners. We measured 32 formulations to-date. For each formulation, we measure the thermal diffusivity using frequency domain probe beam deflection (FD-PBD), thermal effusivity by time-domain thermoreflectance (TDTR), acoustic velocity by picosecond interferometry, density by buoyancy, and for selected compositions, crystalline and liquid-crystalline order by small and wide-angle x-ray diffraction (SAXS and WAXS). We compare the results to predictions based on the model of the minimum thermal conductivity. The thermal conductivity of these 32 epoxy resins spans the range from 0.15 to 1.0 W/m-K. Thermal conductivity is enhanced by extended aromatic structures, high molecular density, and liquid crystalline and crystalline order. We have discovered a striking odd-even effect in the dependence of thermal conductivity on the molecular length of an aliphatic linker segment in epoxide monomers.

11:00 AM EN03.01.02
Amorphous-Like Ultralow Thermal Conductivity in Crystalline $BaZrS_3$ and Its Ruddlesden Popper Phase $Ba_3Zr_2S_7$ Md Shafkat Bin Hoque[1], Boyang Zhao[2], Eric R. Hoglund[1], Ethan A. Scott[1], Mythili Surendran[2], Eric Osei Agyemang[3], Kiumars Aryana[1], John A. Tomko[1], John T. Gaskins[1], Ganesh Balasubramanian[3], Jayakanth Ravichandran[2] and Patrick E. Hopkins[1]; [1]University of Virginia, United States; [2]University of Southern California, United States; [3]Lehigh University, United States

Crystalline materials with amorphous-like ultralow thermal conductivity are highly coveted for thermal barrier coating and thermoelectric applications. However, such behavior is rarely observed in high-quality, bulk crystals with simple crystal structures. In this study, we report on the amorphous-like ultralow thermal conductivity of high-purity, bulk, crystalline chalcogenide perovskite $BaZrS_3$ and its ruddlesden popper phase $Ba_3Zr_2S_7$. Extensive microstructural characterizations and first-principles calculations are performed to explain these exceptional thermal behaviors. Both $BaZrS_3$ and $Ba_3Zr_2S_7$ exhibit very high phonon scattering rates as indicated by some of the highest ever reported elastic modulus/thermal conductivity ratios. The low number density of the acoustic phonon modes, strong gruneisen parameter, and short phonon lifetimes lead to a thermal conductivity of 1.21 ± 0.18 W m^{-1} K^{-1} in $BaZrS_3$. In addition, this material also exhibits an amorphous-like thermal conductivity trend which likely stems from the phonon-domain boundary scattering. The highly ordered layered crystal structure of $Ba_3Zr_2S_7$, on the other hand, leads to a thermal conductivity of 0.46 ± 0.08 W m^{-1} K^{-1}, nearly one third of that of the $BaZrS_3$. Moreover, the thermal conductivity of $Ba_3Zr_2S_7$ is in agreement with the diffuson-mediated thermal conductivity limit indicating the dominance of diffuson like vibrational modes. As a result, at 100 K, the thermal conductivity of $Ba_3Zr_2S_7$ is the lowest reported to date among bulk crystalline materials. Introduction of disorder by ion bombardment gradually reduces the thermal conductivity of $BaZrS_3$. This is in contrast to $Ba_3Zr_2S_7$ where no change in thermal conductivity is observed with irradiation doses. Our study provides conclusive evidence that highly ordered nanostructuring can lead to diffuson like lattice vibrations in already low thermal conductivity crystalline materials.

11:15 AM *EN03.01.03
Thermodynamic Modeling of Hydrogel—Applications to Water Evaporation, Atmospheric Water Harvesting and Desalination Gang Chen; Massachusetts Institute of Technology, United States

Most thermodynamic modeling of hydrogels focused on predicting their final volumes in equilibrium with water, built on Flory theories for the entropy of mixing, rubber elasticity, and the Donnan equilibrium. This work will focus on water and ions in and outside hydrogels. Deficiencies and confusions in the Donnan equilibrium theory and Flory hydrogel model will be discussed and amended. It turns out that Donnan's equilibrium criteria established over 100 years ago neglected the coupling between ion concentrations and the osmotic pressure. The revised model will be employed to study thermodynamic properties of water in hydrogels including (1) the latent heat of evaporation, (2) the ability of hydrogels to retain water and to absorb water from the atmosphere, and (3) the use of hydrogels for desalination. Such thermodynamic studies will also be useful for understanding polymer electrolytes and ion transport in membranes in electrochemical systems.

11:45 AM EN03.01.04
Thermal Conductivity of Dynamic Polymer Network Guangxin Lv, Christopher Evans and David Cahill; University of Illinois at Urbana-Champaign, United States

Polymers typically have low thermal conductivities, ~0.2 W/(m K), which limits their application in systems that must manage high heat loads. Dynamic covalent networks are a class of polymer networks studied for their self-healing and stress relaxation properties and they have potential applications as shape memory polymers, flame retardants, solid electrolytes and shockwave dissipation materials. Thermal conductivity of dynamic polymer network is measured by time-domain thermoreflectance (TDTR) and frequency domain probe beam deflection (FD-PBD). At room temperature, thermal conductivity of dynamic polymer network varies from 0.05 W/(m K) to 1.0 W/(m K) by a factor of 20. Dynamic polymer network with crystal structure can have thermal conductivity of 1.0 W/(m K). Thermal conductivity of amorphous ethylene dynamic networks, synthesized from benzene diboronic acid and alkane diols, decreases from 0.19 W/(m K) to 0.095 W/(m K) at room temperature as ethylene linker length increases from 4 to 12. Thermal conductivity of these amorphous ethylene dynamic networks also decreases from 0.29 W/(m K) to 0.095 W/(m K) by a factor of 3 as the temperature increases across glass transition temperature. Minimum thermal conductivity model (MTCM) successfully predicts thermal conductivity of dynamic polymer network with different ethylene linker length and under different temperatures.

Late News: Quantum Prediction of Ultra-Low Thermal Conductivity in Lithium Intercalation Materials Tianli Feng[1] and Sokrates T. Pantelides[2]; [1]The University of Utah, United States; [2]Vanderbilt University, United States

Lithium-intercalated layered transition-metal oxides, Li_xTMO_2, brought about a paradigm change in rechargeable batteries in recent decades and show promise for use in memristors, a type of device for future neural computing and on-chip storage. Thermal transport properties, although being a crucial element in limiting the charging/discharging rate, package density, energy efficiency, and safety of batteries as well as the controllability and energy consumption of memristors, are poorly managed or even understood yet. Here, for the first time, we employ quantum calculations including high-order lattice anharmonicity and find that the thermal conductivity κ of Li_xTMO_2 materials is significantly lower than hitherto believed. More specifically, the theoretical upper limit of κ of $LiCoO_2$ is 6 W/m-K, 2–6 times lower than the prior theoretical predictions. Delithiation further reduces κ by 40–70% for $LiCoO_2$ and $LiNbO_2$. Grain boundaries, strain, and porosity are yet additional causes of thermal-conductivity reduction, while Li-ion diffusion and electrical transport are found to have only a minor effect on phonon thermal transport. The results elucidate several long-standing issues regarding the thermal transport in lithium-intercalated materials and provide guidance toward designing high-energy-density batteries and controllable memristors.

Transfer Learning for Phonon and Thermal Property Predictions Tengfei Luo, Zeyu Liu and Meng Jiang; University of Notre Dame, United States

Machine learning is trending to be an integral part of thermal science. In this talk, I will introduce our efforts in utilizing machine learning (ML) techniques to predict phonon and thermal properties. I will talk about the use of a new ML method, called transfer learning, to establish accurate models based on limited data for predicting phonon and thermal transport properties, such as phonon frequency gap, heat capacity, speed of sound and lattice thermal conductivity.

First-Principles Calculation of Nernst Effects in Complex Band Structures Jennifer Coulter, Andrea Cepellotti and Boris Kozinsky; Harvard University, United States

As the need for energy-efficient devices has become more pressing, so has interest in finding ways to enhance the thermoelectric performance of materials. While the Seebeck effect has been intensely studied, the Nernst effect has been rarely investigated computationally. Recent results, such as those showing enhanced thermopower in compensated semimetals via the Nernst effect, suggest that it also has potential to provide enhancements in thermoelectric performance in the right circumstances. Additionally, established results such as those for bismuth, which shows a low-temperature peak in the Nernst coefficient, could be better understood and further engineered for potential applications.

However, these interesting and possibly useful behaviors can be difficult to interpret from experimental results alone. Using first-principles solutions of the Boltzmann transport equation as implemented in our new open-source code package, Phoebe [1], we calculate the Seebeck and Nernst coefficients to better understand the physics underlying these effects. Time permitting, we will also discuss the role of phonon drag on these coefficients at low temperatures.

Geometric Parameters to Maximize or Minimize the Thermal Conductivity of Periodic Coaxial Cylindrical Nanowires Yingru Song and Geoffrey Wehmeyer; Rice University, United States

The thermal conductivity (k) of semiconducting nanomaterials is determined by the geometry-dependent phonon boundary scattering mean free path (MFP). Although prior work has investigated phonon transport in periodically corrugated rectangular nanowires, the detailed relationship between geometric parameters and the MFP in recently fabricated diameter-modulated cylindrical nanowires is not known. For example, it is not clear whether enhancing the larger cylinder diameter would reduce the MFP due to the phonon backscattering effect, or enhance the MFP due to the larger average path length between phonon collisions in the larger cylinder. In addition to these fundamental questions about the phonon transport physics, understanding the thermal conductivity in modulated diameter nanowires may be important for future applications of modulated silicon nanowires as photodetectors or optomechanical sensors.

Here, we use Monte Carlo phonon ray tracing simulations to comprehensively study the effect of geometric parameters on the boundary scattering MFP in

periodic coaxial cylindrical nanowires. We find that for a fixed smaller cylinder diameter, the MFP can be maximized or minimized via geometric control of the pitch, length, and diameter ratios. Our simulations show that the phonon backscattering framework is appropriate for small-pitch nanowires and gives rise to the minimum in the dimensionless MFP, while an enhanced path-length mechanism is appropriate for long-pitch nanowires and leads to the maximum in the dimensionless MFP.

Combining our calculations with analytical phonon dispersion and bulk scattering models, we predict that the thermal conductivity of periodic silicon nanowires with a fixed smaller diameter and cylinder length ratio can be tuned by up to 34% via geometric control of the larger diameter and pitch. A stronger geometric enhancement can be observed in the thermal conductance than in the thermal conductivity. Our results provide insight into the mechanisms of thermal conductivity suppression and enhancement in periodically modulated nanowires, and can be used by experimentalists to explore phonon backscattering and path-length effects in modulated nanowires.

2:30 PM EN03.02.06
Evaluating the Roles of Temperature-Dependent Eigenvectors in Predicting Phonon Transport Properties of Anharmonic Crystals Using Normal Mode Analysis Methods Jixiong He and Jun Liu; North Carolina State University, United States

Theoretical modeling of phonon transport process in strongly anharmonic materials at a finite temperature needs to accurately capture the effects of lattice anharmonicity. The anharmonicity of potential energy surface would result in not only strong phonon scatterings but also shifts of phonon frequencies and eigenvectors. In this work, we evaluated the roles of anharmonicity-renormalized phonon eigenvectors in predicting phonon transport properties of anharmonic crystals at high temperatures, using molecular dynamics-based normal mode analysis (NMA) methods in both time domain and frequency domain. Using PbTe as a model of strongly anharmonic crystal, we analyzed the numerical challenges to extract phonon lifetimes using NMA methods when phonon eigenvectors deviate from their harmonic values at high temperatures. To solve these issues, we proposed and verified a better fitting strategy, Sum-up Spectrum Fitting Method (SSFM), than the original frequency-domain NMA method. SSFM is to project the total spectrum energy density data of all phonon modes onto an inaccurate (harmonic or quasi-harmonic) eigenvector base and then manually sum up the peaks that belong to the same phonon mode (at the same frequency). The SSFM relaxes the requirement for accurate temperature-dependent eigenvectors, making it robust for analyzing strongly anharmonic crystals at high temperatures.

2:45 PM EN03.02.07
Machine Learning Based Approach for 2D-3D Thermal Boundary Conductance Cameron Foss and Zlatan Aksamija; University of Massachusetts, United States

Two-dimensional (2D) materials have the potential to be a breakthrough platform for designing next-generation solid-state devices with enhanced performance and novel functionalities. However, the ongoing design concern of heat dissipation is further exacerbated in 2D-based systems due to their weak interlayer van der Waals (vdW) atomic bonding with surrounding three-dimensional (3D), particularly the substrate. Since the primary pathway for heat removal in 2D-devices is suspected to be across the 2D/3D interface and through the 3D substrate, the uniquely poor thermal performance of 2D/3D interfaces is a pressing issue for the development and implementation of 2D-based devices. Therefore, there have been several efforts to experimentally measure 2D/3D TBC as well as to provide explanations of the underlying physical dynamics through theoretical modeling. Simultaneously, materials informatics based on machine learning (ML) algorithms has seen tremendous success in new material discovery and application-specific material selection. However, the existing literature does not hold enough TBC data (both experimental and theoretical) to construct a diverse set of 2D/3D interface pairs which is required to reliably train ML algorithms.
In this work, we use our first-principles-driven TBC model to expand upon available data in the literature by computing the TBC for 156 unique interface pairs, including technologically relevant substrates such as HfO2 and CaF2. Then we employ machine learning to develop a streamlined predictive model that is computationally cheap and demonstrates strong transferability. For single-layer 2D materials our dataset includes dispersions of graphene, silicene, boron nitride, boron arsenide, black phosphorus, blue phosphorus, and 1H-MX_2 transition metal dichalcogenides (with M=Mo, W and X=S, Se, Te). For 3D materials, our dataset includes dispersions of silicon, germanium, diamond, CaF_2, titanium, AlN, GaN, 6H-SiC, Al_2O_3, SiO_2, AlO_x, HfO_2, and PMMA. We then use our 2D/3D thermal boundary conductance (TBC) model to calculate the TBC of each 2D/3D pair from the above lists. We then vary the substrate coupling strength, which is a crucial and highly sample-dependent property, resulting in a total observation pool of 5460 TBC values which are then randomized and split 70/30 for training and testing datasets. We train a range of machine learning models and find that fine tree and wide-neural network (WNN) regression algorithms perform the best out of an array of algorithms (linear, step-wise linear, gaussian process, and support vector) due to their unbiased residuals. We then train fine tree and WNN models on the dependence of TBC on the van der Waals spring coupling constant (K_a) enabling the machine learning algorithm to accurately predict the TBC vs. K_a curve for any 2D/3D interface provided the known list of material descriptors are available and within the extrema of the parameter space.
Our results show that fine tree ensembles and wide neural networks can predict the 2D/3D TBC within +/- 1.41 MW.m^{-2}.K^{-1} and 1.046 MW.m^{-2}.K^{-1}, respectively, with a descriptor set comprised of structural data, select thermal transport properties (e.g., thermal conductivity, Debye temperature, etc.), and the vdW spring coupling constant. The reported R-squared values for either model are 0.98 (fine tree) and 0.999 (WNN). We further show that fine tree ensembles demonstrate good transferability by withholding select materials from the training pool and subsequently testing the trained models on the unseen data. In most cases, the model retains an RMSE < 10 MW.m^{-2}.K^{-1} and R-squared values greater than 0.65. Lastly, we use sensitivity analysis and Pearson correlation coefficients to identify the vdW spring coupling constant, amorphous flag, and resonant frequency gap as the descriptors that are most correlated with the TBC.

3:00 PM EN03.02.08
Fast Simulations of Thermal Transport in Complex Materials Using Machine Learning and Bayesian Force Fields Anders Johansson, Andrea Cepellotti and Boris Kozinsky; Harvard University, United States

Controlling thermal conductivities of materials is important for a wide range of applications, from thermoelectrics for clean energy generation to electronic devices and thermal barrier coatings. The thermal conductivity is commonly estimated using molecular dynamics simulations within the Green-Kubo formulation. This requires a force field that is both 1) an accurate estimate of the interatomic interactions and 2) fast enough to allow simulations with sufficiently large length and time scales. Traditionally, only empirical force fields have fulfilled both of these requirements, which severely limits the applicability of the method.

In this work, we employ the Gaussian Process-based FLARE force field, which automatically learns the interactions of more complex materials than empirical force fields. The resulting model can then be mapped to a low-dimensional, computationally efficient model. Through GPU-acceleration with LAMMPS and the Kokkos library, we achieve excellent performance and obtain well-converged estimates for the thermal conductivity. Furthermore, we investigate state-of-the-art sampling and spectral denoising methods for further acceleration of the simulations.

Thermal Transport in Complex Structures and Across Interfaces Zhiting Tian; Cornell University, United States

Understanding thermal transport processes is essential to design materials and devices with desired thermal transport properties for thermal energy conversion and management. Despite the significant progress in thermal transport of simple inorganic crystals, our understanding of thermal transport in complex structures and across interfaces remains limited. In this talk, I will present my research group's efforts to understand thermal transport in complex structures and across interfaces, using atomic modeling and experimental characterization. I will start with our study on boron suboxides, which have unusually high thermal conductivity despite their complex structures. I will then cover phonon dynamics in 3D and 2D hybrid organic-inorganic perovskites using inelastic x-ray scattering, where we gained useful insights into their ultralow thermal conductivity and remarkably weak anisotropy in 2D hybrid. Last but least, I will share our development of rigorous formalism for anharmonic atomistic Green's function to capture the contribution of inelastic scattering at the interfaces, direct observation of phonon Anderson localization in aperiodic superlattices, and machine-learning-assisted interface design.

4:30 PM EN03.03.02
Objective Oriented Design of Phase Change Material Composites Alison Hoe, Achutha Tamraparni, Chen Zhang, Alaa Elwany, Jonathan Felts and Patrick Shamberger; Texas A&M University, United States

While phase change material (PCM) heatsinks and energy storage modules have been shown to act as highly efficient transient energy storage components in thermal management systems, they have traditionally been limited by the rate at which heat is absorbed into the PCM. Composite thermal energy storage (TES) materials, consisting of highly thermally conductive elements and PCMs can overcome some of the challenges presented by the slow rate of heat absorption by most PCM phases. However, the application of these components is limited by a lack of coherent design guidelines. Here, we present a design framework based around the concept of phase change material (PCM) composites, where the effective thermal properties of a composite are dictated by constitutive relationships relating the composite structure to its transport properties. Under this approximation, relatively simple approximate analytical solutions or numerical solutions reveal the response of PCM composites to different transient heat loads. Furthermore, that response can be optimized, given a particular performance metric of interest (total heat absorbed, heat absorbed per unit mass, etc.).
First, we develop the concept of composite PCM volumes, and demonstrate that the defining criteria of a composite PCM is the critical length scale separating conductive elements. For systems below this length scale, the composite can be defined by effective thermal properties, which dramatically simplifies the description of the system, and computation of transient thermal response. Both numerical and experimental results illustrate that this length scale is on the order of 1 mm for many systems of interest, and thus is easily achievable by a number of manufacturing techniques.
Next, we demonstrate the role of metal volume fraction in governing transient thermal performance by considering heat transfer in both planar and cylindrical systems. Systems which are designed to optimize the total rate of heat transfer into the composite volume (or similarly, to minimize the transient temperature range at an interface) have dramatically higher volume fractions of conductive component than are generally considered. However, if the performance metric is modified to take into account the system volume and mass, the resulting optimal composite structure varies as a function of 1) the thermal boundary condition, 2) the period over which heat is absorbed, 3) material properties, and 4) composite geometry. The outcome of this task is a set of design guidelines for thermal storage composites, valid across a range of geometries, orientations, and material thermophysical properties. Such design guidelines will enable order of magnitude improvements in cooling power densities for TES composites.
Finally, the concept of objective oriented design of PCM composites is presented, and is illustrated with examples based around two design objectives for a finite volume cylindrical PCM composite: 1) Maximizing thermal buffering capacity at a given time, and 2) Maximizing the time the system can achieve a minimum thermal buffering capacity threshold. To this end, we demonstrate that there exist two design regimes where the thermal buffering capacity is either limited by the rate at which the system can absorb thermal energy, or by the total thermal capacitance of the system. We present expressions of the optimal volume fraction for each combination of design objectives, coordinate systems and boundary conditions based on appropriate analytical solutions for the melting problem.

4:45 PM *EN03.03.03
High-Temperature Thermal Transport in Ceramic Materials Renkun Chen; University of California, San Diego, United States

High temperature thermal transport processes are important for a variety of thermal energy conversion and management processes, such as concentrating solar power, thermophotovoltaic, thermoelectric, and thermal storage. While characterization and understanding of high-temperature thermal conductivity of various materials have been studied for several decades, there are still challenges associated with many materials in different forms (bulk, particles, films). In particular, complex high- and medium- entropy ceramic materials have recently emerged as an appealing class of materials due to their various unusual attributes, such as thermal and chemical stability, but their thermal conductivity mechanisms and potential applications as thermal materials are yet to be fully explored. In this work, we study thermal transport properties of both simple and complex (high- and medium- entropy) metal oxides. We use both traditional methods (such as laser flash) and new optical technique to measure thermal conductivity of these oxides in the form of bulk solids, coatings, and particles. The measured thermal conductivity is understood through intrinsic phonon scattering mechanisms from room to high temperature in bulk solids as well as extrinsic effects in coatings and particles.

5:15 PM EN03.03.04
Thermal Conductivity Prediction of Ceramic Materials at High Temperature Zherui Han and Xiulin Ruan; Purdue University, United States

Many applications such as effective thermal barrier coatings require ceramic materials to have low thermal conductivities at high temperature. In these crystals, phonons are the main heat carriers and thermal conductivity is largely determined by phonon-phonon interactions. We predict this key property of ceramic materials using first-principles calculations, where we consider recent theoretical advances: four-phonon scattering and phonon renormalization. We find these two effects to be significant at high temperatures, a condition where ceramics are expected to work. Our predictions agree well with available experimental data and our own measurements, and can guide thermal barrier coating design for high temperature applications.

5:30 PM EN03.03.05

Nanoscale Mechanisms for Increasing Thermal Boundary Conductance via Ion Irradiation Thomas W. Pfeifer[1], Ethan A. Scott[2], Ashutosh Giri[3], John A. Tomko[1], Khalid Hattar[2] and Patrick E. Hopkins[1]; [1]University of Virginia, United States; [2]Sandia National Laboratories, United States; [3]University of Rhode Island, United States

A fundamental understanding of thermal boundary conductance is critical for device
cooling, and with ion bombardment as a prominent method of doping of semiconductors, the impact on TBC must be explored. We present a two-part study in which we experimentally measure the TBC across defected / pristine crystalline-crystalline interfaces, and use molecular dynamics to help explain the results.
Experimentally, we measure Gallium Nitride bombarded with varying doses of Helium, Carbon, Nitrogen, and Gallium ions, with an Aluminum capping layer deposited, and we observe a consistent increase in TBC with increasing ion dose. These measurements are performed using Time Domain Thermoreflectance (TDTR), which is a pump-probe technique that measures the change in thermoreflectance on the surface of a sample as a function of pump-probe delay time from picoseconds to nanoseconds. This change in thermoreflectance is related to both the temporal temperature decay from impulse heating driven by the sub-picosecond pump pulse and the frequency-dependent temperature rise induced from the modulated pump pulse train. Thus, TDTR is well suited to measure the thermal conductance across near surface interfaces. Our TDTR apparatus includes an 800nm 80MHz femtosecond pulsed laser, the pump is modulated at 8.4MHz, and all samples included an aluminum transducer deposited on the surface. Computationally, we explore a Silicon / Heavy Silicon system in which Frenkel defects are introduced. We note an increase in TBC when defects are added, and point to an increased level of lattice deformation (in addition to the sparse defects themselves) as leading to an increase in phonon scattering within the material near the interface. This portion of the study uses Non-Equilibrium Molecular Dynamics (NEMD) simulations using Large-scale Atomic/Molecular Massively Parallel Simulator (LAMMPS). A Stillinger Weber potential is used for the
Silicon - Heavy Silicon system, and the system is initialized with pairs of void / interstitial defects present.

Late News: Modeling the Effect of Thermal Boundary Resistance on the Thermal Behaviors of a Lithium-Ion Battery for Energy-Storage Applications Dongcheul Lee, Byungmook Kim, Seohee Kang and Chee-Burm Shin; Ajou University, Korea (the Republic of)

Any power generation through energy harvesting or from renewable sources should be combined with a suitable energy storage system to complement the intermittency of energy sources. Lithium-ion batteries (LIBs) are by far the most popular energy storage option in the global energy storage market. Thermal management is indispensable to control the temperature of LIB within a suitable range for energy-storage applications. For a proper thermal management of LIB, it is important to establish a thermal modeling methodology which is computationally efficient. An LIB cell consists of multiple alternating layers of positive and negative electrode materials, aluminum and copper current collectors, and porous separators impregnated with electrolyte. For the thermal modeling of LIB, we need a systematic way to obtain the thermal properties of the various compartments of the cell components as well as the thermal boundary resistances of the interfaces between the cell components.
In this work, a thermal modeling methodology is presented with a special emphasis to investigate the effect of thermal boundary resistance on the thermal behaviors of an LIB cell. A 63 Ah LIB cell fabricated by LG Chem. is modeled. The density and specific heat capacities are obtained by using the volume-averaged values of the various compartments of the cell components and the effective thermal conductivities are calculated by using the values estimated based on the equivalent networks of parallel and serial thermal resistances of the cell components including the thermal boundary resistances of the interfaces between the cell components. The non-uniform distribution of the heat generation rate in an LIB cell is calculated based on the modeling results of the potential and current density distributions of the battery cell. Thermal modeling of an LIB cell is validated by the comparison between the experimental measurements and modeling results. The modeling methodology presented in this work can be used to estimate accurately the thermal behaviors of various devices used for thermoelectric and thermophotovoltaic energy conversion.

EN03.04.02
Raman Linewidth Contributions from Four-Phonon and Electron-Phonon Interactions in Graphene Zherui Han[1], Xiaolong Yang[2], Sean Sullivan[3], Tianli Feng[4], Li Shi[3], Wu Li[2] and Xiulin Ruan[1]; [1]Purdue University, United States; [2]Shenzhen University, China; [3]The University of Texas at Austin, United States; [4]The University of Utah, United States

The Raman peak position and linewidth provide insight into phonon anharmonicity and electron-phonon interaction in materials. For monolayer graphene that has emerged as a potential electronic and optoelectronic material, prior first-principles calculations have yielded opposite temperature dependence of the linewidth compared to measurement results. Here, we explicitly consider four-phonon anharmonicity, phonon renormalization, and electron-phonon coupling, all found important to successfully explain both the G peak frequency shift and linewidths in our suspended graphene sample at a wide temperature range. Our calculation shows that the Raman linewidth can be widely tuned by varying carrier doping.

EN03.04.03
Thickness-Dependent Thermal Conductivity of Mechanically Exfoliated *β*-Ga_2O_3 Thin Films Yingying Zhang[1], Qun Su[1], Jie Zhu[2], Sandhaya Koirala[1], Steven Koester[1] and Xiaojia Wang[1]; [1]University of Minnesota Twin Cities, United States; [2]Dalian University of Technology, China

Beta-phase gallium oxide (β-Ga_2O_3), the most thermally stable phase of Ga_2O_3, has stimulated great interest in power electronics due to its ultra-wide bandgap (~4.9 eV) and high breakdown electric field. The relatively low thermal conductivity of β-Ga_2O_3, however, limits the device performance due to excessive temperature driven by self-heating. Recently, integrating β-Ga_2O_3 thin films on substrates with high thermal conductivities has been proposed to improve heat rejection and device reliability. In this work, we prepare high-quality single-crystal β-Ga_2O_3 thin films by mechanical exfoliation of bulk crystals and study their thermal transport properties. Both the anisotropic thermal conductivity of β-Ga_2O_3 bulk crystals and the thickness-dependent thermal conductivity of β-Ga_2O_3 thin films are measured using the time-domain thermoreflectance technique. The reduction in the thin-film thermal conductivity, compared to the bulk value, can be well explained by the size effect resulting from the enhanced phonon-boundary scattering when the film thickness decreases. This work not only provides fundamental insight into the thermal transport mechanisms for high-quality β-Ga_2O_3 thin films but also facilitates the design and optimization of β-Ga_2O_3-based electronic devices.

EN03.04.04
A Pump-Probe Thermoreflectance Technique for Measuring Specific Heat Capacity of Thin Films Milena Milich, John A. Tomko and Patrick E. Hopkins; University of Virginia, United States

From the energy sector to the pharmaceutical industry, there has been a growing need for characterization of thermal properties of materials at the nanoscale. In particular, measuring the specific heat capacity of a material is critical to quantifying heat dissipation in thermal management research as well as optimizing additive manufacturing routines and pharmaceutical development. While traditional methods for determining specific heat capacity, such as differential scanning calorimetry, rely on bulk samples for measurement, it can be both extremely expensive and time-consuming to produce bulk volumes of sample materials.

In this work, we introduce a novel pump-probe thermoreflectance technique for measuring thermal properties of thin films, on the order of nanometers thick. More specifically, we use a boxcar averager to monitor the transient temperature rise of the sample surface as it is periodically heated by the “pump” laser beam. By measuring the laser-induced heating over multiple modulation frequencies we are able to measure not only specific heat capacity, but also thermal conductivity and thermal boundary conductance. We demonstrate the application of the proposed measurement technique by measuring and analyzing standard "film on substrate" samples as well as a collection of low-temperature phase change materials.

EN03.04.05
Nickel-Infused Nanoporous Alumina as Tunable Solar Absorber Xuanjie Wang; Rensselaer Polytechnic Institute, United States

Solar energy can alleviate our dependence on traditional energy sources like coal and petroleum. In this regard, the design and performance of solar absorbers are crucial for capturing energy from sunlight. Specifically, for applications relying on solar-thermal energy conversion, it is desirable to construct solar absorbers using scalable techniques that also allow a variation in optical properties. In this study, we demonstrate the ability to tune the spectral absorptance of nickel-infused nanoporous alumina using a scalable and inexpensive fabrication procedure. With simple variations in the geometry of the nanostructures, we enable broadband absorption with a net solar absorptance of 0.96 and thermal emittance of 0.98 and spectrally-selective absorption with a net solar absorptance of 0.83 and thermal emittance of 0.22. The simple manufacturing techniques presented in this study to generate nanoengineered surfaces can lead to further advancements in solar absorbers with well-controlled and application-specific optical properties.

EN03.04.07
Effect of Temperature on the Solubility of Magnesium in Molten Salt $MgCl_2$-KCl-NaCl and the Resulting Redox Potential and Corrosivity Kalyn M. Fuelling[1,2], Olivia Dale[1], Suhee Choi[1] and Michael Simpson[1]; [1]The University of Utah, United States; [2]University of Michigan, United States

Molten chloride salts are a promising option for heat transfer use in concentrating solar power plants due to their ability to transfer heat efficiently and remain stable at a variety of temperatures. However, these salts are corrosive and therefore break down pipes in the plant. In this study, the aim is to further investigate the solubility of magnesium in $MgCl_2$-KCl-NaCl salt to reduce the formation of corrosive hydroxide/oxide ions. Redox potential was used to indicate the dissolution of the magnesium in the molten chloride salts at different temperatures. A previous study reported that the addition of the magnesium to the $MgCl_2$-KCl-NaCl salt resulted in a lower redox potential than that of pure $MgCl_2$-KCl-NaCl. This study will focus on refining the relationship between the solubility of magnesium and operating temperature. Tests were conducted at 500°C, 600°C, and 650°C. With this data correlating to temperature, concentrating solar power plants can know precisely how much magnesium needs to be added to the molten chloride salt at a certain temperature in order to adequately lower the redox potential and thus result in a less corrosive substance.

EN03.04.08
Single-Nanodiamond Luminescence Lifetime Thermometry for Transient Hotspot Quantification Dinesh Bommidi and Andrea Pickel; University of Rochester, United States

Modern electronic and data storage technologies combine shrinking feature sizes with ever-increasing operating speeds, leading to transient nanoscale hotspots that can limit device performance. Quantifying hotspots in operating devices thus requires a non-invasive thermometer with sub-100 nm spatial resolution and sub-100 ns temporal resolution. One promising approach is to optically probe the time-resolved, temperature-dependent luminescence of an individual nanoparticle placed at a specific critical location. Nitrogen vacancy (NV) centers are bright, photostable luminescent defects found in diamond nanoparticles (nanodiamonds, or NDs) that have emerged as exemplar optical sensors with wide-ranging applications, including nanoscale magnetometry, bioimaging, quantum computing, stress mapping, and thermometry. The spin state of NV centers can be coherently manipulated using resonant microwave pulses and read out via the emitted luminescence, an approach known as optically detected magnetic resonance (ODMR). The ODMR signal has well-known temperature dependence, enabling ODMR-based thermometry. However, the temporal resolution of ODMR thermometry is limited to ~10 ms. Furthermore, ODMR measurements require a microwave antenna, an experimental complication that can also interfere with device operation.

To overcome the limitations of ODMR thermometry while retaining the advantages of ND-based sensing, we utilize the temperature-dependent luminescence lifetimes of NV centers in individual NDs for thermometry. NV centers have luminescence lifetimes of ~25 ns, naturally facilitating high temporal resolution measurements. At elevated temperatures, the probability of phonon-assisted non-radiative relaxation increases, thereby decreasing the luminescence lifetime. To demonstrate single-ND luminescence lifetime thermometry, we first developed robust strategies for cross-identifying single NDs via luminescence, atomic force microscope (AFM), and scanning electron microscope (SEM) imaging, since luminescence emission intensity is not a reliable indicator for distinguishing single NDs from aggregates. We then measured the luminescence lifetimes of individual ~70 nm NDs as a function of temperature using an approach called time-correlated single photon counting (TCSPC). TCSPC relies on the repeated detection of single photons over many excitation and decay cycles, allowing us to overcome the challenge of low photon counts associated with small NDs and high temperatures. We assessed the temperature dependence, repeatability, and ND-to-ND uniformity of single-ND luminescence lifetimes. We find that single-ND lifetimes show reliable, sensitive temperature dependence that can be calibrated and employed for thermometry. We also show that AFM-based nanomanipulation can be used to position individual NDs with ~20 nm precision. The combination of high spatial and temporal resolution along with precise positioning control can enable practical applications of single-ND luminescence lifetime thermometry for transient hotspot characterization.

Surface Phonon-Polaritons as Efficient Cooling Vectors Sebastian Volz, Yunhui Wu, Jose Ordonez, Laurent Jalabert, Saeko Tachikawa, Roman Anufriev and Masahiro Nomura; The University of Tokyo, Japan

Surface phonon-polaritons (SPhPs), electromagnetic modes excited by optical phonons, are investigated to promote heat spreading in nanostructures.
In the first stage, it will be shown that SPhPs can carry heat more efficiently than phonons in ultra-thin SiN amorphous membranes by measuring thermal conductivity as a function of temperature and thickness by using Time-Domain ThermoReflectance. The significant contribution of SPhPs is proven in the 400K-800K temperature range.
By using the 3w technique, we then show the presence of SPhPs in the 300K-400K temperature range and their quasi-ballistic contribution to thermal conduction over a distance larger than 100 microns to be compared to the few hundred100nms of phonon mean path.
In a second stage, we show that SPhPs also impact heat conduction in silicon devices by measuring the SPhP heat flux in $SiO_2/Si/SiO_2$ multilayers with a gap. In this latter case, a predominant SPhP contribution is highlighted.

Late News: New Transport Behavior in Nanostructured Silicon—Increased In-Plane Phonon Scattering Drives Enhanced Thermal Conduction Brendan McBennett[1], Joshua Knobloch[1], Albert Beardo[2], Hossein Honarvar[1,1], Travis Frazer[1], Begoña Abad[1], Lluc Sendra[2], Javier Bafaluy[2], Juan Camacho[2], Jorge Nicolas Hernandez Charpak[1], Henry Kapteyn[1], Mahmoud Hussein[1], Xavier Alvarez[2] and Margaret Murnane[1]; [1]University of Colorado Boulder, United States; [2]Universitat Autònoma de Barcelona, Spain

Understanding nanoscale thermal transport is critical for nano-engineered devices such as quantum sensors, thermoelectrics, and nanoelectronics. However, despite overwhelming experimental evidence for non-diffusive heat dissipation from nanoscale heat sources, the underlying mechanisms are still not understood. In this work, we model nanoscale heat flow with both advanced mesoscopic and microscopic approaches to elucidate the fundamental physics of an unexplained and counter-intuitive behavior: *decreasing nanoscale heat source spacing actually enhances cross-plane thermal conduction* [1].

Using advanced atomic-level simulations, we obtain the microscopic information needed for a fundamental investigation of nonequilibrium phonon scattering amidst *interacting* heat sources [2]. We observe a reduction in in-plane phonon lifetimes with decreasing nanoheater spacing, as phonons from neighboring heat sources scatter downwards into the substrate. The increased scattering is accompanied by elevated cross-plane thermal conduction – a novel *channeling* phenomenon that lies beyond many of the traditional Boltzmann transport equation approximations and opens the door to nanoscale engineering of thermally anisotropic materials. We also note the striking similarities between the non-diffusive temperature profiles calculated from the atomistic data and our second, mesoscopic approach.

The kinetic-collective model (KCM) is a hydrodynamic transport model which uses finite element analysis to solve the Guyer-Krumhansl equation over large, device-relevant geometries [3]. While resistive scattering in bulk silicon is traditionally thought to obscure hydrodynamic effects, we observe good agreement between KCM and experimental data for the thermal relaxation of 1 and 2D nanoscale hot spots [4]. In the case of small, effectively isolated heaters, the temperature decay is double-exponential, with distinct time scales for interface resistance and hydrodynamic-like phonon transport. By tuning a nonlocality parameter in KCM to the limiting length scale, we can also predict the increased conduction observed experimentally for closely-packed sources. Moreover, we predict the full thermomechanical physics in ultrafast laser-based experiments, even in complex and general geometries, without the need for geometrical fit parameters, an advance beyond traditional simulations. The combined models explain the counterintuitive experimental observations of enhanced cooling for close-packed heat sources, from atomic to >micron length scales and represent a new fundamental behavior in materials, with far reaching implications for electronics and future quantum devices.

The Influence of Extrinsic Lattice Defects on Thermal Transport in Single Crystal Thorium Dioxide Cody A. Dennett and David H. Hurley; Idaho National Laboratory, United States

Actinide and lanthanide fluorite oxides, UO2, CeO2, ThO2, form an important class of ceramic energy materials with applications ranging from nuclear fuels to solid oxide fuel cells. Of these systems, ThO2 (thoria), has been the least explored and offers unique features including an extremely high melting temperature and a fixed tetravalent oxidation state. Many potential application environments for thoria include high radiation fields or temperatures which either promote or directly generate lattice defects. Such defects drastically influence thermal transport, a controlling safety and performance property in many applications. To date, little experimentally-validated understanding has been generated on the role of defect formation and clustering on thermal transport in thoria due to the lack of high-quality starting material in which these effects may be explored. In this work, high-quality oriented single crystals of thoria are grown using hydrothermal synthesis and then exposed to proton irradiation to generate extrinsic lattice defects (both nanoscale point defects and extended dislocation loops). The thermal conductivity of these damaged crystals is measured direction using a spatial domain thermoreflectance (SDTR) technique and defects are quantified using optical spectroscopy and electron microscopy. Experimental values are compared with the calculation of thermal conductivity from the linearized Boltzmann transport equation for phonons taking into account the relevant scattering mechanisms. This combined experimental and computational approach provides a framework for predicting the thermal performance of this class of materials from first principles in a variety of environmental conditions.

Anomalous Thermoelectric Transport Phenomena from Interband Electron-Phonon Scattering Boris Kozinsky[1,2], Natalya Fedorova[1,3] and Andrea Cepellotti[1]; [1]Harvard University, United States; [2]Bosch Research, United States; [3]Luxembourg Institute of Science and Technology, Luxembourg

The Seebeck coefficient and electrical conductivity are two central quantities to be optimized simultaneously in designing thermoelectric materials, and they are determined by the dynamics of carrier scattering. We uncover a new regime where the presence of multiple electron bands with different effective masses, crossing near the Fermi level, leads to strongly energy-dependent carrier lifetimes due to intrinsic electron-phonon scattering. In this anomalous regime, electrical conductivity decreases with carrier concentration, Seebeck coefficient reverses sign even at high doping, and power factor exhibits an unusual second peak. We explain the origin and magnitude of this effect using a general simplified model as well as first-principles Boltzmann transport calculations in recently discovered half-Heusler alloys. We identify general design rules for using this paradigm to engineer enhanced performance in thermoelectric materials.

Engineering Grain Boundaries in Thermoelectric Materials G. J. Snyder; Northwestern University, United States

Grain boundaries have a remarkable effect on the thermal and electrical transport properties of polycrystalline materials but are often ignored by prevailing physical theories. Grain boundaries and interfaces can adversely alter the properties of Solar Cells, Batteries and Thermoelectrics. To devise strategies for improving the thermoelectric performance of materials, it is essential to understand the coupled charge and thermal transport mechanisms including an interfacial Seebeck effect. The inhomogeneous nature of materials, such as that caused by grain boundaries, must be taken into account to rethink engineering strategies based on Mathiessen's rule which interprets scattering homogeneously.
Prevailing models for thermal transport treat interfaces and grain boundaries as structureless even though at the atomic scale they are better described as arrays of linear defects of various types. Allowing for this inherent structure, several fundamental characteristics of heat transport arise, such as diffraction conditions when heat carrying phonons scatter off the periodic, linear defect arrays that should be present in grain boundaries. Furthermore, a dimensionality crossover is observed in diffusive heat transport where phonons with a wavelength longer than the linear defect spacing see the interface simply as a structureless planar defect, and phonons with see the interface as a collection of independently scattering linear defects.

2:00 PM EN03.06.02
Influence of Thermoelectric Leg Shape on Power Generation Potential Under Constant Temperature and Heat Flux Boundary Conditions Bengisu Sisik and Saniya LeBlanc; The George Washington University, United States

Thermoelectric devices offer the potential to convert wasted heat into electricity, and they can be used for thermal management by pumping heat. The shape of thermoelectric devices, particularly the active semiconducting material units (or thermoelectric legs) within the device, has remained largely unchanged – thus limiting our ability to customize device thermal resistances. The advent of new manufacturing techniques such as additive manufacturing enables customizable device shapes, but there is little knowledge about what shapes are desirable. In this work, we show the effect of different (non-rectangular) thermoelectric leg designs on thermoelectric device performance. Various leg shapes (rectangular prisms, rectangular prisms with interior hollows, trapezoids, hourglass, and Y-shapes) were modeled numerically to determine their thermal and electrical performance under constant temperature and heat flux boundary conditions. Two thermoelectric materials, bismuth telluride and silicon germanium, were modeled to capture low and high temperature applications, respectively. An hourglass-shaped thermoelectric leg subjected to a fixed temperature boundary condition has the best thermal and electrical performance: the hourglass-shaped leg results in more than double the electrical potential and maximum power compared to the conventional rectangular shape. Under a fixed heat flux boundary condition on the hot side, a trapezoid-shaped leg results in almost double the electrical potential and a 50% increase in the power output compared to the conventional leg shape. Varying boundary conditions, which reflect different device operating conditions, result in different performance values for the same leg shapes. These findings underscore the importance of leg geometry on electrical and thermal performance of a thermoelectric leg, as well as the importance of considering the device operating condition when selecting the best leg shape. The results are relevant as new processing techniques emerge and enable topological optimization of thermoelectric devices.

Synthesis, Structure and Properties of Pnictide-Based Clathrates Kirill Kovnir[1,2]; [1]Iowa State University, United States; [2]US DOE Ames Laboratory, United States

Unique class of 3D framework materials with large polyhedral cages, clathrates, is a promising platform for the development of novel thermoelectric materials due to intrinsically low thermal conductivity. Traditionally the tetrahedral clathrate frameworks are based on tetrels, group 14 elements, Si, Ge, and Sn. In this work we will present recent advances in the design, synthesis, order-disorder structural transitions, and properties of unconventional clathrates with three-dimensional frameworks comprised of oversized metal-pnictide (P, As, and Sb) polyhedral cages that encapsulate guest cations.

2:30 PM EN03.06.05
$Sr_2Sb_2O_7$ as a Novel Thermoelectric Material Luisa Herring Rodriguez[1] and David O. Scanlon[1,2,3]; [1]University College London, United Kingdom; [2]Diamond Light Source, United Kingdom; [3]Thomas Young Centre, United Kingdom

Around 60% of primary energy consumption is wasted as heat energy, representing an untapped source of energy with huge potential to reduce our overall consumption.[1] Thermoelectric materials convert heat energy into electricity through the use of temperature gradients. The materials historically used for this purpose include bismuth chalcogenides and lead tellurides. However, issues relating to their natural abundance and toxicity, combined with the increasing demand for environmentally friendly energy sources, is driving research into novel materials with potential thermoelectric properties to replace these.
The effectiveness of a thermoelectric is measured by the dimensionless figure of merit ZT. Materials with a high ZT need to balance a high electrical conductivity and a low thermal conductivity. Oxides generally exhibit properties valuable for thermoelectric applications, including low cost, thermal and chemical stability and environmental benignity. However, their thermoelectric performance has been hindered by their high lattice thermal conductivities. Novel ternary oxides have advanced research in this field as their complex crystal structures possess lower lattice thermal conductivities than traditionally seen in oxides.
In this study, we conduct a detailed investigation into the thermoelectric properties of the ternary wide band semiconductor $Sr_2Sb_2O_7$, which has previously been synthesised under high temperature conditions and shown to be thermally stable.[2,3] Our study uses the latest approach to separately calculate the different contributions to overall scattering rates, in order to more accurately predict thermal conductivity as compared to the constant relaxation time approximation (CTRA).[4] We benchmark this approach against the CTRA and show that $Sr_2Sb_2O_7$ possesses a ZT greater than many existing oxide thermoelectric materials, and has the potential to perform as a high-performance n-type thermoelectric component. We go on to investigate the defect chemistry of this exciting new thermoelectric candidate to further assess its suitability.

Classifying ($p \times n$)-Type Transverse Thermoelectric Semimetals and Semiconductors Qing Shao and Matthew Grayson; Northwestern University, United States

Unlike the longitudinal 2-leg thermoelectrics, ($p \times n$)-type transverse thermoelectrics (TTE) function with a single leg hosting orthogonal *p*- and *n*- Seebeck behavior. The anisotropic ambipolar thermoelectric behavior is originated from the anisotropic effective masses of electrons and holes, leading to opposite dominant transport types along different crystal axes despite the parallel transport of electrons and holes along both directions. Whereas doped unipolar thermoelectrics have activated conduction to a single band, these ($p \times n$)-type materials can have activated conduction to both bands since both electrons and holes simultaneously contribute to the anisotropic conduction in all directions. As such an important concept here is that of the "partial gap", i.e. the gap between the Fermi energy and the electron or hole band edges for the *n*- and *p*-type partial gaps, respectively. The partial gap is defined as positive for non-degenerate doping, designated n or p, and negative for degenerately doping, designated n^+ or p^+. Consequently, we categorize intrinsic semiconductors with the label $p \times n$ given the positive electron and hole partial gaps, while the intrinsic semimetal is labelled $p^+ \times n^+$ given the heavy doping resulting in two negative partial gaps. There remain two intermediate hybrid cases, namely $p^+ \times n$ and $p \times n^+$ where one band is degenerately and the other non-degenerately doped. Theoretical analysis and simulations show that among all four types of bulk TTE materials, the semiconducting ($p \times n$)-type TTEs have the largest transverse power factors. By comparison, the metallic transport of both electrons and holes of ($p^+ \times n^+$)-type TTE leads to the lowest transverse power factors, though these might be the most promising TTE candidates in extreme low-temperature applications. The dependence of transverse Seebeck coefficient on electron and hole effective mass anisotropy is explored as a function of Fermi energy for different directional effective mass ratios for both electrons and holes. All categories of semiconductor, semimetal, and hybrid ($p \times n$)-type TTE are modeled with band gap $E_g = \pm 3\ k_B T$ to illustrate peak TTE performance, including Seebeck tensor terms and transverse power factors. We point out unusual scenarios in the hybrid case where, for example, the valence band can be degenerately doped, yet the Seebeck coefficient in one of the transport directions can still be *n*-type, dominated by activated conduction to the electron band. The introduction of this classification method will greatly help the characterization and performance enhancement of ($p \times n$)-type TTE materials, allowing broader application of this type of emerging TTE material.

Uncovering Intrinsic Thermoelectric Properties of Polycrystalline SnSe In Chung; Seoul National University, Korea (the Republic of)

Despite the extraordinarily high maximum thermoelectric figure of merit (ZT) ~2.2-2.8 discovered in single-crystal SnSe materials, their performance has been severely debated. Many research groups have observed paradoxically higher thermal conductivity in polycrystalline samples than the reported values for single crystals, leading to much lower ZT. Accordingly, the widely sought goal in the thermoelectric society has been to realizing polycrystalline SnSe samples with comparable to or even higher performance than the single-crystals. In this talk, I will discuss the origin of such higher thermal conductivity and poorer ZT of polycrystalline SnSe samples. Then, I will introduce our facile synthesis process to remedy this problem. Our properly prepared, hole-doped SnSe polycrystalline samples show a record-breaking peak ZT greater than ~3.0 at 783 K and average ZT ~2.0 between 300 and 783 K. Their lattice thermal conductivity is finally ultralow at ~0.07 W m^{-1} K^{-1} at 783 K, much lower than that of the single crystals.

Advances in Understanding and Modeling Phonons Asegun Henry; Massachusetts Institute of Technology, United States

From the standpoint of pure crystalline materials, phonons have been long considered a solved problem. The standard model is sometimes termed the phonon gas model (PGM), and it provides a useful physical picture for both understanding and predicting behavior of phonons in pure crystalline materials. However, a variety of studies over the last decade have highlighted the fact that when symmetry is broken, for example by compositional or structural defects (e.g., random alloys, amorphous materials and interfaces) the mode shapes can change from what is traditionally envisaged for phonons, namely plane waves. The physics of these alternative types of phonons, how they interact, and how they impact phenomena such as chemical reaction is still being explored, and this talk will review progress made on these questions by the Atomistic Simulation & Energy (ASE) research group at MIT. This talk will also review recent progress on techniques to model the interactions between atoms and phonon transport.

Electronic Transport Properties Beyond the Boltzmann Equation Andrea Cepellotti[1], Jennifer Coulter[1], Anders Johansson[1], Natalya Fedorova[2,1] and Boris Kozinsky[1]; [1]Harvard University, United States; [2]Luxembourg Institute of Science and Technology, Luxembourg

In this talk we will present some of our efforts for characterizing materials transport properties from first-principles simulations. First, we will discuss how first-principles calculations, typically limited to semiclassical models, are unable to capture the electronic transport properties of Bi2Se3, a narrow-gap semiconductor. In fact, we show that transport in this material at low doping concentrations is dominated by Zener tunneling [1], a phenomenon in which carriers tunnel between the valence and the conduction band, rather than just diffusing under the action of the electric field. This transport mechanism can be described using a novel first-principles model based on the Wigner distribution. Surprisingly, we find that Zener tunneling is not limited to low-energy carriers, but occurs also between band subvalleys of energy larger than the band gap.
Next, we will introduce Phoebe [2], a software for computing thermoelectric properties by solving the electron and phonon Boltzmann equation. Phoebe can compute electron-phonon and phonon-phonon scattering properties from first-principles simulations, allowing a fully ab-initio prediction of thermoelectric properties. Additionally, we implemented an efficient mixed MPI and OpenMP parallelization and GPU acceleration, allowing us to take advantage of contemporary computing infrastructure.

4:45 PM *EN03.07.03
Thermal Transport in Topological Materials Bolin Liao; University of California, Santa Barbara, United States

Topological phase transitions occur when the electronic bands change their topological properties, typically featuring the closing of the bandgap. While the influence of topological phase transitions on electronic and optical properties has been extensively studied, its implication on phononic properties and thermal transport remains unexplored. In this work, we use first-principles simulations to show that certain phonon modes are significantly softened near topological phase transitions, leading to increased phonon-phonon scattering and reduced lattice thermal conductivity. We demonstrate this effect using two model systems: pressure-induced topological phase transition in $ZrTe_5$ and chemical composition induced topological phase transition in $Hg_{1-x}Cd_xTe$. We attribute the phonon softening to emergent Kohn anomalies associated with the closing of the bandgap. Our study reveals the strong connection between electronic band structures and lattice instabilities and opens up a potential direction towards controlling heat conduction in solids. This work is based on research supported by DOE under the award number DE-SC0019244 and the UC Santa Barbara NSF Quantum Foundry funded via the Q-AMASE-i program under award DMR-1906325.

5:15 PM EN03.07.04
Interplay Between Electron-Phonon Coupling and Ballistic Transport in Thin Films Ali Alkurdi, Julien Legendre and Pierre-Olivier Chapuis; CNRS - INSA Lyon, France

Thermal management is essential in many electronic devices, the components of which have been scaled down to the nanometer. When the characteristic size becomes comparable to the mean free path of energy carriers, interactions with boundaries can dominate thermal transport and the quasi-ballistic heat conduction regime arises: Fourier's diffusive law is no more valid to describe thermal transport and 'temperature jumps' appear at contacts. This heat conduction regime takes place for both phonons and electrons, however these two types of energy carriers do not have the same mean free path. In addition, it is known that electron and phonon temperatures can differ under some circumstances, when they are driven out of equilibrium.
In this contribution, we investigate the deviation from the diffusive regime in thin films. To this end, we solve the Boltzmann Transport Equation (BTE) both for phonons and electrons using the Discrete Ordinate Method (DOM) [1-4], in particular in the isotropic-crystal and single relaxation time approximations. A coupling term reminiscent of the two-temperature model is added in the BTE equations [5]. This method accounts for the directional and non-local aspects of the energy flux, which can be tuned by the electron-phonon coupling constant. We analyze the impact of the electric field and the geometry on the flux transport, and compare the results with diffusion-based energy/charge conservation equations.
These results shed light on the relation between local energy non-equilibrium and transport properties.

Tuning Network Topology and Vibrational Mode Localization to Achieve Ultralow Thermal Conductivity in Amorphous Chalcogenides Kiumars Aryana[1], Derek Stewart[2], John T. Gaskins[1], Joyeeta Nag[2], John Read[2], David H. Olson[1], Michael Grobis[2] and Patrick E. Hopkins[1]; [1]University of Virginia, United States; [2]Western Digital Corporation, United States

In recent years, there have been numerous efforts to synthesize materials with ultralow thermal conductivities, a crucial parameter in the development of thermoelectric materials, memory devices, and thermally protective coatings. It has been generally believed that amorphous solids possess the lowest thermal conductivity possible. The heat transport mechanisms in ultralow thermal conductivity materials are often described using formalisms originally put forth by Einstein, and later refined by others, which account for some degree of localization of the vibrational modes or strong suppression of vibrational scattering length scales. These concepts, which partially form the basis of analytical minimum thermal conductivity models, are able to successfully predict the thermal conductivity of a wide range of amorphous solids. With advances in nanofabrication, several studies have shown that, by reducing the mean free paths of the vibrational modes, the thermal conductivity of crystalline materials can be significantly lower than this aforementioned minimum limit. In amorphous materials, however, manipulating the atomic structure to reach values below the minimum limit is more complicated, as it is already in its highest disordered state. Thus, a question remains: how can the thermal conductivity of a fully dense amorphous solid be further reduced?

Here, we report on a mechanism to suppress the thermal transport in a representative amorphous chalcogenide system, silicon telluride (SiTe), by nearly an order of magnitude via systematically tailoring the cross-linking network among the atoms. As such, we experimentally demonstrate that in fully dense amorphous SiTe the thermal conductivity can be reduced to as low as 0.10 ± 0.01 W m^{-1} K^{-1} for high tellurium content with a density nearly twice that of amorphous silicon. Using ab-initio simulations integrated with lattice dynamics, we attribute the ultralow thermal conductivity of SiTe to the suppressed contribution of extended modes of vibration, namely propagons and diffusons. This leads to a large shift in the mobility edge - a factor of five - towards lower frequency and localization of nearly 42% of the modes. This localization is the result of reductions in coordination number and a transition from over-constrained to under-constrained atomic network.

EN03.08.03
Investigating Phonon Transport in Dense 2D and 3D Random Nanoparticulates Ongira Chowdhury, Rohit Kakodkar and Joseph P. Feser; University of Delaware, United States

The frequency domain perfectly matched layer method is used to study phonon scattering and localization in two and three dimensional domains of randomly embedded nanoparticles. We show the FDPML method has the capability of capturing mode-by-mode phonon transport in domains with up to 100 million atoms with the use of parallel computing. From simulations of phonon-nanoparticle scattering across a wide range of volume fractions of nanoparticles, in the Mie and Rayleigh regime, we show that the elastic mean free path scales inversely with the number density of nanoparticles, for volume fractions as high as ~23% before exhibiting dependent scattering effects which causes the mean free path to increase again. We also observe phonon localization by using the Landauer method in 2D and 3D domains of random nanoparticles, at volume fractions up to ~40%. The modal decomposition method is also used to study localized modes in 2D and the results of the two approaches are compared.

EN03.08.04
New Incoherent and Coherent Models for Metal-Metal Thermal Interface Conductance Joseph P. Feser; University of Delaware, United States

Since both sides of a metal-metal interface can support high intensity of electron emission and absorption, thermal transport at metal-metal interface is dominated by electronic carriers. Metal-metal thermal interface conductances (ITC) are at least 1-2 orders of magnitude higher than for interfaces that contain at least one dielectric material, yet the current state of knowledge of thermal transport across metal-metal interfaces remains surprisingly underdeveloped, with just a single simplified model - the electron diffuse mismatch model (eDMM) in the parabolic band approximation - having been employed and compared against experimental data. Here we develop several more advanced models of electronic transmission that can handle diffuse and coherent transport, using realistic band structures derives from first principles calculations. Using a tetrahedron interpolation method, we develop an accurate full-dispersion, multiband implementation of the electronic diffuse mismatch model that is particularly useful for capturing transport in transition metals, intermetallics, and transition metal compounds (XN, XC, XB2, X= transition metals); even in the case of Al-Cu we show that previous apparent experimentaly agreement with the eDMM is less convincing when using realistic band strucure, and that agreement found in previous studies on Ir-Pd, hinges on the inclusion of electron-phonon coupling corrections to the electronic heat capacity. We give eDMM preditions for ITCs of a variety of interfaces types both with and without inclusion of electon-phonon coupling corrections. We also present two coherent electron transmission frameworks: (1) an analytic approach valid for nearly free-electron metals and (2) and NEGF approach appropriate for epitaxial metal-metal interfaces.

Late News: Quantized Thermoelectric Hall Effect Induces Giant Power Factor in a Topological Semimetal Thanh Nguyen[1], Fei Han[1], Nina Andrejevic[1], Vladyslav Kozii[1], Quynh Nguyen[1], Tom Hogan[2], Zhiwei Ding[1], Ricardo Pablo-Pedro[1], Shreya Parjan[3], Brian Skinner[1], Ahmet Alatas[4], Ercan Alp[4], Songxue Chi[5], Jaime Fernandez-Baca[5], Shengxi Huang[6], Liang Fu[1] and Mingda Li[1]; [1]Massachusetts Institute of Technology, United States; [2]Quantum Design, Inc., United States; [3]Wellesley College, United States; [4]Argonne National Laboratory, United States; [5]Oak Ridge National Laboratory, United States; [6]The Pennsylvania State University, United States

Identifying new materials that have a large thermoelectric response would be beneficial for global energy production by converting waste heat into useful electric power. While conventional thermoelectric have regularly faced challenges with regards to vanishing electronic entropy at lower temperatures, topological materials offer an alternative pathway to surpass them through the topological protection of electronic states. Notably, theories have proposed that topological semimetals can large to a large, non-saturating thermopower and quantized thermoelectric Hall conductivity at the quantum limit. We experimentally demonstrate these unique features in topological Weyl semimetal tantalum phosphide (TaP), showcasing an ultrahigh longitudinal thermopower and a giant power factor which are predominantly attributable to the quantized thermoelectric Hall effect. Our findings demonstrate a confluence in the pursuit of effective thermoelectrics and novel topological materials in addition to the realization of the quantum thermoelectric Hall effect towards low-temperature energy harvesting applications.

Radiative Energy Transport in Hyperbolic Materials Hakan Salihoglu and Xianfan Xu; Purdue Univ, United States

Hyperbolic materials (HM) have unique properties of opposite signs in the principal components of dielectric permittivity in frequency ranges called Reststrahlen bands. These properties enable a significantly greater number of propagating radiation modes inside the bulk material compared with other materials, called hyperbolic phonon polaritons. Hexagonal boron nitride (hBN) is one of the natural HMs with low loss and supports propagation of hyperbolic phonon polaritons in the Reststrahlen bands. Thermal energy can excite hyperbolic phonon polariton modes in hBN at around room temperature and above. We study contributions of hyperbolic polariton modes to energy transport inside bulk hBN. Using the fluctuation-dissipation theorem, a theoretical model is derived to compute the energy transport by the hyperbolic modes. This model employs the many-body scattering method to account for radiative interactions within the bulk, across an interface, and across a small gap between two surfaces in the near-field radiation regime. The calculation results showed that hyperbolic polaritons in the Reststrahlen bands contribute to a significant amount of energy transport inside the bulk. The model also revealed that the equivalent radiative thermal conductivity by phonon polariton increases with temperature increase and can be comparable to phonon thermal conductivity at elevated temperatures. Experimental measurements conducted over a temperature range between 300 K - 600 K agree with the result of the theoretical model. Additionally, enhancement of near-field radiation due to the bulk phonon polaritons is also illustrated. In additional to hBN, other hyperbolic materials are also being investigated. This work reveals the significance of radiative transfer as a new energy transfer mode inside the hyperbolic materials and across an interface.

Thermal Conductivity Switching in Polymeric Photonic Mirrors for Building Envelope Thermal Management Daron R. Spence and Shannon K. Yee; Georgia Institute of Technology, United States

Dynamic management of heat loads in building envelopes can utilize polymeric photonic mirrors as dynamic thermal switches. This work investigates both the tunable thermally radiative and thermally conductive properties of photonic mirrors as a function of fabrication parameters and humidity. In particular, a sequential sol-gel process is used to fabricate distributed Bragg reflectors (DBRs) consisting of periodic multilayers of hydrophobic Polymethyl methacrylate (PMMA) and hydrophilic Poly Vinyl Alcohol (PVA). Variable volume fractions of optically transparent titania hydrate (TiO_x) are added to the PVA, forming a hybrid material that increases the refractive index contrast between layers and is moisture sensitive. UV-vis spectroscopy is employed to quantify the dynamic optical responses from polymer swelling obstructing the periodic conditions required to achieve constructive (reflective) interference. Corresponding changes to the films thermal conductivity using a differential 3 Omega technique are also observed beyond film swelling resulting from the degree of moisture uptake that is hypothesized to be effect by the degree of titania hydrate crosslinking. The results of this work provide novel insight into the dynamic nature of polymeric photonic mirrors and suggest applications for these materials as energy saving building technologies.

11:15 AM EN03.09.03
Smart Building Envelopes—Dynamic Switching Between Solar Heating and Radiative Cooling Po-Chun Hsu; Duke University, United States

Solar thermal energy has been one of the major energy sources to realize zero energy buildings for a sustainable future. The high efficiency and low cost make it particularly attractive to reduce the energy consumption for hot water and space heating. On the other hand, the radiative cooling uses the rest of the sky, i.e. the outer space, as the cold source to generate cooling that can reduce the usage of refrigeration and space cooling. Recent progress in photonics and thermal science have further pushed this field to daytime subambient cooling, which created vast opportunities for sustainability and energy. Both technologies showed rapid improvement in the past decade, which become the enablers for the next generation smart net zero energy buildings.
In this talk, I will introduce our recent research progress of switchable building envelope that can change between solar heating and radiative cooling. The dual-mode switchable device can be applied to buildings at various climate zones (spatial variation) under different weather or demand (temporal variation). I will give two examples of the dynamic envelope: (i) The mechanically switchable device can produce ~600 W/m^2 of solar heating or ~100 W/m^2 of radiative cooling with less than one minute switching time. This high performance is the outcome of heat transport analysis and thermal interface engineering. we perform building energy simulation for all the climate zones in the U.S. The results show our dual-mode device, if widely deployed, can save 45.8% of the heating, ventilation and air conditioning (HVAC) energy, which is 2.46 times higher than cooling-only and 1.43 times higher than heating-only approaches. (ii) The electrochromic device has continuous tunability and operates without any moving part. Rational photonic modeling and electrochemical cell design were implemented to achieve synergistic multispectral (solar + mid-IR) radiative heat management. At solar heating state, the device exhibits high solar absorptivity and low thermal emissivity; whereas at cooling state, the device shows high solar reflectivity and high thermal emissivity.

Late News: Ultrahighly Thermally Conducting Templated-MWCNT Coatings John Texter, Xiumin Ma and Rene Crombez; Eastern Michigan University, United States

Polymeric stabilizers derived from imidazolium-based ionic liquids have been developed to prepare high concentration nanocarbon dispersions in water to yield aqueous dispersions up to 17 percent in MWCNT (and dispersions 1.4 percent in SWCNT and 6.4 percent in graphene). Stable MWCNT dispersions require a stabilizer/MWCNT weight ratio of 0.2 - 0.3 for effective stabilization in water. MWCNT concentration variations demonstrate slow equilibration effects that affect stabilizer demand, which increases with concentration. Highly scalable and anisotropic templated coatings have been prepared by drawdown-bar coating these aqueous dispersions on mulberry paper and fiberglass tissue substrates. Electrical and thermal conductivities for such coatings exhibit in-plane/through-plane anisotropies of up to 200 and 2,000, respectively. Electrical conductivities measured by a four-point method and broadband dielectric spectroscopy yield high but unremarkable in-plane conductivities in the 1 - 10 S/cm range, consistent with stabilizer-resistive connectivity between MWCNT. Ultrahigh thermal diffusivities (1,000 - 6,000 mm^2/s) were obtained by a Fourier-transform analysis of Xenon flash data. Heat capacities of coatings measured by modulated differential scanning calorimetry and coating densities measured gravimetrically along with such diffusivities yield thermal conductivities in the range of 0.5 - 3 **kW**/m/K. These conductivities appear to be the largest observed for MWCNT assemblies produced outside a vacuum chamber and 500-fold higher than available commercially. The stabilizer-induced electrical resistance at MWCNT junctions appears not to impede phonon transport across such junctions significantly. This thermal transport is likely related to stabilizer binding to the MWCNT sp^2 surfaces by π-orbital overlap. But bulk phonon transport through stabilizer assemblies seems unlikely. Photoacoustic experiments to examine thermal transport by such stabilizers are proposed. However, the de facto highly efficient phonon transport between MWCNT is more likely due to stabilizer rearrangement, promoting physical contact, and near contact at connecting junctions.

Radiative Cooling Paints With High Figure of Merit Xiangyu Li, Joseph Peoples, Peiyan Yao and Xiulin Ruan; Purdue University, United States

Cooling consumes a great portion of energy in both residential and commercial applications. Passive radiative cooling can provide cooling power without any energy consumption by directly emitting heat to deep space. Conventional air conditioners only move the heat from the inside of the space to the outdoors while consuming electricity. Hence, passive radiative cooling holds great promises for addressing the global warming effect. A recent review paper on commercial heat reflective paints shows solar reflectance around 80% to maybe 92%, but none of these paints has achieved full daytime below-ambient cooling. To achieve passive daytime radiative cooling, current state-of-the-art solutions often utilize complicated multilayer structures or a reflective metal layer, limiting their applications in many fields. Attempts have been made to achieve passive daytime radiative cooling with single-layer paints, but they often require a thick coating or show partial daytime cooling. Therefore, it is a pertinent task to develop radiative cooling paints similar to commercial paints, since they provide ease of use, low cost, scalable fabrication, and are able to take advantage of the reliability engineering in the paint industry.

Here we have demonstrated that with the right fillers under certain concentrations and a broad particle size distribution, we can achieve below-ambient cooling in paints under direct sunlight. Monte Carlo simulations show consistent results with experimental characterization, validating the strategies we adopted to achieve high radiative cooling power. One of the designs showed a solar reflectance of 98% among paints and a high sky-window emissivity of 0.95. Outdoor tests exhibited that our paints showed comparable or better cooling performance than the other state-of-the-art approaches while offering unprecedented benefits including the convenient paint form, a fraction of the cost of the other approaches, and compatibility with the commercial paint fabrication process. A system figure of merit is defined in this work to evaluate the cooling power performance of different radiative cooling systems regardless of weather conditions. Additional testings of viscosity, abrasion resistance and outdoor weathering indicate the potential of the paints as a replacement for commercial white paints. Due to the abundance of the filler materials and a similar fabrication cost with commercial paint, our cooling paints are expected to save $0.7 to $1.5 for a moderate 100m2 apartment during a summer sunny day compared to commercial white paints.

Transient Thermoreflectance Pump-Probe Imaging for 3D Heterogeneous Integrated Circuit Characterization Sami Alajlouni and Ali Shakouri; Purdue University, United States

Recent advances in integrated circuits require integration of multiple chips in the same package as well as 3D chip modules with multi-layer metallization, copper through silicon vias and more complex heterogeneous integration. Heat dissipation in such devices require careful optimization of bonding interfaces, thermal interface materials and heat sink integration. During operation, small defects or voids can create hot spots and overtime reduce the chip performance and reliability. It is advantageous if the integrity of complex ICs could be characterized during manufacturing before full packaging and powering of the device which require integration on test boards and complex electrical work load. Laser heating and transient thermoreflectance full field imaging is used to characterize heat flow in 3D ICs. While inverse problems in heat diffusion are ill-posed, transient temperature profile provide valuable information about in-plane and out-of-the-plane material and interface properties. Applications to material characterization during manufacturing will be also discussed.

2:00 PM EN03.10.02
Structured Illumination with Thermal Imaging (SI-TI)—A Dynamically Reconfigurable Optical Method for Parallelized Thermal Property Measurements Qiye Zheng[1,2], Divya Chalise[1,2], Mingxin Jia[1,2], Yuqiang Zeng[1], Minxiang Zeng[3], Mortaza Saeidi-Javash[3], Sumanjeet Kaur[1], Tengfei Luo[3], Yanliang Zhang[3], Ravi Prasher[1,2] and Chris Dames[2,1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States; [3]University of Notre Dame, United States

The recent push for the “materials by design” paradigm requires synergistic integration of synthesis, characterization, theory, computation and data-driven approaches. Among these, techniques for efficient measurement of thermal transport are still challenging, especially for diverse materials with a range of roughness, porosity, and anisotropy. Traditional contact methods like steady-state, 3ω, and transient plane source methods suffer from relatively slow throughput, sometimes the requirement of large sample volumes, and the lack of spatially resolvable property mapping capability for parallel measurements. Non-contact pump probe laser methods (e.g., TDTR, FDTR) often need mirror smooth sample surfaces and serial rastering for property mapping which can be inefficient when applied to larger sample areas. Here, we present a new thermal characterization tool which has the potential to significantly improve the measurement throughput based on Structured Illumination with Thermal Imaging (SI-TI). SI gives convenient software control of the shape and frequency of heating light pattern, and thermoreflectance based TI enables efficient large area temperature mapping with good temperature and spatial resolutions. Experimental results will be presented showing how the SI-TI method enables: (1) paralleled measurement of multiple samples in a single field of view without any raster scanning; (2) software control of the dynamically adjustable heating pattern, which can be tuned to optimize the measurement sensitivity in different directions for anisotropic materials; and (3) can tolerate porous, rough, and/or scratched sample surfaces. This work highlights a new avenue in efficient thermal characterization for “materials by design.”

2:15 PM EN03.10.03
Thermal Conductivity Measurement of Flowing Granular Media using Modulated Photothermal Radiometry Jian Zeng, Ka Man Chung, Xintong Zhang, Sarath Reddy Adapa and Renkun Chen; University of California, San Diego, United States

Granular media such as Carbo ceramic particles and silica sands have been used as heat transfer media in heat exchangers for solar-thermal energy storage systems. However, thermal transport processes in the particulate heat exchangers are still not fully understood. In particular, it is still not clear whether and how the thermal conductivity of the particles in the near-wall region could be impacted by the particle -wall interaction. While numerous models exist, there is a lack of suitable experimental technique to probe the thermal transport processes of granular media when they are flowing in a heat exchanger. In this work, we report the instrumentation development of high-temperature thermal conductivity measurement of flowing ceramic particles within a confined channel. We use an existing technique called modulated photothermal radiometry (MPR) and first develop it for high temperature measurements (up to 800 deg. C). MPR is a non-contact technique where the surface of the sample is heated by an intensity-modulated laser and it utilizes the intrinsic thermal emission from the specimens for thermometry, which is favorable for the measurement at high temperature in harsh environment. The high-temperature MPR setup is validated by measuring bulk and thin coating materials with known thermal conductivity. We then develop the technique for measuring both stationary and flowing ceramic particles. The measurement results are compared with modeling based on the discrete element method (DEM) to understand thermal transport in both bulk and near-wall regions of flowing granular media.

2:30 PM *EN03.10.04
Magnetization Dynamics of Functional Materials Enabled by Ultrafast Optical Metrology Xiaojia Wang; Univ of Minnesota, Twin Cities, United States

As an updated version of the ultrafast pump-probe laser technique, the time-resolved magneto-optical Kerr effect (TR-MOKE) metrology can capture the magnetization dynamics of materials with superb temporal (sub-picosecond) and spatial (diffraction-limited beam spot) resolutions. With optical excitation and detection, TR-MOKE can probe spin precession at high resonance frequencies (up to a few hundreds of GHz), beyond those achievable by conventional Ferromagnetic Resonance (FMR) approaches. Thus, it is a powerful tool to reveal the rich physics of magnetization dynamics of magnetic thin films, in addition to thermal transport properties. In this talk, I will highlight several representative applications of the TR-MOKE metrology for capturing the magnetization dynamics in technologically important spintronic materials. Examples include the studies of temperature-dependent Gilbert damping, the spin-strain coupling, and the interlayer exchange coupling of materials with strong perpendicular magnetic anisotropy (PMA). The structure-property relationships of these emerging materials established by TR-MOKE open up opportunities of tailoring material properties by structural engineering for applications in spintronic and memory devices with low energy consumption, high thermal stability, and fast switching.

3:00 PM EN03.10.05
Single-Scan Quantitative Mapping of Steady Temperature Fields with Nanometer Resolution Amin Reihani, Shen Yan, Yuxuan Luan, Edgar Meyhofer and Pramod Sangi Reddy; University of Michigan, United States

Quantitative mapping of temperature fields at the nanoscale is critical in various areas of scientific research and technology, such as nanoelectronics, surface chemistry, plasmonic and quantum systems. Scanning Thermal Microscopy (SThM) techniques, developed in the past, enable temperature mapping with ~10 nm spatial resolution. The main challenge in achieving quantitative thermal imaging with SThM is a lack of knowledge of the tip-sample thermal resistance (R_{TS}) which is critical for quantifying the sample temperature. A recent advance in SThM enabled the quantification of R_{TS} in situations where the temperature field is modulated. However, such an approach is not directly applicable to situations where the device operates under conditions where it is not readily possible to modulate the temperature field. Here, we present a novel SThM measurement technique using custom-fabricated scanning thermal probes (STPs) with a sharp tip and an integrated heater/thermometer where the steady-state temperature field of the device can be quantitatively mapped in a single scan with <5 nm spatial resolution and ~50 mK temperature resolution. This is accomplished by introducing a modulated heat input to the STP and measuring the AC and DC response of the probe temperature which allows for simultaneous mapping of tip-sample thermal resistance and sample surface temperature. The advances presented here can greatly facilitate temperature mapping of a variety of microdevices under practical operating conditions.

3:15 PM EN03.10.06
Thermal Conductivity Measurement of Stationary and Flowing Molten Salt Using Modulated Photothermal Radiometry Ka Man Chung, Jian Zeng, Tianshi Feng and Renkun Chen; University of California, San Diego, United States

Molten salts are being used or studied for thermal energy conversion systems, such as concentrating solar power and nuclear power. Thermal conductivity is an important thermophysical property dictating the performance of these systems but its accurate measurement of molten salts has been challenging. The corrosive and conductive nature of these fluids makes it difficult to use traditional contact methods such as the hot wire method. Techniques that require a large volume of the fluids, such as the steady-state method, could also be prone to errors caused by natural convection. Commonly used non-contact optical thermoreflectance techniques are difficult to operate at high temperatures. Here, we report the thermal conductivity measurement of molten salts using a modulated photothermal radiometry (MPR) technique. MPR is a laser-based, non-contact, frequency domain method that has been used to measure thermophysical properties of various materials. We develop the technique for the measurement of molten salts at both stationary and flow states. Stationary molten salts, including nitrate and chloride salts, have been measured using a high-temperature MPR holder. The measurement results are compared with those obtained from a laser flash analyzer (LFA). Our results demonstrate the reliability of the MPR method to measure the thermal conductivity of stationary molten salts. We further extend the technique to perform in-operando measurements on flowing fluids and show that the intrinsic thermal conductivity can be reliably obtained under certain experimental conditions. Finally, the in-operando technique is applied to a laboratory-scale molten salt loop to demonstrate the capability of measuring flowing molten salts in real-time. Our work shows that the MPR technique is a convenient tool to provide reliable molten salt thermal conductivity data and could serve as a diagnostic tool for flowing molten salts.

A Green Materials Processing Route to Graphitic Heat Spreaders on Organic Substrates Mostafa Abuseada, Yang Li and Timothy Fisher; University of California, Los Angeles, United States

This work describes a new material deposition process to synthesize graphitic layers using a custom system that employs a concentrated xenon light source (3.5 kW optical) that simulates solar irradiance. A peak heated zone of approx. 3 cm diameter (q_{max} = 3.2 MW/m^2) can heat samples up to 1000°C in less than 1 sec, orders of magnitude faster than electric heaters integrated within conventional CVD systems. We have found clear signs of surface graphitization on organic samples exposed in vacuum. Recent tests on pulsed heating at ~1 Hz indicates further graphitization via a controlled heating/cooling process that avoids pyrolysis. Significant advantages of this unique approach include: (1) ultrafast heating and cooling of substrates, allowing more flexibility to tune physical and electrical properties of the graphitic layer; (2) improved graphitic growth speed because of the ultrafast response to concentrated light heating; (3) ability to build a substantial depth of graphitic layering due to the optical transparency that emerges in the upper layers that transform under pulsed heating; and (4) low cost and easy serviceability of concentrated light as compared to laser-induced graphene (LIG) systems that in theory could produce similar results. Process optimization for this problem will be important, and as such, we apply adaptive Bayesian experimental design as in prior work to maximize a heat spreading metric (a combination of thermal conductivity and layer thickness). Parameters to be optimized include: gas composition and pressure; light pulse intensity, duration, and pulse duty cycle; and substrate type. The output metric, thermal spreading capability, is captured to first order by the product of film thickness and thermal conductivity. Here, we employ an extensive set of capabilities for heat conduction testing and modeling, including a highly accurate, rapid screening approach for heat spreading.

4:30 PM EN03.11.02
Late News: Atomistic Simulations of Heat Transfer in Polymer Linked Gold Nanoparticle Networks for Autonomous Computing Xingfei Wei and Rigoberto Hernandez; Johns Hopkins University, United States

Polymer linked nanoparticle networks are important to many applications, such as advanced composite materials and nano-phononics. Developing networked materials capable of emulating neuronal networks for information processing is critical to the construction of a brain-like cognitive computing system. In this work, we elaborate heat transfer mechanisms between polymer linked gold nanoparticle (AuNP) dimers. We find the effects of different polymer types on heat flux, using 6 different polymers, *viz.* polyethylene (PE), polyacetylene (PA), poly(*p*-phenylene) (PPP), polyacene (ACE), polythiophene (PT) and poly(3,4-ethylenedioxythiophene) (PEDOT). We also uncover the effects of AuNP size on heat flux, using three different AuNP sizes: 2, 4 and 8 nm diameter. By steering the AuNPs to different distances, the heat flux is compared between a straight polymer conformation and a loose (or bended) polymer conformation. The effect of heat transfer channels on the total heat flux between AuNP dimers is revealed using 1, 2 and 3 polymer links. The discussion of AuNP facet effect is also included using different linked facets: (111)-(111), (111)-(001) and (001)-(001). Dimers made of different AuNP sizes --- *viz*. 2 nm AuNP linked 8 nm AuNP --- can have different heat fluxes towards two directions like a thermal diode. Finally, we use four simple networks constructed from 3, 4, 5 and 6 AuNPs, to mimic neuronal networks for information processing. In our models, the information is recorded by the thermal potential (temperature)—that is, the driving heat flux—in analogy to the neuronal networks where the electric potential drives the ion flux. We expect that this work can help improve our understanding of heat transfer mechanisms inside polymer linked nanoparticle networks. Our

simulations can also provide guidance for developing new materials and devices of use in brain-like computing.

4:45 PM EN03.11.03
The Potential Impact of Thermochromic Smart Windows on the Dutch Built Environment—A Simulation Study Daniel Mann[1,2], Cindy Yeung[1,2], Roberto Habets[1,2], Zeger Vroon[1,2,3] and Pascal Buskens[1,2,4]; [1]TNO, Netherlands; [2]Brightlands Materials Center, Netherlands; [3]Zuyd University of Applied Sciences, Netherlands; [4]Hasselt University, Belgium

With progressing climate change and global warming, we face the challenge to reduce our energy consumption and CO_2 emission. In Europe, more than one third of the total energy consumption and CO_2 emission result from the built environment, with energy for heating and cooling of buildings as a major share. A recent study analyzing the energy and CO_2 emission savings potential, has shown that by equipping all buildings in Europe with commercially available energy-efficient glazing the total energy consumption of the building sector can be reduced by over 30% for most countries. Current energy efficient glazing systems are static and therefore best suited for either hot or cold climates. In climates that vary between hot summers and cold winters, the windows have to adapt to the environment for optimized energy efficiency. Thermochromics can be used for adaptive glazing since they can autonomously switch their solar infrared (IR) transmission depending on the glazing temperature. In a recent study we have shown that thermochromic windows are perfect for intermediate climate regions. Using building energy simulations, we demonstrated that energy savings of up to 22% could be achieved with our thermochromic smart window, outperforming commercially available energy-efficient glazing systems.
For a more detailed analysis of the performance of thermochromic smart windows in the Netherlands, we here present a study on the 4 main building types: free-standing buildings, duplex houses, terraced houses and apartments. In our labs we have developed a thermochromic coating with excellent optical properties for application in smart windows. The coating shows high visible transmission (T_{vis}) of 74% combined with a large solar modulation (ΔT_{sol}) of 10%, which as a combination is unrivaled by thermochromic VO_2 based coatings reported in literature to date.
For the building energy simulation study we modeled the annual energy consumption for heating, cooling and lighting of the 4 selected building units equipped with our smart window, where our thermochromic coated glass is combined with a commercial low-e coated glass to yield a double glass window, and compared the results to building units with uncoated double glazing.
The free-standing building with the largest floor area and all 4 outside walls in contact with the environment showed the largest benefit of the smart window on annual energy consumption. Here annual energy savings of 21.2% could be reached. With reduced floor area and either three or two outside walls being in contact with the environment, for duplex and terraced houses, respectively, the impact of the smart window on total energy consumption was lower. Here annual energy savings of 16.1% and 15.4% were achieved for the duplex and terraced house, respectively. The apartment was a more special case, since it is a one floor unit with large window surfaces on the two outside walls in contact with the environment. Here the large window surface area in relation to the total floor area leads to a big impact of the thermochromic smart window on annual energy consumption. Here annual energy savings of 29.4% could be reached in comparison to non-coated insulating glass units (IGUs).
Suggesting that natural gas was used for heating and electricity for cooling and lighting, the average cost price for gas and electricity in the Netherlands was used to calculated annual cost savings for each building type. Here annal cost savings of up to 445 € could be calculated. Due to the cheap material and processing costs a return on invest within 7 years will be possible with attributed annual cost savings of 6-7.5 €/m^2.
Furthermore, we have analyzed the impact on CO_2 emissions the smart window can have in the Netherlands. By extrapolating the data to the complete Dutch built environment, we could show that annual CO_2 emissions for building operations can be reduced by 46%. This means annual CO_2 emission savings of 5.8 Mt for the Dutch built environment.

5:00 PM EN03.11.05
Understanding the Thermodynamics of Metal–Organic Phase-Change Materials for Thermal Energy Storage Ryan McGillicuddy, Surendra Thapa, Malia Wenny, Miguel I. Gonzalez and Jarad A. Mason; Harvard University, United States

With most of the primary energy generated in the USA being thermal in nature, developing materials that can reversibly store thermal energy is critical to more efficiently using and managing thermal energy. Metal–organic phase-change materials, which consist of meltable metal coordination complexes with organic ligands, offer an opportunity to expand the library of existing phase-change materials for thermal energy storage and further establish fundamental structure-property relationships to design energy-dense thermal energy storage materials. Herein, we study an isostructural series of divalent metal amide complexes featuring expanded hydrogen bond networks that can undergo tunable, high-enthalpy melting transitions over a wide temperature range. We investigate the influence of coordination bonds, hydrogen bonds, neutral ligands, and outer sphere anions on the phase change thermodynamics, studying how metal dependent hydrogen and coordination bond breaking across the melting transitions alters the melting thermodynamics of metal–organic phase-change materials. Importantly, despite having lower volumetric hydrogen bond densities than the structurally similar metal-salt hydrate systems, the metal–organic phase-change materials investigated here show similar volumetric energy densities to metal-salt hydrates, indicating that metal–organic phase-change materials offer alternative pathways to designing new thermal energy storage materials.

5:15 PM EN03.11.06
Carbide Precipitation Study During Tempering in Model Ferritic Alloys for Nuclear Power Plant Application Anna Benarosch[1,2], Caroline Toffolon-Masclet[1], Bernard Marini[1], Estelle Meslin[1], Raphaelle Guillou[1], Jean-Marc Joubert[2], Dominique Thiaudière[3], Cristian Mocuta[3], Zofia Trzaska[2] and Ivan Guillot[2]; [1]Université Paris-Saclay, France; [2]Univ. Paris Est, France; [3]Synchrotron SOLEIL, France

Large components of the primary circuit of nuclear reactors, made with 16MND5 low alloy bainitic steels, operate at 300°C under a pressure of 155 bars, undergoing thermal aging and irradiation, and must retain their mechanical properties throughout the plant life. A thorough understanding of the links between microstructure and mechanical properties is therefore crucial to be able to predict their evolution under operating conditions. Carbides are known to play an important role in explaining the mechanical properties of the steels. [1–3] Their population, size and distribution, evolve mainly during temper heat treatments performed after a step of austenitisation and quenching. However, after quenching, chemical heterogeneities can appear, locally affecting the microstructure, the carbide population, hence the mechanical properties. Therefore, it is necessary to understand the impact of alloying elements on carbide populations to be able to predict the mechanical properties of these heterogeneous areas. Furthermore, understanding the impact of alloying elements on the carbide precipitation sequence can lead to an optimisation of the heat treatments, and the design of steels with enhanced mechanical properties, as well.
Amongst the three main alloying elements (Mn, Ni, Mo) of 16MND5 steels, molybdenum, and manganese to a lesser extent, contribute to define the carbide population. In this context, to isolate the contribution of each alloying element, high-purity model alloys, FeCMo, FeCMn and FeCMoMn were investigated, which compositions were chosen close to the industrial alloy.
Two tempering temperatures were explored, 650 and 700°C, for times of several seconds up to two months. The starting microstructures of the model alloys were selected to be as close as possible to the 16MND5 steel bainite, using continuous cooling transformation diagrams and the associated examinations.
The carbide crystallography and chemistry were determined by TEM and STEM/EDS on carbon extractive replicas, while their size distributions and morphologies were obtained by SEM image analysis. Their volume fraction and lattice volume were measured by *ex-situ* synchrotron X-ray diffraction. It resulted in the complete characterization of the precipitation sequences and in the quantification of the impact of Mo and Mn on these precipitation

sequences. The use of thermodynamic calculations gave valuable information on the carbides thermodynamical stability.
At last, these precipitation sequences were modelled using the Prisma module from the Thermocalc suite and compared to the experimental results obtained within this study.

Universal Model for Predicting the Thermal Boundary Conductance of a Multilayered-Metal/Dielectric Interface Alan McGaughey, Henry Aller and Jonathan A. Malen; Carnegie Mellon University, United States

A model is developed to predict how the effective thermal boundary conductance (TBC) of a metal cap/metal contact/dielectric junction varies with the contact thickness. Two-temperature model molecular dynamics (MD) simulations are applied to qualitatively recreate the experimental observation that the junction TBC increases and then saturates as the contact thickness increases. The MD simulations reveal a strong correlation between the junction TBC and the fraction of the electron-phonon coupling that occurs in the contact versus that in the cap. This correlation is then combined with insights gained from an analytical solution to the two-temperature model in the cap and contact to propose a model that predicts how TBC varies with contact thickness. The model, which contains no fitting parameters, is validated against more than one hundred experimental measurements from the literature on a variety of cap/contact/dielectric junctions. By normalizing the TBC and the contact thickness, all the experimental data collapse onto a single curve, with 92% of it lying within 10% of the model. Through physically-motivated approximations, the model reduces to a simple thermal circuit that maintains high predictive ability. Population-weighted phonon density of states extracted from the MD simulations suggest that the TBC contact thickness dependence is strongly influenced by electron-phonon coupling in the contact. The model provides guidance for streamlining the design of thermally-efficient electrical contacts.

8:30 AM EN03.12.02
Non-Equilibrium Phonon Thermal Resistance at MoS_2/Oxide and Graphene/Oxide Interfaces Weidong Zheng[1], Connor McClellan[2], Eric Pop[2,2] and Yee Kan Koh[1]; [1]National University of Singapore, Singapore; [2]Stanford University, United States

Accurate measurements of interfacial thermal conductance (*G*) of two-dimensional (2D) materials are imperative for effective thermal management of 2D material devices. Despite the importance, there is a large discrepancy in the literature on *G* of interfaces of 2D materials. Here, we accurately measure *G* of oxide/MoS_2/oxide and oxide/graphene/oxide interfaces for three oxides (SiO_2, HfO_2, Al_2O_3) by differential time-domain thermoreflectance (TDTR). We find that TDTR measurements of *G* of these interfaces are 2-to-4 times larger than previously reported *G* of the similar interfaces measured by Raman thermometry. Using a simple model, we show that the observed discrepancy can be explained by an additional internal thermal resistance between non-equilibrium phonon modes in Raman thermometry measurements. Moreover, the additional internal resistance in Raman thermometry measurements also leads to a stronger temperature dependence of *G* of 2D materials. Our work provides important guidelines for correct interpretation and analysis of Raman measurements of heat transport across interfaces of 2D materials.

Thermal Interfacial Resistance of Water with Solids—A Nanoscale Investigation Using Molecular Dynamics Simulations William Gonçalves and Konstantinos Termentzidis; Université de Lyon, France

The fabrication of nano-architected materials has improved considerably over the last decade. It is now possible to synthesize series of nanoporous materials with functionalized internal surfaces. However, the impact of humidity on heat transfer at the nanoscale is not fully understood. The structural and vibrational properties of nanoconfined water differ from those of the bulk near the solid/liquid interface [1]. Thus, for materials with nanoscale features, macroscopic models such as Fourier's law or the Effective Media Approach (EMA) can not predict the effective thermal properties of solid/liquid composites [1]. In addition, experimental measurements are difficult due to humidity. During Scanning Thermal Microscopy (STM) experiments, the presence of a water meniscus at the mechanical contact between the tip and the sample creates capillary forces that impact the thermal conductance [2,3].

In this study, we simulate solid/liquid interfaces using molecular dynamics (MD) simulations. The interfacial thermal resistance (Kapitza resistance) is calculated between a film of water and various solids such as crystalline and amorphous silicon or amorphous silica with functionalized surfaces. The impact of the average temperature, the heat flux and the thickness of the water slab on the Kapitza resistance is investigated. Finally, we modified the hydrophobicity level of the silica by grafting hydrophobic molecules on the hydroxylated surface. The results of this study provide interesting insights about the nanoscale heat transfer through solid/liquid interfaces.

Inelastic Phonon Transport Enhanced Thermal Conductance Across Atomically Sharp Interfaces Qinshu Li[1], Fang Liu[2,3], Song Hu[4], Xiaokun Gu[4], Xinqaing Wang[2,3] and Bo Sun[1,5]; [1]Tsinghua University, China; [2]State Key Laboratory of Artificial Microstructure and Mesoscopic Physics, School of Physics, Peking University, China; [3]Collaborative Innovation Center of Quantum Matter, China; [4]Institute of Engineering Thermophysics, School of

Mechanical Engineering, Shanghai Jiao Tong University, China; [5]Tsinghua Shenzhen International Graduate School, and Guangdong Provincial Key Laboratory of Thermal Management Engineering & Materials, China

Understanding thermal transport across interfaces is crucial for the thermal management of electronic devices. Phonons, the dominant heat carriers across solid-solid interfaces, have been shown to transport elastically in most experiments, except for a few extreme cases where inelastic phonon transport occurs when the two materials of the interface are highly dissimilar. However, there is still limited information on when the inelastic transport will occur. Here, we measured the interface thermal conductance of atomically sharp Al/Si and Al/GaN interfaces, and found that the thermal conductance linearly increases with temperature at high temperatures, suggesting inelastic phonon transport dominates heat conduction across interfaces, though the two materials have similar Debye temperatures. Moreover, we found that when the interface roughness increased to 5-7 atomic layers, inelastic thermal transport diminishes. Our molecular dynamics calculation indicates that phonon non-equilibrium drives the inelastic phonon transport when the interface is atomically sharp. When the interface becomes rough, phonon non-equilibrium reduces, leading to a saturated thermal conductance at high temperatures. Our results provide new insights on phonon transport across interfaces and open up opportunities for rengineering their thermal conductance.

Determination of Interfacial Thermal Resistance Inside Thermal Interface Materials Enabling High-Throughput Computational Screening of the Material Formula Jibao Lu[1], Xiaoxin Lu[1], Rong Sun[1] and Ching-Ping Wong[2]; [1]Shenzhen Institute of Advanced Electronic Materials, Shenzhen Institutes of Advanced Technology Chinese Academy of Sciences, China; [2]Georgia Institute of Technology, United States

Thermal interface materials (TIMs), usually composed of polymer matrix filled with thermally conductive particulate fillers, are pivotal for heat transfer between the layers in high-density electronic packaging. Numerical simulation provides a versatile tool for understanding the mechanism of thermal transport and design of TIMs; however, the insufficient efficiency and accuracy in modeling the composites with complex microscopic structures hinders its application in engineering the formula of material. Here we present a strategy of modeling the effective thermal conductivity of polymer-based composites with high efficiency and accuracy, which enables a high-throughput screening of the formula of TIMs. The efficiency of the strategy comes from an implementation of a numerical homogenization algorithm based on fast Fourier transform, in which the unit cell problem is solved by means of a polarization-based iterative scheme. The algorithm shows good precision and requires dramatically reduced computational cost compared with finite element modeling. The accuracy of the strategy originates from an accurate determination of the interfacial thermal resistance (ITR) between different components inside the TIM composites, which is achieved by combining high-throughput calculations, machine learning and experiments. As an example of application of the strategy, the ITRs for the interfaces of filler-silicone and filler-filler in the Al_2O_3/silicone composites are determined as 2.2e-08 m^2K/W and 1.0e-07m^2K/W, respectively. We further conduct a high-throughput computational screening of the gradation scheme for the silicone based composite TIMs filled with Al_2O_3 and AlN fillers with different size distributions, weights, and surface characteristics, and validate the results by comparing the results with experiments. The proposed strategy could be an effective tool for the smart engineering of the formula of TIMs for electronic packaging, as well as other thermally conductive composite materials.

Late News: Understanding Thermal Transport in Polymer-based Composites Yijie m. Zhou and Yanfei Xu; University of Massachusetts Amherst, United States

Polymer-based thermal interface materials play key roles in thermal management applications thanks to their unique combination of properties not available from any other known materials.[1-3] They are lightweight, corrosion-resistant, easy to process, and among others. However, common polymers are thermal insulators with low thermal conductivity on the order of 0.1 $Wm^{-1}K^{-1}$.[4,5] To achieve high thermal conductivity in polymers, highly thermally conductive fillers such as graphene and nano-diamond powder have been added into polymers.[6-9] Although polymers are blended with highly thermally conductive fillers (e.g. silver nanoparticle ~400 $Wm^{-1}K^{-1}$) at a high loading volume fraction of 70 vol%, thermal conductivity in polymer-based composites is limited to ~5 $Wm^{-1}K^{-1}$.[10] This is because low thermal conductivities in common polymer matrices, high thermal interface resistance between filler and polymer, and high thermal interface resistance between filler and filler.[3,11] In this poster, we will present our current research on developing polymer-based thermal interface materials. To increase effective thermal conductivity in polymer-based composites, we strive to increase thermal conductivity in pure polymer matrices (e.g. polyethylene, polyvinyl alcohol, and epoxy) and reduce thermal interface resistances between fillers and polymers by enhancing vibrational couplings. We believe that polymer-based thermal interface materials will play a key role in many existing and unforeseen thermal management applications.

Unraveling Ultrafast Electrical-Thermal-Structural Coupling in Electronic Devices Aditya Sood[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

Identifying the ultimate operating limits of electronic devices requires an understanding of how atomic motions couple to changes in electronic transport -- a coupling that is often mediated by energy dissipation (i.e. Joule heating) and thermal transport. One class of electronics where this coupling has been especially challenging to understand is phase-change Mott-memory. Mott insulators (e.g. VO2) have long been known to undergo an insulator-to-metal transition under an applied voltage. However, several aspects of this electric-field-driven transition has remained unclear, in particular, the role of Joule

heating in triggering the transition on fast timescales, and the thermal relaxations on slow timescales. We address these questions by developing a new platform for ultrafast, correlative electrical-thermal-structural characterization of phase-change electronics [1]. Following electrical excitation of VO2, we directly probe the role of Joule heating on short timescales, distinguishing it from direct field-induced effects. We discover a new phase of this material under electrical excitation, which points towards a non-equilibrium modification of the free-energy landscape. On long timescales, we uncover a regime of thermally-bottlenecked structural relaxation, which determines the fastest turn-off speed of the device. Taken together, our approach identifies the ultimate speed and energy-efficiency limits of phase-change electronics.

10:30 AM EN03.13.01
Insights in the Aqueous Precursor Chemistry during the Synthesis of Thermochromic Vanadium Dioxide Ken Elen[1,2], Lavinia Calvi[2,1], Pascal Buskens[2,3,4], An Hardy[2,1] and Marlies Van Bael[2,1]; [1]Imec - Imomec, Belgium; [2]UHasselt, Belgium; [3]TNO, Netherlands; [4]Brightlands Materials Center, Netherlands

Vanadium dioxide (VO_2) is a multipurpose material with notable applications in fields such as energy storage and energy-efficient smart windows. The versatility of VO_2 is related to its extensive crystallography with many polymorphic forms. VO_2 can undergo a reversible metal–insulator phase transition (MIT) at a critical temperature of 68 °C, which is accompanied by a structure transformation from a low-temperature insulator phase VO_2 (M) to a high-temperature metal phase VO_2 (R). This phase transition results in a distinct change of the infrared transmittance, rendering VO_2 suitable as a pigment for thermochromic glazing.

Various methods for the synthesis of VO_2 have been reported, including chemical vapor deposition, atomic layer deposition, pulsed laser deposition and sputtering. Wet chemical synthesis routes are widely considered as valuable alternatives for vacuum based techniques on account of their low cost, limited environmental impact and reasonably simple experimental setup. Also, the versatility of the method allows the direct synthesis of both ceramic (nano)powders as well as thin (nanostructured) films. However, many earlier wet chemical routes intermediately form V_2O_5 and require an additional, reductive anneal to obtain VO_2. This emphasizes the large challenge in the immediate formation of thermochromic VO_2 from an aqueous solution. Given the complex redox chemistry of vanadium, it is therefore essential to gain fundamental insights in the aqueous vanadium precursor chemistry and in their relation to the vanadium oxide stoichiometry and phase formation, obtained via a solution-based strategy.

Our approach starts with the formulation of stable aqueous precursor solutions containing oxovanadium(IV) complexes. To analyze and understand each step, and the associated chemical transformations, during this synthesis, various complementary spectroscopic techniques (UV-Vis, ^{51}V-NMR, FTIR) are used to probe and identify each vanadium species during the entire synthesis sequence. The structure and stability of the final complexes that are present in the aqueous solution, and their relation to the synthesis parameters will be highlighted. Subsequently, the formation of vanadium oxide, starting from aqueous vanadium precursor solution, requires a thermally-induced transformation of the precursor gel into the oxide. As an illustration, the thermal decomposition pathway of a citrato/oxalato-oxovanadium(IV) gel, obtained by evaporation of a precursor solution, is analyzed by Simultaneous Differential Calorimetry Thermogravimetry (SDT), High temperature X-ray Diffraction (HT-XRD) and ex-situ analysis of the remaining products. The thermochromic nature of the resulting VO_2 products is demonstrated by monitoring the underlying structural phase transition with Differential Scanning Calorimetry (DSC) and UV-Vis spectroscopy.

The authors thank the European Fund for Regional Development (crossborder collaborative Interreg V program Flanders-the Netherlands, project SUNOVATE) for their financial support.

10:45 AM EN03.13.02
Solid–State Phononic Thermal Regulator and Rectifier Based on Polyethylene Nanofibers Sheng Shen; Carnegie Mellon University, United States

We have fabricated polyethylene nanofibers with high chain alignment and high degree of crystallinity. The nanofibers show an orthorhombic crystal structure with high thermal conductivity at room temperature. However, rotational disorder occurs at a high temperature close to melting temperature. The nanofibers switch to the hexagonal phase with a high-contrast and abrupt thermal conductivity change. Such a solid-state phase transition makes the polyethylene nanofiber intrinsically a thermal regulator. Measurements show a thermal switching ratio in average ~8x with maximum ~10x, which is the highest among solid-solid and solid-liquid phase transitions of all existing materials. Based on the sharp and high-contrast phase transition, an unusual dual-mode solid-state thermal rectification effect is demonstrated using a heterogeneous “irradiated-pristine” polyethylene nanofiber junction as a nanoscale thermal diode, in which heat flow can be rectified in both directions by changing the working temperature. For the nanofiber samples measured here, we observe a maximum thermal rectification factor as large as ~ 50 %, which only requires a small temperature bias of <10 K. The nanoscale thermal regulators and rectifiers open up new possibilities for developing advanced thermal management, energy conversion and, potentially thermophononic technologies.

11:00 AM EN03.13.03
Achieving Long-Term Condensation with Cell-Inspired Interfaces Jingcheng Ma, Zhuoyuan Zheng, Paul V. Braun, Pingfeng Wang and Nenad Miljkovic; University of Illinois at Urbana-Champaign, United States

Dropwise condensation on thin (< 100 nm) hydrophobic coatings enables exceptional condensation heat transfer. However, hydrophobic coatings can be easily delaminated by the formation of water blisters in wet environments or during steam condensation. To prevent delamination while maintaining nanoscale thickness, designing interfaces with high wet adhesion is a key challenge. In nature, cell membranes face the identical challenge where nanometer-thick lipid bilayers require exceptional adhesion in wet environments to maintain their integrity. Nature achieves high inter-layer adhesion by using a lipid interface having two non-polar surfaces, which does not rely on chemical bonding. Instead, physicochemical resistance is used to prevent biofluids from opening and delaminating the interface. Based on this nature-inspired strategy, we develop fluorine-carbon molecular chains on nanostructured surfaces to build lipid-like interfaces for nanometric fluorinated coatings. Our superhydrophobic materials show unprecedented jumping

droplet condensation stability as demonstrated from continual one-year condensation experiments. Our work presents a solution to the century-old problem of hydrophobic and superhydrophobic coating durability through bio-inspired materials design with robustness beyond what is currently available.

11:15 AM *EN03.13.04
Temperature-Adaptive Radiative Coating for All-Season Household Thermal Regulation Kechao Tang[1], Kaichen Dong[1], Jiachen Li[1], Madeleine Gordon[1], Finnegan Reichertz[1], Hyungjin Kim[1], Yoonsoo Rho[1], Qingjun Wang[1], Costas Grigoropoulos[1], Ali Javey[1], Jeff Urban[2], Jie Yao[1], Ronnen Levinson[2] and Junqiao Wu[1]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

The sky is a natural heat sink that has been extensively used for passive radiative cooling of households. Past experimental works have focused on maximizing the radiative cooling power of roof coating in hot daytime using static, cooling-optimized material properties. However, the resultant overcooling in cold night or winter times exacerbates the heating cost, especially in climates where heating dominates energy consumption. In this work, we approach the thermal regulation from an all-season perspective by developing a mechanically flexible coating that adapts its thermal emittance to different ambient temperatures. The fabricated temperature-adaptive radiative coating (TARC) optimally absorbs the solar energy and automatically switches thermal emittance from 0.20 for ambient temperatures lower than 15 °C to 0.90 for temperatures above 30 °C, driven by a photonically amplified metal-insulator transition. The TARC is simulated to outperform all existing roof coatings for energy saving in most climates, especially those with significant seasonal variations, yielding a cut in annual source energy consumption up to 3.65 GJ for a typical single-family home in the U.S.

11:45 AM EN03.13.05
Sub-Ambient Radiative Cooling Using $CaCO_3$ Micro-Particle Composite Without Metal Reflector Layer Hangyu Lim, Dongwoo Chae, Soomin Son and Sucheol Ju; Korea University, Korea (the Republic of)

Conventional cooling systems, that is, air conditioners, should be replaced because they consume a substantial amount of energy and cause environmental pollution. In this context, radiative cooling systems, which perform cooling without consuming any energy or causing environmental pollution, are emerging as an alternative. However, most of the radiative coolers explored thus far include metals, such as silver, that are used as solar reflectors, thereby entailing problems in terms of practicality, mass production, cost, and light pollution. Herein, we propose calcium carbonate ($CaCO_3$) micro-particle-based radiative cooling, which utilizes the high-energy band gap of $CaCO_3$ for high-performance radiative cooling. As the cooler has only a single layer of a $CaCO_3$ composite without any metal reflector, it is mass-producible, cheap, and does not cause light pollution. To demonstrate the cooling performance of $CaCO_3$, optical properties and temperature changes are measured and compared with those of commercial white paint. As a result, it is demonstrated that the $CaCO_3$-based radiative cooler has cooling power 93.1 W/m^2 in calculation and can be cooled 6.52 ^oC and 3.38 ^oC under ambient temperature in daytime and nighttime respectively. Thus, it can perform as radiative cooler in entire day.

12:00 PM EN03.13.06
Enhanced Superhydrophobicity of Additively Manufactured Metallic Alloys Jin Yao Ho[1,2], Kazi Fazle Rabbi[1], Teck Neng Wong[2], Kai Choong Leong[2] and Nenad Miljkovic[1,1,1]; [1]University of Illinois at Urbana-Champaign, United States; [2]Nanyang Technological University, Singapore

Metal additive manufacturing (AM) has revolutionized engineering design and production of components, eliciting a wide design space for geometrical, material, and functional optimization. This wide design space has led to the development of innovative functional devices for a plethora of applications including energy, transportation, chemical and bioengineering. The new processing phenomena and requirement for use of different alloying materials in AM poses unprecedented nanostructuring challenges of AM surfaces along with opportunities for the development of novel generations of surface architectures. Here, through the understanding of the grain formation mechanisms and material compositions resulting from the AM process, we developed an ultrascalable and cost-effective method to rationally generate nanostructures on metallic AM surfaces for enhanced droplet repellency, condensation, evaporation, and boiling heat and mass transfer. By combining a facile microdroplet impact method with high speed optical imaging, we quantify that the AM structures significantly lower droplet adhesion as compared to state-of-the-art nanostructured surface on conventional aluminum alloys. We further explored the nanostructure morphology governing the departure size and frequency of condensed droplets and developed an AM structuring strategy that categorically reduces condensate flooding and enhanced condensation heat transfer coefficient by 6X, as compared to untreated surfaces in high supersaturation environments. This work not only shows the potential of using AM structured surfaces to achieve multi-functional performance enhancement, but it also outlines design guidelines and performance optimization strategies for structuring metallic AM materials.

Phonon-Mediated Unidirectional Magnetoresistance in a Metal on an Insulator with Highly Nonequilibrium Magnons Sean Sullivan, Hwijong Lee, Annie Weathers and Li Shi; The University of Texas at Austin, United States

Heavy metal (HM)/magnet bilayers host many magnetoresistance (MR) and spin caloritronic (SC) effects. Here we show that the spin Peltier effect and electron-phonon scattering result in a much larger measured unidirectional MR of an HM on a magnetic insulator than existing theories that neglect the interplay between MR and SC effects. This spin Peltier MR and the frequency-dependent spin Seebeck effect (SSE) reveal Onsager reciprocity and offer experimental probes of elusive properties of the nonequilibrium magnons driving these effects, including the magnon-phonon thermalization length and SSE coefficient.

1:30 PM EN03.14.02
Symmetry Consequences on Phonons and Thermal Transport Rinkle Juneja and Lucas Lindsay; Oak Ridge National Laboratory, United States

Structural symmetries determine the underlying physical properties of materials and thereby govern their potential functionalities. Here, I will discuss the role of twist structural symmetry in determining vibrational and thermal transport properties of one dimensional and bulk materials. The developed twist dynamics dictate symmetry-enforced band degeneracies, non-trivial topologies, phonon interactions, and unique scattering observables. This will be demonstrated by first-principles calculations supported by inelastic neutron scattering measurements.

1:45 PM EN03.14.03
Late News: Effects of Impurities on the Thermal and Electrical Transport Properties of Cubic Boron Arsenide Xi Chen[1], Chunhua Li[2], Youming Xu[1], Andrei Dolocan[3], Gareth Seward[1], Ambroise Van Roekeghem[4], Fei Tian[5], Jie Xing[1], Shuncheng Guo[1], Ni Ni[1], Zhifeng Ren[5], Jianshi Zhou[3], Natalio Mingo[4], David Broido[2] and Li Shi[3]; [1]University of California, United States; [2]Boston College, United States; [3]The University of Texas at Austin, United States; [4]Université Grenoble Alpes, France; [5]University of Houston, United States

Cubic boron arsenide (BAs) is a promising compound semiconductor for thermal management applications due to its high thermal conductivity, exceeding 1000 W m^{-1} K^{-1} at room temperature in high-quality samples. However, the as-grown BAs crystals usually exhibit large variations in thermal and electronic transport properties. The origin of these large variations has thus far been inconclusive. Here, we investigate the effects of impurities on the thermal and electrical properties of BAs. Time-of-flight secondary ion mass spectrometry and electron probe microanalysis measurements reveal the presence of several impurities in BAs, including Si, C, O, H, Te, Na, and I. Some of these impurities, especially Si, C, and H, could serve as shallow acceptors, leading to the p-type conducting behavior commonly measured in BAs. The thermal conductivity and hole mobility are reduced more in the samples with higher impurity concentrations due to the enhanced impurity scattering of phonons and holes, respectively. Firstprinciples calculations are used to determine the thermal conductivity reduction induced by different impurities. The calculated results confirm the experimental trends. The substitution of O for As leads to a large bond distortion resulting from the breaking of the T_d symmetry, which yields unusually strong phonon scattering with a correspondingly large reduction in thermal conductivity. Our results offer useful insights into the impurity-sensitive transport properties of BAs.

2:00 PM EN03.14.04
Transition to Ballistic Regime of Nanoscale Heat Transport in Silicon at Room Temperature Samuel Huberman[1], Zhiwei Ding[2], Gang Chen[2], Keith Nelson[2] and Alexei Maznev[2]; [1]McGill University, Canada; [2]Massachusetts Institute of Technology, United States

In the past decade, non-diffusive heat transport by phonons at room temperature at the micro/nanoscale was reported in many single crystal materials. However, the transition to the ballistic transport regime, well studied in heat pulse experiments at the liquid He temperatures, remained elusive at room temperature. Motivated by the recent experimental work at the FERMI free electron laser facility in Trieste, Italy, where the extreme ultraviolet (EUV) laser source was used to produce nanoscale transient thermal gratings (TTGs) with heat transfer distances in the tens on nanometers range, we theoretically study heat transport in silicon in the TTG geometry using the Peierls-Boltzmann phonon transport equation based on first-principles calculations of the phonon dispersion and scattering rates. We find that the transition to the ballistic regime takes place in the sub-100 nm range of TTG periods. We compare the calculations done with the relaxation time approximation and the full scattering matrix and investigate the effect of different initial heat source distributions (e.g. optical phonon excitation). The results will be compared with the experimental EUV TTG data from single crystal silicon membranes.

2:15 PM EN03.14.05
Thermal Conductivity of BAs versus Pressure Songrui Hou[1], Bo Sun[2], Fei Tian[3], Zhifeng Ren[4], Xi Chen[1], Chen Li[1,1] and Richard Wilson[1,1]; [1]University of California, Riverside, United States; [2]Tsinghua University, China; [3]Sun Yat-sen University, China; [4]University of Houston, United States

Boron arsenide (BAs) has ultrahigh thermal conductivity because of its unique phonon-phonon scattering properties [1]. At ambient pressure, “bunching” of acoustic phonon branches in BAs leads to a small phase-space for three-phonon scattering [2]. Density functional theory calculations suggest three-phonon scattering rates increase at high pressures because “bunching” of acoustic phonon branches decrease [2]. To test this hypothesis, we measure the thermal conductivity of BAs vs. pressure using time-domain thermoreflectance (TDTR) with a diamond anvil cell (DAC). We observe a pressure independent thermal conductivity from 0 to 25 GPa. We explain our observations as a result of the pressure dependence of the phonon dispersion relation, three-phonon scattering rates, and mass-disorder scattering.

2:30 PM EN03.14.06
Late News: Magnetocaloric Composites for High Efficiency Thermal Management Christopher Kovacs[1], Timothy Haugan[2], Michael McLeod[2], Devin Grant[3], Leonard Jung[4] and Matt Rindfleisch[1]; [1]Hyper Tech Research Inc., United States; [2]Air Force Research Laboratory, United States; [3]Central State University, United States; [4]Purdue University, United States

Cooling with magnetocaloric materials has been pursued by numerous agencies and companies, but many of the challenges remain unsolved. Some of these challenges are excessive pressure drop across the magnetocaloric regenerator, mechanical failure from magnetostructural and thermal cycling, and material degradation due to exposure. Presented here is a continuously processable powder-in-tube (PIT) composite in which the tube is a high thermal conductivity metal, and the core is dense GdF3. Using this PIT composite, the magnetocaloric material is not exposed to the external environment. Additionally, the metal sheathing keeps the magnetocaloric material in slight compression to prevent mechanical fatigue. The arrangement of these PIT wires into an axially aligned array results in a high effective thermal conductivity, low demagnetization factor, and low impedance regenerator, overcoming some of the most difficult challenges in proposed magnetocaloric systems.

2:45 PM EN03.14.07
Study of Magnetocaloric Properties of Shape-Dependent Nanostructured Gadolinium Oxide Dipesh Neupane[1], Arjun K. Pathak[2] and Sanjay R Mishra[1]; [1]Univ of Memphis, United States; [2]SUNY Buffalo State, United States

Conventional gas compression refrigeration technique needs to replace by alternative cooling technology to reducing the depletion of the ozone layer and carbon production. Nowadays, scientists give more interest on magnetocaloric materials (MCM) for refrigeration to replace the vapor compression technique. MCMs are eco-friendly, more efficient, economical, and easy to use. In general, good magnetocaloric materials should have a low Debye temperature value, phase transition near working temperature, large temperature difference (ΔTad) in the vicinity of phase transition, no thermal or magnetic hysteresis, low specific heat, high thermal conductivity, high electrical resistance, resistant to corrosion, and good mechanical properties. Additionally, eddy current heating depends on the surface morphology that is caused by fast varying magnetic fields. Thus, the morphology of materials play an important role to control the magnetocaloric properties. Gd_2O_3 nanomaterial was reported to exhibit a large magnetocaloric entropy change at ~10K which is suitable to liquifying helium useful for cryogenic space application. Literature shows different values of magnetic entropy change (ΔS_m) with the same Gd_2O_3 nanostructures with different morphology like - 8.7 J/kg.K for nanotubes, - 20 J/kg.K for the rod. Several attempts have been made to study MCE on different morphology but comparative study on different morphology is lacking.
In this present study, we investigate the magnetocaloric properties of Gd_2O_3 nanoparticles of different morphology. Single phase Gd_2O_3 nanoparticles were synthesized via the hydrothermal method and a homogeneous precipitation method followed by heat treatment in air at 1100 ^oC for 12 h. Thus

Gd_2O_3 nanoparticles of different shape viz. bulk, rod, spheres, and plate were prepared. The morphology of the samples was analyzed using SEM. The SEM images of synthesized Gd_2O_3 showed 1D nano-rods, 2D nano-plates like architecture prepared via hydrothermal method while hollow nanosphere morphology achieved with a homogeneous precipitation method. The average area of plates are $1mm^2$, the average length of rods are ~500 nm and diameter of hollow micro sphere are ~600 nm. The phase identification and lattice parameter of the powders performed using x-ray diffraction showed presence of highly-crystalline single phase cubic crystal structure with JCPDS No.11-0604. The average crystallite size of sample were lies between 20-30 nm calculated by using Scherrer formula. The lattice parameter of the sample using profile fitting is lies between 10.810 to 10.832 Å.
Magnetic measurements were performed using a SQUID magnetometer. Temperature dependence of zero-field-cooled (ZFC) curve exhibits unchanged phase. The material demonstrate typical paramagnetic behavior in the whole measured temperature 5K to 100K. The paramagnetic susceptibility follows Curie-Weiss law and the fit parameters yield a paramagnetic Curie temperature (Tc) value of ~5K for all samples. The M-H data in the temperature range of 3–30 K is used to calculate the isothermal magnetic entropy change. The M-H data shows the paramagnetic behavior. The maximum value of ΔS_m for 50 kOe field change at 5K is 11.2 Jkg−1 K−1 for the nanoplate sample, 9.4 Jkg−1 K−1 for the nano-rod and 9.2 Jkg−1 K−1 for the nano-sphere, and 10.7 J/kg.K for Bulk. The reason for achieving large ΔSm could be the surface area and surface geometry of the samples. More surface area indicates more surface spins that enhanced magnetization value. These results shows the Gd_2O_3 nano plates are the promising materials for magnetic refrigeration technology compare with oxide nanoparticles at 5K. Our study suggests that the Gd_2O_3 nanostructures of various morphologies could exhibit interesting magnetocaloric properties at low temperatures.

Advanced Experimental Technique to Measure Thermal Conductivity using Suspended Micro-Island Devices Anh Tuan Nguyen and Woochul Lee; University of Hawaii, United States

Suspended micro-island device has enabled researchers to directly measure thermoelectric properties in nanomaterials spanning from nanowires and nanotubes to 2 dimensional materials. The unique capability of this device of probing thermal conductivity at the level of single nanowire and 2D material has significantly contributed to expanding knowledge in nanoscale thermal transport. While the suspended micro-island device remains a powerful tool to measure thermoelectric properties, we further advanced experimental techniques using suspended micro-island devices in order to increase success rates in sample preparation as well as to increase accuracy in thermal conductivity measurements. We will explain the detailed structure of the newly designed suspended micro-island devices and our experimental configurations. Further, we will describe advantages and versatile usages of our experimental technique in various scenarios.

Thermal Conductivity Mapping of Composite Materials by Time-Domain Thermoreflectance Xiaoyang Ji, Satoshi Matsuo, Zhe Cheng, Ella Pek, Nancy Sottos and David Cahill; University of Illinois at Urbana-Champaign, United States

Time-domain thermoreflectance (TDTR) mapping technique has been applied in many fields for detecting the spatial variation of the thermal properties of materials. Here we report the TDTR mapping work with a micro-scale spatial resolution on single carbon fibers and an oxidized SiC/SiC composite. We determine the transverse thermal conductivity of a single IM7 carbon fiber to be ~1.7 W/m-K and obtain uniform thermal conductivities at different radial positions by mapping a carved step structure on the IM7 carbon fiber. Moreover, we determine both the thermal conductance of the oxide layer and the thermal conductivity of the SiC/SiC composite by mapping at different delay times, and figure out the differences between the fibers and the matrix. The effective thermal conductance of the oxide formed on the fibers (27-40 MW/m^2-K) is lower than the oxide on the matrix (40-47 MW/m^2-K), while the fibers have lower thermal conductivities (15 W/m-K) than the matrix (50-90 W/m-K). TDTR mapping on these two small-size composite materials allows for obtaining accurate thermal property changes that are related to the microstructure discrepancies of materials. In addition, we enable a faster data acquisition rate up to 33 μm/s by introducing heterodyne detection into the conventional TDTR setup, which allows for a 17 times higher scanning speed than the conventional TDTR mapping.

SESSION EN03.15: Thermal Conductivity and Phonon Transport

Principles of Thermal Energy Transport, Storage and Conversion in Diverse Settings Jeff Urban; Lawrence Berkeley National Laboratory, United States

Thermal energy lies at the heart of any irreversible process that constitutes much of the operating world around us. Despite this, there is seldom a unifying call to fashion better thermal materials and understand their phenomenology directly; it is often treated as a secondary problem. However, as technoeconomic modeling and global impact are of increasing prominence in materials design and applied physics, I argue that thermal properties should be a primary consideration. Here, I present recent research on a variety of topics - design of phase change cooling materials, phonons in hybrid materials, water separations, thermoelectrics, hydrogen storage, personal comfort, and computing - all of which orbit around how thermal energy can be better harnessed, guided, and utilized. Some highlights will be design considerations of flexible heat exchangers, interfacial solar evaporation in brine management, thermal storage in molecular-invaded porous crystals, unusual temperature dependent plasmonic catalysis, phonon transport in soft materials, and thoughts on computing limitations.

4:30 PM EN03.15.02
Stacking Order Driven Thermal Transport in ReS_2 Yongjian Zhou and Yaguo Wang; Mechanical Engineering, Texas Materials Institute, The University of Texas at Austin, United States

ReS_2 is a rising star in the transition metal dichalcogenide family. The uniqueness of ReS_2 lies in its distorted 1T triclinic crystal structure where the additional *d* valence electrons of Re atoms form zigzag Re chains parallel to the *b*-axis, drastically reducing its symmetry. As a result, ReS_2 possesses

extremely weak interlayer bonding and anisotropic optical, thermal, and electronic properties. Unlike black phosphorus, ReS_2 is very stable in air, making it more suitable for optoelectronic applications. Recently, two stacking orders were identified in multi-layer ReS_2: AA stacking where adjacent layers sit right on top of one another with minimal displacement, and AB stacking where adjacent layers shift by one-unit cell along *a*-axis. With, Ab-initio calculations, the interlayer distance of stacking AB is determined to be 2.59 Å, smaller than that of stacking AA, 2.71Å, which suggests the stronger interlayer interaction in stacking AB. The carrier dynamics, and both optical and vibrational properties in different stacking orders were found to be drastically distinct. In this study, we prepared ReS_2 flakes via mechanical exfoliation with both AA and AB stacking and measured their thickness dependent cross-plane thermal conductivity. We found that the stacking orders of ReS_2 are very robust. Pure stacking order (either AA or AB) can persist up to the thickness of several microns. For both stacking orders, thermal conductivity increases with sample thickness until around 2µm, indicating an extremely long phonon mean free path along cross plane direction. The thickness dependent thermal conductivity in samples with AA stacking increases much faster than those with AB stacking. Our results suggest that stacking order can be an additional degree of freedom to manipulate thermal transport in 2D materials.

4:45 PM EN03.15.03
Modeling Phase Noise with Machine Learning Potentials in Cu_2O Claire N. Saunders[1], Dennis S. Kim[2], Olle Hellman[3] and Brent Fultz[1]; [1]California Institute of Technology, United States; [2]Massachusetts Institute of Technology, United States; [3]Weizmann Institute of Science, Israel

Higher-order force constants of Cu_2O, cuprite, were calculated with a perturbative *ab initio* effective potential method, and used to predict thermal expansion and other temperature-dependent phonon behaviors. Inelastic neutron scattering was used to measure phonon dispersions in single crystal cuprite at 10, 300, 700, and 900 K. Low- and high-order force constants accounted for the negative thermal expansion of cuprite; however, calculations with high-order force constants were more effective in predicting the observed temperature-dependent phonon behavior. None of these calculations sufficiently accounted for an observed broad, diffuse intensity in the measured phonon spectrum. Classical molecular dynamics with machine learning interatomic potentials models will be compared with perturbative anharmonic calculations. A local dynamics model is proposed to explain this diffuse inelastic scattering, analogous to phase noise in oscillators.

5:00 PM EN03.15.04
Physics-Informed Neural Networks for Solving Multiscale Mode-Resolved Phonon Boltzmann Transport Equation Ruiyang Li[1], Eungkyu Lee[2] and Tengfei Luo[1]; [1]University of Notre Dame, United States; [2]Kyung Hee University, Korea (the Republic of)

Boltzmann transport equation (BTE) is an ideal tool to describe the multiscale phonon transport phenomena, which are critical to applications like microelectronics cooling. Numerically solving phonon BTE is extremely computationally challenging due to the high dimensionality of such problems, especially when mode-resolved properties are considered. In this work, we demonstrate the use of physics-informed neural networks (PINNs) to efficiently solve phonon BTE for multiscale thermal transport problems with the consideration of phonon dispersion and polarization. In particular, a PINN framework is devised to predict the phonon energy distribution by minimizing the residuals of governing equations and boundary conditions, without the need for any labeled training data. Moreover, geometric parameters, such as the characteristic length scale, are included as a part of the input to PINN for learning BTE solutions in a parametric setting. This enables our method to handle structures over a wide range of length scales after a single training. The effectiveness of the present scheme is demonstrated by solving a number of phonon transport problems in different spatial dimensions (from 1D to 3D). Compared to existing numerical BTE solvers, the proposed method exhibits superiority in efficiency and accuracy, showing great promises for practical applications, such as the thermal design of electronic devices.

5:15 PM EN03.15.05
Thermal Conductivity of ZrS_2 Monolayer Driven by Finite-Temperature and Anharmonic Lattice Dynamics Abhiyan Pandit and Bothina Hamad; University of Arkansas-Fayetteville, United States

Two-dimensional (2D) ZrS_2 monolayer (ML) has emerged as a promising candidate for thermoelectric (TE) device applications due to its high TE figure of merit, which is mainly contributed by its inherently low lattice thermal conductivity. This work investigates the effect of the lattice anharmonicity driven by temperature-dependent phonon dispersions on the thermal transport of ZrS_2 ML. The calculations are based on the self-consistent phonon (SCP) theory to calculate the thermodynamic parameters along with the lattice thermal conductivity. The higher-order (quartic) force constants were extracted by using an efficient compressive sensing lattice dynamics technique, which estimates the necessary data based on the emerging machine learning program as an alternative to computationally expensive density functional theory calculations. Resolve of the degeneracy and hardening of the vibrational frequencies of low-energy optical modes were predicted upon including the quartic anharmonicity. As compared to the conventional Boltzmann transport equation (BTE) approach, the lattice thermal conductivity of the optimized ZrS_2 ML unit cell within the SCP + BTE approach is found to be significantly enhanced (e.g., by 21% at 300 K). This enhancement is due to the relatively lower value of phonon linewidth contributed by the anharmonic frequency renormalization included in the SCP theory. Mainly, the conventional BTE approach neglects the temperature dependence of the phonon frequencies due to the consideration of harmonic lattice dynamics and treats the normal process of three-phonon scattering incorrectly due to the use of quasi-particle lifetimes. These limitations are addressed in this work within the SCP + BTE approach, which signifies the validity and accuracy of this approach.

5:30 PM EN03.15.06
Resonant Interaction Between Phonons and PbTe/PbSe(100) Misfit Dislocations Yang Li[1], Adrian Diaz[1], David McDowell[2] and Youping Chen[1]; [1]University of Florida, United States; [2]Georgia Institute of Technology, United States

As a consequence of a lattice mismatch between dissimilar materials, misfit dislocations are unavoidable at the phase interfaces in heterostructures when the epilayer thickness exceeds a critical thickness, regardless of the growth mechanisms and conditions. In this study, we report simulation results of the resonant interaction between long-wavelength transverse acoustic (TA) phonons and misfit dislocations at the PbTe/PbSe(100) interface, using the Concurrent Atomistic-Continuum method. It is found that TA phonons with frequency near a specific value excite the resonance behavior of the misfit dislocations, as identified by large-amplitude, out-of-phase vibration of the atoms on both sides of the slip plane of the misfit dislocations. The vibration amplitude can be up to ten times of the amplitude of the incident phonon wave. The resonant interaction leads to a low energy transmission of TA phonons.

8:00 AM *EN03.16.01
Overview of US DOE Research and Development in Concentrating Solar-Thermal Power Avi Shultz; U.S. Department of Energy, United States

To meet the global threat of climate change and ensure that all Americans benefit from the transition to a clean energy economy, the DOE Solar Energy Technologies Office (SETO) works to accelerate the development and deployment of solar technologies to decarbonize the electricity system by 2035 and decarbonize the energy sector by 2050. A fully decarbonized grid will likely require large amounts of energy storage to provide energy when it is needed and increase the grid's reliability and resilience. While lithium-ion batteries have enabled rapid deployment of energy storage, most commercial applications have been limited to four hours of storage or less. Longer-duration storage can help alleviate the impact of extended periods of cloudy weather, for example, or even seasonal variations of solar energy production.

Concentrating solar-thermal power (CSP) plants use mirrors to capture the sun's energy as heat, which can be stored in a thermal energy storage (TES) system and used to produce electricity on demand, even when the sun is not shining. Commercial CSP plants with TES have demonstrated the viability of thermal storage to be responsive to grid needs, particularly for long durations of daily storage, up to 17 hours, which is not currently economically viable with lithium-ion batteries. Thermal systems can decouple the storage capacity component (e.g., molten salt stored in tanks) from the power-generating component (heat engine). This enables system designers to increase marginal storage capacity or duration—without having to build additional generating capacity—by increasing the size of the storage tank. The combination of readily scalable TES and conventional turbine technology can allow CSP to provide reliable and flexible renewable electricity production.

SETO has set a cost target of $0.05 per kilowatt-hour electric (kWh_e) for baseload plant configurations with 12 or more hours of storage, which could enable deployment of 25 to 160 GW of U.S. CSP capacity by 2050. To reach this target, SETO is supporting the development of next-generation CSP plants that are capable of delivering heat to the power cycle at temperatures exceeding 700°C, increasing plant efficiency. Current technologies that use molten salt cannot exceed 565°C owing to thermal decomposition of the salt, which is used as a heat-transfer fluid. If successful, these third-generation (Gen3) CSP designs will enable CSP systems to utilize advanced power cycles based on supercritical carbon dioxide (sCO_2), which are much more efficient than existing steam-based cycles.

Projects in SETO's Gen3 CSP program have been investigating and designing fully integrated thermal transport systems based on three competing concepts for the heat-transfer media (HTM) organized by the phase of matter for leading HTM candidates—gas, liquid, or solid. In March 2021, SETO announced the selection of Sandia National Laboratories to develop a design based on solid particles as the HTM. Sandia will receive $25 million to construct a 2 megawatt (MW) thermal integrated test facility to validate the proposed system.

Beyond electricity generation, solar-thermal technologies may also be able to help meet the national goal of decarbonizing the entire U.S. energy sector by 2050 by providing industrial process heat. Even with more renewable electricity available, many industrial processes will be difficult to electrify because they require high temperatures or have other challenging process characteristics. SETO aims to make solar industrial process heat cost-competitive with fossil fuels to address high-priority applications, including calcination to produce cement, thermochemical water splitting for producing solar fuels, and ammonia synthesis for producing fertilizer. The solid particle heat-transfer pathway being developed for Gen3 CSP may be particularly relevant for a number of these processes, which have solid-phase components or are mediated by solid-phase catalysts.

8:30 AM EN03.16.04
Materials Challenges Associated with 100-Gigawatt-Hour Nitrate-Salt Crushed-Rock Heat Storage Disha Bandyopadhyay[1,2] and Charles W. Forsberg[1]; [1]Massachusetts Institute of Technology, United States; [2]Imperial College London, United Kingdom

We are developing a 100-GWh Crushed-Rock Ultra-large Stored Heat (CRUSH) System that couples to nuclear reactors or very large Concentrated Solar Power (CSP) heat sources. Heat storage enables nuclear or CSP plants to operate at full capacity with dispatchable electricity. The electric storage capabilities of CRUSH are similar to the Tennessee Valley Authority Raccoon Mountain pumped hydro facility that can provide 1600 MW(e) for 22 hours to address hourly to weekly storage. Heat is transferred into and out of storage using nitrate salts (<600°C). The CRUSH system capital-cost goals are $2-4/kWh—an order of magnitude less than current heat storage systems and a factor of 50 less than batteries.
Existing solar power towers use clean nitrate salt for heat transfer and storage. Cold salt is heated by the CSP system and sent to hot nitrate storage tanks. The power block, sized for peak electricity demand, takes hot nitrate salt, produces dispatchable electricity and sends the cold salt to cold-salt storage tanks. Three advanced nuclear reactor concepts use nitrate salt in the intermediate loop and propose the same system design as CSP plants—cold salt heated with a reactor operating at base load, hot salt sent to the hot salt storage tank, hot salt from storage goes to the power block to produce variable electricity and the resultant cold salt is sent to the cold-salt storage tank. Existing CSP systems have up to several gigawatt hours of heat storage and have capital costs of $20-30/kWh of heat stored. About half the capital cost is associated with the tanks and a third or more of the cost is associated with the nitrate salts.
With the CRUSH system, heat storage is in a crushed rock pile (200 m by 200 m with heights of 20 to 40 m) with heat transfer by hot nitrate salt that is sprayed on the crushed rock and drains to the catch pan below. Heat is recovered by spraying cold fluid onto the hot crushed rock and recovery of the hot fluid from the catch pan below. To minimize costs, nitrate salt is used for heat transfer, not heat storage. This process has similarities to heap leaching of copper ores where solutions are sprayed on top of large crushed rock piles, flow through the piles, dissolve the copper and are collected by the drain pans below. The crushed rock pile has a flat top surface with sloping sides of crushed rock. This allows free expansion and contraction of the rock pile with changing temperatures. The building over the crushed rock is similar to an aircraft hangar with a gas-tight insulation on the inside—no rock or liquid nitrate salt touches the building structure. Unlike current nitrate-salt heat storage systems with clean nitrate salt in clean tanks, the CRUSH salt is in direct contact with the crushed rock.
We are examining materials reactions between the salt, the crushed rock, heat exchangers and piping. The thermal transients will generate fines; thus, filters are required to remove larger solid particles in the liquid salt. Rock choices must be chosen to (1) withstand thermal cycling, (2) forces by 20+ meters of crushed rock height, (3) dissolution of selected components that may or may not be limited by solubility limits in nitrate salts, (4) dissolution and precipitation of rock components with temperature and (5) corrosion and fouling of heat exchangers and other components. There has been some experimental work associated with nitrate salt/crushed rock in proposed heat-storage thermocline systems with hot salt on top of cold salt in a tank filled with crushed rock. Only some crushed rocks are chemically compatible with the nitrate salts. We review the existing work, our analysis and priorities going forward. Major work, including poly-temperature flowing salt loops, will be required to qualify rock types for this service.

8:45 AM EN03.16.02
FeMnNiAlCr High Entropy Alloys with High Efficiency Native Oxide Solar Absorbers for Concentrated Solar Power Systems Xiaoxue Gao, Edwin Jiang, Huan Wang, Weiyang Li, Ian Baker and Jifeng Liu; Dartmouth College, United States

As a complementary technology to photovoltaics in harvesting and converting solar energy, concentrated solar power (CSP) system offers a unique

advantage in that it stores solar energy as heat at low cost, which enables dispatchable solar electricity supply even at night. Same as other heat engine systems, the CSP system follows the Carnot's theorem: the higher the operation temperature of the system, the higher the conversion efficiency. Thus, a key component of the CSP system, the tubing material, is required to be both mechanically strong at high temperatures >873 K and resistant to the corrosion of both the working fluids inside and the oxidation in air outside at this working temperature. Currently, most of the tubing materials employed in power plants could not operate at temperature higher than 873K due to their mechanical and chemical limits. Even though the nickel or titanium-based alloy could have better performance, they would not be economic solutions to this challenge at a cost ~10x that of stainless steels. In this paper, we present FeMnNiAlCr high entropy alloys (HEAs) to address this challenge. Low-cost Fe and Mn constitute >60 at.% of the HEA composition, much more cost-effective than the nickel-based superalloys, while the tensile strength of the HEAs are comparable to Ni-based Inconel alloys at 973K [1,2]. Compared with 304 stainless steels, its yield strength is also twice as high at 973K. Therefore, our FeMnNiAlCr HEA shows promising mechanical properties to satisfy the mechanical requirements of the high temperature tubing material. The other crucial element of the CSP system is the solar selective absorber. High solar absorbance, low thermal emittance loss and stable optical-to-thermal energy conversion efficiency at 1023K for long term are essential properties of the solar selective absorber utilized in this working environment. One of the widely applied solar selective absorber coatings, Pyromark 2500, has high solar emittance loss (~80%) and would need sophisticated fabrication steps to ensure its adherence to the substrate [3]. Its conversion efficiency also degrades after operation at 1023K for just 300h. The native oxide we grown on two phase HEAs, which mostly comprises Mn_2O_3 on the surface and a dense Al_2O_3 at the oxide/HEA interface, provides a facile synergistic solution to solar absorbers. This native oxide layer has high solar absorbance of 91.4%, low thermal emittance of 27% and an optical-to-thermal energy conversion efficiency of 89.7% at 1023K for 1000x solar concentration ratio. The solar absorption is mainly contributed by manganese oxide on the surface, while the dense protective aluminum oxide at the oxide/HEA interface can be engineered to prevent excessive oxidation. Interestingly, the manganese oxide spontaneously forms surface texture upon oxidation, similar to the surface engineering of photovoltaic cells, which enhances the solar absorption while the dense and robust layer itself protects the alloy from both the corrosion of the working fluids and excessive oxidation of the air. In preliminary high-temperature corrosion studies, two-phase FeMnNiAlCr HEAs have sustained bromide molten salts for 14 days at 1023 K with <2% weight loss. Thus, the potential of synergistically addressing mechanical, optical and chemical challenges makes FeMnNiAlCr HEAs a promising cost-effective candidate for high-temperature tubing materials in future CSP systems.

9:00 AM EN03.16.03
Design of Nitrate-Based Molten Salt/Nanoporous Alumina Composites with Improved Thermophysical Properties Göktürk M. Yazlak[1], Martin Steinhart[2], Jürgen Thiel[3] and Hatice Duran[1]; [1]TOBB University of Economics and Technology, Turkey; [2]Universitaet Osnabrück, Germany; [3]Max-Planck-Institute for Polymer Research, Germany

Selection of an appropriate heat transfer agent (HTA) and thermal energy storage (TES) material is important for minimizing the cost of the solar receiver, thermal storage and heat exchangers, and for achieving high receiver and cycle efficiencies. It has also been observed that the use of the molten salt eutectic composition as an HTA / TES fluid in many different areas is effective in increasing system efficiency. Current molten salt HTAs have high melting points (>200°C) and degrade above 600°C. The main problem with this application is that it can easily freeze in the evening or in the winter months and clog the pipeline to make working conditions difficult. For this reason, there is an urgent need for inexpensive salt melt compositions having a lower melting point and a higher thermal stability temperature. To do this, a new nanostructured eutectic molten salt was designed to achieve lower melting point (>200°C) and higher thermal conductivity. In this study, we prepared phase diagrams of molten salts and anodic alumina oxide (AAO) with different pore size (25 to 400nm). Maximum melting temperature depression was observed as ΔT=~170°C for AAO/KNO_3 composites for 35nm pore size. Furthermore, a drastic increase on thermal conductivity (73%) was recorded for the same composite. It was observed that this increase was not systematic in AAO / KNO_3 composite structures, but it was systematic in AAO / $NaNO_3$ composite structure. The highest thermal conductivity increase is seen in AAO / KNO_3 composite structure with pore diameter of 35nm.

9:15 AM EN03.16.05
Transitioning Toward Robust Industry-Grade Predictive Workflows for Thermal Management Applications Kiran Sasikumar[1], Sushant Sonde[2] and Subramanian Sankaranarayanan[3]; [1]Avant-garde Materials Simulation GmbH, Germany; [2]EPIR Inc., United States; [3]Argonne National Laboratory, United States

Ab-initio design or engineering of systems and processes may be considered a holy grail in computational sciences, spanning across the fields of materials science, chemistry, biology, and engineering. The goal here is to integrate multiple simulation modalities, from quantum mechanical calculations to continuum finite element simulations, for a fully ab-initio prediction of device or process operation with limited experimental input. Such an ab-initio predictive workflow, a digital twin, can complement experimental investigation by narrowing the relevant design space.

Specifically, thermal management of electronics is an important aspect in the design of semiconductor devices, where certain applications require device operation in temperature extremes. Chips with electromagnetic detector arrays often have to operate at 77 K and frequently cycle back to room temperature when not in use. One of the design goals here is, thus, to optimise device geometry to minimize thermal stresses upon temperature cycling and improve operational reliability of the resulting integrated detector array.

In this contribution, we introduce the design of Modified Direct Band Interconnect (MoDiBI) detector arrays using artificial-intelligence inspired optimization heuristics integrated with a finite element thermo-mechanical model. While fully ab-initio device engineering is not a reality yet, we use this system as a template to discuss the effect changes in the material properties of device components have on the optimized device geometry. This, in turn, paints a picture on the accuracy needed in the prediction of thermo-mechanical material properties in a fully ab-initio workflow.

Further, we discuss some case studies to evaluate if current state-of-the-art in thermal property prediction from atomistic simulation is sufficient to enable a robust predictive workflow for thermo-mechanical device optimization. Finally, a perspective is provided on recipes to transition toward robust industry-grade predictive workflows for thermal management applications.

9:30 AM EN03.16.06
°Extreme Durability of Grafted Polymer Film in Condensation Heat Transfer Using Initiated Chemical Vapor Deposition Abinash Tripathy[1], M. Donati[1], Cheuk Wing Edmond Lam[1], A. Milionis[1], Chander S. Sharma[2] and Dimos Poulikakos[1]; [1]ETH Zürich, Switzerland; [2]Indian Institute of Technology Ropar, India

Condensation has significant applications in various industries. Commercially condensation can be used for thermal management, power generation,

refrigeration, air conditioning, water desalination etc. Condensation can be distinguished in to two distinct modes commonly termed as filmwise condensation (FWC) and dropwise condensation (DWC). Among these DWC is the preferred mode of condensation in heat transfer applications due to the inherently higher heat transfer coefficient (almost one order of magnitude). However, condensation still manifests as FWC on most of the condenser surfaces (copper, aluminium, steel etc.) used in industry. This is because the metal surfaces are hydrophilic, and an additional hydrophobic coating is required to achieve DWC. An ideal hydrophobic coating should have high droplet shedding efficiency, mechanical durability and low thermal resistance. However, it is difficult to attain all these properties in one coating.
In this work, we report DWC with stable heat transfer performance on poly-[1H,1H,2H,2H- perfluorodecyl acrylate] (pPFDA) coating grafted on flat copper and aluminum substrates using initiated chemical vapor deposition (iCVD) technique. iCVD is environmental friendly as it is solvent-free and vapor phase process. The condensation heat transfer performance and durability of this coating is compared with 1H,1H,2H,2H-Perfluorodecyltriethoxysilane (Silane) functionalized copper and aluminium substrates.
The grafted polymer coating using iCVD was obtained in two steps. First, we coated flat copper or aluminum substrate with trichlorovinylsilane (TCVS) in a custom-made chemical vapor deposition chamber at 10 bar. Post TCVS coating, we utilized the iCVD tool (iLab Coating System, GVD Corporation) to deposit an ultra-thin layer of pPFDA (Advancing contact angle (ACA) – 127°±3°, contact angle hysteresis (CAH) – 10.3°±3.4°). The thickness of the coating was found to be ~40 nm. For silane coating, flat copper and aluminium samples were dipped in a mixture of Silane and hexane for 1 hour followed by baking it on a hot plate (ACA – 123.3°±1°, CAH – 21.3°±1.2°).
The condensation heat transfer performance of both the coatings was evaluated in a harsh condensation environment. The surfaces were mounted in a high saturation pressure chamber (1.42 bar) and exposed to superheated steam (111°C). These are extreme conditions to test the performance of the hydrophobic coatings as compared to a low saturation pressure conditions typical for industrial condensers. The superheated steam was flowing on the test substrates at 3 m/s and 9 m/s during the experiments by exerting a vapor shear on the coating. The heat transfer performance was quantified in terms of the heat transfer coefficient (HTC).
Apart from heat transfer performance, the mechano-chemical robustness of both the coatings was tested for their practical applicability with a protocol consisting of eleven different durability tests. The grafted polymer coating via iCVD outperformed the Silane coating in terms of mechano-chemical durability. Additionally, it survived exposure to superheated steam during condensation experiment and exhibited DWC with a stable HTC during the experiment. This can be attributed to the higher chemical strength of the hydrophobic coating with the substrate deposited via iCVD. Vinyl groups in TCVS are covalently bound to the surface and the reaction between the surface vinyl groups and the vinyl groups in PFDA monomer binds them chemically to the substrate. On the other hand, Silane coating is a monolayer (~2-3 nm) and hence is susceptible to deterioration in extreme environments. Consequently, the silane coating failed in the condensation chamber, and we observed FWC on the surface.
These findings make iCVD coating an ideal candidate for practical applications.

9:45 AM EN03.16.07
Ragone Relationships in Thermal Batteries to Evaluate Phase Change Material Composite Design Charles M. Shoalmire[1], Alison Hoe[1], Michael Shanks[2], Neera Jain[2] and Patrick Shamberger[1]; [1]Texas A&M University, United States; [2]Purdue University, United States

Energy storage technologies are marked by tradeoffs in energy and power density; a Ragone plot is a standard graphical representation used to investigate the relationship between these two quantities. Absolute upper limits on energy density generally derive from intrinsic thermodynamic limits. In contrast, the power density of a substance represents kinetic limits on heat, mass, or charge transfer which limit the rate of energy storage. Viewed through this lens, the relationship between these two quantities represents how much of the potential or theoretical energy storage density must be sacrificed to achieve a particular rate of energy storage. Ragone relationships offer an approach to critically analyze the dependence of material performance on different design parameters.
Phase change materials (PCMs) are of intense interest due to their ability to passively store thermal energy in order to mitigate a transient temperature rise, or to improve the overall efficiency of a system. While PCMs possess high effective thermal capacitance, due to the latent heat of transformation, many suffer from low intrinsic thermal conductivity. To increase conductivity, PCMs can be combined with materials with higher thermal conductivities (e.g., metals, graphite, etc.) to create composite PCMs. In this case, the maximum energy density of a composite PCM volume is defined primarily by the intrinsic material properties of the PCM phase, the fraction of the composite composed of PCM phase, and the temperature rise. In contrast, the power density of a composite PCM volume is a non-trivial quantity, as it depends strongly on the many factors that affect heat transfer rate, including intrinsic material properties, operating conditions, the geometry of thermal energy storage (TES) modules, the coupling between the composite PCM volume and the design of the PCM composite itself.
In this study we develop and validate a numerical finite difference model to interrogate heat transfer from a heat transfer fluid into a planar or cylindrical volume composed of a composite PCM. From this, we extract energy density and power density Ragone relationships over the period of charging or discharging (5 to 5000 s). Here, we focus on the effects of composite structure, including the relative volume fraction of PCM and conductive components, the role of component orientation and anisotropic transport, and the interaction between different PCMs (paraffins, salt hydrates, low melting point metals) and conductive elements (aluminum, graphite). Systems which are optimized for longer timescales allow the system to approach its maximum energy storage density, as minimal mass and volume is devoted to enhancing heat transfer into the composite PCM bed. As an example, a planar module composed of aluminum and hexadecane (a paraffin wax) optimized to store energy over a period of 500 s can achieve energy densities (180 J/g; 175 J/cm^3) that are approximately 70% of the intrinsic limit, corresponding to relatively low power densities (0.36 W/g, 0.35 W/cm^3). In contrast, a module of the same geometry that is optimized to store energy over a period of 50 s can achieve energy densities (130 J/g; 155 J/cm^3) that are approximately 50% of the intrinsic limit, corresponding to an order of magnitude larger energy storage rates (2.6 W/g, 3.1 W/cm^3).[SPJ1] These results reveal the interactions between different thermophysical properties and composite design parameters, and also allow for efficient optimal design of energy storage components to meet application specific requirements.

Towards Massive Material Search Space with Machine Learning and Quantum Annealer—Application to Thermal Radiation Junichiro Shiomi; The University of Tokyo, Japan

Materials informatics (MI), developing or studying materials with an aid of informatics or machine learning, has become popular in academia and industry. Use of MI for heat transfer started later than other fields but now there are growing number of reports showing good compatibility. A general methodology

is to train a black box model that relates basic descriptors (structure, composition, etc) and figure of merit (target properties) and predict or design a material with largest FOM. At Thermal Energy Engineering Lab at University of Tokyo, together with the collaborators, we have been working on MI for heat transfer for about 6 years, starting from nanostructure design using Bayesian optimization[1, 2]. We have applied the methodology to computationally design and experimentally realize aperiodic superlattice that optimally impedes coherent thermal transport[3] and multilayer metamaterial with ultranarrow-band wavelength-selective thermal radiation[4]. While Bayesian optimization has limitation in the size of search space for global optimization, considering the complex system with many dimensions or parameters needed for further MI, the challenge now is to develop a scheme that can efficiency handle massive material search space. Quantum annealing is a powerful tool since it can quickly solve combinatorial optimization problems of the size that scales with the power of number of qubits, and number of qubits commercially available for use is increasing year by year. However, there are some practical challenges. One is that the quantum annealing can only solve the problem in form of Ising model, and this has been overcome by using factorization machine [5]. Another is that even if optimization is quick and large, it is only useful when the speed and size are well balanced with those of data generation. In that sense, radiative heat transfer problem, such as designing metamaterial for wavelength-selective thermal emitter, is most suited to go massive because calculation of electromagnetic field is light and easy to parallelize. In the talk, we will introduce these progresses in applying annealers to thermal radiation problems and discuss the capability and remaining challenges for further development.

Late News: Near-field Heat Transfer by Quantum Mechanics Thomas Prevenslik; QED Radiations, Germany

Near-field heat radiative transfer (NFRHT) is based on the classical Fluctuation Dissipation Theorem that requires the heat produced in macroscopic bodies upon absorbing EM radiation creates temperature fluctuations that is reciprocated by temperature fluctuations producing EM radiation. But NFRHT in nanoscale gaps between hot and cold bodies is governed by quantum mechanics (QM) and not classical physics. Indeed, the Planck law precludes temperature fluctuations in nanoscale gaps upon absorbing heat. However, all known NFRHT theories are based on the difference of surface temperatures of nanoscale gaps. In effect, the Planck law requires theories of NFRHT that do not depend on temperature which means all known NFRHT theories are invalid.

One such temperature independent NFRHT theory is simple QED based on the Planck law that conserves heat by creating temperature independent EM standing or travelling waves across the evacuated nanoscale gaps. But the heat requires EM confinement across the gap to a half-wavelength having the dimension d of the gap. In simple QED, the EM confinement is provided by the momenta of the thermal kT energy of atoms participating in the heat flow between hot and cold bodies, the hot and cold momenta directed toward their respective gap surfaces because of the thermal gradient with gap surface temperatures at absolute zero, the gap surface temperatures taken at absolute zero because the Planck law requires Brownian motion to cease everywhere in the nanoscale gap. Under EM confinement by opposing thermal momenta, heat flows if the hot momentum exceeds its cold counterpart

Simple QED highlights the stark difference between QM and classical physics illustrated by the emission of bright white-light from a Joule heated single graphene layer (0.337 nm) over a nanoscale trench reported in the literature. The application of NFRHT to the nanoscale trench is difficult to implement as the Joule heat from the graphene layer into the nanoscale trench is not known. Instead, the Fourier equation was applied to the graphene layer assuming Joule heating produces electron temperatures of 2800 K giving graphene temperatures near 2000 K. But bright-white light may require higher temperatures, say up to 5000 K.

In contrast, simple QED argues the graphene remains at ambient temperature. Instead, 1.8 keV soft X-rays are produced across the graphene thickness that fluoresce down to about 200 eV, the heat of which is either lost to the surroundings or enters the trench, the latter by simple QED creating IR waves standing in the trench, the overtones of the IR producing the observed bright white-light absent high temperatures. Consistent with simple QED, the graphene does not acquire 2800 K electron temperatures evidenced by the observation of white-light at 10 K. Indeed, there is a stark difference between QM and classical physics and should be expected whenever classical physics including NFRHT is used to explain observations at the nanoscale.

Efficient Heat Shielding of Steel with Multilayer Nanocomposite Thin Film Carolyn T. Long, Ruisong Wang, Charles Shoalmire, Dion Antao, Patrick Shamberger and Jaime C. Grunlan; Texas A&M University, United States

In an effort to protect metal substrates from extreme heat, polymer–clay multilayer thin films are studied as expendable thermal barrier coatings. Nanocomposite films with a thickness ranging from 2 to 35 μm were deposited on steel plates and exposed to the flame from a butane torch. The 35 μm coating, composed of 14 deposited bilayers of tris(hydroxymethyl)aminomethane (THAM)-buffered polyethylenimine (PEI) and vermiculite clay (VMT), decreased the maximum temperature observed on the back side of a 0.32 cm thick steel plate by over 100 °C when heated with a butane torch. Upon exposure to high temperature, the polymer and amine salt undergo pyrolysis and intumesce, subsequently forming a char and blowing gas. The char encases the nanoclay platelets, and a ceramic bubble is formed. The macro-scale bubble, in tandem with the nanocomposite coating properties, increases resistance to heat transfer into the underlying metal substrate. This heat shielding behavior occurs through radiative effects and low aggregate through-plane conductivity resulting from multilayer nanodomains and intumesced porosity (i.e., conduction through the gas as the film expands to form a ceramic bubble). These relatively thin and lightweight films could be used to protect important metal parts (in automobiles, aircraft, etc.) from fire-related damage or other types of transient high-temperature situations.

Enhanced Evaporation via Nanoengineered Materials for Solar Thermal Sterilization and Desalination Lin Zhao[1], Lenan Zhang[1], Zhenyuan Xu[1,2], Arny Leroy[1], Elise Strobach[1], Bikram Bhatia[1], Sungwoo Yang[1], Thomas Cooper[1], Lee Weinstein[1], Omar Labban[1], John Lienhard[1], Anish Modi[3], Shireesh Kedare[3], Ruzhu Wang[2], Gang Chen[1] and Evelyn N. Wang[1]; [1]Massachusetts Institute of Technology, United States; [2]Shanghai Jiao Tong University, China; [3]IIT Bombay, India

Enhancing evaporation processes via nanoengineered materials design offers unique opportunities for a range of energy applications. In this work, we show our ability to enhance evaporation processes and new device designs with various engineered materials sets. First, we show how we achieve a passive high-temperature solar steam generator for medical sterilization. The high performance leverages optimized ultra-transparent silica aerogel to achieve efficient thermal concentration to locally increase the heat flux and temperature. We show nearly a 2x higher energy efficiency compared to past work, and successful sterilization in field tests in Mumbai, India. Next, we show novel architectures that take advantage of thermal localization and multiple stages for

vaporization enthalpy recycling to achieve ultra-high efficiency passive solar desalination. With a ten-stage design with scalable and low-cost materials, a solar-to-vapor conversion efficiency of 385% and total production rate of 5.78 Lm^{-2} h^{-1} under one-sun illumination was achieved. We also present techno-economic analysis that highlights the balance between water production, reliability, and cost. The works presented here promises new opportunities for the development efficient solar thermal systems in energy conversion, storage, and transport, as well as water applications.

Materials and Manufacturing: Keys to Developing Wide Bandgap Power Electronic Devices Samuel Graham[1,2]; [1]Georgia Institute of Technology, United States; [2]University of Maryland, United States

Wide bandgap electronics are currently under development due to their potential to create future power electronics. The growth of materials based on gallium nitride and more recently gallium oxide is expected to help create technological advancements that may yield a range of devices that operate with more efficiency, higher operational frequency, and smaller form factors.
In this talk, we will discuss a range of materials and device architectures that are being developed to enable efficient heat dissipation from both GaN and Ga_2O_3 devices starting at the device level. We will discuss materials integration issues that will enable lower thermal resistance device architectures to assist with thermal management strategies. This will include bonding of heterogenous layers as well as direct growth methods. Finally, we will discuss new aspects of materials processing and properties to create a low CTE mismatch cooled power substrate for packaging power devices. At each step, we will show how considerations for materials development and methods for scalable manufacturing are necessary to help transition these advancements to applications.

1:30 PM EN03.18.02
Monolithic Integration of Copper with Electronics for High Efficiency Cooling Tarek Gebrael[1], Jiaqi Li[1], Joseph Schaadt[2], Logan Horowitz[2], Robert Pilawa-Podgurski[2] and Nenad Miljkovic[1]; [1]University of Illinois at Urbana Champaign, United States; [2]University of California, Berkeley, United States

Power densification of modern electronics is greatly shaped by emerging thermal management technologies. Heat spreaders represent a thermal routing technique implemented to reduce thermal resistance and limit temperature variations. Here, we demonstrate the monolithic integration of copper (Cu) conformal coatings directly on electronics to serve as heat spreaders and temperature stabilizers. We developed a fabrication recipe to electrically insulate the electronics with Parylene C and coat them with the Cu heat spreaders, demonstrating better proximity to heat generating elements, removal of thermal interface materials, and enhanced cooling performance compared to standard thermal components. Our results show that 8 µm thick Parylene C can handle up to 600 V, and that the Cu coatings provide device-to-ambient specific thermal resistance as low as 2.5 (cm^2.K)/W in quiescent air and 0.8 (cm^2.K)/W in quiescent water, with time constants of 110 s in air and 5.61 s in water. Our cooling technology has the potential to enable the continued miniaturization of electronics, potentially extending Moore's law and greatly reducing the energy consumption used for electronics cooling. Furthermore, by removing the need for large external heat sinks, our approach should enable the realization of very compact and highly power dense co-designed power converters.

1:45 PM EN03.18.03
Boron Nitride Nanotube Coatings for Thermal Management of Printed Silver Inks on Temperature Sensitive Substrates Kaitlin Wagner[1,2], Chantal Paquet[2], Yadienka Martinez-Rubi[2], Marc Genest[2], Jingwen Guan[2], Katie Sampson[2], Keun Su Kim[2], Arnold Kell[2], Patrick Malenfant[2] and Benoit Lessard[1]; [1]University of Ottawa, Canada; [2]National Research Council, Canada

One major challenge in printing conductive metal inks onto heat-sensitive plastic substrates is the adverse effects of high temperatures experienced during the sintering process and during operation as a result of joule heating, which leads to substrate damage and current carrying capacity limitations. To combat this issue, incorporating an electrically insulating film interposed between the substrate and the printed feature can aid in spreading heat laterally away from the substrate-feature interface without sacrificing conductive performance or rigidity of the plastic substrate. Boron nitride nanotubes (BNNTs) in particular exhibit relatively high thermal conductivity and impressive thermal stability, and therefore present a promising platform to minimize thermal degradation of the printed feature and the substrate over time.

We report on a highly transparent BNNT heat-spreading interlayer for thermal management of silver components screen-printed onto polyethylene terephthalate (PET) substrates. Printed features of varying widths are investigated to optimize the transparency and conductivity of the resulting design. Upon exposure to increasing photonic energies, the BNNT layer actively dissipates the heat through the tube network, resulting in morphological improvements in both the feature and the substrate and reducing sheet resistance by up to 200%. Thermal imaging demonstrates a reduction in localized areas of excessive heat accumulation, achieving greater uniformity in heat distribution throughout the printed feature upon applied current. In summary, the BNNT thin film provides a simple approach to shield the substrate from deformation and damage at high temperatures while simultaneously improving electrical performance of the printed features and structural integrity of the substrate.

Thermal Considerations for High Density Fast Charging Lithium–Ion Batteries Ravi Prasher[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

Traditionally it has been assumed that battery thermal management systems should be designed to maintain the battery temperature around room temperature. That is not always true as Lithium-ion battery (LIB) R&D is pivoting towards the development of high energy density and fast charging batteries. As the energy density and charge rate increases, the optimal battery temperature can shift to be higher than room temperature. To improve the temperature uniformity and avoid excessive internal temperature rise, heat transfer inside the battery needs to be enhanced, and reducing the thermal contact resistance between the electrodes and separator can significantly increase the effective thermal conductivity of batteries. In this talk various challenges and latest developments related to heat generation, thermal transport and properties of LIBs will be discussed. The importance of heat of mixing due to ion diffusion during fast charging will be also highlighted. Finally *operando* measurement of Lithium concentration inhomogeneity and plating under fast charging conditions using thermal wave sensing will be presented.

2:30 PM EN03.18.05
Late News: High Thermal Conductivity Continuous Fiber Reinforced Alkali-Halides for Cryogenic Electrical Isolation and Mechanical Reinforcement Christopher Kovacs[1], Timothy Haugan[2], Michael Susner[2], Jacob Adams[3], Emanuela Barzi[4], Daniele Turrioni[4], Devin Grant[5] and Leonard Jung[6]; [1]Hyper Tech Research Inc., United States; [2]Air Force Research Laboratory, United States; [3]Massachusetts Institute of Technology, United States; [4]Fermi National Accelerator Laboratory, United States; [5]Central State University, United States; [6]Purdue University, United States

A novel ceramic-ceramic fiber composite for use at cryogenic temperatures is presented in this research. Thermal properties, mechanical properties, and electrical properties are compared to more standard polymeric-ceramic fiber composites such as G-10 and CTD-101K/S-glass. It is shown that this composite can function in certain areas to reduce thermal impedance, while retaining sufficient mechanical properties and electrical isolation capability. Multiphysics simulations are used to predict improvements to applications such as cryogenic motors and magnets. Processing routes will be presented to incorporate this composite into windings.

2:45 PM EN03.18.06
Heat Transfer Between Metallic Nanofilaments and its Impact on the Electric Conductivity of Copper Nanofilament Marius K. Orlowski; Virginia Tech, United States

When a resistive random access memory (RRAM) memory crossbar array is switched repeatedly, a considerable amount of Joule heat is dissipated in the cells of the array [1,2]. A conductive nanofilament (CF) is heated in one cell by switching the cell frequently on and off and the electrical conductance of the CFs of the neighboring cells is measured. The neighboring cells have been set to a conductive low resistance state (LRS). The CF-to-CF heat transfer comprehends nanoscale heat transport from CF to the mesoscopic electrode and from mesoscopic electrode to another CF. When, under such heating conditions the electric properties of the neighboring cells are tested immediately after the heating of the heated cell has ended, we find that in most cases the neighboring cells are in in high resistance state (HRS) despite having been set to an LRS state prior to the heating. Thus remote heating ruptures the CFs, i.e. erases the neighboring cells. The probing of the neighboring cell is done at voltages much smaller than the minimum set voltage. The key findings are: (i) only for robust CFs (low resistance R_{on}) formed at high compliance current I_{cc}>0.2mA we find that the probed cell remains in an LRS state just after the heating of the heated cell. In most cases, we find slightly degraded resistance R_{on} compared with the original R_{on} value. (ii) For all probed cells that have been set at I_{cc}<0.2 mA (high resistance R_{on}), we find that the probed cell is in HRS immediately after completion of the heating of cell. However, when those cells are probed again, after 2 min or longer, we find the cell does no longer persist in HRS but returns of its own accord back to the original LRS state, with R_{on} in most cases the same as the original R_{on}. Thus, during the heat dissipation period, the CF in the probed cell spontaneously recovers and restores itself to the original R_{on} value to which they have been set prior to the heating. (iii) In a few cases we managed to capture the time evolution of the spontaneous restoration of the CF to LRS demonstrating the transient, non-equilibrium behavior of the heat transfer phenomenon. The heat dissipation time constant for our devices is of the order of 15s and depends strongly on the thermal conductivity of the metal electrodes. This behavior can be explained in terms of 3D resistor network with a unit resistance $R_o=1/G_o$ with $G_o=(2e^2/h)\times t$, where t is the electron tunneling probability from Cu atom to Cu atom of the CF and depends on the distance L between the two Cu atoms, thus $t\sim\exp(2kL)$ where the wave vector k depends on the barrier height between the two Cu atoms. The truncated pyramidal resistor 3D network describes accurately the resistance of the CF as a function of the number of surface Cu atoms at the vertex of the pyramid. We demonstrate experimentally the presence of the quantum conductance nature of the filament's resistance for this kind of Cu nanofilaments. The experiments point to a tight interaction between phonons of the oscillating Cu atoms and the electron tunneling rate between the Cu atoms. Harmonic oscillator model argues that the tunneling probability t is proportional to $\exp(-K\sqrt{T})$ with a constant K>0, implying that t decreases exponentially with increasing temperature and thus explains the transient effect of the heat dissipation. As shown elsewhere the local temperature T in a CF can be as high as 1500K [3]. We also show that the same heat transfer effects are substantially mitigated when the thermal conductivity of the electrodes is substantially increased. With modified electrodes replacing a 150nm thick Cu electrode by a 250nm thick and 50 nm thick Pt electrode by a Pt(50nm)/Cu(200nm) composite electrode the time dissipation constant can be reduced to less than 1 second.

Generative Design of Thermoelectric Materials Kedar Hippalgaonkar[1,2]; [1]Nanyang Technological University, Singapore; [2]Institute of Materials Research and Engineering, Singapore

Machine Learning (ML) and feature engineering have had success in predicting the thermoelectric (TE) performance of inorganic materials. Generally, there are two steps: the first involves featurizing the materials into numerical inputs in machine-readable format. The second step is the use of regression models to predict their TE performance, typically the powerfactor given by $S^2\sigma$. We have used this methodology to screen for potential undiscovered materials using a known database of compounds; we found that this ML screening process self-discovers Half-Heuslers as good materials with no prior knowledge. In addition, going beyond screening, there are a wide range of unexplored inorganics, which are not in any existing databases. I will describe our use of generative models, similar to generating new images learning from existing ones, that are expected to have high TE performance[1]. Finally, I will talk about our efforts at synthesizing some of these new predicted compounds and describe our progress in defining synthesizability of such new materials.

High-Throughput Characterization of Thermoelectric CuP_2 in Thin-Film Form Andrea Crovetto[1,2], Danny Kojda[1], Klaus Habicht[1], Thomas Unold[1] and Andriy Zakutayev[2]; [1]Helmholtz-Zentrum Berlin, Germany; [2]National Renewable Energy Laboratory, United States

Certain metal phosphides have recently been proposed as potential thermoelectric materials [1]. In particular, the simple binary CuP_2 possesses multi-valley degeneracy in the valence band and low-frequency acoustic phonon modes. These features are expected to enhance its electrical properties and lower its thermal conductivity respectively.

As CuP_2 has not been experimentally studied as a thermoelectric material yet, we have synthesized CuP_2 thin films for rapid thermoelectric characterization on specialized chips. The films are grown by reactive sputtering of a Cu target in a PH_3-containing atmosphere under a high phosphorus chemical potential.

Thermoelectric characterization is performed on CuP_2 films with different Cu/P ratios and thermal treatments. The films are deposited on multi-purpose chips for simultaneous characterization of electrical conductivity, Seebeck coefficient, and thermal conductivity as a function of temperature. We generally find high Seebeck coefficients, low thermal conductivities, and p-type conductivity. The electrical conductivity is rather low, owing to a low hole concentration in the films without external doping. We suggest that suitable p-type dopants should be found to increase the hole concentration. If these efforts are successful, CuP_2 would be a highly attractive earth-abundant thermoelectric material.

8:45 AM EN03.19.04
Native Defect Chemistry and Extrinsic Dopability Limits of Binary Sn-Based Chalcogenides Ferdaushi A. Bipasha[1,2], Lidia C. Gomes[2] and Elif Ertekin[1]; [1]University of Illinois at Urbana Champaign, United States; [2]National Centre for Supercomputing Applications, United States

In this work, we assess the full range of n-type and p-type dopability achievable in the group IV-VI binary chalcogenides with A1B1 stoichiometry, well-known to be excellent thermoelectric materials. Despite being well-studied, they are more commonly observed as p-type thermoelectric materials while n-type performance is more rarely reported in the literature. Yet, n-type thermoelectric performance is expected to be nearly as good as (SnSe, SnTe) and even better (SnS) than p-type, which has driven recent experimental interest in realizing n-type material. Therefore, we use first-principles methods to assess the limits of dopability in three Sn-based chalcogenides, SnS, SnSe, and SnTe, and establish whether there is room for improvement in reported n-type performance. By analysis of phase stability and defect chemistry, we assess the full range of dopability ranging from maximum p-type to maximum n-type that is possible in these compounds. While SnTe is degenerately p-type in all environments, we find that SnS and SnSe exhibit windows for both p-type and n-type dopability in the proper growth environment. We consider Bi and Br as candidate n-type dopants. This reveals that n-type carrier concentrations of $5(10^{17})$ cm^{-3} and $1.3(10^{18})$ cm^{-3} for SnS and SnSe respectively are achievable, which are in good agreement with experimentally reported concentrations. The differences in the dopability across all three compounds are attributed to differences in band edge positions and the allowable ranges of chemical potentials.

Local Study of the Evaporation Mass Flux in a Thin Liquid Film Using Thermoreflectance Experiments and Numerical Methods Xiaoman Wang, Seyed-Arman Ghaffari-Zadeh, Alan McGaughey and Jonathan A. Malen; Carnegie Mellon University, United States

Thin film evaporation is important in the design of heat pipes, desalination, lubrication, air conditioning, and medical devices. Existing theories suggest that with smaller film thickness, the local evaporation mass flux will increase due in part to an increased interfacial temperature that results from lower conduction resistance in the liquid. However, this mass flux will sharply decrease to zero as the film gets even thinner due to the increased interface forces that inhibit the escape of interfacial vapor molecules.
In this project, we present the first experimental effort to locally measure the evaporation mass flux in a liquid meniscus. The microscale lateral extent of the meniscus and sub-Kelvin liquid-vapor temperature differences (superheats) challenge conventional thermometry. Here, Frequency domain thermoreflectance (FDTR), a non-contact laser-based method with a lateral resolution of micrometers, is used. A non-monotonic experimental signal change is observed as a function of position in the thin film portion of the meniscus, where a high evaporation heat flux is expected. This experimental technique has been hitherto widely employed with micron-scale lateral resolution in thin solid films, but not when evaporation is present. To extract the evaporation heat transfer coefficient in the meniscus region from the obtained signal, we modify the analytical solution to the heat diffusion equation to account for the phase change. This modification provides a new paradigm for investigating heat flux discontinuity in thermal models. Furthermore, to account for the thickness variation in the meniscus we also analyze the data using a finite element simulation performed with ANSYS. The ANSYS simulations are first validated against the modified FDTR equation for uniform liquid thicknesses. The ANSYS model is also able to capture account for the variation in evaporative heat transfer coefficient that occurs within the region interrogated by the 3 ��m laser spot. A machine learning framework that uses neural networks is then used to find the optimal combination of meniscus thickness and evaporative heat transfer coefficient distribution to match the ANSYS model to the experimental data.

Heat Transfer Across Au/thiol Heterojunctions with Atomic Spatial Resolution Yee Kan Koh, Hongkun Li and Yuexiang Yan; National University of Singapore, Singapore

Heat transfer across organic-inorganic heterojunctions and solid/liquid interfaces, is crucial for applications such as photothermal cancer therapy and flexible hybrid thermoelectric materials. However, fundamental knowledge of heat transport at atomic scale is still limited, due to challenges to experimentally probe heat transport with an atomic spatial resolution. In this talk, we will discuss our recent results to experimentally measure the heat transfer across the Au/thiol heterojunctions. We integrate two pump-probe techniques, the picosecond transient absorption and time-resolved Raman spectroscopy, to concurrently monitor heating and cooling of gold nanorods and bonds in the conjugated ligands, with a sub-picosecond time resolution and an atomic spatial resolution. We find that bonds in the conjugated ligands are heated almost instantaneously and reach a peak temperature within ~1 ps after the nanorods were heated by the laser pulse. We attribute this fast heating to direct heating of bond by the non-equilibrium electrons in gold nanorods, due to the remote coupling across the Au-thiol heterojunction. Our analysis suggests that the remote coupling could contribute substantially to heat transport across Au-thiol heterojunctions.

11:15 AM EN03.20.03
Optimization of AuGe Thin Films for High-Sensitivity Thermometry Ethan A. Scott, Sueli Skinner Ramos and Tom Harris; Sandia National Laboratories, United States

Resistive thermometer materials enable transduction of temperature to a measurable electrical signal. Detection of this signal is limited by the material's temperature coefficient of resistance (TCR), the degree to which its fractional resistance changes in response to a change in temperature. AuGe has been demonstrated to yield a high TCR at low temperatures, which lends itself towards applications in cryogenic thermometry. Here, we investigate the role of annealing temperature and film thickness on the TCR of $Au_{0.17}Ge_{0.83}$, a composition of particular interest. Temperature-dependent electrical resistance measurements spanning 10 K to 300 K provide insight into the performance of the film, demonstrating orders-of-magnitude enhancement in sensitivity over commonly used materials such as pure metallic platinum. Furthermore, we observe that a movement towards thinner films provides additional enhancement in TCR with lower required annealing temperatures.

This work was performed, in part, at the Center for Integrated Nanotechnologies, an Office of Science User Facility operated for the U.S. Department of Energy (DOE) Office of Science. A portion of this work was supported by the Laboratory Directed Research and Development program at Sandia National Laboratories. Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

Non-Contact Thermal Metrologies Using SEM and Optical Microscopy Chris Dames[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

I will summarize several collaborative efforts to develop new non-contact methods for heating, thermometry, and thermal property measurements. The main focus will be on nanoscale techniques using SEM. The incident electron beam can serve as a point heat source, and in certain conditions the local sample temperature can also be deduced from the electrons leaving the sample. I also will briefly introduce an all-optical "structured illumination, thermal imaging" (SI-TI) technique which: can tolerate rough, porous, and/or scratched samples; enables parallel measurement of multiple samples in a single field of view; and uses software-controllable heating patterns which can be tuned to extract directional properties like the thermal conductivity tensor.

12:00 PM EN03.20.05
Aerosol Jet Printed 3 Omega Sensors for Thermal Conductivity Measurement Nicholas Kempf and Yanliang Zhang; University of Notre Dame, United States

The 3 omega (3ω) method is a trusted technique for measuring thermal conductivity – a fundamental material property of critical importance in a broad range of applications. However, traditional 3ω sensor processing requires some form of physical vapor deposition, such as metal evaporation or sputtering. Such 3ω sensor deposition techniques limit the materials and sample sizes applicable to the 3ω method. This work demonstrates an aerosol jet printing method to directly print silver 3ω sensors that yield accurate temperature-dependent measurement up to 300°C on materials with thermal conductivity ranging from 13 to 150 W/m-K. Thermal conductivity measurement with 3ω sensors conventionally sintered at 300°C agrees to independent laser flash measurement within 4% from room temperature to 150°C. Beyond 150°C, printed sensors display thermally activated tunneling effects that introduce significant errors in 3ω measurements. An unconventional rapid high-temperature sintering method is shown to eliminate the tunneling effects, producing sensors that agree within 3% of laser flash measurements from room temperature to 300°C. The rapid sintering profiles also reduced the sensor-substrate thermal boundary resistance of the printed sensors by as much as 88%. The direct printing of 3ω sensors creates opportunities for measurement of thermal transport properties in applications previously inapplicable to the 3ω method while the ultrafast sintering technique to eliminate tunneling effects and significantly reduce the sensor-substrate thermal contact resistance has implications for many types of aerosol jet printed sensors.

12:15 PM EN03.20.06
Which Material Property Should be Reconstructed from Thermal Spectroscopy Experiments? Mojtaba Forghani[1] and Nicolas Hadjiconstantinou[2]; [1]Stanford University, United States; [2]Massachusetts Institute of Technology, United States

Phonon transport properties, such as phonon relaxation-time and free path distributions, play an essential role in the study of nanoscale solid-state heat transfer. Reliable descriptions of these properties are required for modeling heat transport at the kinetic level, which becomes necessary due to the failure of Fourier-based analyses at micron/sub-micron scales. Applications of practical interest include improved heat management in nanoelectronic circuits and devices, microelectromechanical sensors, and nano-structured materials for improved thermoelectric conversion efficiency.

Theoretical approaches such as density functional theory (DFT) have been widely used to calculate phonon transport properties, but have yet to gain widespread acceptance, in part due to their inability to consistently reproduce experimental observations. An alternative class of approaches relies on extracting material constitutive information from thermal spectroscopy experiments. However, the analysis of thermal spectroscopy data remains a challenging task. One such analysis technique seeks to extract the cumulative distribution function of thermal conductivity as a function of the phonon free path, $F(\Lambda)$, from the experimentally measured thermal responses using the "effective heat conductivity" concept. This approach attempts to match the experimentally measured response to solutions of the heat conduction equation with the thermal conductivity (or thermal diffusivity) treated as an adjustable, "effective", property. Unfortunately, as it was discussed previously (see [Physical Review B 94, 155439 (2016)] and [Physical Review B 97, 195440 (2018)]), among many other approximations, this procedure implicitly assumes that heat transport is Fourier-like, which is only justified under fairly restrictive conditions of late times and large scales that are not always satisfied under experimental conditions.

In this work, we discuss some fundamental issues associated with the analysis of thermal spectroscopy experiments, such as the uniqueness of reconstructed quantities (e.g., $F(\Lambda)$), as well as their ability to reproduce the experimental results (e.g., temperature profiles). In particular, we show that approaches that are based on reconstruction of $F(\Lambda)$ (as a means to defining "effective heat conductivities") fail to guarantee a unique thermal response. This can be understood by noting that it is the relaxation-time and *not* $F(\Lambda)$ which appears as a primary material-parameter input to the Boltzmann transport equation (BTE). Specifically, we show that the same $F(\Lambda)$ can be arrived at from multiple relaxation-time functions, which, in general, will correspond to multiple thermal responses. This observation seriously questions the reliability of approaches which use $F(\Lambda)$ in the reconstruction. This implies that in the context of thermal transport at the nanoscale within the Boltzmann relaxation-time approximation framework, the "fundamental" property that should be reconstructed from the thermal spectroscopy experiments is the frequency-dependent relaxation-times function (provided group velocities are known), since it explicitly appears in the BTE as the input material property.

In response to the failure of effective heat conductivity-based methods, we developed and extensively validated (on both synthetically generated and experimentally measured data) an optimization-based methodology for directly reconstructing frequency-dependent phonon relaxation-times from thermal spectroscopy data [Physical Review B 94, 155439 (2016); Physical Review B 97, 195440 (2018); Applied Physics Letters 114, 026103 (2019)]. Extensive validation, including global optimization studies, shows that this formulation provides numerically unique solutions and is robust to the noise in the measurement.

SYMPOSIUM EN04

Silicon for Photovoltaics
November 29 - December 7, 2021

Symposium Organizers
James Bullock, The University of Melbourne
Kaining Ding, Forschungszentrum Jülich GmbH
Ivan Gordon, imec

SESSION Tutorial EN04: The Physics and Engineering of Crystalline Silicon Photo-Voltaic Conversion, Technology and Systems
Session Chairs: Kaining Ding and Arno Smets
Monday Afternoon, November 29, 2021
Virtual

1:30 PM
The Physics and Engineering of Crystalline Silicon Photo-Voltaic Conversion, Technology and Systems Arno Smets; Delft University of Technology, Netherlands

All major future energy scenarios forecast a key role for photovoltaic solar energy. The crystalline silicon PV technology will dominate the future residential and large-scale utility PV applications. The learning objective of this comprehensive tutorial are 1) understanding the fundamental principles of photovoltaic energy conversions; 2) understanding of the physics and chemistry behind materials and interface engineering for crystalline silicon PV technology, 3) understanding of the design principles of the various silicon PV device architectures and module concepts and 4) the understanding of the role of a circular value chain of crystalline silicon photovoltaics in the energy transition towards a 100% renewable energy future.

The Fundamental Principles of Photovoltaic Energy Conversion

The key factor in getting more efficient and cheaper solar energy panels is the advance in the development of photovoltaic cells. In part 1 you will learn how photovoltaic cells convert solar energy into useable electricity. You will also discover how to tackle potential loss mechanisms in solar cells. By understanding the semiconductor physics and optics involved, you will develop in-depth knowledge of how a photovoltaic cell works under different conditions.

Materials and Interface Engineering for Crystalline Silicon PV Technology

The nature of the materials and interfaces for crystalline silicon PV will be presented. In Part 2 you will gain the latest insights how impurities, doping, crystal orientation, interstitials, and defects affect the optical and electrical performance of the novel materials and interfaces. A special focus will be on new materials, processing methods and innovative interface engineering (chemical and electrical passivation) for passivating contacts.

Introduction in to Silicon PV Device Architectures and Module Concepts

In part 3 you will be introduced to the recent advances in the development of the various crystalline silicon device architectures. You will use the design rules, to reduce the optical and electrical losses as discussed in Part 1, to understand the underlying principles of Al Back Surface Field solar cells, Partial Back Contact (PERC) solar cells, heterojunction junction solar cells (HJ/HIT), interdigitated back contact (IBC), tunnel oxide passivated contact (TOPCon), bifacial solar cells and hybrid multi-junction PV concepts. In addition, you will be introduced to the design rules to manufacture PV modules using PV cells. The various modules architectures and the recent advances will be reviewed.

The Role of Circular Value Chain of Crystalline Silicon Photovoltaics in The Energy Transition Towards a 100% Renewable Energy Future

All major future energy scenarios forecast a key role for photovoltaic solar energy. In part 4 the important role of crystalline silicon in future residential and large-scale utility PV applications will be discussed. You will be introduced to new metrics -beyond that of module efficiencies- that will be important for the successful upscaling of the PV technologies in the coming decades.

SESSION EN04.01: PV Systems, Light Management and Surface Passivation
Session Chair: Brett Kamino
Wednesday Afternoon, December 1, 2021
Hynes, Level 3, Room 305

1:30 PM *EN04.01.01

New Tools for Modeling and Metrology of Silicon Module Degradation Modes Rishi Kumar[1], Erick Martinez-Loran[1], Guillaume von Gastrow[1], Jacob Clenney[2], April Jeffries[2], Nicholas Theut[2], Tala Sidawi[1], Rico Meier[2], Mariana Bertoni[2] and David P. Fenning[1]; [1]University of California, San Diego, United States; [2]Arizona State University, United States

In this talk, I will share our recent findings regarding silicon module durability arising from tools we have developed to study potential induced degradation (PID) and the effects of moisture. PID has re-emerged as an alarming reliability issue in silicon PV. Sodium is known to be correlated with PID of the shunting type, but a quantitative description of its kinetics in PV modules has been lacking. I will describe a finite element method model of PID we have developed that relies only on parameterization of Na kinetics within the module stack. This parameterization can be directly correlated with the bill of materials. We use a series of bottom-up and top-down experimental approaches to validate the model, including a new method to measure the kinetics of mobile ion migration through dielectric layers. Ultimately, we provide a sensitivity analysis of PID rates on the bill of materials that can serve as a guide toward robust modules.

The second part of the talk will focus on moisture impacts. Moisture is implicated in many modes of performance degradation in silicon PV, but it has proved difficult to assess the water content within modules to determine its direct role in degradation reactions. We have developed a short-wave IR optical Water Reflectometry Detection (WaRD) technique to quantify moisture levels within the module. We combine this moisture measurement with correlative luminescence imaging to track water content and cell performance at millimeter resolution over 2500 hours of accelerated testing at multiple levels of humidity and temperature. The approach reveals dominant modes of power loss with distinct and rather counterintuitive moisture sensitivities in glass-glass vs. glass-backsheet packages. Metallization interrupts in fingers occur earliest in dry conditions and are delayed in backsheet modules at higher humidity, suggestive of plasticization of the backsheet. Background series resistance sharply increases in backsheet modules at high humidity, by a mechanism not seen in glass-glass modules. Overall, we dissect the losses over time to attribute the marginal power loss from each mode as a function of temperature, humidity, and package type.

These new tools for durability science should aid in understanding the progression and severity of module degradation modes, the development of targeted accelerated tests, and ultimately new technologies that extend silicon durability.

2:00 PM EN04.01.02

Late News: Circularity Impacts of Waste-Management Scenarios for Photovoltaics Acadia Hegedus[1], Silvana Ovaitt[2], Julien Walzberg[2], Heather Mirletz[2,3] and Teresa Barnes[2]; [1]Middlebury College, United States; [2]National Renewable Energy Laboratory, United States; [3]Colorado School of Mines, United States

Solar photovoltaic (PV) technologies are at the forefront of the clean energy transition, with at least 1 TW of PV installations projected by 2050. There will be a cumulative demand for 56 million metric tonnes of virgin material by 2050, considering future PV technology evolution and current end-of-life (EoL) management practices. 17 million metric tonnes of waste will need to be managed as PV modules have a lifetime of around 30 years. To mitigate negative impacts and ensure the increased solar energy deployment is sustainable, a circular economy (CE) for PV must be implemented. A quantitative analysis of waste-management interventions is needed to identify which actions should be taken to promote a CE for crystalline-Silicon (c-Si) PV while integrating future technology improvements and social factors. Here, we use a novel, dynamic, Python-based tool called PV ICE (PV in the Circular Economy), created by researchers at the National Renewable Energy Laboratory (NREL), to quantify the future mass flow impacts of ten waste-management interventions. The interventions and corresponding EoL pathway rates come from Walzberg et al.'s agent-based model (ABM). This ABM considered social factors to predict human behavior and decision-making surrounding PV EoL. Progressive simulations were run using PV ICE to explore the impact of improving circular EoL pathways, recycling efficiencies, and module reliability. The results suggest that a certain intervention, *Landfill ban*, can drastically reduce cumulative PV EoL waste to only 2 metric tonnes by 2050. Improving module reliability (*Improved lifetime*) is shown to have a powerful impact on maintaining installed capacity, increasing from 0.77 TW to 0.95 TW by 2050. When seeking to maintain a target capacity, lower quality modules can demand up to 16% more virgin materials and produce 200% more waste, pointing to the importance of module reliability for circularity. Further research should widen the scope of the intervention analysis to include energy and cost considerations.

2:15 PM EN04.01.03

Photonic Mirror Light Management in Bifacial Photovoltaics Bryan Cote[1], Ian M. Slauch[1], Timothy J. Silverman[2], Michael Deceglie[2] and Vivian E. Ferry[1]; [1]University of Minnesota Twin Cities, United States; [2]National Renewable Energy Laboratory, United States

Bifacial photovoltaics are expected to gain significant market share over the next decade due to the reduced levelized cost of energy. However, the thermal performance of bifacial modules is not yet well understood, nor have thermal management strategies been developed for this module configuration. Elevated operating temperatures in Si photovoltaics led to both diminished efficiency and accelerated module degradation.
A significant percentage of this waste heat is generated by sub-bandgap parasitic absorption within the module. Because of this, spectrally selective mirrors that act as above bandgap antireflection coatings and sub-bandgap light rejectors are a promising photon management strategy for reducing the operating temperature of monofacial photovoltaics. However, it remains an open question whether bifacial photovoltaics that possess partial sub-bandgap transparency thermally benefit from this light management strategy. Here we use rigorous finite-element simulations to study the performance benefits of spectrally-selective mirrors on bifacial modules.
The optical properties of test modules containing commercial, 20.6 % efficient bifacial PERC cells were modeled using a combination of ray-tracing, Beer's law, and transfer matrix calculations. This optical description was combined with a view-factor irradiance model with SMARTS2 integration and a finite-element model to solve for the module's temperature and power output over a typical meteorological year.
We first studied idealized mirrors, with unity above-bandgap transmittance and unity sub-bandgap reflectance, to determine the limits to performance. To mimic laboratory tests, AM1.5G irradiance was normally incident on the module's front face while irradiance on the rear face was varied. When there is no rear irradiance, applying mirrors at either the front only or the front and rear provided an approximate 4 % optical benefit, corresponding to the reflectance of an air/glass interface, as well as a 1.1 % thermal benefit, equating to 2.7 °C of module cooling. These results show that partial sub-bandgap transparency does not prohibit spectrally selective mirrors from being a promising thermal management strategy. As the rear irradiance increased, the configuration with the mirror only on the front exhibited decreasing optical and thermal benefits, due to a decreasing percentage of above-bandgap light incident on the front face and sub-bandgap light trapping of rear side incident light, respectively. With mirrors on both interfaces, the optical benefit was maintained as rear irradiance increased, and the thermal benefit increased linearly due to the linear increase in sub-bandgap irradiance rejection.

We then developed 4- and 6-layer photonic mirrors using real materials and compared performance to a traditional antireflection coating (ARC). The mirror designs were classified as thermally aware ARCs, providing 0.2 and 0.6 % more above bandgap antireflection than a traditional ARC, without the associated -0.13 % thermal penalty. Adding a rear spectrally-selective mirror improved the optical benefit when placed over high albedo ground, but also led to an increase in sub-bandgap light trapping, as observed by a small, 0.02 % thermal penalty.
In addition to the studies described above, the idealized and realistic mirrors' performance were tested in single-axis tracking arrays at varying row spacings, array height, and at 12 different US cities. Each study provided insight into how varying angle of incidence distributions, rear irradiance fractions, total irradiance, and varying climate affect the optical and thermal benefits the mirrors can provide.
Our results indicate that spectrally-selective mirrors enhance the energy yield of bifacial photovoltaics through a combination of improved anti-reflection and reduced operating temperature.

Biomimetic Broadband Antireflection Coatings for Highly Efficient Crystalline Silicon Photovoltaics Peng Jiang; University of Florida, United States

Millions of years before people began to generate functional nanostructures, biological systems were using nanometer-scale architectures to produce unique functionalities. Some nocturnal moths use hexagonal arrays of subwavelength nipples as antireflection coatings to reduce reflection from their compound eyes. Similar periodic arrays of nanopillars have also been observed on the wings of cicada to render superhydrophobic surfaces for self-cleaning functionality. Inspired by these natural nanostructures, we have developed three scalable nanofabrication technologies based on colloidal self-assembly, maskless reactive ion etching, and metal-assisted chemical etching for producing wafer-scale, self-cleaning, broadband antireflection coatings on a large variety of PV-relevant substrates, such as single-crystalline silicon, multicrystalline silicon, GaAs, GaSb, and glass. These techniques combine the simplicity and cost benefits of bottom-up self-assembly with the scalability and compatibility of standard top-down microfabrication. The resulting subwavelength-structured antireflection coatings can greatly suppress light reflection from both crystalline silicon and encapsulating glass surfaces, enhancing light absorption and ultimate conversion efficiency of the crystalline silicon solar panels. Importantly, optimal moth-eye antireflection nanostructures with tapered geometries can be easily passivated by conventional passivation technologies, resolving an outstanding challenge faced by many other black silicon approaches.

Effectively Transparent Contacts for Elimination of Shading Losses in Concentrator Solar Cells Stefan Tabernig[1], Anastasia Soeriyadi[2], Udo Roemer[2], Andreas Pusch[2], Dimitry Lamers[1], Michael Nielsen[2], Albert Polman[1] and Nicholas Ekins-Daukes[2]; [1]AMOLF, Netherlands; [2]University of New South Wales, Australia

Concentrator solar cells have served as the absolute efficiency record holder for more than 25 years. Contrary to non-concentrator photovoltaics (PV), where silicon has been the flagship absorber material, concentrator PV research has been dominated by high efficiency III-V absorber layers. The main reason for this is that high Auger losses impose a comparably lower efficiency limit onto Si solar cells under concentration. Beyond the higher efficiencies of concentrator solar cells due to a logarithmic gain in open-circuit voltage, the amount of material needed per unit area scales inversely with increasing concentration. While Auger recombination might be an overall limit for efficiencies of Si concentrator solar cells, the option of saving material per unit area is becoming increasingly attractive. Considering projections of worldwide shortages for elements such as Ag, Cu, In etc, partially caused by the quickly rising demand of the Si PV industry itself, the time for concentrator Si PV might have come.

In this work we introduce a patterned and transparent polymer structure that attempts to address two problems that do not only apply to Si concentrator PV (CPV) but to CPV in general. First of all we want to solve the unsatisfying trade-off between shading losses that arise from high front metal coverage and Joule losses that increase with lower front metal coverage. Secondly, the same structure will actually allow for a decrease of the total area required to obtain a certain short-circuit current density (J_{SC}), due to lower shading losses.

The mentioned structure is a transparent polymer layer with V-shaped grooves, imprinted above the cell's metal fingers. These V-grooves redirect light away from the metal grid and onto the absorber material. This renders the contacts effectively transparent and breaks the trade-off between shading losses and Joule losses from the metal grid, thus allowing for higher concentration ratios and higher efficiency. We will demonstrate how performance of a Si solar cell with 25% front metal grid coverage and an initial short-circuit current density (J_{SC}) of 29.95 mA/cm^2 can be improved to a J_{SC} of 39.12 mA/cm^2 after adding the patterned polymer, mitigating shading losses almost completely. Optical microscope images as well as reflection data from integrating sphere measurements confirm that the contacts have become effectively transparent, showing little to no metal-grid-related features in the reflection spectrum. Furthermore, we will show that the angular performance of the V-grooves allows for shading losses to remain absent for concentrations beyond 1000 suns. Lastly, we present experimental IV-data of solar cells with V-grooves under concentration.

To conclude, the polymeric V-groove design allows for complete mitigation of shading losses, even with high metal coverage. In a concentrator system, this would allow for higher efficiencies, and especially higher power output per unit solar cell area compared to non-concentrating PV. Furthermore, lower shading losses also mean less area usage per concentrator system, as less concentration is needed to achieve the same J_{SC}. This could be beneficial as it might allow for cheaper and simpler concentration optics.

Understanding the Role of Hydrogen Plasma Treatment and Thermal Annealing in Improving the a-Si:H/c-Si Interface Passivation Anishkumar Soman, Dhamelyz Silva-Quinones, Steven Hegedus, Andrew Teplyakov and Ujjwal Das; University of Delaware, United States

The solar industry has seen rapid growth over the last few decades with installations over 600 GW contributing to over 2.2% of the global electricity[1]. Silicon (Si) solar cells contribute to the bulk of the PV market, having more than 95% of the total production. The trend is for advanced high-efficiency device structures on n-type monocrystalline silicon to dominate by 2025%[2]. Current examples having commercial-scale production include tunnel-oxide passivated contact (TOPCon), Interdigitated back contact (IBC), and Heterojunction (HJ), which employs advanced improved interface passivation. In particular, Si HJ structures could be favorable due to their ease of fabrication, compatibility with thin wafers (< 100 µm), low thermal budget (< 300°C), and potential to reduce the cost per watt. The performance of these solar cells critically depends on the interface passivation quality of the amorphous silicon (a-Si:H) and crystalline silicon (c-Si) hetero-interface. It has been shown that extrinsic methods like hydrogen plasma treatment (HPT) and thermal annealing treatment (AT) strongly enhance the passivation of dangling bonds at the a-Si:H/c-Si interface[3]. In this work, we have investigated the underlying surface passivation mechanism of HPT and AT by analyzing the hydrogen bonding using Fourier transform Infrared spectroscopy. The hydrogen bonding environment in a-Si:H samples undergoing different treatments has been corroborated with the passivation quality in terms of effective minority carrier lifetime and implied open-circuit voltage (iV_{OC}) measured by quasi-steady-state photoconductance. Our initial results show that just AT reduces the Si-H_2 dihydrides, whereas a combination of HPT with AT improves monohydride concentration, in addition to the reduction of the dihydride

complexes, and resulted in higher minority carrier lifetime & implied V_{OC}. Temperature-dependent infrared spectroscopic analysis helps to understand the kinetics of hydrogen redistribution and effusion from the a-Si:H films due to annealing and will probe the activation energies of these processes. This will provide a complete understanding of the passivation improvement mechanism under the post-deposition extrinsic treatments. Additional characterization of the HJ structures was performed using Raman and UV-VIS-NIR spectroscopy to validate the quality of the a-Si:H films and interfaces to be used for making Silicon Heterojunction solar cells.

Spotlight Talk—Scanning Nonlinear Dielectric Microscopic Investigation of Active Dopant Density Distribution in Black Silicon Solar Cell Yasuo Cho[1], Beniamino Iandolo[2] and Ole Hansen[2]; [1]Tohoku University, Japan; [2]Technical University of Denmark, Denmark

Black silicon (Si) is a nanostructured type of Si capable of near-total absorption of light. Therefore, the use of black Si can lead to highly efficient solar cells. The performance of Si solar cells is dependent on the active dopant carrier distribution in emitters. The carrier distribution in black Si solar cells has been difficult to measure, and thus to optimize, due to the irregular, nano-scaled structure of the emitter.[1]-[5]
Thus, obtaining more information regarding active dopant density distribution in black Si solar cell requires measurements of carrier distributions on a nanoscopic scale.
One of the authors have previously succeeded in quantitatively analyzing such distributions in monocrystalline Si solar cells using scanning nonlinear dielectric microscopy (SNDM) [6]-[9].
In the present study, we investigated quantitatively the carrier distribution in a phosphorous (P) diffused black Si solar cell using SNDM. As a reference, we also measured the carrier distribution on a flat Si sample fabricated under the same P diffusion conditions. The precise carrier distributions in the emitter were visualized, which revealed the feature of carrier distribution in the emitter of black Si solar cell. Super-higher-order-SNDM was also employed to perform a quantitative analysis of the depletion layer distribution. It was found that the carrier density profile and the depletion layer thickness is less regular in the black Si than in the flat emitter, suggesting that this fluctuation may affect the power conversion efficiency of black Si solar cell.
This work demonstrates that SNDM is a very useful means of investigating carrier distributions in the nano-scaled emitter of black Si solar cell.

Spotlight Talk—CV Analysis of c-Si Surface Passivation by H2S Reaction Isaac K. Lam[1,2], Tasnim K. Mouri[1,2], Anishkumar Soman[1,2], William Shafarman[1,2] and Ujjwal Das[2]; [1]University of Delaware, United States; [2]Institute of Energy Conversion, United States

The desired direction for modern c-Si solar cells is to make them both thinner and higher efficiency, which makes passivation of the c-Si surface to reduce interface recombination a top priority. Traditional passivation techniques such as thermal oxidation and a-Si can cause issues in processing due to various temperature limitations [1]–[3]. Passivation of the c-Si surface using H_2S gas has been demonstrated to produce high quality passivation and has resulted in high (>2000 µs) minority carrier lifetimes [4]. It has been demonstrated that by H_2S reaction, c-Si surface dangling bonds can be reduced by bonding with S [4].

This work presents an investigation of the surface passivation mechanism by S by capacitance-voltage-frequency (C-V-f) measurements and will be compared with the surface passivation process by SiN_x, and a-Si. Surface passivation quality is quantified by effective minority carrier lifetime (τ_{eff}) measured by quasi-steady-state photoconductance and the interface trap density (D_{it}) and fixed charge (Q_{fix}) are obtained from C-V-f measurements. The metal-insulator-semiconductor (MIS) structures were fabricated with the Si surface passivated by different materials for C-V-f measurements.

Lifetime and CV data are used together to characterize the passivation quality of the different treatments on two types of c-Si wafers. Both the a-Si and H_2S treatments ($\tau_{eff} \approx 1000$ µs and 1700 µs for a-Si and H_2S treatment, respectively) show better passivation than the SiN_x,($\tau_{eff} \approx 14$ µs) with the H_2S giving the highest lifetime. Additionally, the data shows a reduction in Q_{fix} when the H_2S passivation process is used compared to the SiN_x sample, with $Q_{fix} = 7.5\times10^{11}\,cm^{-2}$ and $2.1\times10^{13}\,cm^{-2}$, for H_2S and SiN_x respectively.

The change in lifetime is explained by Q_{fix} and D_{it} which are functions of passivation quality. CV data allows calculation of Q_{fix} and D_{it}, which are used to fit the lifetime data using the method of Shu et al. [7][8], and further allowing for extraction of electron and hole capture cross sections (σ_n, σ_p).

In summary, two types of c-Si wafer with three different passivation treatments will be used to prepare MIS devices for CV measurement. Fixed charge calculated based on CV data shows a reduction in Q_{fix} for H_2S samples compared to the SiN_x passivated sample. Additionally, qualitative analysis of the CV curves as well as fitting of lifetime data shows a reduction in D_{it} for the H_2S samples, indicating high-quality passivation of the c-Si surface is due to low $D_{it} \approx 4.0\times10^{10} cm^{-2}eV^{-1}$ with a moderate positive Q_{fix}.

A detailed comparative study of interface passivation mechanisms by SiN_x, a-Si, and H_2S treatment will be provided in the final conference submission. Additionally, low frequency capacitance measurements, and conductance vs. AC frequency measurements will be included for all samples, which will allow for an accurate and quantitative determination of D_{it} for all samples. This in turn will yield a more robust lifetime fit to extract values for capture cross sections.

[7][8], and further allowing for extraction of electron and hole capture cross sections (σ_n, σ_p).

In summary, two types of c-Si wafer with three different passivation treatments will be used to prepare MIS devices for CV measurement. Fixed charge calculated based on CV data shows a reduction in Q_{fix} for H_2S samples compared to the SiN_x passivated sample. Additionally, qualitative analysis of the CV curves as well as fitting of lifetime data shows a reduction in D_{it} for the H_2S samples, indicating high-quality passivation of the c-Si surface is due to low $D_{it} \approx 4.0\times10^{10}$cm^{-2}eV^{-1} with a moderate positive Q_{fix}.

A detailed comparative study of interface passivation mechanisms by SiN_x, a-Si, and H_2S treatment will be provided in the final conference submission. Additionally, low frequency capacitance measurements, and conductance vs. AC frequency measurements will be included for all samples, which will allow for an accurate and quantitative determination of D_{it} for all samples. This in turn will yield a more robust lifetime fit to extract values for capture cross sections.

Spotlight Talk—Scanning Nonlinear Dielectric Microscopic Investigation of Active Dopant Density Distribution in Black Silicon Solar Cell Yasuo Cho[1], Beniamino Iandolo[2] and Ole Hansen[2]; [1]Tohoku University, Japan; [2]Technical University of Denmark, Denmark

Black silicon (Si) is a nanostructured type of Si capable of near-total absorption of light. Therefore, the use of black Si can lead to highly efficient solar cells. The performance of Si solar cells is dependent on the active dopant carrier distribution in emitters. The carrier distribution in black Si solar cells has been difficult to measure, and thus to optimize, due to the irregular, nano-scaled structure of the emitter.[1]-[5]
Thus, obtaining more information regarding active dopant density distribution in black Si solar cell requires measurements of carrier distributions on a nanoscopic scale.
One of the authors have previously succeeded in quantitatively analyzing such distributions in monocrystalline Si solar cells using scanning nonlinear dielectric microscopy (SNDM) [6]-[9].
In the present study, we investigated quantitatively the carrier distribution in a phosphorous (P) diffused black Si solar cell using SNDM. As a reference, we also measured the carrier distribution on a flat Si sample fabricated under the same P diffusion conditions. The precise carrier distributions in the

emitter were visualized, which revealed the feature of carrier distribution in the emitter of black Si solar cell. Super-higher-order-SNDM was also employed to perform a quantitative analysis of the depletion layer distribution. It was found that the carrier density profile and the depletion layer thickness is less regular in the black Si than in the flat emitter, suggesting that this fluctuation may affect the power conversion efficiency of black Si solar cell. This work demonstrates that SNDM is a very useful means of investigating carrier distributions in the nano-scaled emitter of black Si solar cell.

Production Application of Poly-Si Junction Passivated Contact Technology—Champion Solar Cell and Module Product Performance Xinyu Zhang, Peiting Zheng, Menglei Xu and Zhiqiu Guo; JinkoSolar Co., Ltd, China

The global power generation is in a transition toward renewable energy forms in a visible speed. Photovolotaic (PV) technology using crystalline silicon solar panels is playing a more important role, with more than 500GW global installation and relevant solutions becoming more mature. Continuous solar cell efficiency improvement is a dominating factor that accelerates PV industry in recent years, where the mainstream technology Passivated Emitter and Rear Contact (PERC) allows an average solar cell efficiency from 21% to 23%. However, further efficiency increase is limited by the significant carrier recombination loss at the metal-silicon interface regions. Hence, the passivating contacts have attracted great attention in both the research and the industry society, where polysilicon (poly-Si) tunnel junction technology using a thin silicon oxide tunneling layer and doped polysilicon carrier selective layer combination. It allows the contact interface region to achieve a significantly reduced recombination rate and increased open circuit voltage reaching 720mV. The laboratory world records for homo-junction cells, either front-rear contacted or back-contacted, utilized such passivating contact structure: the 25.8% efficiency n-type TOPCon cell from ISE Freiburg and the POLO-IBC cell from ISFH. Strong interests from the PV industrial players promote a rapid development of passivated contact technology in the manufacturing level. This work presents JinkoSolar’s latest attempt of achieving over 25% efficiency for passivated contact structure solar cells using production size n-type silicon wafers.

Solar cell performance
This work presents the overall performance of solar cells from several production batches, where the average efficiency is over 24.8%. Among the batch results, the champion cell achieve a third-party certified efficiency of 25.25%, with an open circuit voltage (Voc) of 715 mV and a fill factor of 84.9%. The distribution of batch cells’ electrical performance indicates a strong alignment between the cell efficiency and the fill factor, where the fill factor parameters vary in a relatively large range. It well suggests that the contact quality of the passivated contact solar cells using screen printing technique is crucial, which is determined by various factors such as the screen paste composition, contact region surface morphology, poly junction thickness and doping concentration, quality of the tunneling oxide layer, etc. This work presents some specific characterization resulting aiming to explain the contacting mechanism of a high efficiency poly-Si passivated contact solar cell. In addition, several loss analysis have been performed for the champion cell.

Module performance and the field performance
Manufacturing produced passivated contact solar cells, particularly those commonly referred as n-type TOPCon cell by the PV industry, are relatively new to the market, with only limited field performance record. Thus the module reliability research for passivated contact technology is a hot research topic, major evaluation methods include a serious of IEC standard tests such as temperature circle, dump heat test, potential induced degradation test, and so on. This work will present some testing and result details. In addition, this work will also present some field power generation results of passivated contact technology modules, including the analysis of performance improvement comparing to conventional PV modules.

8:30 AM EN04.04.03
Fabrication of solar cells with poly-SiO_x Carrier Selective Passivating Contacts on Ultra-Thin Thermal Tunnelling Oxide Manvika Singh[1], Aswathy Amarnath[1], Guangtao Yang[1], Arthur Weeber[1,2], Miro Zeman[1] and Olindo Isabella[1]; [1]Delft University of Technology, Netherlands; [2]TNO Energy Transition, Netherlands

Polycrystalline silicon (poly-Si) has proven to be a game-changing material in the field of high thermal budget carrier-selective passivating contacts (CSPCs) for c-Si solar cells beyond PERC architecture [1]-[4]. However, doped poly-Si exhibits a very high free carrier absorption (FCA), which has turned the attention of researchers towards wide bandgap materials, such as poly-SiO_x [5][6]. In these materials, the opto-electronic properties depend on oxygen [6][7] alloying. Such CSPCs consist of heavily doped poly-Si alloyed with oxygen and deposited on an ultra-thin SiO_x layer, prepared by thermal oxidation [8], wet-chemical process [6], UV/O_3 process [9], or low temperature plasma oxide [10]. Solar cells fabricated with such CSPCs on wet-chemical tunnelling SiO_x have exhibited illuminated efficiency of around 21% in front/back contacted (FBC) architecture [11]. In this work, building on our single-side poly-SiO_x processing, an ultra-thin SiO_x layer prepared by thermal oxidation was used as tunnelling oxide. The advantages of using this type of oxide are better uniformity on textured interfaces and better control over the oxidation rate by changing the oxygen flow rate, temperature, and time.
First, we optimized the passivation of n-type and p-type doped poly-SiO_x CSPCs symmetric samples. Ultra-thin thermal oxide of around 1.5 nm was grown at 675 °C for 6 minutes. The standard thickness of the poly-SiO_x layer is around 30 nm for both polarities. An in-situ, single side, doping approach using PH_3 or B_2H_6 gas flow was used to dope the poly-SiO_x CSPCs to n-type or p-type, respectively. Double side textured n-type and double side flat p-type doped poly-SiO_x symmetric samples give an iV_{oc} of 690 mV after annealing and iV_{oc} of 710mV after hydrogenation.
Single side textured FBC c-Si solar cells passivated with poly-SiO_x were fabricated on n-type FZ wafers and using the optimized n-type and p-type doped

poly-SiO_x CSPCs. These were realized by using n-type poly-SiO_x layer on the sunny side and p-type poly-SiO_x layer on the rear flat surface. All solar cells were annealed at 950 °C for 10 minutes to crystallize the poly-SiO_x layers and drive in the dopants. In this high temperature process, hydrogen effuses from c-Si bulk/SiO_x interface. So, these cells were hydrogenated by forming gas annealing (FGA) at 400 °C for 1 hour after being preliminarily capped with 100-nm thick PECVD SiN_x layer. Upon the removal of SiN_x, indium tin oxide (ITO) layers were sputtered (75-nm and 150-nm thick at front and back side, respectively) to ensure efficient lateral carrier transport of charge carriers. The front ITO layer also acts as anti-reflective coating. Screen printing was used to deposit front and rear metallic contacts. The best solar cell gave an illuminated efficiency of 21.44% (V_{oc} = 697 mV, J_{sc} = 38.52 mA/cm^2, FF = 79.86%, metallization faction ~3%, illuminated area = 3.92 cm^2). Moving from wet-chemical tunnelling SiO_x and evaporated metallic contacts [11] as well as further optimizing our doped poly-SiO_x layers, we could improve both the V_{oc} and the FF of our solar cells based on poly-SiO_x by an absolute 0.7%. Currently we are analysing the integration of this poly-SiO_x passivated c-Si solar cell as bottom cell in 2T perovskite/c-Si tandem configuration. The results will be presented at the conference.

Structure and Electronic Properties of Mesopores in Si PV Devices with PLEO Contacts Harvey Guthrey[1], Caroline Lima de Souza[1,2], William Nemeth[1], Matthew Page[1], David L. Young[1], Sumit Agarwal[2] and Paul Stradins[1]; [1]National Renewable Energy Laboratory, United States; [2]Colorado School of Mines, United States

All current state-of-the-art silicon photovoltaic (PV) devices employ some flavor of passivating contact structure to minimize detrimental recombination while providing good conductivity. These properties are most often provided by a dielectric layer (SiN_x, Al_2O_3, or SiO_x) that is in contact with the crystalline silicon (c-Si) substrate. The effectiveness of these layers is heavily dependent on the nanoscale structure of both the dielectric layers and the crystalline silicon interface. As an example, the tunneling probability for charge carriers across thin SiO_x layers, a process that is critical to maintain high conductivity, is extremely sensitive to the SiO_x thickness. SiO_x with a thickness below 2 nm readily allows charge carrier tunneling, whereas it is impeded for greater thicknesses. In the latter case it has been shown that modifications to the thermal processing schedule can induce disruptions, or pinholes, in thick SiO_x layers that allow transport of charge carriers while maintaining excellent passivation. However, this requires higher temperatures processes that may inhibit widespread adoption by industry. Recently, another option has been presented that may circumvent the necessity for high temperature processing to produce pinholes, namely metal assisted chemical etching (MACE) of the SiO_x layer. MACE relies on deposition of Ag nanoparticles onto the SiO_x layers with subsequent electroless etching to form mesopores in the SiO_x layers that are analogous to the pinholes created with high temperature processing. The size and density can be controlled based on the Ag nanoparticle deposition conditions. The resulting contact structure is known as polysilicon on locally etched oxide (PLEO) contacts. The nanoscale structure of the mesopores in PLEO contacts define the device level observables such as recombination current (J_o) and junction resistance. In this work we present atomic resolution transmission electron microscopy (TEM) analysis of mesopores in PLEO contacts formed with different processing conditions to provide insight into how the nanoscale structure of the SiO_x layer influences PV device properties. Additionally, we have previously used electron beam induced current (EBIC) to probe local transport properties in Si PV devices with a SiO_x layer containing pinholes formed with high temperature processing. Using EBIC we were able to directly show the enhance charge carrier transport through the pinholes. Here we also employ EBIC to study non-uniformities in charge carrier recombination and transport associated with mesopores in PLEO contacts and compare these results with our previous work on devices with pinholes in the SiO_x formed through high temperature processes. The products of this work provide critical information that is required to both further optimize performance of Si PV devices with PLEO contacts and to drive future adoption of this technology by industry.

Black Silicon for PV—Which Technology to Choose? Xiaolong Liu, Behrad Radfar, Kexun Chen, Olli Setälä, Toni Pasanen, Ville Vähänissi and Hele Savin; Aalto University, Finland

Black silicon (b-Si) surface texture that consists of nanoscale structures is well known to reduce the optical losses both in multi- and monocrystalline silicon solar cells. The enhanced surface recombination related to the increased surface area of nanostructures is no longer an issue as conformal atomic layer deposited thin films provide excellent surface passivation. [1] Furthermore, pn-junction formation and related control of dopant atoms inside nanostructures has resulted recently in totally recombination-free emitters yielding external quantum efficiencies even above unity in front-junction Si solar cells. [2] These developments have made the b-Si technology attractive for the PV industry as well.

So far only one black silicon fabrication technology has emerged as cost competitive technology to conventional texturization, that is, metal assisted chemical etching (MACE). [3] However, there are other b-Si fabrication technologies that have their benefits over MACE (e.g. extended infrared absorption) and which could find interest among PV industry, too. These include dry-etching as well as laser-based methods. All these technologies have seen lately great progress, so in this contribution we give an updated overview of b-Si fabrication methods and related achievements. Furthermore, in order to make a direct comparison of the methods easier, we present a systematic study on the properties of b-Si wafers fabricated in the same facility on sister wafers using three different fabrication methods: i) MACE ii) reactive ion etching and iii) femtosecond-laser. A special emphasis is placed on optical properties, recombination and surface passivation quality, surface morphology, silicon consumption, throughput, and patternability. Finally, the pros and

cons of each method are discussed and the future outlook is given for each technology.

11:00 AM *EN04.05.02
Scalable Nano and Macro Light Management Approaches for Silicon Photovoltaics Bingtao Gao, Jacob Sindt, Wenqi Duan and Fatima Toor; The University of Iowa, United States

In this talk I will introduce low-cost and scalable light management approaches for crystalline silicon (x-Si) photovoltaic (PV) cells utilizing, (i) lithography-free inverted pyramids, (ii) electroless plated metal nanoparticles (NPs), and (iii) 3D printed light trapping films, that my team has been developing recently.

Industrial-scale passivated emitter rear contact (PERC) solar cells typically utilize upright pyramids fabricated utilizing potassium hydroxide (KOH) based alkaline etching of c-Si. ISFH's champion cell also utilizes the upright pyramid texture. While high efficiency lab-scale PERC solar cells utilize inverted pyramids because of higher antireflection (AR) relative to upright pyramids; these inverted pyramids are fabricated utilizing photolithography and an alkaline etch. Photolithography required to fabricate inverted pyramids is a slow and high cost process that is not compatible with low cost solar cell manufacturing needed for competitive solar energy generation. Hence, to-date, inverted pyramid texture has not been utilized in industrial-scale c-Si PERC cells. I will present results on a vacuum- and lithography-free wet chemical etching process that results in inverted pyramid textures on c-Si with extremely low spectrum weighted surface reflectivity (Rave) of 4.4% and 10% relative improvement in power conversion efficiency (PCE) as compared to c-Si solar cells with no surface texture.

Next I will present our work on a light management structure on c-Si utilizing electroless plating of silver nanoparticles (AgNPs). With the help of a MATLAB-based analytical model on Mie theory, the size distribution of AgNPs for desired optical properties was determined, and experimental results confirmed the reduction in reflection by up to 24.8% at a wavelength of 371 nm. An atmospheric degradation study of the AgNPs was also conducted, which demonstrated that the LSPR response of unprotected AgNPs is markedly impaired after 14 days, while the LSPR response of aluminum oxide (Al2O3) protected AgNPs is unchanged even after 90 days. AgNPs covered with an Al2O3 layer on a c-Si solar cell exhibit the highest absolute gain of 19.2% in external quantum efficiency (EQE) at 700 nm and an overall 20% relative increase in PCE compared to the reference c-Si solar cell without NPs.

Finally, I will discuss our recent work on 3D-printed solar concentrators using acrylonitrile butadiene styrene (ABS) printing filament and designed using a CAD software. Post designing and printing, the concentrators underwent a layer of varnish to both smoothen the 3D-printed surface and improve the overall strength. Varnished 3D-printed structures were then spray coated with a layer of metal. The metals chosen were aluminum (Al) and chromium (Cr), due to both having low cost and high reflectivity in the visible spectrum. We obtained around 4x light concentration with the 3D-printed concentrators while reducing the weight of the concentrators to that of milled metal concentrators by two times and reducing the production cost compared to binary-optics by up to 500 times.

11:30 AM EN04.05.03
Optical and Electronic Properties of Type II Silicon Clathrate Films with Low Na Content Yinan Liu[1], Joseph Briggs[1], William K. Schenken[2], Lakshmi Krishna[1], Ahmad A.A. Majid[1], Thomas E. Furtak[1], Michael Walker[1], Carolyn A. Koh[1], P. Craig Taylor[1] and Reuben T. Collins[1]; [1]Colorado School of Mines, United States; [2]University of California, Santa Barbara, United States

Si has been widely used in nearly all aspects of semiconductor technology. However, Si in the bulk, diamond-structured form (d-Si) has an indirect bandgap and weak absorption. Exotic forms of crystalline silicon (silicon allotropes) that have been stabilized at ambient temperature and pressure include caged, open channel, and layered structures. One of the most well-known Si allotropes is Si clathrate, a cage-like, crystalline Si inclusion compound. Si clathrate has been synthesized to form either type I (Na_8Si_{46}) or type II Na_xSi_{136} ($0 < x < 1$) phases in the presence of alkali atoms, such as Na, which sits inside the cage acting as an interstitial guest. If the Na content is low enough, which can only be achieved in type II ($x << 1$ in Na_xSi_{136}), Si clathrate can become a semiconductor with Na as a shallow, n-type, dopant. Theoretical studies have predicted type II Si clathrate to have a direct or nearly direct bandgap, near 2.0 eV, making it an exciting alterative to d-Si in optoelectronic applications. Most studies of Si clathrate have focused on powder synthesis. Compared with clathrate powder, thin-film Si clathrate is more interesting due to its potential for practical applications. Si clathrate films can be formed using a two-step process adapted from powder synthesis: formation of a Zintl precursor NaSi film and decomposition of the precursor into the clathrate phase. However, this thermal decomposition technique is very sensitive to growth parameters and the local environment, limiting controllable synthesis and complicating the characterization of film properties.
Here, we explore systematically the two-step synthesis technique in more detail by studying the key factors leading to thin, low-Na content, and high-quality films. Films have been synthesized with Na concentrations, varying from near the metal insulator transition ($x \sim 10$) values, comparable with the lowest Na content reported for powder samples. However, X-ray diffraction, Raman scattering spectroscopy, and Electron Paramagnetic Resonance measurements all provide evidence for a disordered or amorphous silicon-like phase that can dominate the surface and grain boundaries of the film. Time-of-Flight Secondary Ion Mass Spectrometry also demonstrates inhomogeneity of the ion profiles, showing regions of high Na content at the film surface and near boundaries surrounding low Na content regions, where high-quality clathrate material is located. We find that the presence of disordered Si and the inhomogeneity can significantly affect the film properties, complicating determination of the intrinsic properties of the clathrate.
Several growth and post growth techniques are studied to improve the film crystallinity and isolate the desired type II clathrate phase with low Na content. By exfoliating the film surface from the Si substrate, the high-quality clathrate structure is exposed and detected at the buried interface. Wet and dry acid etching are also applied, of which SF_6reactive ion etching (RIE) is shown to selectively remove the disordered phase, while also decreasing the Na concentration in the films. These techniques provide promising methods of isolating high-quality clathrate material for investigation and application. Using these techniques, band edge characteristics were probed on high-quality films and surfaces using a range of measurements including absorption, photoluminescence (PL), and ellipsometry. A bandgap near 1.7 eV and an absorption coefficient about two orders of magnitude higher than diamond Si were observed. Room temperature PL is also detected in the near infrared region. An analysis of the temperature dependent PL emission confirms that Na in type II Si clathrate films can be a shallow donor with an activation energy of about 19 meV. This makes type II Si clathrate a n-type Si allotrope with exciting potential for Si based solar cells, LEDs, and sensors. This work was supported by National Science Foundation Awards 1810463.

11:45 AM EN04.05.04
Deterministic Broadband Absorption and Antireflection Using Deep Subwavelength Scalloping Arrays Ashish Prajapati[1], Jordi Llobet[2], Patricia C. Sousa[3], Helder Fonseca[3], Carlos Calaza[3], João Gaspar[3] and Gil Shalev[1]; [1]Ben Gurion University of the Negev, Israel; [2]IMB-CNM CSIC, Spain; [3]International Iberian Nanotechnology Laboratory, Portugal

Light trapping and the broadband absorption of the solar radiation are significant to a plethora of absorption-based photonic devices. Specifically, efficient broadband absorption was recently demonstrated with arrays of subwavelength structures. The current study examines both numerically and experimentally light trapping driven by deep sidewall subwavelength structures (DSSS) in silicon nanopillar (NP) arrays (DSSS arrays). Particularly, the focus is on DSSS geometries that are an inherent outcome of the top-down dry etch approach used in arrays of high aspect ratio NPs due to the periodical operationality of the Bosch dry etch method. ~10% enhancement in the broadband absorption of DSSS arrays compared with NP arrays is demonstrated numerically, as well as the generation of near-IR absorptivity peaks of ~25% for DSSS arrays. Importantly, it is shown that the introduction of DSSS systematically blue-shifts the absorptivity peaks of the NP arrays and in this manner a deterministic light trapping is possible. Finally, decrements of ~40% in direct reflectivity and ~7% in diffused reflectivity in DSSS arrays realized on silicon wafers is demonstrated experimentally.

SESSION EN04.06: Perovskite-Silicon Tandems

4:00 PM *EN04.06.01
Low-Cost, High-Efficiency, Stable Monolithic Si/Perovskite Tandem Solar Cell Heping Shen; Australian National University, Australia

Increasing the power conversion efficiency of silicon (Si) photovoltaics is a key enabler for continued reductions in the cost of solar electricity. A two-terminal perovskite/Si tandem design that increases the Si cell's output in the simplest possible manner: by placing a perovskite cell directly on top of the Si bottom cell. The advantageous omission of a conventional interlayer eliminates both optical losses and processing steps and is enabled by the low contact resistivity attainable between n-type TiO_2 and Si, established here using atomic layer deposition. The fabricated proof-of-concept perovskite/Si tandems on both homojunction and passivating contact heterojunction Si cells to demonstrate the broad applicability of the interlayer-free concept. Stabilized efficiencies of 22.9 and >25% were obtained for the homojunction and passivating contact heterojunction tandems, respectively.
Based on this, a clear route is provided for minimizing optical losses aided by optical simulations which result in tandem current densities of ≈20 $mAcm^{-2}$ with front-side texture. In addition, electrical modeling on the Si-subcell has also been conducted in order to understand the efficiency potential of this cell under filtered light in a tandem configuration. The possibility of increasing the Si subcell efficiency by 1% absolute is offered through joint improvements to the bulk lifetime, which exceeds 4 ms, and improves surface passivation quality to saturation current densities below 10 fA cm^{-2}. A combination of optical modeling of the complete tandem structure alongside electrical modeling of the Si-subcell, both with state-of-the-art modeling tools, provides the first complete picture of the practical efficiency potential of over 30% for perovskite/Si tandems.

4:30 PM EN04.06.02
Ligand-Bridged Charge Extraction and Enhanced Quantum Efficiency Enable 27% Efficient n-i-p Perovskite/Silicon Tandem Solar Cells Erkan Aydin[1], Jiang Liu[1], Esma Ugur[1], Randi Azmi[1], George T. Harrison[1], Yi Hou[2], Bin Chen[2], Shynggys Zhumagali[1], Michele De Bastiani[1], Mingcong Wang[1], Waseem Raja[1], Thomas Allen[1], Atteq ur Rehman[1], Anand S. Subbiah[1], Maxime Babics[1], Aslihan H. Babayigit[1], Furkan H. Isikgor[1], Kai Wang[1], Emmanuel Van Kerschaver[1], Leonidas Tsetseris[3], Edward H. Sargent[2], Frédéric Laquai[1] and Stefaan De Wolf[1]; [1]King Abdullah University of Science and Technology, Saudi Arabia; [2]University of Toronto, Canada; [3]3National Technical University of Athens, Greece

Monolithic perovskite/silicon tandem solar cells are of interest thanks to their high power conversion efficiency (PCE) potential at affordable cost. Also, the possibility to fabricate silicon heterojunction bottom cells either in the *n-i-p* or *p-i-n* polarity provides considerable flexibility to choose the device architecture. The initial perovskite/silicon tandems were in the *n-i-p* configuration. However, as light in this architecture enters from the *p*-side, applying the typical electron and hole selective contacts of single-junction devices to the tandem configuration resulted in devices with a poor blue response, mainly due to parasitic absorption in the front-contact stack. Therefore, global tandem research refocused on the inverted structure (*p-i-n* configuration, with electron collection at the front). So far, several efficient devices have been reported in this configuration. Increasingly the PCE of *p-i-n* tandems further is constrained by parasitic absorption and recombination-active defects in the front SnO_x/C_{60} ESL stack, prompting us to revisit the *n-i-p* structure to benefit from the expansive library of efficient hole selective layers in single-junction *n-i-p* perovskite solar cells.

In this study, we overcome the challenges of the *n-i-p* perovskite/silicon tandem solar cell platform and unveil the true potential of this architecture. We do so by developing novel electron and hole selective contacts which combine high broadband transparency with efficient charge extraction. First, we needed to develop efficient electron selective layers exhibiting high conformality on macroscale textured silicon substrates: the texture is needed to minimize light reflection. We implemented this concept by developing room temperature sputtered amorphous niobium oxide (a-NbO_x) films, combined with a C_{60} self-assembled molecular monolayer. On the sunward side, we needed to overcome the high parasitic absorption and fast degradation challenges of spiro-OMeTAD. We developed conformal, transparent, and efficient hole selective layers (molecularly doped evaporated spiro-TTB). We combined this contact with a low-temperature atomic layer deposited vanadium oxide (VO_x) layer, which prevented sputtering damage and did not introduce significant optical losses. To enhance the stability of this contact stack, we introduced ultrathin TPBI layers between the spiro-TTB and VO_x.
Combining these advancements with a two-dimensional perovskite passivation layer on the perovskite absorber, we achieved a power conversion efficiency exceeding 27%. This represents a significant advance over the best prior report in the *n-i-p* configuration of only 21.8% on similar bottom cells. The new device platform allows for translating the achievements of *n-i-p* single-junction solar cells into the context of tandems. The rich library of broadband transparent small-molecule HSLs and the possibility to utilize two-dimensional perovskite passivation strategies can now be easily implemented in tandems. From this, we expect rapid progress to be achieved in the field of perovskite/silicon tandems in the *n-i-p* configuration. We expect that our research will also propel the perovskite/perovskite tandem solar cells research which has been suffering from a lack of efficient vacuum-deposited hole selective contacts, where we offer a unique solution here.
