We have also imaged the transport of interlayer CT excitons in 2D organic-inorganic vdW heterostructures constructed from WS_2 layers and tetracene thin films. Photoluminescence (PL) measurements confirm the formation of interlayer excitons with a binding energy of ~ 0.3 eV. Electron and hole transfer processes at the interface between monolayer WS_2 and tetracene thin film are very rapid, with time constant of ~ 2 ps and ~ 3 ps, respectively. TAM measurements of exciton transport at these 2D interfaces reveal mobile CT excitons, with diffusion constant of ~ 1 cm^2s^{-1}. The high mobility of the delocalized CT excitons could be the key factor to overcome large CT exciton binding energy in achieving efficient charge separation.

Tuning Exciton Extraction Dynamics by Twisting and Stacking van der Waals Materials Matt W. Graham; Oregon State University, United States

Using time-space resolved ultrafast microscopy on 2D materials or single-crystal singlet-fission crystals, we show how long-range interlayer electronic coupling can be selectively enhanced either by applying an *E*-field or by twisting the layer stacking orientation. In both cases, transient interlayer exciton states form and drive the optoelectronic material response. Considering first twisted bilayer graphene (*t*BLG), we discovered how stacking-angle tunable absorption resonances form a strongly-bound exciton state owing to the symmetrized rehybridization of the interlayer 2*p* orbitals. Using two-photon photoluminescence and intraband-transient absorption microscopies, we have recently imaged the photoemission and exciton dynamics from single-grains of *t*BLG. After resonant excitation, our results suggest the formation of strongly bound (up to 690 meV), metastable interlayer exciton states. Our observation of resonant PL emission from twisted bilayer graphene materials is best explained by the theoretically predicted coexistence of strongly bound interlayer excitons and metallic graphene continuum states. We show how stacking angle-tunable interlayer excitons states may permit new photocurrent extraction routes from quasi-stable interlayer excitons.

Unlike stacked graphene, semiconducting 2D transition metal dichalcogenides (TMDCs) have diffuse interlayer *d*-orbital overlap. To enhance interlayer electronic coupling in TMDCs, we apply an interlayer-directed *E*-field, inducing electron-hole dissociation. Time-resolved photocurrents show that stacked WSe_2 devices can have both IQE >50% and fast (<60 ps) picosecond electron escape times. Our ultrafast photocurrent rates kinetics give the same *E*-field-dependent electronic escape and dissociation rates seen from optical ultrafast microscopy. To rationalize these fast electronic escape rates, we show the ratio of the electronic rates accurately predicts the actual WSe_2 device photocurrent generation efficiency. Collectively, we show how optical and photocurrent-based ultrafast microscopies together provide an analytical extraction of the photocurrent-generating ultrafast dynamics in van der Waals stacked materials and organic singlet fission materials.

The impact of annealing at different temperatures and times on the morphology, composition, the transformation of crystal phases, and emission of Si-rich-HfO_2 films prepared by radio-frequency magnetron sputtering and doped with the rare-earth Pr element has been investigated. The follows methods: scanning electronic microscopy (SEM), energy dispersive X-ray spectroscopy (EDS), X-ray diffraction (XRD), Raman scattering and photoluminescence (PL) have been used. Thermal annealing was carried out at 800, 900, 1000 and 1100C for 30 min or for times 5, 15, 20 and 60 min at 1000ºC in nitrogen atmosphere.
The films are characterized by the fine grain structures with the maximum grain size of 40nm. The composition of the films varied significantly at annealing with the oxidation increasing at high annealing temperatures. The annealing causes the transformation and separation of the crystal phases from the hafnia silicates at low annealing temperatures to the tetragonal HfO_2 and SiO_2 phases detected after high temperature (1000 or 1100ºC) treatments. The great variety of the visible and infrared PL bands related to the optical transitions in the 4f inner shells of the Pr^{3+} ions and via native host matrix defects were detected in the PL spectra. Their contribution depends on the annealing temperature and governs the shape of total PL spectra. The impact of crystalline phase transformation at annealing on the peculiarities of the PL excitation and emission spectra of rare-earth Pr^{3+} ions are analyzed and discussed.

Phase Change Vanadium Dioxide Microstructures—Size Dependence and Photodetection Sumaiya Kabir[1], Shruti Nirantar[1], Cuong Ton- That[2], Sharath Sriram[1], Sumeet Walia[1] and Madhu Bhaskaran[1]; [1]RMIT University, Australia; [2]University of Technology Sydney, Australia

The conventional high-speed semiconductor-based photodetectors involve limited wavelengths of operation and usually incorporate complex and expensive fabrication. Vanadium dioxide is a phase change material that undergoes an insulator to metal transition near room temperature. This material has drawn attention to broadband optoelectronic applications due to its unique band structure and versatile electronic and optical properties. However, vanadium dioxide-based photodetectors reported so far involve complex structures that lack scalability and constrained wavelength response similar to commercial photodetectors. Herein, two-terminal planar devices based on vanadium dioxide thin film are presented where devices were fabricated by using

standard micro-/nano-fabrication. To enhance the photoresponse of our photodetector devices, we use two novel techniques. Firstly, we explore the effect of the size of photodetector devices in photoresponse at broadband wavelengths ranges from ultra-violet to near-infrared. With the miniaturization of device size, the photoresponsivity increases. Finally, we investigated photoresponse in the insulator-to-metal transition slope (50-60 ^{o}C) and beyond insulator-to-metal transition slope (65 ^{o}C) regions. The co-existence of the insulator and metallic domains in these regions significantly enhances the photoresponse. The ability to manipulate the phase transition and the photoresponse with device size opens opportunities for designing and controlling functional domains of vanadium dioxide for scalable micro- and nano-scale devices and sensor applications. This work enables a technology where phase change oxides can contribute to ultra-fast and compact optoelectronic applications.

WITHDRAWN 12/6/2021 EQ12.13.04 Triplet Energy Transfer from Semiconductor Nanocrystals to Organic Molecules: Fundamentals and Applications Kaifeng Wu; Chinese Academy of Sciences, China

In recent years, sensitization of molecular triplets using inorganic semiconductor nanocrystals *via* triplet energy transfer (TET) has emerged as a new area with potential applications ranging from photochemical photon upconversion to organic synthesis. We investigated the fundamental mechanisms of the inorganic/organic TET by building well-defined model systems and applying state-of-the-art time-resolved spectroscopy tools. In doing so, we uncovered the essential role of quantum confinement of nanocrystals in facilitating electronic coupling required for triplet energy transfer. We also established a unified picture of charge-transfer-mediated triplet energy transfer mechanisms, which greatly expanded the scope of molecular triplet sensitization using nanocrystals. Additionally, we demonstrated that nontoxic nanocrystals such as $CuInS_2$ and InP were also capable of sensitizing molecular triplets for efficient photon upconversion. These contributions will serve as a roadmap for the design of nanocrystal-molecule triplet sensitization systems for photon upconversion as well as many other photochemical applications.

5:20 PM EQ12.13.05
Late News: Enhancement of Photoelectron Emission Efficiency from Quantum Dot Solids, Through Electrical Field Biasing of Interfaces Kassra D. Eshraghi and Prab Bandaru; University of California, San Diego, United States

It is shown through comparison with experimental results that the efficiency of quantum dot (QD) film-based photoemission would be impacted by an inadequate supply of electrons from an electron source. An explanation for the related photocurrent *droop*, as arising from restricted electron transmission at the substrate-QD interface as well as between the QDs, is proposed. It is suggested that interfacial potential based biasing schemes could considerably enhance electronic coupling for improved transmission and quantum efficiency. Modeling of the system through application of a 1-dimensional transfer matrix algorithm (TMA) to smoothly varying potential profiles indicates that electric fields of ~450 MV/m would be necessary for ensuring electron transmission coefficients close to unity.

Optimizing the Efficiency of Solid-State Photochemical Upconversion Systems—Effects of Temperature and Morphology Ferdinand C. Grozema; Delft University of Technology, Netherlands

Triplet-triplet annihilation upconversion is a promising approach for application in solar cell devices since it allows the conversion of sub-bandgap infrared photons into visible photons that can be absorbed by the underlying cell. Most examples of photochemical upconversion are either in solution or glassy polymer matrices, which is undesirable from a technological point of view. In this contribution we demonstrate a solid state approach in which absorption of near infrared light is followed by direct electron injection into an inorganic substrate. We use time-resolved microwave photoconductivity experiments to study the injection of electrons into the electron-accepting substrate (TiO2) in a trilayer device consisting of a triplet sensitizer (fluorinated zinc phthalocyanine), triplet acceptor (methyl sub- situted perylenediimide) and smooth polycrystalline TiO2. Absorption of light at 700 nm leads to the almost quantitative generation of triplet excited states by intersystem crossing. This is followed by Dexter energy transfer to the triplet acceptor layer where triplet annihilation occurs and concludes by injection of an electron into TiO2 from the upconverted singlet excited state.

The effect of temperature on the triplet upconversion process in the solid is largely unexplored. We have investigated the effect of temperature on exciton diffusion and overall charge injection efficiency into metal oxide TiO_2 resulting from upconversion in a triple-layer system composed of TiO_2, methyl substituted perylene diimide (PDI-CH_3) and hexadecafluorinated zinc phthalocyanine (F_{16}ZnPc). We used the time resolved microwave photoconductivity technique to probe free mobile charge carriers that are generated at a planar heterojunction interface from upconverted singlet excitons. The charge yield is found to be thermally activated, which is attributed to thermally activated exciton diffusion, in combination with a phase change in the PDI-CH_3 crystalline material at higher temperature. These results show that crystal engineering can be a valuable approach to optimization of solid state upconversion.

2D Electronic Spectroscopies Towards Quantum Technology Applications—The Example of Semiconductor Quantum Dots and Metal-Organic Hybrid Systems Elisabetta Collini[1,2]; [1]University of Padova, Italy; [2]Padua Quantum Technologies Research Center, Italy

Multidimensional coherent techniques in the visible range, 2D electronic spectroscopy (2DES) in particular, have been developed starting from the beginning of 2000, and historically they have been mainly exploited for the investigation of subtle dynamic mechanisms of energy and charge transport in biological complexes. Only later, these techniques have been recognized to be particularly valuable also for the study of transport processes in artificial

nanomaterials and nanodevices.
Recent results obtained applying 2DES (including 'action-based techniques') to the study of nanomaterials will be overviewed, focusing the attention on semiconductor nanocrystals ('quantum dots') in solid-state devices and metal-organic hybrid systems.
In particular, the characterization of coherent mechanisms active in the transport of excitation energy in these materials will be presented. This is particularly meaningful towards the possible application of these nanomaterials for quantum technology.

8:30 AM EQ12.14.02
Tip-Enhanced Second Harmonic Generation Microscopy for *In Situ* Nanoscale Corrosion Imaging Yoonsoo Rho[1], SeokJae Yoo[1], Dan Durham[1], Andrew M. Minor[1,2], Hee K. Park[3] and Costas Grigoropoulos[1]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Laser Prismatics LLC, United States

Second harmonic generation (SHG), a nonlinear optical process where two photons of the same energy generate a single photon of twice the energy, is an optical fingerprint to probe an inversion symmetry of crystal structure of nonlinear materials. This symmetry-dependent characteristics of SHG are particularly important in the study of chemical properties in functional nanostructures whose crystal structure can be altered by chemical reactions facilitated by their high surface-to-volume ratio. SHG also provides a simple, non-invasive, and vacuum-free optical method, which can be easily integrated with various gas flow and temperature control systems for in-operando study. However, the fundamental limitations such as the intrinsically low SHG efficiency and the limited spatial resolution have rendered the nanoscale nonlinear optics studies for the functional nanostructures challenging. Here, we developed a tip-enhanced *in-situ* nano-imaging of second harmonic generation (SHG) for nanoscale corrosion process studies based on the scanning near-field optical microscopy (SNOM) platform. We proposed that strong nonlinear responses of Au tips can be used as an optical probe for SHG signals of a nonlinear sample. This possibly originates from a resonant energy transfer between the Au tip and the sample in nonlinear process, while neither the Purcell effect nor the plasmonic field enhancement can explain the SHG enhancement in our tip-enhanced microscopy. Integrated with environmental control system, we probed *in-situ* nanoscale corrosion process occurred at the surface of zinc oxide (ZnO) nanowires, which was supplemented by correlative tunnelling electron microscopy (TEM) studies. Further, our tip-enhanced SHG nano-mapping can visualize multipolar SHG by Mie-resonance in dielectric silicon nanowires, manifested by the characteristic fringe patterns apparent in nanoscale SHG images. Thus, we believe that the presented tip-enhanced SHG microscopy for in-operando test can provide powerful means for nanoscale probing of optical and chemical properties of nanostructures.

Excitonic and Spin Dynamics of the Antiferromagnetic 2D Semiconductor $NiPS_3$ Andrii Shcherbakov[1], Stanislav Bodnar[1], Kevin Synnatschke[2,3], Claudia Backes[2] and Felix Deschler[1]; [1]Walter Schottky Institute Technical University of Munich, Germany; [2]Universität Heidelberg, Germany; [3]Trinity College Dublin, The University of Dublin, Ireland

Antiferromagnets (AFMs) are promising materials for spintronic and opto-electronic applications due to natural spin dynamics in the THz range and, at the same time, no net magnetization. This leads to the absence of stray fields which is a key property for data storage applications. A promising approach here is to combine the unique magnetic properties of AFMs with the strong coupling of optical and magnetic properties of semiconductors. Recently, semiconducting AFMs attract a lot of attention with several studies focusing on van der Waals layered AFMs from metal phosphotrichalcogenides such as NiPS3, FePS3, and MnPS3. For our studies, we have chosen NIPS3 because of its non-trivial exciton behavior of singlet and triplet states. To investigate light-induced dynamics in the excited, state spin, and electronic populations in semiconducting NiPS3, we use time-resolved transient absorption (TA). This technique provides access to spectral information about changes in absorption induced by excitation of non-equilibrium carrier populations and the dynamics of the carrier and exciton recombination. We will further report our results on time and spectrally resolved optical detection of the Neel vector at cryogenic temperatures through complex Zhang-Rice excitonic states of NiPs3 antiferromagnet by using Faraday rotation experiments. We also demonstrate the manipulation of the spin structure via application of the external magnetic field in the range of 1 T. Application of the external magnetic field leads to changes in polarization properties of PL. Finally, we provide a comparison of such dynamics for chemically exfoliated NiPS3 from scalable solution-based fabrication, by varying the size of flakes and their thickness from monolayers, up to bulk materials.

Spectroscopic Signatures of Magnetic Ordering and Coupling to Excitons in 2D Xiaoyang Zhu; Columbia University, United States

We have developed spectroscopic techniques to probe unprecedented properties of a 2D layered semiconductor, CrSBr. Using second harmonic generation (SHG), we find that monolayers are ferromagnetically (FM) ordered below a Curie temperature T_C = 146 K, an observation enabled by the discovery of a large magnetic dipole SHG effect in the centrosymmetric structure. In multilayers, the ferromagnetic monolayers are coupled antiferromagnetically (AFM) with a Néel temperature of T_N = 148 - 132 K (decreasing with increasing thickness). Symmetry analysis establishes magnetic dipole and magnetic toroidal moments as order parameters of FM monolayer and AFM bilayer, respectively. The embodiment of both magnetic and semiconducting properties in this material allows the magnetic control of interlayer electronic coupling, as manifested in tunable excitonic transitions. Excitonic transitions in bilayer CrSBr and above can be drastically changed when the magnetic order is changed from paramagnetic to AFM as T is lowered below T_N or as it is switched from layered AFM to the field-induced FM state. The magnetic-excitonic coupling is attributed to the spin-allowed interlayer hybridization of electron and hole orbitals in the FM, but not AFM state. Our work uncovers a magnetic approach to engineer electronic and excitonic effects in layered magnetic semiconductors.

11:00 AM *EQ12.15.02
Electron-Phonon Coupling and Carrier Transport in Halide Perovskites from First Principles Feliciano Giustino; The University of Texas at Austin, United States

During the past decade halide perovskites have risen to prominence as a novel class of energy and optoelectronic materials. A fundamental question in the materials science of halide perovskites is how lattice vibrations influence their electronic and transport properties. In this talk I will describe first-principles investigations of electron-phonon couplings in hybrid organic-inorganic lead halide perovskites [1,2] and all-inorganic lead-free halide double perovskites

[3], and I will analyze the atomic-scale mechanisms underpinning charge transport in these systems. I will show how the lower mobilities of halide perovskites, as compared to standard inorganic semiconductors, are linked with the heavy atomic masses and the resulting low vibrational frequencies. Furthermore, I will show that lead-free halide double perovskites exhibit lower carrier mobilities than their lead-halide counterparts because they possess much heavier band effective masses. For both lead-based and lead-free perovskites, carrier scattering by longitudinal optical polar phonons is found to be the main source of mobility degradation. Building on this understanding, I will discuss a universal scaling law for the carrier mobility in these compounds, and illustrate possible avenues to design new halide perovskites with improved carrier transport properties.

11:30 AM EQ12.15.03
Amplified Spontaneous Emission in Quasi-2D and 3D Perovskite Gain Materials—Influences of Excitonic Versus Free Carrier Emission Yang Li[1,2], Isabel Allegro[2], Milian Kaiser[1], Aditya J. Malla[2], Bryce Richards[1,2], Ulrich Lemmer[1,2], Ulrich W. Paetzold[1,2] and Ian Howard[1,2]; [1]Institute of Microstructure Technology, Karlsruhe Institute of Technology, Germany; [2]Light Technology Institute, Karlsruhe Institute of Technology, Germany

Quasi-two-dimensional (2D) perovskites are promising optoelectronic materials for lighting due to their excellent luminescent properties and color tunability. The recent demonstration of optically pumped continuous-wave (CW) lasing at room temperature stipulated the promise that these materials are also candidates for realizing electrically driven lasers from solution-processed materials. Excitonic emission from the quantum wells (QWs) of quasi-2D perovskite accounts for their superior light emission at low excitation fluences and can enhance LED performance. However, at high excited-state densities (necessary for lasing) the emission efficiency of 3D samples overtakes that of quasi-2D samples whose excited-state population is dominated by excitons. In this contribution, it is explained by the 2nd order rate of bimolecular radiative recombination increasing with fluence in the 3D sample (whose excited-state population is dominated by free charge carriers) making the emission more efficient and the radiative rate faster with increasing excitation density. Before the lasing threshold, the bimolecular radiative rate in the 3D materials apparently exceeds the radiative rate in the excitonic materials. The efficiency of the excitonic emission is also reduced by exciton-exciton annihilation, leading the 3D samples to become brighter at high fluences. In terms of amplified spontaneous emission (ASE) threshold, these effects mean that the ASE threshold is higher for the quasi-2D samples (~600 μJ cm^{-2}) whose excited-state population is dominated by excitons than for the 3D samples (~130 μJ cm^{-2}).

Furthermore, we then demonstrate that the ASE threshold in quasi-2D samples is significantly affected by the type and concentration of the 2D spacer used. The 2D spacer content affects the ASE threshold by two mechanisms. Firstly, the spacer content has a large influence on the surface roughness. The smoother the film, the longer the photon lifetime within the film, and therefore the higher the photon density within the film. As the ASE threshold is related to the product of the photon and excited-state density in the film, these higher photon densities work to reduce the ASE threshold. Secondly, the spacer nature and content influence the excited states that are present in the quasi-2D films. Moving from butylamine to napthymethylammonium (NMA) 2D spacers and decreasing the spacer concentration in the film shifts the emission mechanism towards free carrier radiative recombination and away from excitonic emission. This shift towards free carrier recombination based emission is associated with a reduction in the ASE threshold (from > 600 μJ cm^{-2} to ~200 μJ cm^{-2}) of the quasi-2D materials. The best ASE thresholds in quasi-2D materials that we achieved used low concentrations of 40% NMA spacer, and thermal imprinting to reduce the roughness. In this case, we achieved a threshold of 200 μJ cm^{-2} similar to those in the 3D material. Our findings are closely relevant to many of the widely concerned 2D/3D perovskite materials these days.

In terms of optimizing quasi-2D materials for gain applications, our results suggest that careful consideration of the excited-state population and emission mechanism should be made. We propose that an excited-state population in the quasi-2D material dominated by free charge carriers may be the most favorable for their gain performance, and should be the focus of further material engineering efforts. Irrespective, a close examination of the excited states present in the quasi-2D materials and their influence on the optical gain in these materials will be of continued relevance to their development.

11:45 AM EQ12.15.04
Mobility, Quantum Efficiency and Defect Density from High Throughput Spectroscopy of CsPbBr3 Nanowires Stephen Church[1], Hoyeon Choi[1], Nawal Al-Amairi[1], Ella Sanders[2], Eitan Oksenberg[3], Ernesto Joselevich[2] and Patrick Parkinson[1]; [1]University of Manchester, United Kingdom; [2]Weizmann Institute of Science, Israel; [3]AMOLF, Netherlands

Structural and material inhomogeneities in microstructures can have large effects on the optical properties and functional performance [1]. In this study, we demonstrate a novel way to harness this variation to probe the optoelectronic properties of the material. This is achieved using high-throughput spectroscopy to gather statistically significant, large experimental datasets of microstructures [2]. The methodology was applied to in-plane CsPbBr3 nanowires (NWs), which are promising for nano-photonic applications, showing good waveguiding [4] and luminescence properties [3] as well as demonstrating lasing at elevated carrier densities [5].

Optical microscopy with a machine vision camera was used to identify and measure the width and length of >10,000 NWs. The optoelectronic properties of each nanowire were characterised using room temperature photoluminescence (PL) spectroscopy and time correlated single photon counting techniques. The measurements were repeated when exciting carriers at the air/NW interface and the substrate/NW interface to probe the inhomogeneity in each NW. Differences in the bandgap were observed due to tensile effects at the NW/substrate interface [6]. Two carrier lifetimes were observed: a fast lifetime (~2ns) associated with carriers at the air/NW interface and a slow lifetime (~8ns) associated with carriers in the bulk. A single recombination model was developed to explain correlations between the NW geometry and the results. This model, when applied to the large volume of experimental data, is unique in that it provides a large breadth of information about the growth, and can simultaneously determine values for the diffusion length, carrier mobility, trap densities and internal quantum efficiency (IQE). These values are compatible with those from small-scale studies in the literature, and the IQE was verified independently using temperature dependent PL. Importantly, the model requires minimal a-priori knowledge and can therefore be applied to other material ensembles in a statistically rigorous way, including those which have not been previously studied.

Photoexcited Charge Carrier and Spin Dynamics in Methylammonium Lead Bromide Doped by Magnetic Transition Metals Stanislav Bodnar[1],

Jonathan Zerhoch[1], Timo Neumann[1,2], Lissa Eyre[1], Barbara Sergl[1] and Felix Deschler[1]; [1]Walter Schottky Institute of Munich Technical University (Walter Schottky Institut Technische Universität München), Germany; [2]University of Cambridge, United Kingdom

One of the most challenging tasks for LED applications is emitting 100% polarized light from the device. Typically, this is achieved by introducing an additional layer of polarization filter which leads to losing half of the light intensity. To overcome this issue, one has to find a system with a high degree of photoluminescence (PL) polarization. A promising approach here is using magnetic metal doping in combination with a highly efficient semiconductor. Metal-halide perovskites have attracted the attention of many scientific groups around the world as one of the most promising candidates for solar cell applications and light-emitting diode (LED) technology. In our work, we will present how doping of methylammonium lead bromide ($CH_3NH_3PbBr_3$) with the transition metals Ni, Co, and Mn induces dramatic changes in the magneto-optical properties and carrier dynamics due to interactions between the magnetic moments of the dopants and Coulomb interactions of the excitons.
We have chosen to use transient absorption (TA) spectroscopy at cryogenic temperatures with applied magnetic fields of up to 1 T to investigate changes in the optical properties induced by magnetic metal doping in $CH_3NH_3PbBr_3$, since it gives spectral information about the energies of electronic states and dynamic properties of the photoexcited carriers. We find a change in the main ground state bleach (GSB) peak position in doped $CH_3NH_3PbBr_3$, which depends on the transition metal used. The main GSB peak of pure $CH_3NH_3PbBr_3$ at 4 K is at 2.32 eV. Doping $CH_3NH_3PbBr_3$ with Mn and Ni leads to a shift of the main peak to lower energies by 0.04 eV and 0.08 eV, respectively, while doping with Co leads to a shift to higher energies by 0.02 eV. The modifications of the TA spectra are associated with changes of the bandgap energy, which is the result of doping-induced lattice expansion or compression. For all investigated samples, we observed energy splitting of the TA spectra for two different circular polarizations of the pump pulse. We interpret this splitting as the result of a light-induced Zeeman effect which arises from the spin-polarized photoexcited charge carriers due to angular momentum selection rules of the optical transitions. For the pure $CH_3NH_3PbBr_3$ case, we observed splitting in the range of the 8 meV, while for the Ni-doped material, this splitting is around 17 meV. We attributed this significant enhancement in the splitting energy to the exchange coupling of the photoexcited charge carrier spins with the Ni ion spins. The presence of the Ni spins in the crystal lattice also affects the lifetime of the photo-induced Zeeman splitting. Undoped $CH_3NH_3PbBr_3$ shows a lifetime of the Zeeman splitting in the range of 30 ps, while for the Ni-doped samples this lifetime is exceeding 1300 ps which is an indication of one order of magnitude longer spin lifetime in the Ni-doped sample, compared to undoped $CH_3NH_3PbBr_3$. The reason for this significantly different behavior could be a long-range order of the Ni spins, potentially indicating magnetic spin order, which we are currently exploring. The long lifetime of the Zeeman splitting could also indicate a long lifetime of circularly polarized PL.

1:00 PM *EQ12.16.01
Excited State Dynamics of a Conjugated Polyelectrolyte Self-Assembled with ss-DNA Sophia C. Hayes[1], Eliana Nicolaidou[1], Anthony Parker[2] and Michael Towrie[2]; [1]University of Cyprus, Cyprus; [2]Central Laser Facility, Science & Technology Facilities Council, Rutherford Appleton Laboratory, United Kingdom

Control over the conformation of conjugated polymers using nucleic acids (NAs) as templates can be very advantageous in inducing unique and readily controllable properties. Complexation of NAs with conjugated polyelectrolytes (CPEs) such as cationic polythiophenes (CPT) is facilitated by the presence of charged side groups on the backbone.[1] Previous studies on the biosensing ability of a certain CPT has revealed a tremendous impact of the ssDNA sequence on the conformational and optical response of the polymer.[2,3] The complex formed of CPT and oligocytosine (dC_{20}) strands is especially noteworthy due to the formation of highly ordered and extended chains due to π-stacking between the cytosine bases and thiophene rings, further stabilized by π-stacking with the imidazole side chain.[4,5] This stands in contrast to the complex with oligoadenosine (dA_{20}), where π-stacking between the bases limits any stacking interactions with the polymer resulting in a flexible and torsionally disordered conformation. Interestingly, though, our previous ultrafast transient absorption (TA) work showed that both complexes showed only excitonic behavior, with similar and much faster decay dynamics compared to the polymer alone, which forms interchain aggregates.[5]

Therefore, we used TRIR to directly probe the role of NA templating in the excited state species formed in the two complexes, which is responsible for the faster dynamics observed with vis-nIR probes, as well as compare the photophysics of loosely bound complexes with the more rigid and ordered systems. We find that with excitation of the polymer in the visible (532 nm) both complexes form the P_0 intrachain polaron evidenced by a broad absorption background that decays faster than the delocalized polaron DP_1 formed in the case of CPT alone. The lower intensity of the P_0 absorption in the CPT/dA_{20} case is consistent with increased intrachain disorder, while higher interchain long range order leads to the higher DP_1 absorption.[6] The rigid complex formed in the case of CPT/dC_{20} limits the geometric relaxation observed in the C=C stretch Fano antiresonance, in agreement with the reduced reorganization energy calculated from resonance Raman intensity analysis and the limited evolution of the stimulated emission in the TA data.[5] Excitation in the UV (266 nm) shows that a charge transfer complex is formed between CPT and dC_{20} with the observation of the cytosine anion and a broad absorption background, in contrast to CPT/dA_{20} case, where the TRIR spectra solely reflect the excited state behavior of the oligoadenosine. These results show that non-covalent interactions between NAs and CPTs can determine the excited state species formed, which has implications to the applicability of these complexes in molecular electronics.

Control of Exciton Dynamics for Efficient Photon Upconversion in Solid Materials Nobuhiro Yanai; Kyushu University, Japan

Controlling the behavior of molecular excitons in solids is crucial for the expression of optical functions. We have been interested in the triplet diffusion and upconversion of triplet into singlet in solid materials, especially in densely packed dyes in solid environments where molecular diffusion is limited. As an example, we present a system of emitter dyes densely integrated in epoxy resins. Epoxy resins have a high oxygen barrier property, which is used as

an encapsulant for OLEDs. We have succeeded in dispersing the dye in epoxy resins with a high concentration of more than 1 M by appropriate molecular design, and achieved a high upconversion efficiency in air. We will show how the emitter density plays an important role not only in the triplet diffusion between emitters, but also in the circumvention of back energy transfer from emitter to sensitizer.
The introduction of singlet energy collectors to more actively prevent back energy transfer will also be presented. We show that the singlet energy collectors play an important role in effectively suppressing the back energy transfer from emitter to sensitizer, and can also compete with the free triplet generation by the singlet fission.

Exploring the Multiple Resonance Thermally Activated Delayed Fluorescence Mechanism and Its Contribution to the State of the Art 3rd Generation OLEDs Kleitos Stavrou[1], Andrew Danos[1], Toshiki Hama[2], Takuji Hatakeyama[2] and Andrew Monkman[1]; [1]Durham University, United Kingdom; [2]Kwansei Gakuin University, Japan

Organic light emitting diodes (OLEDs) are consider the most recent commercially available lighting and display technology. Until now, only the first two generations of OLEDs were used in the market but not until recently the 3rd generation made huge steps towards real life applications. Using a thermally activated delayed fluorescence (TADF) sensitizer and a multiple resonance (MR) TADF emitter in a host matrix, hyper-fluorescence (HF) OLEDs already achieved higher efficiencies and comparable lifetimes with the ones already in the market. In this work, we focus on understanding the mechanism of the MR-TADF emitters using steady-state and time-resolved spectroscopic methods. Evidence of hot transitions from vibrational excited states is shown experimentally along with a temperature dependant singlet-triplet state energy gap (ΔE_{ST}). Combining the two, a reverse intersystem crossing (rISC) mechanism that involves thermally activated reverse internal conversion (rIC) from the T_1 to the T_n ($n \geq 2$) state followed by rapid (r)ISC to the S_1 state, is deduced. The existence of an intermolecular specie, due to the planarity/rigidity of the molecule, is assigned to an excimer which affects the optical performance even at concentrations below those used in devices. HF-OLEDs, using v-DABNA as the emitter, exhibit an increase of maximum external quantum efficiency (EQE), compared to a control device. Forster resonance energy transfer (FRET) studies show that although FRET efficiency decreases with decreasing emitter concentration, the overall device efficiency is higher, indicating that excimer quenching affects the OLED's performance.

Entropy, Delocalization, and Marcus-Theory Explain Ultrafast Free-Charge Generation in Excitonic Semiconductors Joshua Carr[1,2], Taylor Allen[2], Bryon Larson[2], Obadiah Reid[1,2] and Garry Rumbles[1,2]; [1]University of Colorado Boulder, United States; [2]National Renewable Energy Laboratory, United States

Understanding how Frenkel excitons efficiently split to form free-charges in low-dielectric constant organic semiconductors has proven extremely difficult, with many different models proposed in recent years to explain this exceptional phenomenon. Here, we present evidence that a simple model invoking a modest amount of charge delocalization, a sum over the available microstates, and the Marcus rate constant for electron transfer can explain many seemingly contradictory phenomena reported in the literature. We use an electron-accepting fullerene host matrix dilutely sensitized with a series of electron donor molecules to test this hypothesis. The donor series enables us to tune the driving force for photoinduced electron transfer over a range of 600 meV, mapping out normal, optimal, and inverted regimes for free-charge generation efficiency, as measured by time-resolved microwave conductivity. However, the photoluminescence of the donor is found to be rapidly quenched as the driving force increases, with no evidence of inverted behavior, or the linear relationship between photoluminescence quenching and charge generation efficiency one would expect. This behavior is self-consistently explained by competitive formation of bound charge-transfer states and long-range or delocalized free-charge states, where both rate constants are described by the Marcus rate equation. Moreover, the model predicts a suppression of the inverted regime for high-concentration blends and efficient ultrafast free-charge generation, providing a mechanistic explanation for why Marcus inverted-behavior is rarely observed in device studies.

Photophysical Approach to Study Matrix Effects on TADF Materials Larissa G. Franca, Kleitos Stavrou and Andrew Monkman; Durham University, United Kingdom

Thermally activated delayed fluorescence (TADF) emitters are considered a novel class of molecules for applications in organic light-emitting diodes (OLEDs). Due to the small energy gap between triplet and singlet state, reverse intersystem crossing (rISC) is allowed. This efficient mechanism has the ability to convert triplet states into an emissive singlet state, which enhances the internal quantum efficiency (IQE) towards 100%. In the context of an OLED, the TADF emitters are mainly incorporated in a matrix of host molecules. Apart from a better control of the electrical transport properties in the emission layer, the host molecules also prevent emitter self-quenching, a great source of non-radiative loses. The aim of this work is the use of DMAC-TRZ as a TADF emitter 'probe' to differentiate the environmental effects of a range of solid state host materials in guest-host systems. A variety of typical TADF OLED hosts with different characteristics was studied. This provides a clearer understanding of guest-host interactions and what effects emitter performance in solid state. Using time-resolved photoluminescence (PL) measurements, the CT state energy distribution was obtained from the full width at half maximum (FWHM) of the emission band. By correlating FWHM with other photophysical properties such as the apparent dynamic redshift of CT emission onset, we obtain the disorder-induced heterogeneity of D-A dihedral angles. Concentration dependence studies show that aggregation contributes to reducing photoluminescence efficiency. In our study, we explore the hosting potential of two host materials of similar chemical structure: mCPCN and mCBPCN, demonstrating the divergent photophysical behavior of DMAC-TRZ as a guest molecule.

Controlling Light-Matter Interaction with Molecular Vibrations in Mid-Infrared Resonators Felipe Herrera[1,2]; [1]Universidad de Santiago de Chile,

Chile; [2]ANID - Millennium Institute for Research in Optics, Chile

Nanoscale infrared (IR) resonators with sub-diffraction limited mode volumes and open geometries have emerged as new platforms for implementing cavity quantum electrodynamics (QED) at room temperature [1,2]. The use of infrared (IR) nano-antennas and tip nanoprobes to study strong light-matter coupling of molecular vibrations with the vacuum field can be exploited for IR quantum control with nanometer and femtosecond resolution. In order to accelerate the development of molecule-based quantum nano-photonic devices in the mid-IR, we developed a generally applicable semi-empirical quantum optics approach to describe light-matter interaction in systems driven by mid-IR femtosecond laser pulses.

The theory is shown to reproduce recent experiments on the acceleration of the vibrational relaxation rate in infrared nanostructures [3], and also provide physical insights for the implementation of coherent phase rotations of the near-field using broadband nanotips [4]. We then apply the quantum framework to develop general tip-design rules for the experimental manipulation of vibrational strong coupling and Fano interference effects in open infrared resonators. We finally propose the possibility of transferring the natural anharmonicity of molecular vibrational levels to the resonator near-field in the weak coupling regime, to implement intensity-dependent phase shifts of the coupled system response with strong pulses. Our semi-empirical quantum theory is equivalent to first-principles techniques based on Maxwell's equations, but its lower computational cost suggests its use a rapid design tool for the development of strongly-coupled infrared nanophotonic hardware for applications ranging from quantum control of materials to quantum information processing.

Molecular Polaritons—Photophysics and Photochemistry Joel Yuen Zhou; University of California San Diego, United States

Strong light-matter coupling reveals itself in dramatic changes in linear and nonlinear response spectroscopy. In particular, the emergence of so-called polariton (hybrid light-matter) modes that are well-separated in energy from bare material transitions indicates the onset of strong coupling. However, a more subtle question arises as to the extent to which polariton modes can alter photochemical and photophysical processes of interest. An important aspect that is not highlighted enough in molecular polaritonics studies is that whether the strong coupling happens with one or a few molecules (as in plasmonic nanocavities) or with a thermodynamic ensemble (of >10^6 molecules/photon mode) dramatically affects the outcome of the molecular process of interest. Here I will discuss effective strategies to take advantage of the various flavors of strong coupling phenomena to control photochemistry and photophysics.

Phase-Field Model of Coupled Electron and Lattice Dynamics in Correlated Material Systems Tiannan Yang[1], Yihuang Xiong[1], Yin Shi[1], Yakun Yuan[2], Yi Wang[1], Venkatraman Gopalan[1], Ismaila Dabo[1] and Long-Qing Chen[1]; [1]The Pennsylvania State University, United States; [2]University of California, Los Angeles, United States

We establish a phase-field model for coupled electron and lattice dynamics in correlated material systems under ultrafast excitation. The model integrates a phase-field description of phase transitions with other notable mechanisms at picosecond-to-nanosecond timescales to deliver a comprehensive spatiotemporal profile of excitation and relaxation transients of the system. Combined with first-principles calculation of electronic and phonon properties, we theoretically examine the light-excited electron and lattice dynamics in strongly correlated material $Ca_3Ru_2O_7$ involving a coupled electronic and magnetic phase transition. We demonstrate that the excited-state dynamics contains a three-component relaxation process of carrier concentration across picosecond-to-nanosecond timescales, which is supported by evidence from previous experimental works. A strong temperature dependence of all relaxation components within a wide range across the phase transition temperature is revealed. This model provides in-depth theoretical insights of the dynamical properties of complex electronic systems and ultrafast phenomena that lies within them. It can be applied to various material systems for predicting the electronic and lattice dynamics under different ultrafast external stimuli, including light pulses, electric fields, and currents, etc.

Electron-Phonon Coupling and Carrier Transport in Halide Perovskites from First Principles Feliciano Giustino; The University of Texas at Austin, United States

During the past decade halide perovskites have risen to prominence as a novel class of energy and optoelectronic materials. A fundamental question in the materials science of halide perovskites is how lattice vibrations influence their electronic and transport properties. In this talk I will describe first-principles investigations of electron-phonon couplings in hybrid organic-inorganic lead halide perovskites [1,2] and all-inorganic lead-free halide double perovskites [3], and I will analyze the atomic-scale mechanisms underpinning charge transport in these systems. I will show how the lower mobilities of halide perovskites, as compared to standard inorganic semiconductors, are linked with the heavy atomic masses and the resulting low vibrational frequencies. Furthermore, I will show that lead-free halide double perovskites exhibit lower carrier mobilities than their lead-halide counterparts because they possess much heavier band effective masses. For both lead-based and lead-free perovskites, carrier scattering by longitudinal optical polar phonons is found to be the main source of mobility degradation. Building on this understanding, I will discuss a universal scaling law for the carrier mobility in these compounds, and illustrate possible avenues to design new halide perovskites with improved carrier transport properties.

Optical Probes of Exciton / CT Mixing in Long-Lived Donor/Acceptor Complexes David S. Ginger[1], Yun Liu[1], Zilong Zheng[2,3], Veaceslav Coropceanu[4,2] and Jean-Luc Brédas[4,2]; [1]University of Washington, United States; [2]Georgia Institute of Technology, United States; [3]Beijing University of Technology, China; [4]The University of Arizona, United States

We seek to understand the lower limits of non-radiative recombination losses from charge transfer states in organic donor/acceptor systems. These factors underpin applications ranging from organic photovoltaics to organic LEDs and lasers. As an extreme case, we study a model thermally activated delayed fluorescence (TADF) system that exhibits both a high photoluminescence quantum efficiency (PLQY = ~22%) and comparatively long PL lifetime, while simultaneously yielding appreciable amounts of free charge generation (photocurrent external quantum efficiency EQE of 24%). In solar cells, this blend exhibits non-radiative voltage losses of only ~0.1 V, among the lowest reported for an organic system. Notably, we find that the non-radiative decay rate, knr, is on the order of 1E-5 /s, roughly 4-5 orders of magnitude slower than typical OPV CT states. Surprisingly however, this rate is still orders of magnitude too *fast* compared to predictions by Marcus-Levich-Jortner two-state theory. By comparing experimental PL and electroabsorption spectroscopy with theory, we conclude that CT-local exciton (LE) hybridization is present and that this mixing greatly increases the non-radiative recombination rate of the CT state. We discuss implications of this finding for different optoelectronic devices.

11:00 AM *EQ12.18.03
***In Situ* Transient Absorption Spectroscopy of Evolving Molecular Aggregates** Cathy Y. Wong; University of Oregon, United States

The electronic structure and exciton dynamics of the molecules and polymers that form the active layer in organic electronic devices can change dramatically during solution deposition and thermal annealing. As solvent vaporizes, molecules aggregate and become electronically coupled, sometimes dramatically changing the exciton dynamics and thus the suitability of the material for electronic devices. Similar changes occur during thermal annealing, as the relative orientation of molecules change. The exciton dynamics of molecules in solution and in films of aggregates can be measured using transient absorption spectroscopy. However, the progression of exciton dynamics during film formation and thermal annealing is unknown, as measurements typically cannot be performed quickly enough to collect accurate transient absorption spectra of the evolving molecular aggregates. The exciton dynamics of evolving material systems can be measured by increasing the speed of data collection. Single-shot transient absorption spectroscopy using tilted pulses can measure transient spectra with up to a 60 ps pump-probe time delay in 8 ms, with an adequate signal-to-noise ratio achieved in just a few seconds. The exciton dynamics of intermediate aggregation states are revealed during the formation of an organic film and during thermal annealing. This type of measurement provides insight into the complex process of organic film formation and how the excitonic properties of a film emerge.

Activated Carbon Aging Processes Characterization by Raman Spectroscopy Sari Katz[1], Alexander Pevzner[2], Vladislav Shepelev[2], Sharon Marx[2], Hadar Rotter[2], Tal Amitay Rosen[2] and Ido Nir[2]; [1]On Sabbatical leave from Soreq NRC, Israel; [2]Israel Institute for Biological Research, Israel

Activated carbon is used as an adsorbent material for various hazardous materials. Typically, active carbon is impregnated with metal oxides in order to improve its adsorbing capabilities towards inorganic low molecular weight gases, and high vapor pressure compounds by chemisorption mechanism. Exposure of activated carbon to humid air leads to water adsorption. As a result, the carbon surface and the impregnants are changing over time. The impregnants are dissolve and migrate to the external surface of the carbon following gradual recrystallization. The aging process may reduce the chemisorption capacity of the activated carbon.
In this study, the effect of aging on activated carbon from coconut husks source, impregnated with zinc oxide and the organic additive triethylenediamine, was studied by non-destructive Raman spectroscopy as well as energy dispersive spectroscopy. Raman spectroscopy enables the chemical characterization of a packed activated carbon samples. Energy dispersive spectroscopy was used to characterize the surface elements of the native and aged activated carbon. Accelerated aging was achieved by water adsorption on the carbon, followed by storage at 50^{o}C in a closed container. The study shows that the aging process increased the oxygen content on the carbon surface, both by introducing carboxyl and epoxides groups on the carbon surface, as well as migration of the metal oxide impregnants to the carbon granules' external surface. The aging process was studied by two laser excitation wavelengths (532 nm and 785 nm) Raman spectroscopy. Raman spectroscopy is commonly used to study carbonaceous materials molecular structure. It allows to characterize the graphitic sp^2 versus disordered sp^2 carbon, amorphous carbon sp^3 degree, and their stress state. In general, the G-band at ~1582 cm^{-1}, is of E_{2g} mode symmetry, which is common to all sp^2 carbon systems, and results from the in-plane bond stretching of the C-C bond in graphitic materials. The full-width at half-maximum of the G band increases monotonically with the degree of disorder in the graphitic lattice. The D-band at ~1350 cm^{-1}, is an A_{1g} breathing mode symmetry, it is associated with carbon atoms having disordered sp^3 carbon atoms. The intensity ratio ($R = I_D/I_G$) of D and G bands, is used to assess the sp^3/sp^2 carbon ratio, which represents the degree of disordered carbon atoms. An increase in this ratio results from a reduction in the crystalline size. The Raman D and G band shifts were followed by double Lorentzian model fitting. The aging outcome indicated by a D band position upshift from 1337 cm^{-1} to 1340 cm^{-1} and 1342 cm^{-1}, that can be explained by the compression of the activated carbon structure. The aging process leads to I_D/I_G increase indicating a reduction in the size of the crystal. In addition, the low frequency Raman bands were used to study the aging process of the carbon. Higher oxygen content on the carbon external surface was presented by elevated Raman intensities of the epoxide's groups at 643 cm^{-1}. This finding indicates oxidation of the carbon surface during the aging. Furthermore, higher content of the sp-sp^2 amorphous carbon at 405 cm^{-1} and 418 cm^{-1} was found in aged carbon, indicating carbon structure configuration changes with aging. The increased content of zinc on the carbon granules external surface, due to its migration during the aging, was portrayed by the creation of new vibration bands at 333 cm^{-1} and 991 cm^{-1} with aging. In addition, the higher content of oxygen on the carbon surface with aging, and the higher content of the impregnated metal was demonstrated by energy dispersive spectroscopy characterization.
Raman spectroscopy was found to be a powerful non-destructive method for analyzing the aging process of impregnated activated carbon.

11:35 AM EQ12.18.05
Influence of Surface Modification of $BaTiO_3$ Nanoparticles by Hydrolyzed Chitosan on the Optical Response Intensity of the Second Harmonic Luis M. Angelats Silva[1], Fredy R. Perez-Azahuanche[1], Jose A. Roldan-Lopez[1,2], Nikita A. Emelianov[3], Rudy B. Céspedes-Vasquez[1] and Miguel A. Valverde-Alva[2]; [1]Universidad Privada Antenor Orrego, Peru; [2]Universidad Nacional de Trujillo, Peru; [3]Kursk State University, Russian Federation

Spherical titanium barium nanoparticles with an average size about 100 nm in the tetragonal crystal phase were obtained by peroxide synthesis and then with formation of OH groups on its surface by hydrogen peroxide. To reduce the toxic effect, the surface of nanoparticles was chemically modified with hydrolyzed chitosan obtained from shrimp exoskeleton (*Penaeus vannamei*). The chitosan obtained and the modified surface were analyzed by X-ray diffraction, Raman spectroscopy and Infrared. Influence of surface modification on the optical response intensity of the second harmonic was investigated using a Nd:YAG laser 1064 nm (2.8, 4.5 and 8.1 mJ/pulse).

11:40 AM *EQ12.02.03
Carrier, Exciton and Spin Dynamics in Perovskite 2D Layered Systems Matthew C. Beard; National Renewable Energy Lab, United States

Controlling charge and energy flow in functional systems can be beneficial for solar energy conversion and utilization. The marriage of colloidal semiconductor nanocrystals and functional organic molecules has brought unique opportunities in emerging photonic and optoelectronic applications. In this presentation I will discuss our studies of controlling the charge carrier dynamics, light/matter interactions, and spin populations in these novel hybrid systems. In one effort we are exploring the use of novel organic hybrid systems at and near interfaces to control the carrier dynamics and reduce surface recombination but also to protect grain boundary surfaces from degradation. With respect to controlling spins we have recently studied and developed a novel class of chiral hybrid semiconductors based upon layered metal-halide perovskite 2D Ruddlesden-Popper type structures. These systems exhibit chiral induced spin selectivity whereby only one spin sense can transport across the film and the other spin sense is blocked. From these systems we can achieve a high degree of spin current polarization and injection when used as a contact layer. We have developed novel spin-based LEDs using mixed NCs as the light emitting layer that promotes light emission at a highly spin-polarized interface. The LED spin-polarization is limited by spin-depolarization within the MHP NCs. Thus understanding and controlling the spin-depolarization is an important goal. Here we discuss the charge carrier recombination rate and spin-coherence lifetimes in single crystals of 2D Ruddlesden-Popper perovskites. Layer thickness dependent charge carrier recombination rates are observed with the fastest rates for n = 1 due to the large exciton binding energy and the slowest rates for n = 2. Room temperature spin-coherence times also show a nonmonotonic layer thickness dependence with an increasing spin-coherence lifetime with increasing layer thickness from n = 1 to n = 4, followed by a decrease in lifetime from n = 4 to bulk.The longest coherence lifetime of ~7 ps is observed in the n = 4 sample. We also studied the spin-coherence lifetimes as a function of exciton binding energy and find that the spin-lifetime increases with decreasing exciton binding energy.

Transition Metal Nitride Semiconductors Daniel Gall; Rensselaer Polytechnic Institute, United States

We explore new transition metal nitride compounds using a combination of epitaxial layer growth, first-principles calculations, and measurements of electronic and optical properties as a function of composition and structure. (1) Rock salt structure: ScN has a E_g = 0.92 eV indirect bandgap and a carrier concentration that is controlled by F doping. CrN forms a charge-transfer insulator with E_g = 0.2+/-0.4 eV, but oxygen exposure results in a two-dimensional metallic CrN_xO_y surface layer. The addition of Al to form $Sc_{1-x}Al_xN$ and $Cr_{1-x}Al_xN$ compounds increases the bandgap with d E_g/dx = 2.75 and 2.81 eV, respectively. $Ti_{0.5}Mg_{0.5}N$ has a 0.7-1.7 eV bandgap. However, a high density of N vacancies act as n-type dopants resulting in a highly degenerate semiconductor. The vacancy formation is suppressed when alloying with Al, yielding $(Ti_{0.5}Mg_{0.5})_{1-x}Al_xN$ alloys with E_g increasing with x. (2) Wurtzite structure: Alloying AlN with Sc causes a drop in the direct bandgap for $Al_{1-x}Sc_xN$ with d E_g/dx = -9.23 eV and a structural instability with a non-linear composition dependence in bond angle and length that causes the reported piezoelectric enhancement. $(Ti_{1-x}Mg_x)_{0.25}Al_{0.75}N$ exhibits a stability peak at x = 0.5 with a minimum in the lattice constant ratio c/a that is caused by a Fermi-level shift into the bandgap and a trend toward nondirectional ionic bonding, leading to a maximum in the expected piezoelectric stress constant.

11:00 AM EQ13.01.03
Analysis of Niobium Nitride Films for Saturated Micrometer Wide Superconducting Single-Photon Detectors Owen Medeiros, Marco Colangelo, Akshay Agarwal, Ilya Charaev, Brenden Butters and Karl Berggren; Massachusetts Institute of Technology, United States

Superconducting single-photon detectors used for quantum optics, LIDAR, and astronomy, have traditionally been fabricated in a meander with strip widths around 100 nm. The narrow width was designed to be similar to the diameter of a hot spot formed by an incident photon. However, recent work has shown strips as wide as 3 μm were able to detect single photons by fine tuning the film's sputtering conditions[1–3]. Wider detectors show improved signal-to-noise ratio, and higher fabrication yield when compared to traditional detectors of the same active area. The increased performance of these detectors obtained by material deposition optimization suggests that by porting this process to traditional-width detectors may increase their sensitivity at mid-infrared wavelengths. This has prompted the recent work towards wide detectors in nitrogen rich niobium nitride (NbN)[4,5], however this work has ignored any characterization of the atomic structure of the material, instead focusing on electrical characterization of the thin film only. Here we study thin film NbN using sputtering conditions similar to previous work and fabricate single photon detectors between 0.5 and 3 μm wide. We observe saturated photon counts at 1550-nm wavelength in a 2.5 μm wide strip with a large inductor patterned in series to prevent latching. We characterize the film's atomic structure by performing x-ray diffraction (XRD) and transmission electron microscopy (TEM) and compare the results with RF-bias sputtered NbN[6]. We observe an increase in the 111-phase of NbN for the nitrogen rich films used to fabricate wide wire single photon detectors. These results suggest that the continued development of the NbN phase shown here would improve the detector performance. This optimization would allow for the detection of low energy photons in the mid-infrared[7] and lead to the development of large area single-photon detectors for dark matter detection[8], high energy physics[9], or biomedical imaging[10].

Advances and Challenges in Mapping the Stability Landscape of Novel Nitride Materials Wenhao Sun; University of Michigan, United States

Despite the great promise of nitrides as functional materials, exploration of the nitrides chemical space has been relatively limited compared to oxides and other chalcogenides/pnictides. Recently, we used a suite of computational materials discovery and informatics methods to construct a large stability map of the inorganic ternary metal nitrides [W. Sun. *et al.*, Nature Materials, 2019], revealing exciting opportunities for the discovery of novel nitride materials. Here, I will briefly review the computational methods we used to construct this stability map and will describe a new class of II_x-TM-N ternary nitride semiconductors experimentally realized from our 2019 search. However, since our 2019 search efforts, we have encountered new challenges to more comprehensively survey and design nitride materials. In this talk, I will examine these challenges and discuss our strategies for their solution: in particular, 1) search strategies for Zintl-based metal-rich nitrides which are relevant as permanent magnets, ammonia synthesis catalysts and superhard materials; 2) strategies for the facile synthesis of metastable nitrides based on computationally-guided ammonolysis and metathesis reactions, and 3) the pO_2 and pN_2 chemical potential boundaries between nitrides, oxynitrides and oxides.

Electrical Control in $ZnSnN_2$ by Tailoring Intrinsic and Extrinsic Defects Vegard S. Olsen, Simon Cooil, Vetle Øversjøen, Lasse Vines and Andrej Yu Kuznetsov; University of Oslo, Norway

Ternary nitrides are a novel and emerging class of semiconductors with potential impact within a wide range of applications, including solar cells, power electronics, and overall water-splitting [1]. Zn-IV-N_2, with IV = Sn, Ge or Si, represents an earth-abundant alternative to conventional III-nitrides, currently dominating the optoelectronic market and playing a vital role in a quest for record-high efficiency solar cells, specifically in multi-junction architectures. Zn-IV-N_2 semiconductors exhibit close similarities to the III-nitrides in terms of the functional properties, e.g., optical band gap tunability [2-4]. Such close similarities invite for both the knowledge transfer and combinational utilization of the III-nitride and Zn-IV-nitride systems. The main challenge for Zn-IV-N_2 in general, and for $ZnSnN_2$ in particular, is in controlling intrinsic and extrinsic defects, governing the carrier concentration (*n*).
Typically, for as-grown stoichiometric $ZnSnN_2$, *n* remains in the range of 5×10^{19} - 5×10^{20} cm^{-3}, where possible defects causing the degeneracy have been identified by first-principles calculations; the tin-zinc antisite (Sn_{Zn}), the nitrogen vacancy (V_N), and the zinc interstitial (Zn_i), are all defects probable to occur and form shallow donors [5,6]. Furthermore, common impurities such as oxygen substituting for nitrogen (O_N), hydrogen interstitials (H_i) and

substitutional hydrogen (H_N), also form donor states in $ZnSnN_2$ [5,6]. The prevailing route for controlling *n* is the fabrication of Zn-rich $ZnSnN_2$, effectively reducing and enhancing the formation probability of Sn_{Zn} donors and Zn_{Sn} acceptor [7], but the carrier mobility (μ) remains unacceptably low (< 10 $cm^2 V^{-1}s^{-1}$). Possible *p*-type dopants in $ZnSnN_2$ have also been identified by first-principles calculations, where Na_{Zn} and K_{Zn} are predicted to exhibit deep acceptor levels, while Li_{Zn} is predicted to be a shallow acceptor [8]. However, the corresponding experimental explorations are rare or missing. Here, we report on $ZnSnN_2$ thin films grown by high-power impulse magnetron sputtering (HiPIMS), with carrier concentration reducing strategies, such as shallow acceptor doping with Li and off-stoichiometric growth. We thus extend our work on epitaxial $ZnSnN_2$ growth exhibiting a dislocation density of 1×10^{10}-5×10^{10} cm^{-3}, i.e., comparable to III-nitrides grown without dislocation-reducing strategies [9], in order to obtain electrical control. Our preliminary results confirm that the Sn_{Zn} antisite is the dominant intrinsic defect, as *n* is reduced, and hence also the optical band gap (from ~1.78 eV to ~1.28 eV) due to reduced Burstein-Moss shift, when moving towards more Zn-rich conditions. Moreover, we confirm that Li acts as an acceptor in $ZnSnN_2$, reducing *n* in the stoichiometric film by an order of magnitude, while keeping μ at a reasonable high value, μ ~ 60 $cm^2V^{-1}s^{-1}$. As predicted by Wang *et al*. [8], Li_{Zn} is a shallow acceptor in $ZnSnN_2$; however, in the interstitial configuration (Li_i), Li may act as a donor too. Nevertheless, even though both Li_{Zn} and Li_i are possible to occur in our samples, the significant reduction in *n* for the stoichiometric film suggests that the majority of the incorporated Li is in the form of Li_{Zn} acceptors. Thus, controlling the interplay between intrinsic and extrinsic defects may lead to a breakthrough in the development of $ZnSnN_2$.

Accelerated Simulation of Elastic and Thermodynamic Properties of Materials at High Temperature Ferenc Tasnadi[1], Florian Bock[1], Qurat Ul-Ain[1], Alexander Shapeev[2], Magnus Odén[1] and Igor A. Abrikosov[1]; [1]IFM Linköping University, Sweden; [2]Skolkovo Institute of Science and Technology, Russian Federation

Refractory nitrides (TiN, ZrN, Hf, etc.) and nitride alloys ($Ti_{1-x}Al_xN$, etc.) form a class of materials with high industrial relevance for hard coatings of cutting tools [1] or for plasmonic-based devices [2]. For these applications the major objectives are the material's high-temperature thermal and elastic properties. A recently developed combination of quantum mechanical calculations with machine-learning interatomic potentials [3], is utilized to calculate materials elastic constants with high accuracy. On-the-fly training of these potentials allows us to perform the calculations with more than two orders less computational effort than using state-of-the-art ab initio molecular dynamics simulations. The derived elastic constants are used to calculate surface acoustic waves and Brillouin light scattering (BLS) spectra. The results are compared with experiments. Furthermore, we investigate high-temperature bcc phase of titanium and predict very weak temperature dependence of its elastic moduli [4], called Elinvar effect, similar to the behavior observed for so-called GUM alloys. However, the effect in bcc-Ti is intrinsic and therefore unique.

Atomistic Modeling of Hot-Press Sintering of AlN Ceramics Aoyan Liang, Chang Liu and Paulo Branicio; University of Southern California, United States

The sintering of AlN ceramics has been intensely investigated and it is reasonably understood. The increasing possibilities offered by the outstanding properties of nanostructured ceramics underline the necessity to also understand the sintering process of AlN ceramic nanoscale powder. Here, we use atomistic molecular dynamics simulations to study the hot-press sintering of AlN nanoceramics. We employ nanopowder samples composed of nanoparticles with 8, 12, and 16 nm: namely, samples AlN-8, AlN-12, and AlN-16. Densification simulations are run for 6 ns under a hydrostatic pressure of 1 GPa and sintering temperature of 1,900 K. An extra simulation is performed for an 8 nm sized nanoparticle system at a lower pressure of 0.1 GPa (sample AlN-8-0.1). Results show that the sample AlN-8 reaches 99% densification, the highest of all systems. 96.2%, 95.6%, and 93.2% densifications are achieved for the samples AlN-8-0.1, AlN-12, AlN-16, respectively. Grain size distribution statistics shows that the AlN-8 system experience significant microstructural evolution from 3 to 6 ns of the sintering process developing a wide distribution of grain sizes from 4 to 15 nm with a large average grain size of ~11 nm. These results reveal a two-stage sintering process: (1) Initial swift densification that is rooted at the high diffusivity of surface atoms. (2) Intense grain growth driven by grain boundary migration. Moreover, a wurtzite-to-rocksalt structural phase transformation occurs at the nanoparticles contact points in the AlN-16 sample during the sintering. These exciting results offer nanoscale insights into the intriguing hot-press sintering of nanoscale ceramics and shed light on the densification and microstructural evolution processes.

Molecular-Level Sintering Additives for Densification of SiAlON Ceramics Kade McGarrity and Holly Shulman; Alfred University, United States

SiAlON ceramics are solid solutions of Al and O in the Si_3N_4 lattice. They are used as wear parts and gas turbine engine blades, and more recently have shown promise for application as biomedical implants. The densification of SiAlONs is generally achieved using sintering additives and/or pressure-assisted sintering techniques. Traditionally, additives such as alumina and yttria powders are utilized. In this work, we investigate the use of organic precursors rather than powders in order to incorporate sintering additives at the atomic or molecular level. This presentation will highlight the densification, strength, elastic modulus, hardness, microstructure, and phase assemblage of SiAlONs fabricated via atomic-scale as well as conventional additives. It was found that the use of molecular precursors may enhance densification by providing a very fine scale distribution of solute atoms which are more readily available to the Si_3N_4 starting powder than atoms confined to powder particles.

Synthesis of Silicon Nitride Nanoparticle Films from Silane-Nitrogen Non-Thermal Radio-Frequency Plasma Gunnar Nelson, Himashi P. Andaraarachchi, Ognjen Ilic and Uwe R. Kortshagen; University of Minnesota Twin Cities, United States

Silicon nitride (SiN_x) is ubiquitous in photovoltaic technology as a dual-purpose passivation layer and antireflection-coating. It also is used as a durable coating/material in industrial settings as it is a high-strength ceramic. Recent work has explored nanoscale silicon nitride morphologies such as nanowires, nanopores, nanocomposites, and others. Specifically, nanoparticle (NP) SiN_x is a promising nano-scale form as it has applications in battery technology, passive radiative cooling films, and as passivation layer on silicon nanoparticles for improving photo-luminescence. Also hot-pressed and sintered SiN_x from a powder is an attractive route to high mechanical strength materials. These studies outline the need for SiN_x NP with a narrow size distribution, minimal aggregation, high purity, and high throughput. However, producing SiN_x nanoparticles with current top-down techniques does not meet the high yield and narrow size distribution requirements. Bottom-up techniques such as gas phase synthesis typically require very high temperatures and use ammonia as the nitrogen precursor as it has lower bonding energy than diatomic nitrogen. Ammonia, however, is caustic and requires several safety precautions. Nonthermal plasma NP synthesis has been shown to be a promising technique which meets these production requirements and can deposit uniform films over a wide area with tunable thickness and porosity. Here, we report SiN_x NP synthesis with this technique using a silane-nitrogen plasma. After synthesis, the particles are accelerated through a nozzle to sonic speeds to deposit ballistically onto a rastered substrate. Resulting SiN_x NP films show low visible absorption suggesting stoichiometric silicon nitride. This study shows that silicon nitride nanoparticles can be produced in this high-yield, scalable, and tunable synthesis process.

Switching Dynamics in Ferroelectric AlN-Based Films Keisuke Yazawa[1,2], Daniel Drury[1,2], Andriy Zakutayev[2,1] and Geoff L. Brennecka[1]; [1]Colorado School of Mines, United States; [2]National Renewable Energy Laboratory, United States

The 2019 report from Fichtner, et al.[1] of ferroelectric switching in $Al_{1-x}Sc_xN$ thin films further increased interest in this materials system that was already the darling of the piezoelectric thin film community. This system now promises both resonator-quality piezoelectric properties and the potential to enable a class of next-generation compute-in-memory hybrids if switching voltages can be sufficiently scaled. Hayden, et al.[2] recently expanded the family of AlN-based ferroelectrics to include $Al_{1-x}B_xN$ and even unmodified AlN, adding to the excitement over potential for integrated functionality. The large switchable spontaneous polarization values, enormous coercive fields, and remarkably square hysteresis loops of AlN-based ferroelectrics draw sharp contrast to HfO_2-based ferroelectrics and highlight the need for better understanding the switching behaviors in these novel ferroelectrics to effectively leverage this switchable polarization.

Using a custom-built high power measurement capability in addition to commercial test equipment, we have studied the polarization reversal behavior of AlN-based ferroelectric thin films across more than 9 orders of magnitude in time. This talk summarizes our findings on the effects of chemistry (intentional alloying elements such as scandium and boron as well as unintentional contaminants such as oxygen), measurement temperature, film structure and stress state, and electrodes on switching dynamics. Combined with complementary measurements of Rayleigh behavior and polarization retention, these studies provide strong hints at the underlying mechanisms controlling ferroelectricity in these new AlN-based ferroelectrics.

Characterization of the Structure, Composition and Strain in Ultrathin Ferroelectric Aluminum Scandium Nitride Films Pariasadat Musavigharavi, Andrew C. Meng, Dixiong Wang, Jeffrey Zheng, Alexandre Foucher, Roy H. Olsson and Eric A. Stach; University of Pennsylvania, United States

We present characterizations of the local atomic structure and nanoscale chemistry of ferroelectric aluminum scandium nitride thin films ($Al_{1-x}Sc_xN$) using advanced transmission electron microscopy (TEM) techniques. An $Al_{1-x}Sc_xN$ (x = 0.36) film of ~20 nm thickness was grown on a Pt(111)/Ti/SiO2/Si(100) substrate via pulsed DC co-sputtering. The homogeneous distribution of scandium and the formation of defects in the epitaxial growth of 2.1% lattice-mismatched AlScN on Pt are reported. We also examined the strain distribution across the AlScN/Pt interface. The "four-dimensional scanning TEM" (4D-STEM) technique was employed to systematically investigate the nanoscale order by measuring the average spacing between atoms within certain regions in the film and determining the strain. It was conclusively shown that AlScN crystallites preserve the piezoelectric wurtzite-type structure in the (001) preferential orientation normal to the substrate. The strain map confirms a significant increase in the out-of-plane component of the lattice parameter (~9%) at the AlScN/Pt interface. The lattice parameter in the Pt template decreases as a function of distance from the Pt/Si interface. The study of the atomic crystal structure and the chemical composition of the AlScN thin film provides useful information that will aid future applications of this material in ferroelectric memories and microelectromechanical systems.

SESSION EQ13.06: III-N Semiconductors for Optoelectronics

2:00 PM *EQ13.06.02
Distribution of Ge Dopants in AlGaN—A Chemical and Structural Investigation Down to the Nanoscale Catherine Bougerol[1], Eric Robin[2], Enrico Di Russo[3], Edith Bellet-Amalric[2], Vincent Grenier[2], Akhil Ajay[2], Lorenzo Rigutti[3] and Eva Monroy[2]; [1]Institut Néel - CNRS, France; [2]CEA-IRIG, France; [3]UNIROUEN-CNRS, France

The potential of Ge as n-type dopant for AlGaN materials is currently under consideration. Ge is known to generate significantly less local tensile strain than silicon, whatever the Al mole fraction of the alloy. However, at high doping concentrations, the issue of the effective dopant incorporation and its spatial distribution is relevant. Formation of precipitates or diffusion of dopants along structural defects may occur [1]. Recently, we have demonstrated plasma-assisted molecular-beam epitaxy growth of $Al_xGa_{1-x}N$ planar layers with Ge nominal concentrations up to 10^{21} cm^{-3} [2]. Here, we present a structural analysis of $Al_xGa_{1-x}N$:Ge samples with x covering the full compositional range ($0 \leq x \leq 1$), together with the measurement of Ge concentration and its spatial distribution from the µm range down to the nm scale [3]. Our study is based on a combination of X-ray diffraction (XRD) and quantitative energy dispersive X-ray spectrometry (EDX) coupled to high-resolution scanning transmission electron microscopy (HR-STEM) and atom probe tomography (APT).

In $Al_xGa_{1-x}N$:Ge samples with $x>0.4$, top-view SEM observations reveal the presence of µm-size crystallites at the surface. The nature of such crystallites is pure Ge, as verified by EDX. Inside those layers, we have also identified Ge-rich inclusions with a size of tens of nanometers, generally associated with Ga-rich regions around structural defects. With these local exceptions, the $Al_xGa_{1-x}N$:Ge matrix presents homogenous Ge composition. The Ge concentration in the matrix, i.e. away from the precipitates, was obtained from the ratio of the EDX signal between doped and undoped samples. The Ge content in the binary AlN matrix is extremely low, and it increases linearly with the Ga mole fraction in ternary $Al_xGa_{1-x}N$, which suggests that the Ge incorporation takes place by substitution of Ga atoms. The maximum percentage of Ga sites occupied by Ge saturates around 1%. These solubility issues and the Ge segregation phenomena should play a role in the efficiency of Ge as n-type dopant, even at Al concentrations where Ge DX centers are not expected to manifest. In view of these results, the extracted solubility limit of Ge in $Al_xGa_{1-x}N$ can have direct impact on the performance of $Al_xGa_{1-x}N$-based UV light emitting diodes. In principle, the Ge content should be kept below these limits to prevent a degradation of carrier transport due to scattering at structural defects. Co-doping or the use of surfactant species should be explored to attain Ge concentrations beyond the solubility limit.

Has the InGaN Nanowires Surface an Influence on Luminescence Efficiency? Alexandre Concordel, Joël Bleuse and Bruno Daudin; CEA Grenoble, France

The remarkable properties of InGaN/GaN nanowires (NWs) heterostructures emitting at 480 nm and grown by PA-MBE, namely a large amount of free surface favouring strain relaxation and the expected absence of extended defects make them attractive for the development of a new generation of highly efficient light emitting diodes (LEDs). However, as a counterpart of these potential advantages, the surface itself may act as a non-radiative recombination centre. To clarify this issue, the effect of surface passivation by deposition of an aluminium oxide material, using the Atomic Layer Deposition technique was investigated by time resolved photoluminescence experiments. It appears that the photoluminescence decay - which follows a power law - before passivation is markedly shorter than following passivation, emphasizing the role of the NW surface as a non-radiative recombination channel in the case of InGaN/GaN NWs heterostructures. Furthermore, Micro-photoluminescence spectroscopy experiments performed on InGaN/GaN NWs for laser excitation power density ranging from 10^{-4} $W.cm^{-2}$ to 10^{6} $W.cm^{-2}$, exhibit a bell shape curve, typical of a defect saturation regime. As the power law dependence of the photoluminescence prevents from determining a single lifetime, the standard phenomenological ABC model cannot be used to describe it. Hence, we developed a theoretical model that accounts for the carrier generation, the radiative recombination, the capture of carriers by non-radiative defect states — leading to their saturation, as well as the Auger losses. The internal quantum efficiency and the nature of carrier recombination (monomolecular or bimolecular) are quantitatively assessed by this model, as a function of the excitation power.

SESSION EQ13.07: III-N Epitaxy and Nanowires

4:00 PM *EQ13.07.01
Exploring the Properties of GaN Epilayers on van der Waals Substrates—The Case of Graphene and Muscovite Mica Ana Cros[1], Saül Garcia-Orrit[1], Núria Garro[1], Oleksii Klymov[1], María José Recio-Carretero[1], Marion Gruart[2], Remy Vermeersch[2], Fabrice Donatini[2], Catherine Bougerol[2], Bruno Gayral[2], Stéphanie Pouget[2], Edith Bellet-Amalric[2], Nicolas Mollard[2], Hanako Okuno[2], Jean-Luc Rouvière[2], Nathaniel Feldberg[2] and Bruno Daudin[2]; [1]Univ de Valencia, Spain; [2]Univ. Grenoble-Alpes, France

The quality of III-nitride epilayers depends strongly on the characteristics of the substrate. The reduction of the number of extended defects in lattice mismatched epitaxial GaN layers grown on the most used substrates, namely sapphire and silicon, requires complex growth strategies that, despite the continuous advances, result in higher costs of the final device. The mismatch in thermal expansion coefficients of III-nitride layers and, for instance, Si substrate, is an additional source of extended defects associated with a strong substrate/layer chemical bonding. This motivates the exploration of alternative substrates, including the renewed interest in van der Waals epitaxy, where epitaxial growth is achieved through weak dipolar interactions. Materials such as graphite, mica, MoS_2 or GaSe, have layered structures bonded via weak van der Waals interaction and can be easily cleaved, presenting very flat surfaces and the absence of dangling bonds. When GaN is grown on them, these substrates allow a significant relaxation of the epilayer strain and facilitate, at the same time, layer detachment [1].

We study the case of GaN grown by molecular beam epitaxy on graphene and muscovite mica as possible van der Waals substrates, addressing epilayer morphology, crystallographic phase and orientation, surface potential and strain. We also study the changes experienced by the graphene substrate during growth: doping, strain and, under certain conditions, the intercalation of a self-limited bilayer of metal atoms below graphene [2, 3]. In the case of mica, we observe that part of the strain accumulated in the GaN layer during growth relaxes by the formation of three-dimensional structures in the shape of telephone cord buckles, straight blisters or by more complex arrangements. The characteristics of these structures are analyzed in relation to the compressive strain of the surrounding material, the achieved relaxation and layer adhesion [4].

Chemical and Kinetic Mechanisms to Overcome Perceived Limitations in III-Nitride Epitaxy William A. Doolittle, Zachary Engel, Habib Ahmad, Christopher Matthews and Keisuke Motoki; Georgia Institute of Technology, United States

III-Nitride epitaxy is fraught with many challenges ranging from phase separation to high defect densities to doping limitations. Traditional epitaxy has suggested that high temperatures are required to maintain long surface diffusion lengths and thus, high material quality. Unfortunately, high temperature environments also introduce significant complications and limitations in practically achievable compositions and doping ranges. Furthermore, huge variations in the effective metal-fluxes from one growth system to another at traditional epitaxy growth temperatures makes it difficult to achieve commercial scalability. By deviating from the normal high temperature epitaxy via the control of surface chemistry and adding intentional kinetic limitations on adatom diffusion, we can achieve significant improvements in the material quality of traditionally difficult materials to grow such as AlInN and InGaN. Non-phase separated InGaN has been grown throughout the miscibility gap and record Indium-content solar cells produced via a low temperature variant of molecular beam epitaxy called metal modulated epitaxy (MME). MME offers the ability to control major factors in phase separation: growth at low temperature avoids InGaN decomposition and indium desorption; high growth rates limit the lateral separation of surface adatoms; and fine-control of excess-metal dose per shutter cycle prevents extreme build-up of a metal adlayers and allows control over vertical segregation of indium and gallium. Likewise, highly luminescent AlInN has been produced that has x-ray diffraction (XRD) figures of merit 11 times better than previous literature. Furthermore, MME has been expanded to grow high crystal quality AlInN over the entire composition range. Additionally, low temperature MME AlInN growth near the composition that would be latticed matched to GaN (~18% In) shows XRD figures of merit rivaling the best in the literature. By modeling and controlling surface chemistry, especially vertical phase segregation, remarkably coherent superlattices can be obtained in AlGaN and InGaN ternary systems and can be maintained coherent for many microns thicknesses. MME achieves excellent uniformity and thickness control suitable for commercial use primarily because of low temperature growth while simultaneously achieving high quality films via enhanced adatom diffusion through its additional growth control parameter of excess-metal dose per shutter cycle.
Additionally, by using substantially lower growth temperatures than other methods, MME can enhance the doping concentration of traditionally difficult dopants such as magnesium and beryllium exceeding prior doping limits by more than 40 times and for more traditional dopants like Si and Ge by factors of 2 to 4. This has led to a new understanding of the acceptor energy wherein a wide acceptor energy band forms because of the Pauli Exclusion principle compared to a single isolated energy in traditionally doped cases. Using these highly advanced low temperature doping methods, tunnel junctions with record conductance and strong negative differential resistance have been demonstrated and used in GaN and AlGaN homojunction devices even up to 58% Al. These advances have enabled the first tunnel junction contacted III-Nitride solar cell with much higher uniformity and improved the 270 nm DUV optical output of LEDs by as much as 110%. Finally, we will demonstrate that by a combination of low temperature growth and control of surface chemistry, for the first time we have been able to demonstrate p-type aluminum nitride with hole concentrations exceeding $1x10^{18}$ cm^{-3} and showed a first time heterojunction p-AlN/n-GaN diode with modest rectification showing future potential for future deep ultraviolet, high-power and high-frequency devices capable of operation in extreme radiation and heat environments.

Towards a Better Understanding of Electronic Transport in Si Doped AlN Nanowires Remy Vermeersch[1,2], Eric Robin[1], Ana Cros[3], Gwénolé Jacopin[2], Bruno Daudin[1] and Julien Pernot[2]; [1]CEA Grenoble, France; [2]CNRS Neel Institute, France; [3]University of Valencia, Spain

Thanks to its ultra-wide band gap, AlGaN and AlN nanowires (NWs) are attractive candidates for deep UV light emitting diodes (LED). The absence of extended defects, such as dislocations, as well as the morphology of nitride NWs, are favorable to improve the dopants incorporation, the internal quantum efficiency and light extraction. In this context, some of us recently reported axial pn junction realization with Mg acceptors in the p-region and Si donors in the n-region [1]. Thus, it becomes crucial to understand and describe in detail the transport mechanisms at the origin of the current flow inside the individual nanodevices. The n-type doping of AlN nanowires remains a blind spot in recent research and is as important as its p-type counterpart in order to achieve the best performances for nanowire-based DUV LEDs.

In this work, we investigate the electrical properties of n-type AlN NWs grown by molecular beam epitaxy using several silicon fluxes. The current voltage measurements show that all the samples exhibit an Ohmic regime at low bias (< 0.2 V) and a space charge limited current regime assisted by traps for higher voltage (> 0.2 V). This regime occurs in semiconductor with moderate carrier density either because of a near-surface depletion or because of a weak ionization of relatively deep dopants. The conductivity reaches a maximum of 6.10^{-6}S/cm for intermediate Si flux before dropping down to 4.10^{-}

^{9} S/cm at larger flux, in good agreement with high compensation effects observed in bulk AlN [2]. Temperature dependent measurements from 180 K to 600 K revealed that NW conductivity is a combination of the two identified silicon levels at 75meV and 270meV [3]. Due to a high surface level pinning energy of 2.1eV [4], the NW diameter is shown to be a key parameter of particular importance in order to not reach its full depletion, decreasing the free electrons concentration at thermal equilibrium and leading to poor conductivity. The full model and analysis will be presented and discussed in this presentation. Those results point towards the need for larger nanowires and/or surface passivation to ensure better electron injection, enabling the realization of efficient UV LEDs.

Inhomogeneous Si and Mg Dopant Distribution in GaN Nanowires Ece Aybeke[1,2], Alexandra-Madalina Siladie[3,4], Remy Vermeersch[3,4], Eric Robin[3,4], Oleksandr Synhaivskyi[1,2], Bruno Gayral[3,4], Julien Pernot[4], Georges E. Bremond[1,2] and Bruno Daudin[3,4]; [1]Institut des nanosciences de Lyon, France; [2]Institut National des Sciences Appliquées, France; [3]CEA Grenoble, France; [4]Université Grenoble Alpes, France

Introduction of electrical dopant species in semiconductors generally results in increasing built-up strain for increasing dopant densities, till reaching the solubility limit and/or a strain relaxation stage associated with extended defect formation. By contrast doping in nanowires (NWs) obeys a specific regime, associated with their unique morphology. In the case of GaN NWs grown on Si (111) by molecular beam epitaxy, the eased strain relaxation due to the large amount of free surface favors the incorporation of Si dopant at concentrations higher than in layers [1]. Also, specific adatom surface diffusion and reconstruction-stabilized sidewall stoichiometry are affecting dopant incorporation. Hence, atom probe tomography [2] and energy-dispersive X-rays spectroscopy (EDX) [3] experiments at the nanoscale demonstrate that preferential Mg incorporation through the m-plane side walls of GaN NWs leads to a higher Mg density in the NW periphery, about ten times larger than in the NW core. Scanning spreading resistance microscopy (SSRM) experiments were performed to investigate the effect of inhomogeneous dopant distribution on the electrical transport properties of n-type and p-type GaN NWs at the nanoscale. In Si-doped GaN NWs a conductive core surrounded by a more resistive shell was put in evidence, which is assigned to the depletion resulting from Fermi level pinning on m-plane surface states. By contrast, in the case of Mg-doped GaN NWs, the SSRM is one order of magnitude smaller at the periphery than at the centre of the Mg-doped GaN. This experimentally demonstrates that peripheral Mg incorporation in GaN NWs indeed counterbalances the depletion resulting from Fermi level pinning on m-plane surface states, which results in preferential current flow in the highly doped shell. For the same samples as measured by SSRM, EDX reveals a Mg concentration of about 2-4 × 10^{20} /cm^3 in periphery, higher by more than one order of magnitude compared to the NW centre where the Mg content is below the experimental detection limit of 10^{19}/cm^3. The coexistence of these different electrical conduction channels, specific to NWs, opens new prospects on the full understanding of the opto-electrical properties of NW-based devices such as visible or UV light emitting diodes.

Computational Design and Exploration of Ternary Zinc Nitride Semiconductors Fumiyasu Oba; Tokyo Institute of Technology, Japan

The search for novel semiconductors is increasingly important as the applications of semiconductors become more prevalent in modern society. This situation stimulates not only experimental but also computational explorations of as-yet-unreported semiconductors, typically using first-principles calculations. In such computational searches, reliable design principles, as well as accurate and efficient computational schemes, are key requirements for the successful identification of target materials and functionalities. In this talk, I will discuss the design and exploration of nitride semiconductors using first-principles calculations, with a focus on ternary zinc nitrides. Topics to be covered include the theoretical prediction and experimental verification of new nitride semiconductors such as CaZn2N2, SrZn2N2, and related alloys with direct band gaps covering most of the visible light range [1-3]. Computational methods for predicting fundamental and defect properties of semiconductors and their applications to nitride semiconductors will also be discussed [4].

Exploring Polymorphism and Cation Disorder in Mg-IV-N_2 Semiconductors Ann L. Greenaway[1], Rekha Schnepf[1,2], Amanda Loutris[1], Karen Heinselman[1], Rachel Woods-Robinson[1,3], Celeste Melamed[1,2], Jesse Adamczyk[2], Brooks Tellekamp[1], Sage Bauers[1], Andriy Zakutayev[1], Steven Christensen[1], Stephan Lany[1] and Adele Tamboli[1]; [1]National Renewable Energy Laboratory, United States; [2]Colorado School of Mines, United States; [3]University of California, Berkeley, United States

While the III-N compounds revolutionized solid-state lighting, there is ongoing work to identify nitrides which enable technologies currently inaccessible with III-Ns, such as bridging the “green gap”. This has led to the investigation of increasingly complex materials which potentially have increased property tunability over the III-Ns, such as II-IV-N_2 compounds $ZnGeN_2$ and $ZnSnN_2$. Interest in these materials is driven by their cation site disorder, which may be harnessed to tune bandgap without a corresponding change in lattice parameter [1]. At the same time, it is increasingly clear that metastable nitrides are highly synthesizable compared to other compounds [2], increasing the diversity of nitride materials which can be utilized in emerging technologies.

While interest in the Zn-based II-IV-N_2 compounds has been high, Mg-IV-N_2 compounds (IV = Si, Ge, Sn) are substantially underexplored in comparison. However, these materials not only display the potential for bandgap tunability *via* cation disorder of II-IV-N_2 compounds, but also multiple low-energy metastable polymorphs, as exemplified by $MgSnN_2$ [3]. The wurtzite-type, ground-state polymorph of $MgSnN_2$ has a ~2.4 eV bandgap, but it can also form as a >2.9 eV, high dielectric constant rocksalt-type metastable phase. Here, we present ongoing work on the synthesis of the Mg-IV-N_2 family of compounds, seeking to understand and control polymorph formation to enable property tuning across the group.

First, we discuss our combinatorial approach to the synthesis of the Mg-IV-N_2 compounds, beginning with $MgSnN_2$ [3]. The metastable rocksalt-type polymorph of $MgSnN_2$ was found to form as a secondary phase to the wurtzite-type polymorph at substrate temperatures below 200 °C and at high Mg content on Si substrates, but also as part of a mixed wurtzite/rocksalt phase on GaN substrates at high temperatures. The close effective lattice match between GaN (001) and rocksalt $MgSnN_2$ (111) surfaces promotes the formation of the rocksalt at those high temperatures, an effect that we seek to leverage in ongoing work exploring control of polymorph formation *via* epitaxial strain energy of different substrates. We will discuss related phenomena in $MgSiN_2$ and $MgGeN_2$, and present trends across this family of materials, with broad lessons for development of emerging nitride semiconductors.

This material is based on work funded by a Director's Postdoctoral Research Fellowship (LDRD) at
the National Renewable Energy Laboratory and by the Office of Science, Basic Energy Sciences, Material Sciences and Engineering Division.

Strain-Induced Creation and Switching of Anion Vacancy Layers in Perovskite Oxynitrides SrV(O,N)$_3$ Hiroshi Kageyama; Kyoto University, Japan

In oxides, the oxygen-vacancy ordering often occurs, leading to the emergence of novel functional properties, as exemplified by YBCO. On the other hand, oxynitrides are expected to have functions beyond oxides due to the difference in nitrogen and oxygen (e.g., valence and polarizability), but there are no reports on anion-vacancy ordering. In my talk, a successful example of anion-vacancy order is shown by $SrVO_{2.2}N_{0.6}$, where anion-vacant layers appear periodically along the 111 direction when perovskite oxide SrV(IV)O3 powder is treated with NH3 at about 600°C. We suggest that the anion-deficient ordering is originated from the oxidation of V^{4+} to V^{5+} by N_3-/O^{2-} exchange and the preference of pentavalent V for tetrahedral coordination. More surprisingly, when the same treatment was applied to a single-crystal $SrVO_3$ thin film, the direction of the vacancy planes (111, 112) and the periodicity (5-fold, 6-fold) changed depending on the substrate used. The biaxial strain effect was verified by first-principles calculations. Like oxide heterostructures, the oxynitride has a superlattice of insulating and metallic blocks. Given the abundance of perovskite families, this study provides new opportunities to design superlattices by chemically modifying simple perovskite oxides with tunable anion-vacancy patterns through epitaxial lattice strain.

9:30 AM *EQ13.08.04
New Polar Oxynitride Perovskites Amparo Fuertes; ICMAB-CSIC, Spain

Perovskite oxynitrides *AB*O_2N or *AB*ON_2 (*A*=rare earth or alkaline earth metal; *B*=transition metal) are important heteroanionic materials that show high permittivities, photocatalytic activity under visible light and colossal magnetoresistance among other relevant properties. (1) Pseudocubic oxynitride perovskites derived from the Pm-3m aristotype are centrosymmetric and show symmetry lowering for tolerance factors (t) below 1. All anion sites show similar coordination environments with cations, which favours the partial or total disorder of nitrogen and oxygen. The observed high relative permittivities and ferroelectricity in compounds such as $SrTaO_2N$ and $BaTaO_2N$ have been ascribed to local electrical dipoles (2) from cis order of nitrides, induced by covalency. (3)

Hexagonal perovskites formed by sequences of cubic and hexagonal close packed AX_3 layers are stabilized for tolerance factors greater than 1 and show two well differentiated environments for anions, in sharing vertex and sharing faces of the BX_6 octahedra, providing the possibility of selective occupation by nitride and oxide. This talk will present results on the new polar compound $BaWON_2$ that is the first example of a hexagonal perovskite oxynitride. (4) It shows the *6H* polytype and crystallizes in the non-centrosymmetric space group $P6_3mc$, with cell parameters a=5.85073(2) and c=14.53220(9) Å. The two anions N^{3-} and O^{2-} are completely ordered in the vertex shared and face shared positions of the WX_6 octahedra respectively. The preferred occupation of the more electronegative O atom at face-shared sites is a consequence of the weaker bonding for these positions, with W-X-W angles ≈90°, compared with corner-shared sites, with W-X-W angles≈180°. Total anion order, together with the large electrostatic repulsion between W^{6+} cations in the face shared octahedra, and second order Jahn-Teller effect induce highly distorted environments in three inequivalent WX_6 octahedra stabilizing the non-centrosymmetric structure. The spontaneous polarization, calculated from the crystal coordinates and formal electrical charges of all atoms, is ≈17.7 μC/cm^2, parallel to the c axis. $BaWON_2$ is a semiconductor with a band gap of 1.1 eV and a relative permittivity of 200-230 in the 10-100 K temperature range, and shows a second harmonic generation (SHG) signal under excitation with a Ti:sapphire laser. The observed remarkably large permittivity is consistent with anisotropic, multi-anionic bond network in the structure, which in turn shall promote anharmonicity of the bond dynamics and subsequently the observed non-linear optical response. This achievement contrasts with earlier results on *AB*O_2N perovskites with pseudocubic centrosymmetric structures that lead to large dielectric permittivity and piezoresponse under electric field bias, ascribed to field-response of nanopolar regions, but without long range polar order.

Zn-IV-N^2 Semiconductors, Homovalent Alloys and $ZnGeN_2$–GaN Alloys Grown by MOCVD for Optoelectronic Applications Kathleen Kash; Case Western Reserve University, United States

The prospect of combining members of the large family of heterovalent ternary nitride semiconductors with each other and with the III-nitrides opens up new avenues for band structure engineering, lattice matching with different substrates, and new applications. There is interest in $ZnSnN_2$, with a band gap in the range of 1-2 eV that tunes with the degree of disorder on the cation sublattice, for its application to single junction solar cells [1]. Alloys of $ZnGeN_2$ and GaN are of interest for photocatalytic applications such as water splitting [2].

A major aim of our work on developing the growth of these materials by MOCVD is to improve the efficiency of nitride LEDs at green and longer wavelengths by taking advantage of the large predicted type II band offsets of the Zn-IV-nitrides with the III-nitrides. Band offsets at the $ZnGeN_2$-GaN interface greater than 1 eV in both the conduction and valence bands have recently been confirmed experimentally [3]. Appropriate insertion of a few-unit-cell-wide Zn-IV-nitride layer into a conventional InGaN quantum well is predicted to improve the electron-hole wave function overlap substantially, thus increasing the emission efficiency while also providing the benefit of reducing the In content in the InGaN quantum well for emission at a given wavelength, compared to the conventional InGaN structure [4].

In order to realize these proposed LED structures, the growth temperature for the Zn-IV-nitride or alloy insertion layer should be matched to that for the InGaN quantum well. However, the temperatures for the growth of high quality $ZnGeN_2$ by sub-atmospheric-pressure MOCVD are substantially higher than those used for the growth of high quality InGaN [5]. On the other hand, the case is reversed for $ZnSnN_2$, and the growth temperature for producing high quality $ZnSnN_2$ layers is too low. $ZnSn_xGe_{(1-x)}N_2$ presents a solution to matching the optimal growth temperature of the insertion layer to InGaN; the growth window of the homovalent alloy is fortuitously broadened over that for pure $ZnSnN_2$.

Growth of thick layers of $ZnSnN_2$, as are necessary for other applications such as photovoltaics, is problematic by MOCVD. We find that if the precursors (in this work, DEZn, TMSn and NH_3) are flowed continuously with a DEZn-to-TMSn ratio that produces stoichiometric $ZnSnN_2$ for thin layers, for thicker layers Sn droplets accumulate on the growth surface and cause decomposition of the underlying $ZnSnN_2$, in a reversal of the process that produces vapor-liquid-solid growth of $ZnSnN_2$ [6]. Pulsing the Sn precursor is an effective route to preventing the accumulation of Sn droplets.

The temperature window for MOCVD growth of the heterovalent $ZnGeN_2$-GaN alloy is also broadened over that for pure $ZnGeN_2$. The incorporation rate of Zn into the film is enhanced by the addition of Ga, and, correspondingly, the incorporation of Ge is depressed.

This work was supported by funding from the U.S. Department of Energy (DE-EE0008718) and from the National Science Foundation (DMREF-SusChEM-1533957).

Synthesis and Characterization of Sputter-Deposited Zn_2VN_3 Thin Films—A Combined Theoretical and Experimental Study Siarhei Zhuk and Sebastian Siol; Empa, Switzerland

Nitrides are promising functional materials for a variety of applications. Despite their technological importance many promising theoretically predicted metal nitrides are yet to be discovered.[1] This is partly rooted in their challenging synthesis as compared to oxides. Non-equilibrium PVD in ultra-high vacuum conditions, such as reactive RF-magnetron sputtering, provides ideal prerequisites for the formation of novel metastable nitride thin films.[2] Furthermore, combinatorial sputtering approaches are extremely effective for a rapid screening of the associated complex synthesis phase-spaces.[3]

In this study, an epsilon-support vector regression machine learning (ML) algorithm was used in combination with density functional theory (DFT) calculations using Heyd–Scuseria–Ernzerhof (HSE) functionals to identify interesting candidates from computational materials databases for a combinatorial PVD screening.[4,5] Zn-V-N was selected as a promising material system for a comprehensive experimental phase screening mainly due to the presence of a potentially stable Zn_2VN_3 semiconducting phase with properties suitable for optoelectronic applications.[4,5]. We carried out a combinatorial PVD screening of the entire Zn-V-N phase space. RF co-sputtering of Zn and V targets was carried out in mixed plasma of Ar and N_2 to grow combinatorial libraries on plain glass substrates. N_2 was supplied directly to the sputter plasma to increase the N_2 dissociation rate and consequently increase the N chemical potential. Automated mapping characterization of the sample libraries was performed using X-ray diffraction (XRD), X-ray fluorescence (XRF), X-ray photoelectron spectroscopy (XPS) and four-point probe techniques. In addition, selected samples were studied using hard X-ray photoelectron spectroscopy (HAXPES), Rutherford backscattering spectrometry (RBS), elastic recoil detection analysis (ERDA), photoluminescence (PL) and optical spectrophotometry.

XRD analysis revealed the presence of an orthorhombic $Zn_{1-x}V_xN$ phase over a large compositional range from Zn_2VN_3 to $ZnVN_2$, with a narrow process window for single-phase Zn_2VN_3. The measured XRD patterns are consistent with the corresponding calculated patterns.[4] Following the combinatorial screening, we were able to improve the crystallinity and isolate the Zn_2VN_3 phase on larger substrates (51 x 51) mm^2. A combined RBS/ERDA analysis on these samples demonstrates that the material is stoichiometric with only trace amounts of O, well below 1 at. %. Further, XPS/HAXPES analysis confirms this result with Zn and V being present in oxidation states of +2 and +5, respectively, as expected for Zn_2VN_3. The Fermi level is located ~ 1 eV above valence band maximum indicating a weak p-type doping. Zn_2VN_3 thin films exhibit a resistivity of 0.42 Ωcm. Moreover, PL spectra measured at room temperature exhibits three distinctive peaks at 2.65 eV, 2.85 eV and 3.05 eV with a tail towards 2 eV. The latter is consistent with a significant amount of sub-band gap absorption measured using optical spectrophotometry. This could be due to the presence of anti-site defects and as well as scattering on amorphous phase impurities.

In conclusion, we performed an experimental screening of the Zn-V-N phase space and isolated the novel semiconducting Zn_2VN_3 phase. The experimental

results are consistent with DFT calculations, which predict direct band gap of 2.35 eV and p-type conductivity for Zn_2VN_3. However, further studies are required to improve optoelectronic properties of the compound.

The Impact of Oxygen on the Degeneracy of Zinc Nitride Layers Elise I. Sirotti, Stefan Böhm and Ian Sharp; Technische Universität München, Walter Schottky Institut, Germany

Zinc nitride (Zn_3N_2) has a small direct bandgap, is composed of only earth-abundant elements, and possesses characteristics such as a high mobility that make it a promising semiconductor material for optoelectronic applications. However, non-degenerate Zn_3N_2 is rare and the cause of the high charge carrier concentration remains unknown. Prior density functional theory calculations have predicted oxygen and hydrogen as being responsible for the strong n-type doping but this has not been conclusively verified experimentally. In this work, we studied the role of oxygen on the structural, electrical, and optical properties of Zn_3N_2 grown by plasma-assisted molecular beam epitaxy. The crystalline quality is optimized by tuning both flux and growth temperature, resulting in single phase (222) oriented Zn_3N_2 with a rocking curve full width at half maximum of 0.031°. In addition, we have developed an amorphous GaN capping layer that can be directly deposited onto air-sensitive Zn_3N_2, which shows excellent promise for protecting the material without adversely impacting its electronic properties. To analyze the influence of oxygen on the material properties, the amount of incorporated oxygen in the layer was tuned by changing the elemental base pressure in the growth chamber. Hall and temperature-dependent conductivity measurements reveal high mobilities ranging from 100 to 210 $cm^2V^{-1}s^{-1}$, as well as a clear correlation between the oxygen concentration in the sample and the bulk charge carrier concentration. In particular, the carrier concentration of nominally oxygen-free Zn_3N_2 can be decreased from 10^{20} cm^{-3} to 10^{17} cm^{-3} via controlled oxygen incorporation, without significantly impacting the high mobility of the material. Photothermal deflection spectroscopy shows a concurrent decrease in the bandgap with increasing oxygen concentration (decreasing free electron concentration), consistent with a reduced Burstein-Moss shift.

11:30 AM EQ13.09.04
Deposition and Characterization of Copper Nitride and Tantalum Nitride Thin Films for Electronic Applications Md Maidul Islam and Daniel Georgiev; The University of Toledo, United States

Copper nitride (Cu-N) and tantalum nitride (Ta-N) films have potential applications in photovoltaic solar cell technology and electronic devices, in general. These thin film materials are non-toxic and can be obtained from readily available low-cost precursors. Cu-N can be used in absorber layers of solar cells because of its high optical absorption coefficient and energy band gap that are almost ideal for efficient absorption of light in the solar spectrum. Cu-N films can be doped both p-type and n-type, they are defect tolerant, and their surfaces can be passivated by a native oxide. On the other hand, Ta-N films are chemically inert and corrosion resistant, which makes them very attractive for various functions in integrated circuits, including thin film resistors and diffusion barrier layers. Furthermore, carrier-selective contact materials, rectifying contacts, and Schottky diodes have been developed based on Ta-N. Recently, there has been interest in the Cu-Ta-N ternary semiconductor alloy system for electronic device applications, which has been the motivation for our work and interest in the binaries that comprise this ternary system. Our intention is to work on the fabrication and study applications of films from the ternary system after gaining a good understanding of the sputtering deposition of the related binaries as well as their properties.
In this work, Cu-N and Ta-N films were deposited on glass or Si substrates by reactive RF magnetron sputtering of Cu or Ta in a nitrogen-containing atmosphere. Films with thicknesses of several hundred nanometers were obtained by systematically varying the substrate temperature at a fixed N:Ar sputtering gas ratio or by varying the N:Ar gas ratio at a fixed substrate temperature. The film morphology was examined by both top-view and cross-sectional-view scanning electron microscopy, and the films' chemical composition was established by energy-dispersive X-ray spectroscopy. Four-probe resistivity measurements and optical spectrophotometry were performed, and the optical band gaps were calculated by a standard Tauc's plot technique. The crystallinity of the film's material was studied by X-ray diffraction in a small-angle X-ray scattering geometry.
The film properties are influenced by the RF power used during the deposition, the substrate temperature, the overall deposition pressure, and the N:Ar gas ratio. The color of the Cu-N films that were obtained was reddish-brown with slight variation among the different types of samples, while the Ta-N films had a metallic luster for lower nitrogen gas fractions and were more brownish-transparent for higher nitrogen gas fractions. Both types of film surfaces were relatively smooth and uniform, with a granular structure, which contained dense pyramid-like grain shapes for Cu-N and irregular cauliflower-like shapes for Ta-N. The optical band gap of Cu-N films ranges from 1.3 to 1.4 eV and decreases with increasing the substrate temperature. For Ta-N, the band gap varies from 1.62 to 1.77 eV and shows an increasing trend with increasing the nitrogen concentration in the sputtering gas mixture.
This work is in progress and some of the results obtained so far appear to match published reports, while in other cases there are differences, or there is no published work that could be used for reference. All indications are that reactive RF sputtering can be used as an efficient, low-cost, and flexible method to fabricate Cu-N and Ta-N films and stacks of such films for device applications. We will report on these and any new results that are becoming available as well as on their analysis, and we expect that this work will be of significant interest to applications and the understanding of metal nitrides, in general.

Site Disorder and Its Impact on Simulated Band Gap in $ZnGeN_2$ Jacob Cordell[1,2], Jie Pan[2], Linda Pucurimay[2,3], Celeste Melamed[1,2], Garritt Tucker[1], Adele Tamboli[2] and Stephan Lany[2]; [1]Colorado School of Mines, United States; [2]National Renewable Energy Laboratory, United States; [3]Princeton University, United States

The ability to tune electronic structure through cation ordering while maintaining lattice constants closely matched to III-Vs makes II-IV-N_2 materials promising for tuning band gaps for use in energy-relevant devices such as LEDs and PV. However, characterizing the degree of ordering in synthesized materials presents challenges due to the large number of variables besides ordering which also influence diffraction and spectroscopy techniques. Through simulations, we develop a picture of site disorder in $ZnGeN_2$ at short- and long-range, isolated from other structural effects as the state of the system relates to the energetics under nonequilibrium conditions. In $ZnGeN_2$, the non-isovalent character of the disordered species (Zn^{2+} and Ge^{4+}) subjects the cation ordering to strong short-range order effects which influence band structure by decreasing the band gap relative to ordered $ZnGeN_2$ from 3.5 eV to 2.0 eV with small but non-dilute fractions of cations present as anti-site pairs. $ZnGeN_2$ exhibits pronounced discontinuities in enthalpy and order parameters, which correspond to a first-order phase transition and narrowed forbidden gap in the density of states as well as an onset in localized states in disordered material. We use Monte Carlo simulations to model cation disorder, which in turn use a cluster expansion to approximate the formation enthalpy of a cation configuration. Converged configurations are relaxed in volume and lattice parameters through Density Functional Theory as 1,024 atom supercells. We calculate nitrogen coordination as a short-range order parameter and the Bragg-Williams and stretching parameters as long-range order parameters. We then relate these order parameters with the mixing entropy, free energy of the system and electronic properties to draw relations between order and

electronic structure.

12:00 PM EQ13.09.06
Late News: Characterization of ZnGeN2 Thin Films on Heteroepitaxial Mismatched AlN Substrates Brooks Tellekamp[1], Moira Miller[2,1], Anthony Rice[1] and Adele Tamboli[1]; [1]National Renewable Energy Laboratory, United States; [2]Colorado School of Mines, United States

The GaN ternary analog $ZnGeN_2$ is proposed as a green-to-amber emitter able to be integrated easily into current GaN light emitting diode (LED) heterostructures. However, growing $ZnGeN_2$ on GaN makes accurate material characterization difficult due to their similar optical and structural properties. This ambiguity motivates this work where we present $ZnGeN_2$ grown on lattice mismatched AlN templates and regrown AlN buffer layers by molecular beam epitaxy. We present highly accurate lattice parameters using multiple reflections and a least squares regression (a = 3.1962 A ± 0.0032 A and c = 5.2162 A ± 0.0015 A [c/a ratio = 1.632]) enabled by the full relaxation of ZnGeN2 and get a lattice-mismatch of 0.22%. We find the preferred growth temperature for $ZnGeN_2$ on AlN is 450 C by reflection high-energy electron diffraction, X-ray diffraction, and atomic force microscopy characterization. We also present photoluminescence attributed to $ZnGeN_2$ with a broad recombination band centered around 2.96 eV. Theory suggests that disordered material will emit light as a broad peak in the 2.5-3 eV region, suggesting that we have disordered material. Here we provide insight into the properties of $ZnGeN_2$ and provide direction for further studies modeling and characterizing GaN/$ZnGeN_2$ heterostructures.

Chemical State Analysis of Ternary Zinc Nitride by Photoelectron Spectroscopy—Applications in Materials Discovery and Design Sebastian Siol, Siarhei Zhuk and Jyotish Patidar; Empa-Swiss Federal Institute of Materials Science and Technology, Switzerland

Photoelectron spectroscopy (PES) has long been considered a standard characterization technique in the development of new semiconducting materials. Despite its mainstream use for the analysis of surface chemistry and electronic structure of new materials, conducting meaningful PES on nitrides is challenging. Handling nitride samples in air usually results in surface oxidation as well as the formation of adsorbate layers, which complicates and quite often prevents meaningful PES measurements.[1] Unfortunately, few labs possess the experimental infrastructure to perform clean (i.e. UHV) transfers from synthesis to characterization environments and sputter cleaning the samples often results in sputter damage or a reduction of the surface.

In this study, we show how a combination of X-ray photoelectron spectroscopy (XPS) and laboratory based hard X-ray photoelectron spectroscopy (HAXPES) was successfully used on ex-situ treated ternary zinc nitrides to complement accelerated phase discovery in Zn-V-N thin films deposited by combinatorial reactive co-sputtering.

The presented concepts can be applied to many different material systems. In particular, we discuss how to gain valuable insights for the design and discovery of new nitrides using chemical state analysis based on the Auger parameter (AP) concept.[2] The core level emission lines of many oxides and nitrides show considerable overlap, which makes analysis of nitride samples exhibiting surface oxides challenging. Auger lines are more sensitive to changes in the local chemical environment, which can make it easier to distinguish oxide and nitride phases. In addition, the AP can show considerable shifts upon the formation of new phases or changes in the microstructure, providing valuable, complimentary insights to conventional structural analysis (e.g. X-ray diffraction or Raman spectroscopy).[3]

For the Zn-V-N material system, a new potentially stable phase was discovered by XPS mapping characterization via analysis of the modified AP for Zn. The latter was calculated using the kinetic energy of the Zn LMM Auger line as well as the binding energy of the Zn 2p3/2 core level emission. The Zn AP showed a distinct shift for some samples (>0.3 eV), which directly correlated with the occurrence of a new phase, as confirmed by XRD and RBS.
In addition, we used a laboratory-based HAXPES system equipped with monochromatic Cr-Kα X-ray source (5414.7 eV) to perform measurements with an information depth of over 20 nm. In a contrast, an XPS measurement using monochromatic Al-Kα excitation (1486.7 eV) can probe only up to 10 nm deep.[3] Consequently, the results of the HAXPES analysis are muss less affected by the presence of surface oxides or adsorbates, which allowed us to not only to probe the chemical composition of the material, but more importantly investigate the Zn and V oxidation states as well as the doping of the material without the need of any sputter cleaning.
These results highlight how novel photoelectron spectroscopy techniques can produce important insights for the discovery and design of new nitride materials, even when the samples exhibit surface oxides or adsorbates. Specifically, measurements of the AP can be used to identify new phases and changes of the microstructure in previously underexplored material systems.

Structural and Electronic Effects of Cation Radius Mismatch in II-IV-N_2 Semiconductors Malhar Kute, Zihao Deng, Sieun Chae and Emmanouil Kioupakis; University of Michigan, United States

The II-IV-N_2 class of heterovalent ternary nitrides have gained significant interest as alternatives to the III-nitrides for electronic and optoelectronic applications. In this study, we apply first-principles calculations based on density functional theory to systematically investigate the effects of structural distortions due to cation size mismatch on the cation sublattice disorder and the valence band structure in this class of materials. We find that larger size mismatch between the group-II and the group-IV cations results in stronger lattice distortions from the ideal hexagonal ratio, which in turn inhibits the propensity of these materials towards octet-rule violating cation disorder. We also demonstrate that the formation energy of a single cation antisite pair, which is fast and simple to calculate, is a strong indicator of a material's propensity towards disorder. Furthermore, the breaking of in-plane symmetry leads to a splitting of the top three valence bands at Γ, which is also directly related to the magnitude of structural distortions. Our work demonstrates that the structural and functional properties of the II-IV-N_2 materials can be finely tuned through controllable structural distortions that stem from the choice of cations.

A Two-Dimensional Layered Semiconductor, Alkaline Earth Transition Metal Nitrides; High-Purity Bulk Synthesis and Electronic Properties Characterization Shigeru Kimura, Akihiro Shiraishi, Xinyi He, Takayoshi Katase, Keisuke Ide, Hidenori Hiramatsu, Hideo Hosono and Toshio Kamiya; Tokyo Institute of Technology, Japan

Ternary transition metal nitrides, *AETM*N_2 (*AE* = Sr, Ba; *TM* = Ti, Zr, Hf), are expected to exhibit unique electro-magnetic properties since they possess two-dimensional (2D) electron transport layers in their natural layered crystal structures, and their conduction band minimums are formed mainly of *TM* d_{xy} orbitals like $SrTiO_3$-based 2D electron gas system [1,2]. However, high purity bulk samples of *AETM*N_2 have not yet been synthesized,

hindering their intrinsic physical properties. To overcome the problem, we herein propose a 2-step process for the synthesis of high purity *AETM*N_2. We realized high-purity polycrystalline bulks and investigated the electronic structure and electronic properties of *AETM*N_2.
Polycrystalline bulks of *AETM*N_2 were synthesized by the high-temperature solid-state reactions of 2*AE*NH + 2*TM*N → 2*AETM*N_2 + H_2. Since the complete nitridation of Sr and Ba metals, i.e. SrN_x and BaN_x phases, by direct annealing under N_2 gas is difficult, we made *AE*NH powders through the nitridation of *AE*H_2 hydrides as the starting precursors. Then, to achieve a high nitrogen chemical potential during the solid state reactions of *AE*NH + *TM*N, the NaN_3 powder is used as N-source.
By optimizing the annealing temperature and stoichiometric ratio, high purity *AETM*N_2 bulks with phase purity more than 90 mol% were obtained. From diffuse reflectance spectra, the optical bandgap was estimated to be 1.7 eV ($SrTiN_2$), 2.0 eV ($BaZrN_2$), and 2.2 eV ($BaHfN_2$). The ρ-T of all *AETM*N_2 exhibit semiconducting behavior. Arrhenius plot of ln σ (1/ρ) versus 1000/T is nearly linear over the temperature range 100-300 K, and an activation energy (E_A) increased from 2.9 meV ($SrTiN_2$) to 116 meV ($BaHfN_2$). Seebeck coefficient of all *AETM*N_2 were negative and increased from -26 μV/K ($SrTiN_2$) to -117 μV/K ($BaHfN_2$), indicating that *AETM*N_2 are n-type semiconductor and the unintentional impurity doping is suppressed in $BaHfN_2$. We will discuss the difference of impurity incorporation in *AETM*N_2 by calculating the defect formation enthalpies of intrinsic defects and oxygen/hydrogen impurities in *AETM*N_2 at the conference.

Characteristics of Hf(*M*)SiBCN (*M* = Y, Ho, Ta, Mo) Materials—Role of the *M* Choice Martin Matas, Michal Prochazka, Jaroslav Vlcek and Jiri Houska; University of West Bohemia, Czechia

Nitride-, carbide- and boride-based alloys of light main-group elements are attractive due to unique combinations of properties ranging from optical transparency through high hardness to high-temperature stability and oxidation resistance. The properties, in the first place electrical conductivity, can be further modulated by addition of early transition metals. In this contribution, amorphous nitrogen-rich Hf(*M*)SiBCN thin films are investigated by combining magnetron sputtering of composite B_4C–Si–Hf–*M* targets in Ar + N_2 reactive atmosphere with *ab-initio* calculations [1]. First, we study the effect of the *M* choice and fraction on calculated mechanical properties and formation energy of crystalline *M*N and $Hf_xM_{1-x}N$ nitrides. We discuss the dependence of formation energy on the crystal structure and on the distribution of Hf and *M* in the metal sublattice. The calculated mechanical properties of *M*N correlate with those measured on Hf*M*SiBCN. The driving force towards N incorporation, monotonically decreasing with increasing periodic-table group number of *M* according to the calculated formation energy of *M*N, very well correlates with measured electrical conductivity and extinction coefficient of Hf*M*SiBCN. Second, we use *ab-initio* molecular dynamics to model the amorphous Hf*M*SiBCN materials themselves. The calculated band gap, localisation of states around the Fermi level and bonding preferences of *M* atoms (in particular their tendency to bind with N) also correlate with the measured metallicity and confirm the possibility of predicting the trends in characteristics of Hf*M*SiBCN using those of *M*N. Third, we identify an optimum target composition leading to hard (>20 GPa) Hf*M*SiBCN materials with a relatively high conductivity at a given extinction coefficient. The results are important for the design of transparent and/or conductive hard high-temperature coatings.

Novel Nitride Thin-Film Materials for Thermoelectrics Studied by Experiments and Theory Per Eklund; Linkoping Univ, Sweden

Thermoelectric devices have the potential to contribute to energy harvesting in society by directly converting heat into electricity or vice versa. However, the conversion efficiency of thermoelectric devices of today is limited. The critical material-dependent parameter is the figure of merit ($ZT = S^2T/rk$, where r is the electrical resistivity, S is the Seebeck coefficient and k is the total thermal conductivity). In this lecture, I present an overview of our experimental and theoretical investigations of CrN-, ScN-, and $Ca_3Co_4O_9$-based thin films. ScN thin films exhibit an anomalously high power factor (S^2/r) for transition metal nitrides of 2.5-3.3×10^{-3} W/mK^2 at 800 K. We have explained this result, from first-principles calculations, by nitrogen vacancies generating an asymmetric sharp feature in the density of states which allows low electrical resistivity with relatively large S. However, ScN has high thermal conductivity, thus its ZT is low (~0.2). To reduce lattice thermal conductivity, potential strategies are nanostructuring, alloying or nanoinclusion formation. We have modeled the thermal conductivity in pure ScN as a function of grain size using time-dependent effective potentials (TDEP), correlating the ideal thermal conductivity of an infinite ideal crystal with the thermal conductivity reduction of grain-size effects, and alloying trends in mixing thermodynamics of ScN-based solid solutions. Pure CrN exhibits n-type conduction with a high power-factor enabled by a high electron concentration thermally activated from N vacancies, and alloys can be made of rocksalt-$Cr_{1-x}Sc_xN$. We have demonstrated that it can be rendered p-type by Al alloying in combination with N superstoichiometry.

Extending the Nitride Material Platform for Classical and Quantum Information Systems Debdeep Jena; Cornell University, United States

The nitride semiconductor materials GaN, AlN and InN revolutionized solid state lighting in the last two decades and are currently doing the same for high-speed and high-voltage electronics, and deep-ultraviolet photonics. As the semiconducting properties, it is becoming increasingly clear that this material

family has far more to offer ranging from communication at high frequencies, to harsh environment and high voltage digital electronics, to quantum communications and computation. In this talk, I will present recent developments in the synthesis and integration of nitride semiconductors, magnets, ferroelectrics, and superconductors towards an exciting new platform that feeds off the many past successes of photonics and electronics with GaN.

A missing piece in the classical computation paradigm for nitride semiconductors was the p-channel transistors with high hole mobilities. This problem has found an exciting solution in the discovery of undoped polarization-induced 2-dimensional hole gases in epitaxially grown GaN quantum wells on AlN substrates. This new material-driven discovery is a key enabler for digital CMOS with wide-bandgap nitride semiconductor that can operate in harsh environments.

Substitution of Al or Ga of AlN or GaN with other group-III metals such as the transition metals Sc and Y, or the metal B is bringing in new physical properties into the nitride family. In particular, I will talk about a) the growth and properties of ScN, a narrow-bandgap semiconductor, and b) the impact of substitution of Al by Sc, Y, and B on the structural and electro-mechanical properties of AlN. These materials boost the piezoelectric properties of AlN so much so that for certain compositions ferroelectricity is observable in both sputtered and MBE grown layers.

The epitaxial growth of metallic and superconducting NbN and TiN, and its heterostructures with AlN and GaN polar semiconductors will be discussed. Epitaxial metal/AlN heterostructures are enabling new forms of integrated epitaxial bulk acoustic wave (epiBAW) filters with the potential to scale to far thinner structures and extend the speed of such devices. It is allowing the direct integration of such filters with AlN/GaN/AlN quantum well high-electron mobility transistors (HEMTs) for highly integrated RF systems. These epitaxial heterostructures are also finding use in superconducting single-photon detectors (SNSPDs) and in new forms of microwave qubits.

Novel Rocksalt Nitride Semiconductors—From Prediction, to Realization, to Integration Sage Bauers[1], Anuj Goyal[1], Sarah Jones[2], Brian Gorman[2], Serena Eley[2], Stephan Lany[1] and Andriy Zakutayev[1]; [1]National Renewable Energy Laboratory, United States; [2]Colorado School of Mines, United States

Integrated discovery workflows are effective tools for identifying candidate functional materials in underexplored chemistries. Nitrides represent one such chemical space: the number of known nitrides is an order of magnitude less than known oxides. At the same time, many of the known inorganic nitrides—and (Al, Ga, In)-N semiconductors in particular—are useful in thin-film technological applications. Thus, our team has developed a workflow for discovering new inorganic nitrides based on data-mining the materials project, performing structure prediction calculations, experimentally screening materials using combinatorial exploration, and performing targeted, epitaxial growth of compelling candidate compositions.

One family of new compounds, described as either Mg*TM*N_2 (*TM*=group 4 transition metal) or Mg_2*TM*N_3 (*TM*=group 5 transition metal), were identified using such a discovery pipeline. These materials represent a class of medium-gap (E_G=0.9-2.4) semiconducting nitrides which adopt a rocksalt-derived crystal structure. This is a departure from normal structure/property relationships in functional inorganic nitrides, where compounds tend to belong to one of two primary families—hexagonal main-group metal nitride semiconductors or cubic transition-metal nitride superconductors. Furthermore, the material properties can be controlled with the metal composition in these ternary composition spaces. For example, electronic transport properties can be tuned using the cation Mg:*TM* ratio from metallic (*TM*-rich) to non-degenerately doped (Mg-rich).

We found that the lattice parameters of some these materials are compatible with the two primary families of technologically important nitrides, suggesting the possibility for epitaxial integration of these materials into functional devices. For example, we have observed epitaxial alignment when $MgZrN_2$ and Mg_2NbN_3 are grown via sputter-deposition onto MgO, GaN, and Al_2O_3 substrates, as well as underlying superconducting ZrN and NbN epilayers. Inspired by these results, we are now evaluating Mg_2NbN_3 as a barrier layer in tunnel junctions with NbN superconducting layers. The combination of elemental abundance, compelling properties, and structural compatibility highlights the potential of these new Mg-*TM*-N materials for integration with known nitrides.

2:30 PM EQ13.01.02
NbN/III-N Heterostructures Grown by MBE for Superconducting Electronic Devices John G. Wright[1], Maxwell Drimmer[2], Yiwen Chu[2], Huili G. Xing[1] and Debdeep Jena[1]; [1]Cornell University, United States; [2]ETH Zürich, Switzerland

The development of single crystal III-N semiconductor heterostructures has been central to the success of III-N materials in wide range of electronic and optoelectronic applications. With this fact in mind, we have pursued the ability to integrate materials with previously inaccessible properties, such as metals, superconductors, and piezoelectrics, into single crystal III-N heterostructures. New and improved III-N devices become possible with access to the larger design space offered by these new materials and properties.

We present our development of novel III-N heterostructure containing NbN grown by molecular beam epitaxy (MBE). NbN, a metal and superconductor with critical temperature around 15 K, has been shown to possess structural and chemical compatibility sufficient to enable epitaxial integration of NbN into III-N heterostructures. We have investigated the growth of both GaN and AlN on NbN thin films by MBE. Our systematic study of the nucleation and growth of AlN on NbN demonstrate that lattice and symmetry matching between AlN and NbN enables the growth of high crystal-quality AlN on NbN. Atomically smooth ultra-thin AlN films can be nucleated directly on NbN, and thicker AlN films grown on NbN exhibit [0 0 2] rocking curve FWHM values as low as 250 arcsecond, which we believe to be the lowest value reported for AlN grown on a metal.

The crystal quality of our AlN films significantly surpasses that of AlN films deposited on non-epitaxial metallic electrodes, which are commonly utilized to produce piezoelectric acoustic resonators. We utilize our AlN/NbN heterostructure to produce high-overtone bulk acoustic resonators (HBARs), and are investigating the coupling of NbN/AlN HBARs to qubits to create hybrid quantum systems.

In addition, we have developed epitaxial NbN/AlN Josephson junctions grown on low dielectric loss sapphire substrates. We are exploring the properties of these materials and devices, and the suitability of these structures for quantum computing applications. MBE grown single crystal AlN/NbN heterostructures are a promising platform for the development of high coherence time Josephson junctions for quantum computing due to the chemical purity and lack of structural defects at the MBE grown NbN/AlN interface. This is especially promising in light of the limit on qubit coherence time set by two-level systems in the amorphous barriers of Nb/Al/AlO_X/Nb Josephson junctions.

Control of Ferroelectric Property in $(Al_{1-x}Sc_x)N$ Films Prepared by Sputtering Method Hiroshi Funakubo[1], Shinnosuke Yasuoka[1], Ryoich Mizutani[1], Takahisa Shiraishi[1], Akinori Tateyama[1], Takao Shimizu[1,2], Masato Uehara[3], Hiroshi Yamada[3], Morito Akiyama[3], Yoshiomi Hiranaga[4] and Yasuo Cho[4]; [1]Tokyo Institute of Technology, Japan; [2]National Institute for Materials Science, Japan; [3]National Institute of Advanced Industrial Science and Technology, Japan; [4]Tohoku University, Japan

Experimental evidence of ferroelectricity of $(Al_{1-x}Sc_x)N$ films by Fichtner *et al* in 2019 open the novel applications of nitride films using ferroelectric properties [1]. It includes low power nonvolatile ferroelectric memories (FeRAMs) as well as resistance-type memories using ferroelectric tunnel junction (FTJ). The most important feature of the ferroelectricity of these nitrides is their large remanent polarization (P_r) after releasing an applied voltage that is more than 5 times larger than that of present-fashioned HfO_2-based ferroelectric films and more than 3 times larger than that of $Pb(Zr,Ti)O_3$ films presently used in FeRAMs. This large P_r has a potential to realize high density FeRAMs. High Curie temperature beyond 1000 ^oC is another feature of the ferroelectricity of nitrides that makes it possible to use at high temperatures.
In my presentation, we introduce our results of ferroelectricity of $(Al_{1-x}Sc_x)N$ films prepared by sputtering method. Obtained results are listed as follows [2,3].
1) P_r and coercive filed (E_c) values can be controlled by the crystal anisotropy of $(Al_{1-x}Sc_x)N$ films
2) Ferroelectricity was observed down to 9 nm in thickness. This means a fundamentally small decrease of Pr with decreasing film thickness.
3) Ferroelectricity was observed for the films deposited at low temperature including room temperature.
These results show that ferroelectric nitrides are novel and one of the most promising candidates for memory applications using their ferroelectricity.

Inversing the Polarity of Scandium Aluminum Nitride (ScAlN) Piezoelectric Thin Films by Using Si Addition Sri Ayu Anggraini, Masato Uehara, Kenji Hirata, Hiroshi Yamada and Morito Akiyama; National Institute of Advanced Industrial Science and Technology, Japan

Among nitride semiconductor materials, wurtzite phase scandium aluminum nitride (ScAlN) has the highest piezoelectric coefficient which is why it has been touted as a future material for many promising electronic applications including the radio frequency (RF) resonators [1-2]. A highly *c*-oriented ScAlN piezoelectric thin film could exhibits either aluminum/scandium (Al/Sc) or nitrogen (N) polarity. The use of thin films with Al/Sc-polarity or N-polarity could lead to different electronic property which potentially affect the performance of the developed devices. For example, integrating both N-polar and Al-polar layers in a solidly mounted resonator BAW (SMR-BAW) was found to enhance the ability of the device to work at higher frequency when compared with that using a single layer Al-polar thin film [3]. Since ScAlN has been widely used as filter material for wireless telecommunication devices, controlling the polarity of ScAlN-based thin films is expected to promote the development of broadband filter that can function at higher frequency range in 5G communication technology. As a method to control the polarity, addition of silicon (Si) into AlN has been reported to inverse the polarization direction of non-doped aluminum nitride (AlN) from Al-polar to N-polar [4]. Therefore, in this study, we propose the use of Si as dopant to control the polarity of ScAlN piezoelectric thin film.
All thin films were fabricated by using radio frequency (RF) magnetron sputtering system. The concentration of Sc and Si was controlled by adjusting the power of cathodes for each corresponding target during deposition process. Positive d_{33}value indicates that the thin film has Al/Sc-polarity while negative d_{33} value indicates that the thin film has N-polarity. All $Sc_xAl_{1-x}N$ thin films exhibited positive d_{33} values which indicate that the thin films have Al-polarity. However co-addition of Sc and Si into AlN was found to resulted in thin films with inversed polarity. For example, co-addition of 30 at.% Sc and Si with concentration in the range of 8-20 at.% (Sc/Si < 4) was found to results in thin films that exhibited N-polarity. While co-addition of 10 at.% Si and Sc with concentration higher than 40 at.% (Sc/Si 4) yielded in thin film that showed Al-polarity. It is evident that the polarity inversion of $(ScSi)_xAl_{1-x}N$ was found to be largely relies on the concentration of Sc, Si and their ratio. These results indicate that Si addition can also be used not only to inverse the polarity of AlN but also to control the polarization direction of ScAlN, particularly for Sc concentration that is less than 40 at.%. Other than changes in polarization direction, effect of co-addition of Sc and Si into AlN on changes in crystal structure, lattice parameters and surface state have been studied and will be discussed.

Pyroelectric Tomography of AlScN with Sub-Micron Resolution Stefan Tappertzhofen; TU Dortmund University, Germany

Novel lead-free ferroelectric and pyroelectric materials such Aluminum Scandium Nitride (AlScN) show great potential for development of CMOS-compatible temperature and motion sensors. A key challenge is the understanding of the origin of pyroelectricity and the profile of the spontaneous polarization in AlScN, that could be, for example, related to thermal deformation and corresponding piezoelectric mechanical clamping. A powerful tool to analyze the spontaneous polarization in three dimensions with sub-micron resolution is the Laser Intensity Modulation Method (LIMM). In this study, we report on the LIMM tomography of ferro-/pyroelectric AlScN thin-films using Fabry-Perot quantum-cascade mid-infrared, and near-infrared lasers. We discuss the influence of Scandium on the thermal and pyroelectric properties of AlScN based on our LIMM measurements. In particular, we report on thermal conductivity levels of AlScN two to three orders of magnitude lower than for conventional AlN films, which we contribute to phonon/alloy scattering mechanisms. We also characterized the profile of the spontaneous polarization as a function of the sample temperature, ambient conditions, and bias-voltage. Our tomography results are complemented by thermal simulations, and advanced microscopic and spectroscopic techniques. Our findings gain insight into important material properties of AlScN and provide guidelines for engineering of novel lead-free pyroelectric devices.

Combinatorial Synthesis of Ferroelectric $Al_{1-x}Sc_xN$ Films Keisuke Yazawa[1,2], Daniel Drury[2,1], Geoff L. Brennecka[2] and Andriy Zakutayev[1]; [1]National Renewable Energy Laboratory, United States; [2]Colorado School of Mines, United States

Wurtzite ferroelectrics such as $Al_{1-x}Sc_xN$ are promising nitride materials for piezoelectric and ferroelectric applications in 5G communication and non-

volatile memories. Finding the upper Sc concentration limit and the lower thickness limit, both of which reduce the coercive voltage of the materials system, is important for the applications due to the large coercive electric field of the $Al_{1-x}Sc_xN$ nitride alloys. However, rocksalt phase transition in Sc rich side and ferroelectric hysteresis degradation in thinner films hinder the efforts in decreasing coercive voltage. Combinatorial approaches have emerged in the past decade as important tools for rapidly screening new compositions and thicknesses, in the search for new and improved structures and properties of the materials. One of the common concerns voiced about combinatorial approaches is that a focus on chemistry and thickness de-emphasizes effects of microstructure, which is very important in piezoelectric and ferroelectric applications. This common concern implies that the properties of combinatorial libraries are often not representative of the structures and properties of traditionally-fabricated homogeneous samples.

In this study, we demonstrate $Al_{1-x}Sc_xN$ films deposited by combinatorial co-sputtering with ferroelectric response across the sample library rivaling that of single-composition samples [1] . The composition and thickness gradients in the combinatorial $Al_{1-x}Sc_xN$ library co-sputtered from Al and Sc metal targets range from x = 0.25 to 0.5 and 250 to 150 nm. XRD *q* -2*q* patterns show the wurtzite – rocksalt phase transition across the composition gradient. Even in this inhomogeneous library, the Al rich region (x = 0.25) exhibits a well saturated ferroelectric hysteresis loop and larger breakdown field. As expected, the Sc rich region (x = 0.5) side does not show fully opened hysteresis loop due to the larger leakage contribution and lower breakdown electric field. As for the thickness gradient, thinner region (150 nm) possesses large leakage current contribution to the hysteresis loop compared to the thicker side (250 nm) at the same composition. As a result of this study, the systematic comparison map among composition, thickness, crystal structure, microstructure, and electric characterization gives us insights of physics and chemistry behind the ferroelectricity in $Al_{1-x}Sc_xN$ nitride alloys with wurtzite structure.

9:15 AM *EQ13.11.05
Nitrides at Multimegabar Compressions—From Fundamental Discoveries to practical applications Igor A. Abrikosov[1], Ferenc Tasnadi[1], Alena V. Ponomareva[2], Maxim Bykov[3], Elena Bykova[3], Ekaterina A. Smirnova[2], Maxim Belov[2], Natalia Dubrovinskaia[4,1] and Leonid Dubrovinsky[4]; [1]Linköping University, Sweden; [2]NUST "MISIS", Russian Federation; [3]Howard University, United States; [4]University of Bayreuth, Germany

Behavior of matter at extreme conditions challenge accepted concepts within materials science [1]. Nitrides have been found to have the largest fraction of metastable phases, and very high accessible thermodynamic range of metastability [2]. Combining theoretical simulations with experiment and broadly varying external parameters, pressure, temperature and composition we report on several novel nitrides with fascinating crystallochemistry [3] and properties attractive for applications [4,5]. First, we explore the Re-N system at high pressure up to 1 TPa and compare thermodynamics of experimentally synthesized phases with those obtained in theoretical structure predictions and reported in the literature. We point out a remarkable observation: tough most of the synthesized Re nitrides are stable at the synthesis pressure, and their energies are below the convex hull formed by the predicted structures, they have not been identified by the state-of-the-art structure prediction algorithms.
Next, we pay attention to a serious drawback of the high-pressure synthesis: the discovered materials cannot be always recovered at ambient conditions and the quantity of the produced material does not allow to carry out a characterization of their physical and mechanic properties. We argue that theoretical simulations have important role in identifying materials of interest for various applications, and in guiding their quenching to ambient pressure. We report the synthesis of metallic, ultraincompressible and very hard rhenium nitride pernitride $Re_2(N_2)(N)_2$. Unlike known transition metals pernitrides, it contains both pernitride $(N_2)^{4-}$ and discrete N^{3-} anions, which explains its exceptional properties. Importantly, $Re_2(N_2)(N)_2$, which was discovered via a reaction between rhenium and nitrogen in a diamond anvil cell at pressures from 40 to 90 GPa has been recovered at ambient conditions, and a route to scale up its synthesis has been developed [4].
Finally, we demonstrate that the diamond anvil cell technique can be used for synthesis of layered materials, precursors of novel 2D-materials. We illustrate this considering a triclinic phase of beryllium tetranitride tr-BeN_4 which upon decompression from the synthesis pressure of ~85 GPa to ambient conditions, transforms into a compound with atomic-thick BeN_4 layers interconnected via weak van der Waals bonds. Theoretical calculations for a single BeN_4 layer show that its electronic lattice is described by a slightly distorted honeycomb structure reminiscent of the graphene lattice and the presence of Dirac points in the electronic band structure at the Fermi level. The BeN_4 layer, i.e., beryllonitrene, represents a qualitatively new class of 2D materials that can be built of a metal atom and polymeric nitrogen chains and host anisotropic Dirac fermions [5].
In summary, the fundamental understanding of the physical principles behind the formation of high-pressure materials generated in our studies is essential for the accelerated knowledge-based design of novel materials.

SESSION EQ13.12: Transition Metal Nitrides and Related Materials
Session Chairs: Bjorn Alling and Rebecca Smaha
Tuesday Morning, December 7, 2021
EQ13-Virtual

10:30 AM *EQ13.12.01
New Transition Metal Nitrides John P. Attfield; University of Edinburgh, United Kingdom

Transition metal nitrides are typically based on metals in low oxidation states and have many useful properties, for example, ZrN was recently discovered to be an outstanding ORR (Oxygen Reduction Reaction) catalyst for electrochemical applications [1]. However, stabilisation of solid nitrides of transition metals in high oxidation states, comparable to those in oxides and fluorides, has proved difficult due to the well-known inertness of nitrogen and the tendency to evolve dinitrogen gas. A high pressure method using sodium azide has recently been demonstrated to overcome these issues leading to the synthesis of a highly oxidised iron(IV) nitride, Ca4FeN4 [2].

High Throughput Fabrication of Plasmonic Nitride Nanostructures Panos A. Patsalas[1], Spyridon Kassavetis[1], Stavros Panos[1], Afroditi Koutsogianni[1], Christos Kapnopoulos[1], Gregory Abadias[2], Sophie Camelio[2], David Babonneau[2], Ilias Fekas[1], Spilios Dellis[1] and Nikolaos Kalfagiannis[3]; [1]Aristotle University, Greece; [2]University of Poitiers, France; [3]Nottingham Trent University, United Kingdom

Conductive transition metal nitrides (TMN) have been considered for applications in micro- and opto-electronics such as diffusion barriers and ohmic contacts to III-nitrides; recently, they are revisited as alternative plasmonic materials, which are refractory, spectrally tunable, CMOS-compatible, and durable in high electric fields. The most prominent examples of TMNs are TiN and ZrN. The refractory character of TMN and their growth predominantly by reactive sputtering are simultaneously blessings and curses, as they limit the fabrication of nitride plasmonic nanostructures to top-down processes, so far. Despite of the spatial accuracy of top-down processing, such fabrication is time consuming, costly, and of limited scalability. In this work, alternative routes of fabrication of TMN nanostructures are critically reviewed and presented. In particular, we focus on the fabrication of nano-islands and dichroic nanowires supported on silicon wafers and silica, and colloidal nanoparticles. We emphasize on emerging techniques that may be applied on meso- or macro-scopic scales, such as nanosphere lithography (NSL) combined with ionized reactive magnetron sputtering, glancing angle deposition (GLAD), and laser ablation in liquids (LAL). We critically evaluate the assets and drawbacks of each individual fabrication technique, and we evaluate the optical and plasmonic performance of the produced nanostructures using finite difference time domain (FDTD) calculations. There is, unfortunately, a feature that is present in all the presented manufacturing schemes: TMN typically contain a considerable amount of point defects that are known to affect the properties of the host crystal. We provide thorough experimental evidence that in TMN nanostructures the point defects tend to be outdiffused to the surface, thus limiting the deterioration of their performance, at least from the optical and plasmonic point of view; in fact, we show that for many TMN and under certain conditions the polycrystalline samples may be equivalent, if not superior, to epitaxial samples. This feature adds to the feasibility of NSL, GLAD and LAL to produce efficient TMN nanostructures on large areas and/or in large volumes.

11:30 AM *EQ13.12.03
MXenes - 2D Nitrides and Carbonitrides for Future Technologies Christopher E. Shuck, Grayson Deysher, Patrick Urbankowski, Kanit Hantanasirisakul and Yury Gogotsi; Drexel University, United States

2D carbides and nitrides, known as MXenes, are among the most recent, but quickly expanding material families. The field is experiencing rapid growth with more than 1000 papers published on MXenes each year. Major breakthroughs have been achieved in the past 3-4 years, including the discovery of 2D M_5C_4 carbides with the twinned layers and CVD synthesis of $MoSi_2N_4$, representing a new family of 2D nitrides. Synthesis of dozens of predicted MXenes, demonstration of superconductivity in MXenes with specific surface terminations, stronger interactions with electromagnetic waves compared to metals, metallic conductivity combined with hydrophilicity and redox activity, have led to numerous applications. The outstanding mechanical properties of Ti_3C_2, combined with its conductivity and strong interfaces, have been used in polymer, ceramic, and metal matrix composites. The reversible redox activity of transition metal atoms in the outer layers of MXene flakes combined with high electronic conductivity have led to applications in a variety of batteries and electrochemical capacitors. MXenes are promising candidates for energy storage and related electrochemical applications, but applications in optoelectronics, plasmonics, electromagnetic interference shielding, electrocatalysis, medicine, sensors, or water purification are equally exciting. At the same time, the majority of studies were conducted using carbide MXenes. Relatively few nitrides (Ti_2N and Ti_4N_3) and carbonitrides (Ti_3CN and $Ti_2C_{0.5}N_{0.5}$) have been produced by etching MAX phases. A few more were synthesized by replacing carbon by nitrogen in 2D carbides using high-temperature retreatments. While synthesis of nitrides is more challenging compared to carbides, theoretical predictions of attractive optoelectronic and magnetic properties of 2D nitrides fuel further efforts.

12:00 PM EQ13.12.05
Metal Nitrides—From Structure Design to Applications Yao Yuan, Fengdong Qu, Siqi Liu, Hangjia Shen, Haichuan Guo and Minghui Yang; Chinese Academy of Sciences, China

Transition metal nitrides (TMNs) as a class of metallic interstitial compounds, by tuning chemical composition through suitable selection of parent metals and introducing different amounts of nitrogen atoms into the lattice of parent metals could allow TMNs to be either semiconducting or metallic. In the last 5 years, our team using different synthetic methods have successfully prepared TMNs which show great practical value to catalysis and sensors. The observations have been theoretically rationalized. Using both experimental and theoretical results, we have been analyzing the relationship of crystal and surface structure and have correlated it to the activity for the related applications. In particular, major breakthroughs from our lab involved the discovery that ZrN shows better catalytic property than Pt/C for oxygen reduction reaction [1], Surface oxide-rich activation layer (SOAL) on Ni_2Mo_3N for rapid and durable oxygen evolution reaction [2] and ternary metal nitride based fuel cell type methanol sensor [3].

SESSION EQ13.13: Rare Earth Nitrides and Related Materials
Session Chairs: Sage Bauers and Panos Patsalas
Tuesday Afternoon, December 7, 2021
EQ13-Virtual

1:00 PM *EQ13.13.01
The Outrageous Ferromagnetism of Rare-Earth Nitride Semiconductors Joe Trodahl; Victoria University, New Zealand

Most of the 14 rare-earth nitrides (REN) are *intrinsic* ferromagnetic semiconductors. Their magnetism resides in the 4*f* shell with a strong spin-orbit interaction that locks the spin and orbital magnetic moments together, a contrast to the quenched orbital magnetic moments in the *d* shell of transition-metal ferromagnets. The contribution of both spin *and* orbital magnetic moments delivers outrageous magnetisations across the series: coercive fields from 0.01T to 10 T, zero magnetic moment in otherwise conventional ferromagnetic SmN, composition tuning of magnetic moment, coercive field and the net angular

momentum in (Gd,Sm)N and (Gd,Nd)N alloys. All of these promise enhanced efficacy in various device structures, for which the doping control of electronic conduction further broadens their technical potential.
The REN are a favourite playing field of theorists, but experimentalists are deterred by the reputation of nitride film growth as problematic. We began growing them in 2006, motivated by a prediction that some are half metals, to find that they are semiconductors. They are readily grown in a N_2 atmosphere of 10^{-5} mbar; there is no need for activated nitrogen. Surprisingly a freshly deposited rare-earth film spontaneously breaks the enormously strong triple bond of N_2, a reaction which is itself of substantial chemical interest. We have developed growth of polycrystalline and epitaxial films, mixed rare-earth nitride alloys and superlattices, both stoichiometric and n-doped by nitrogen vacancies when grown at a reduced N_2 pressure.
Following a brief description the thin-film growth that is at the core of our programme, I will describe the highlights from our 15 years exploring these materials: their huge range of magnetic states, their coupled electronic-magnetic responses, a surprising incidence of heavy-fermion superconductivity and hints of a Kondo lattice state. The study is supported by DFT computations, a variety of laboratory-based transport and magnetisation measurements and X-ray spectroscopic investigations at various synchrotrons.

1:30 PM EQ13.13.02
Rare-Earth Nitride Alloys Jackson Miller[1,2], Joe Trodahl[1] and Ben Ruck[1,2]; [1]Victoria University of Wellington, New Zealand; [2]MacDiarmid Institute, New Zealand

The rare-earth nitrides are associated with many remarkable magnetic behaviours. These range from the near-zero moment of ferromagnetically aligned samarium nitride (SmN), through the J = 0 ground state of europium nitride (EuN) to the more conventional magnetism of gadolinium nitride (GdN). In all cases, the electrical transport of these materials can be controlled over multiple orders of magnitude through n-type nitrogen vacancy doping. Thus they may be classed as intrinsic ferromagnetic semiconductors.

The coupling of gadolinium and samarium in a ternary alloy ($Gd_xSm_{1-x}N$) allows the independent tuning of the magnetic properties, as well as the electrical conduction. The magnetism comes from the localised 4f moments of the rare-earths and interpolates the magnetic behaviours of the two endpoints GdN and SmN, whose disparate behaviours offer a deal of scope in tuning the alloy magnetism. Moreover, the orbital dominated nature of the magnetic moment of SmN ensures that these alloys host magnetic moment (net m = 0) and angular momentum (net J = 0) compensation points. These features, added to the exhibition of perpendicular magnetic anisotropy offer significant benefits for magnetic recording applications. We will describe the features of these materials with reference to studies of their magnetization, XMCD (X-ray Magnetic Circular Dichroism) and electron transport, which establish their suitability for future device development.

1:45 PM EQ13.13.03
Cryogenic Magnetic Memory Element Using Rare Earth Nitrides Catherine Pot[1,2], William F. Holmes-Hewett[1,2], Jackson Miller[1,2], Sam Devese[1,2], Joe Trodahl[1] and Ben Ruck[1,2]; [1]Victoria University of Wellington, New Zealand; [2]MacDiarmid Institute, New Zealand

The rare-earth nitrides are mostly intrinsic ferromagnetic semiconductors at cryogenic temperatures and have vast potential applications in magnetic memory (MRAM) structures. The 15 members of the series offer the selection of both saturation magnetisation and coercive field required for these devices. We will report layered MRAM structures with two compositions of $Gd_xSm_{1-x}N$, separated by an exchange-blocking layer, and describe their performance under (i) current applied through an insulating exchange-blocking layer (tunnelling MRAM geometry) and (ii) in-plane current in a metallic exchange-blocking layer (GMR geometry). Both the high-impedance tunneling and the low-impedance GMR devices show binary data storage action.

2:00 PM EQ13.13.04
Defect Hopping to Ballistic Band Transport—Investigating the Insulator to Metal Transition in Vacancy Doped SmN William F. Holmes-Hewett, Bob Buckley, Ben Ruck and Joe Trodahl; Victoria University of Wellington, New Zealand

The magnetic properties of the rare-earth nitride series are determined largely by the occupation of the 4f electron shell. In a select few members of the series this shell also directly influences electrical transport. Here we discuss a combined experimental and computational study of nitrogen-vacancy doped SmN. We show that the material crosses an insulator-to-metal transition as samples are increasingly doped with nitrogen vacancies. At low doping levels, the transport can be understood as variable range hopping between defect states, while at high doping levels extended state metallic transport is seen. In the intermediary 'anomalous metallic' region where transport is in a mixed 4f-5d band, there are indications of more exotic ground states, such as unconventional superconductivity and a Kondo lattice. These may coexist with ferromagnetic order.

2:15 PM EQ13.13.05
Synthesis and Characterization of the First Nitride Perovskite, $LaWN_3$ Rebecca Smaha[1], Kevin Talley[1], Sage Bauers[1], Rachel Sherbondy[2,1], Craig L. Perkins[1], David Diercks[2], Geoff L. Brennecka[2] and Andriy Zakutayev[1]; [1]National Renewable Energy Lab, United States; [2]Colorado School of Mines, United States

While the impressive flexibility and tunability of the perovskite crystal structure ABX_3 has allowed materials in this family to exhibit a very wide range of properties, nearly all reported perovskites have oxygen or halides as the anion. Nitride perovskites have long presented a synthetic challenge due to the difficulty of completely excluding oxygen during synthesis and the high oxidation states required for the *A* and/or *B* site cations. This phase space is nearly unexplored, and the greater covalency of nitrogen makes nitrides attractive for semiconducting and other functional applications in renewable energy. Recently, we reported on the experimental realization of the first oxygen-free nitride perovskite—$LaWN_3$—as a thin film, crystallizing in polar space group R3c.[1] The oxygen-free character of $LaWN_3$ is determined by Auger Electron Spectroscopy, and the structure is determined by synchrotron based X-ray diffraction. $LaWN_3$ exhibits a large piezoelectric response and signs of ferroelectricity, making it the first stable nitride ferroelectric compound. This opens a host of possible avenues to target novel compounds for functionalization, including as potential multiferroics for spintronic applications.
Here we report on the synthesis and detailed investigation of the structure and electronic properties of thin film $LaWN_3$ and analogous novel nitride perovskites. The films were grown through using combinatorial radiofrequency plasma sputtering and characterized via spatially-resolved structural, electronic, and optical measurements, allowing correlation to the films' composition. The combinatorial synthesis methods and high-throughput characterization used in this study allows rapid exploration of the phase space, accelerating the discovery of novel materials and pinpointing which have promising properties for functional applications.

[1] Talley, K.; Perkins, C.; Diercks, D.; Brennecka, G.; Zakutayev, A. arXiv:2001.00633, **2020.**

2:30 PM EQ13.13.06
Growth of New Cerium-Containing Nitride Perovskites Rachel Sherbondy[1], Rebecca Smaha[2], Allison Mis[1], Megan Holtz[1], Kevin Talley[2], Andriy Zakutayev[2] and Geoff L. Brennecka[1]; [1]Colorado School of Mines, United States; [2]National Renewable Energy Laboratory, United States

Perovskite materials, those with a crystal structure related to the mineral perovskite and typically with the formula ABX_3, are well known across a number of fields, such as ultrasonics and photovoltaics. These fields use perovskites that have oxygen or halides on the X (anion) site of the perovskite structure, but there are relatively few perovskites that have nitrogen as the anion. In this work, new nitride perovskites of composition $CeMoN_3$ and $CeWN_3$ were grown as thin films using a high-throughput approach. These films were grown using reactive sputtering with a chemical gradient in cation stoichiometry. After growth, films were annealed under flowing nitrogen to explore the phases present at a number of different conditions. The crystallization path revealed a competing defect phase within the fluorite family of crystal structures, which is reported here for the first time and is similar to the fluorite family phase that is observed in the $Pb(Zr,Ti)O_3$ (PZT) system.. For $CeMoN_3$, the perovskite phase was grown using post growth annealing of thin films in a flowing nitrogen atmosphere at a temperature of 900°C for 10 minutes. For the $CeWN_3$ system, growing a perovskite phase was best accomplished during growth conditions that emphasized nitrogen reactivity. The fluorite-family phase was present for both compositions at high Ce content (well above the 1:1 perovskite stoichiometry) and when either temperature or nitrogen reactivity were low. A nitrogen plasma source offered a way to increase nitrogen reactivity at the surface of the film growth to induce growth, especially in $CeWN_3$. For both of these composition families, the high-throughput technique offered insight into the defects that form in off-stoichiometry regions of the film, which serve as a comparison to tell a more complete story of the crystallization of the perovskite phase. For both films, a crystallization path to the perovskite phase is presented and verified by x-ray diffraction. Preliminary property information was also gathered to demonstrate the changes after crystallization of the perovskite phase from the fluorite phase.

SESSION EQ13.14: GaN and Related Nitride Materials
Session Chairs: Huili Xing and Minghui Yang
Wednesday Morning, December 8, 2021
EQ13-Virtual

8:00 AM *EQ13.14.01
Chemistry of Ammonothermal Nitride Semiconductor Synthesis Rainer Niewa; Univ of Stuttgart, Germany

The ammonothermal process is a promising route for the synthesis and crystal growth of various nitride-based semiconductor materials with potential for technological applications. This method typically employs ammonobasic or ammonoacidid mineralizers in supercritical ammonia and was proven to be capable of growing a broad variety of nitrides like InN crystals and freestanding GaN wafers as well as a broad variety of further interesting nitride-based materials. Such chemical transport reactions for crystal growth require use of high-pressure autoclaves, typically operated at process parameters of up to 3 MPa and 600 °C and protection against corrosion provoked by the aggressive medium.

For a successful synthesis and crystal growth, not only a good knowledge of the process parameters and technological challenges is necessary, but also a profound understanding of the chemical processes that govern the feedstock dissolution, the material transport and the deposition in the crystallization zone. In order to obtain deeper insights, we have studied the chemistry of the ammonothermal crystal growth utilizing various mineralizers. Soluble intermediates and their influence on the crystal growth in supercritical ammonia depending on the chemical nature of the mineralizer as well as the pressure and temperature conditions will be discussed with emphasis on crystal growth of AlN, GaN, InN and the feasible synthesis of Zn_3N_2.

8:30 AM *EQ13.14.02
Laser-Assisted MOCVD GaN Epitaxy and Developments of Ternary Nitrides, Heterostructures and Quantum Wells Hongping Zhao; The Ohio State University, United States

Wide bandgap GaN (E_g ~ 3.4 eV) with the intrinsic breakdown field E_{br} ~ 3.5 MV/cm and high electron mobilities μ_n ~ 1000 cm^2/Vs possesses the Baliga figure-of-merit (FOM) at least 5X better than SiC and almost 1000X better than Si for power devices. Vertical GaN devices have been demonstrated with true avalanche breakdown [1]. The current key challenge to achieve high power operation for GaN vertical device with high breakdown voltage (V_{br}) and low on resistance (R_{on}) is on the development of thick GaN drift layer with low controllable doping (N_d-N_a). Key impurities in MOCVD GaN serving as charge compensation centers were systematically investigated. For example, mechanisms of Fe incorporation in MOCVD GaN were identified and addressed [2]. Laser-assisted MOCVD (LA-MOCVD) growth technique was used to enable fast GaN epitaxy while suppressing C impurity incorporation [3]. The effects of LA-MOCVD GaN growth parameters on GaN growth rate, impurity incorporation and charge transport properties will be discussed. GaN PN diodes with breakdown voltage ~ 3kV are demonstrated.

Expanded from III-nitrides, ternary II-IV-N_2 material system possesses unique properties beyond well-developed III-nitrides. Particularly, II-IV-N_2/III-N heterostructures with close lattice matching and large band offsets can potentially address existing challenges facing in pure III-nitride based devices. Closely lattice-matching $ZnGeN_2$/(In)GaN heterostructures have been demonstrated with large band offsets of >1 eV [4, 5]. In this talk, MOCVD developments of $ZnGeN_2$, $ZnGeN_2$/GaN heterostructures and InGaN/$ZnGeN_2$ quantum well structures will be discussed.

9:00 AM DISCUSSION TIME

9:15 AM EQ13.14.05
Late News: Multi-Carbon Complexes in Highly C-Doped GaN John L. Lyons[1], Evan R. Glaser[1], Mary Ellen Zvanut[2], Subash Paudel[2], Malgorzata Iwinska[3], Tomasz Sochacki[3] and Michal Bockowski[3]; [1]Naval Research Laboratory, United States; [2]The University of Alabama at Birmingham, United

States; [3]Polish Academy of Sciences, Poland

Due to its deep acceptor level, carbon doping can lead to highly resistive gallium nitride. But recent experiments indicate that other configurations of carbon become important in heavily C-doped GaN. Here we investigate the properties of heavily C-doped GaN grown by hydride vapor phase epitaxy using optical experiments and hybrid density functional theory (DFT) calculations. Prior work established that carbon acceptors (C_N) give rise to a yellow luminescence (YL) band near 2.2 eV, along with a blue luminescence band (BL) near 2.9 eV. Photoluminescence measurements show the YL band shifting as a function of carbon concentration, suggesting a change in the behavior of carbon species as carbon content increases. With hybrid DFT we calculate the electrical and optical behavior of multi-carbon complexes which may arise in heavily doped material. We compare the behavior of these complexes to the isolated centers, and find that the dicarbon donor-acceptor (C_{Ga}-C_N) complex is a candidate to explain the shift in the YL peak. Tricarbon complexes have modest binding energies but high formation energies, and also give rise to optical transitions inconsistent with the observed spectra. The split dicarbon interstitial on the gallium site is identified as a low-energy species with a large binding energy, that may act to compensate carbon acceptors. Local vibrational modes are calculated for carbon impurity centers and compared to recent experiments. Dicarbon and tricarbon complexes involving C_{Ga} and C_N exhibit modes only slightly higher than the isolated species, while carbon interstitials and related complexes give rise to vibrational modes significantly higher than C_{Ga} and C_N.

Thermodynamics and Growth of V-pit Defects on Wurtzite GaN Polar Surfaces Su-Hyun Yoo, Liverios Lymperakis and Jorg U. Neugebauer; Max-Planck-Insitut for Iron research, Germany

Controlling surface defects is a key to reduce efficiency losses in wurtzite (WZ) GaN-based optoelectronic and power electronic devices. Inverted pyramids or V-pits are a prominent and often observed extended defect in heteroepitaxially grown GaN surfaces. They are widely accepted to be detrimental for optoelectronic devices. Recently, there is an increasing interest in the effect of V-pits on the efficiency of power electronic devices. V-pits are commonly associated with threading dislocations, can reach lateral sizes as large as a few hundred nms, and are buried inside the buffer layer of the heteroepitaxial structures [1]. The buried nature of this defect makes experimental investigations challenging. Therefore, despite their importance, an in-depth understanding of their origin, size, and shape is still lacking.

In the present work, we combine first-principles calculations with elasticity theory and investigate thermodynamic stability and growth of V-pits at GaN (0001) surfaces. The nucleation and properties (e.g., size and shape) of these defects are governed by the complex interplay between dislocation's strain and core energies, surface energies, and oversaturation. A prerequisite to accurately describe these defects is the identification of their absolute surface energies that constitute the inverted pyramid, i.e., polar, semipolar, and/or non-polar planes. Therefore, in the first step, we calculate roughly 300 different GaN surfaces having low index (0001), (10-1n), and (11-2n) orientations, where n=0,…, 3. Although absolute polar and semipolar WZ surface energies are ill-defined, the energies of the semipolar planes can be aligned with respect to those of polar ones. Furthermore, we exploit geometric similarities between {0001} WZ surfaces with higher symmetry {111} zincblende surfaces to calculate "absolute" polar surface energies. For these calculations, we employ our recently developed methodologies, which address the spontaneous polarization fields and allow us to identify accurate surface energetics and electronic structures of WZ surfaces [2, 3]. Based on these calculations we construct a 'V-pit' phase diagram, which describes the equilibrium size and shape of V-pits as a function of the ambient growth conditions, i.e., the Ga and H chemical potentials reflecting oversaturation. This diagram reveals that under typical MOCVD growth conditions, the GaN polar planes are intrinsically unstable against the formation of V-pits at sites where screw threading dislocations reach the surface. The defect formation is driven by the preferential decoration of the surfaces by hydrogen, which reduces the surface energies. The remaining surface energy is compensated by releasing the energy stored in the dislocation core and strain field. Our calculations predict equilibrium lateral sizes up to a few tenths of a nm. Although this is smaller than the experimentally observed maximum size, the size of the energetically favorable V-pit nucleus may be enhanced by surface kinetics, i.e., the presence of Ehrlich–Schwoebel barriers. On the other hand, under typical MBE growth conditions and the lack of hydrogen, V-pits are energetically unfavorable. Based on these results we will further discuss the electronic properties of the V-pit side facets and how they influence critical device parameters such as work functions and ionization energies.

Investigation of Self-Assembled GaN Nanowire Growth Mechanism Nian Jiang, Hannah J. Joyce, Saptarsi Ghosh, Simon M. Fairclough, Rachel Oliver and Carmen M. Fernandez-Posada; University of Cambridge, United Kingdom

One of the major challenges faced by the III-Nitride materials is caused by the absence of a suitable substrate, which results in high dislocation densities in epitaxially grown planar structures. Nanowire geometries are drawing the attention of the III-nitride community for their narrow diameter and small footprint, enabling efficient strain relaxation, thus dislocation free III-nitride nanowires. Yet, a solid understanding of the grow mechanisms for self-assembled III-Nitride nanowires is to be developed, despite many successfully demonstrated devices based on the III-nitride nanowires.

The self-assembled GaN nanowires/nanorods can be achieved via two major growth methods: one with a dielectric mask and one without a pre-deposited dielectric mask. Typically, the GaN nanowires grown with dielectric masks have metal (e.g. Ga) polarity, and have a growth rate comparable to their planar counterparts, while the ones grown directly on a sapphire substrate has a growth rate that is of orders of magnitude higher, and they are mostly with N-polarity.

In this study, we conducted a systematic study of self-assembled GaN nanowires on c-Sapphire substrates grown by metalorganic chemical vapor deposition (MOCVD) through X-ray photoelectron spectroscopy (XPS), atomic force microscope (AFM), scanning electron microscopy and transmission electron microscope. Self-assembled GaN nanowires were grown on c-sapphire substrates in a Veeco Propel Power GaN MOCVD, using ammonia (NH_3), trimethylgallium (TMGa) and silane (SiH_4) as precursors. The substrates were kept in H_2 flow at 1060°C for 5 min to decontaminate the surface followed by a 10 min nitridation step at 1080°C. The temperature was then dropped to (1035 – 1050)°C for GaN nanowire growth. Growth was initiated with a

nucleation step followed by a 15s growth interruption before 10 min nanowire growth with $[NH_3]/[TMGa] = 6 – 24$ and $[SiH_4] = 0.8$ -1.6 μmol/min. The substrate surfaces after the decontamination, nitridation and nucleation steps were studied by XPS and AFM to understand the initiation of nanowire growth. The polarities of as-grown structures were studied by SEM after 30 min etching by KOH solution at room temperature.

We confirmed that the nitridation treatment of the c-Sapphire substrate forms a thin layer of AlN that leads to the N-polarity of the subsequently grown GaN nanowires. The reported Al(NO)x complex associated with the metal-polar III-nitride growth[1], is not observed in the samples after nitridation step, and is consistent with the observation of predominate N-polar GaN nanowires. The nucleation step is essential for GaN nanowire growth, yet this step does not control the nanowire diameters as reported[2]. We found that the broad distribution of nanowire lengths is caused by the different growth mechanisms. Typically, N-polar GaN nanowires' growth rate is 15 – 23 atomic bilayers/sec compared to 2 – 4 atomic bilayers/sec of the Ga-polar nanowires. The N-polar GaN nanowires were found with two distinctive growth rate region – one with (15±2) atomic bilayers/sec and one with (23±2) atomic layers/sec. TEM results suggest screw dislocations may be one of the causes of the growth rate differences.

Understanding the underlying growth mechanisms of N-polarity GaN nanowire growth and their fast growth rate will provide insides to the III-Nitride materials growth community and shine lights to explore the full potential of III-nitride nanowires.

Amorphous Boron Nitride—Ab Initio Study of Its Vibrational Properties David Hinojosa[1], Isaías Rodríguez[1], Alexander Valladares[2], Renela M. Valladares[2] and Ariel Valladares[1]; [1]Universidad Nacional Autónoma de México - Instituto de Investigaciones en Materiales, Mexico; [2]Universidad Nacional Autónoma de México - Facultad de Ciencias, Mexico

Boron nitride (BN) is a structurally versatile insulator since it can be found in several crystalline structures with outstanding mechanical and electrical properties, making this material to be attractive for technological applications. Seeking to improve its features, first principles studies for the amorphous phase (a-BN) have been carried out by several groups, focusing on the electrical [1] and structural [2] properties, pressure-induced phase transformations [1], and hydrogenated a-BN [3]. In this work we shall contribute to the understanding of the a-BN by generating an amorphous structure by means of *ab initio* Molecular Dynamics on a 216-atom supercell, following the *undermelt-quench* approach which has proven to give good structures for structurally disordered materials [4, 5] and studying the vibrational density of states for the samples obtained.

Late News: UV Photodetector Based on Wide Bandgap Gap p-type MnO Quantum Dots /n-type GaN Structures via pn Junction Hadeel Alamoudi, Bin Xin, Mohamed Nejib Hedhili, Somak Mitra and Iman S. Roqan; King Abdullah University of Science and Technology, Saudi Arabia

Developing p-type wide-bandgap semiconductors with bandgap energy corresponding to UV-C spectral region (> 280 nm) is still challenging. This issue motivated us to explore wide-bandgap p-type MnO quantum dots (QDs) with the bandgap of > 4 eV synthesized by femtosecond laser ablation in liquid (FLAL), which is a cost-effective technique. In this study, we demonstrate for the first time a pn-junction photodetector based on p-MnO QDs/n-GaN. As a part of this work, MnO target in ethanol was ablated by ultrafast Ti:Sapphire laser (at 800 nm and 75 MHz) to synthesize the wide-bandgap p-MnO QDs under ambient conditions. We subsequently demonstrate the p-type conductivity of the QDs using Kelvin probe (KP), as well as via field-effect transistor (FET) measurements. X-ray diffraction (XRD), transmission electron microscopy and Raman spectroscopy were also performed to ascertain the p-type MnO composition. Absorption spectroscopy findings indicated that the bandgap was in the 4−5 eV range. The solution-processed MnO QDs were simply spray-coated on Si-doped GaN to fabricate MnO/GaN-based solar-blind DUV photodetector. X-ray Photoelectron Spectroscopy (XPS) analysis reveals the heterojunction band alignment of p-MnO QDs/n-GaN and the band offset at the heterojunction interface, demonstrating a good band alignment between GaN and MnO QDs with type II. Electrical characterizations show a good photocurrent response, as well as self-powered characteristics. This study provides new insights into the use of p-type MnO QDs for III-nitride devices.

Late News: Optical Characterization of Carrier Recombination Process in GaPN Alloys: Excitation Source and Nitrogen Concentration Dependence Hiroki Iwai, Sanjida Ferdous, Norihiko Kamata, Shuhei Yagi and Hiroyuki Yaguchi; Graduate School of Science and Engineering, Saitama University, Japan

III-V-N alloys have been receiving much attention for optoelectronic device applications because of their attractive features, for example, large gap bowing and splitting of conduction band. In particular, GaPN alloys are candidate materials for intermediate band solar cells (IBSCs). Since some defects due to nitrogen atoms in III-V-N alloys are found to act as nonradiative recombination (NRR) centers, however, it is crucial to study non-radiative recombination processes in GaPN alloys for improving the efficiency of solar cells. In this study, therefore, we evaluate the carrier recombination process in GaPN alloys with various nitrogen concentrations by using an optical technique, two-wavelength excited photoluminescence (TWEPL).
The samples used in this work were grown by metalorganic chemical vapor deposition. A 300 nm-thick GaP buffer layer and a 500 nm-thick $GaP_{1-x}N_x$ (x = 0.105%, 0.56%, 0.75%, 1.4% and 3.2%) were grown in sequence on 400 μm-thick GaP substrates with an orientation of (100). Trimethylgallium, phosphine, and dimethylhydrazine were used as Ga, P, and N sources, respectively.
The TWEPL measurements were carried out using above-gap excitation (AGE) and below-gap excitation (BGE) light. While the sample was excited by AGE light, BGE light was irradiated at the same point of AGE spot. We measured PL intensities with BGE ($I_{AGE+BGE}$) and without BGE (I_{AGE}), and derived the normalized PL intensity (I_N=$I_{AGE+BGE}$/I_{AGE}). We used two light sources for AGE; λ=374 nm, 3.32 eV and λ=532 nm, 2.33 eV for conduction band (CB) excitation and intermediate band (IB) excitation, respectively. For BGE, we used 0.81 eV (1532 nm), 0.93 eV (1340 nm), 1.17 eV (1064 nm), 1.27 eV (980

nm), and 1.46 eV (850 nm). The sample was immersed in liquid nitrogen (77 K) to prevent temperature rise effect due the excitation light sources.
First, we studied the nitrogen dependence of the integrated PL intensity by AGE and found that the PL intensity of 3.2% sample was the lowest in all the samples, indicating that 3.2% sample is the most significantly affected by NRR centers. The PL intensity of 1.4% sample was the highest and the samples with nitrogen concentration of 0.105%, 0.56% and 0.75% showed the PL intensity between 3.2% and 1.4%; however, the PL intensity of 0.105% sample was a little lower than 0.56% and 0.75% because isolated N-N pairs emissions are dominant for 0.105%.
Second, we investigated the BGE power dependence of normalized PL intensity (I_N) based on TWEPL method. For IB excitation, I_N value increased and became saturate for all the BGE sources, showing that some electrons are excited from valence band (VB) to NRR centers or from NRR centers to IB. The I_N value of 3.2% was higher than that of 1.4% sample. This is consistent with the integrated PL intensity result that 3.2% sample is significantly affected by NRR centers. For CB excitation, in contrast, I_N value was almost constant for 1.4% and 3.2% samples, which is clear evidence that the carrier relaxation and subsequent recombination processes are much different for CB and IB excitation. Therefore, we found that the reduction of NRR centers located between VB and IB is important for reducing the relaxation from CB to NRR centers, and thus improving the efficiency of CB excitation.
We will clarify the carrier recombination process in GaPN alloys with different nitrogen concentrations by combining the experimental results of time-resolved photoluminescence measurements.

Why Should We Invest in Ultrawide Bandgap Nitride Semiconductors? Huili G. Xing; Cornell University, United States

To fully unleash the potential of a semiconductor, it is critical to 1) control its defect levels below the limits that the targeted applications can tolerate, 2) control its doping in both n-type and p-type, and 3) engineer the most effective carrier injection into the conduction and valence bands, i.e. excellent ohmic contacts. A DUV emitter is an epitome of devices where these requirements need to be met. Even for an application that can be successful in engineering only one band of the semiconductor, availability of adequate control of the other band expands the design and operation space of the device tremendously. I will discuss advances in fundamental science and technology development that promise solutions for DUV devices, power and RF electronics.

Novel Approach for Growth of High-Quality Aluminum Indium Nitride Covering the Entire Composition Range Zachary Engel, Habib Ahmad and William A. Doolittle; Georgia Institute of Technology, United States

Aluminum Indium Nitride (AlInN) has shown great potential in the fields of optoelectronics, photovoltaics, and electronics. It has shown potential as an electron blocking layer and quantum well material in light emitting diodes (LEDs), as an absorbing material in solar cells, and as a barrier layer in high electron mobility transistors (HEMTs). Additionally, AlInN has a wide range of useful properties, including a tunable bandgap from 0.65 to 6.1 eV, a high absorption coefficient, high polarization coefficients to allow for high density 2D hole and electron gasses, and the ability to be grown lattice matched to GaN at a composition of about 18% indium. However, despite the proven useful applications and properties of the alloy, crystal quality issues have plagued this material. Due to the large mismatches between the two binary alloys, AlN and InN, a large miscibility gap exists for the ternary material. Additionally, the growth temperatures required to achieve state-of-the-art quality InN and AlN differ in extremes of ≥500 °C. At the preferred temperature required for superb AlN, it is difficult to incorporate indium into a film. Conversely, at growth temperatures that allow for high or complete indium incorporation, aluminum adatom mobility is traditionally extremely low. Thus, a nontraditional method must be employed to grow this challenging material.

For these reasons, Aluminum Indium Nitride was grown over the entire composition range from InN to AlN using a non-traditional method, Metal Modulated Epitaxy (MME). MME is an extremely low temperature modification of molecular beam epitaxy (MBE) performed at temperatures where desorption and thermal decomposition are negligible, utilizing cyclic, high metallic doses to establish a low bond strength surface layer resulting in higher adatom mobility. MME has shown great potential in the past for the growth of AlInN, demonstrating the ability to grow high indium content AlInN with state-of-the-art crystal quality and sub-nm RMS roughness. By utilizing pulsed cation fluxes with high metal fluxes, short metal doses, and a metal rich III/V ratio at substrate temperatures low enough to prevent In-N decomposition and In desorption, adatom kinetics have been improved, improving film structural and optical properties. Using this approach, MME has produced $Al_{0.3}In_{0.7}N$ with X-ray rocking curves 11 times better than prior literature. This non-traditional approach was expanded to look at 9 compositions from 10% to 90% Al, each at multiple substrate temperatures. Because the optimal substrate temperature varies with composition, 27 samples ranging from: 10-40% Al were grown at 300, 350, and 400 ºC; 50-70% Al were grown at 350, 400, and 450 ºC; and 80-90% Al were grown at 400, 450, and 500 ºC. High structural quality was observed over the entire composition range but varied with growth temperature for different compositions, with (0002) X-ray diffraction (XRD) rocking curve full-width at half-maximum (FWHM) values as low as 163 arc-sec even near the center of the composition range where phase separation is predicted to be problematic. Atomic force microscopy (AFM) measurements showed smooth surfaces throughout the composition range with RMS roughness' ranging between 0.16 to 3 nm. Photoluminescence measurements of high indium content AlInN show promising luminescence at wavelengths traditionally difficult for efficient InGaN emission while the luminescence efficiency varies with composition and growth conditions.

11:15 AM EQ13.15.03
Enhanced Performance of $Al_{0.4}Ga_{0.6}N$ Solar-Blind Photodetectors by Localized Surface Plasmon Resonance in Pd Nanoparticles Shuchi Kaushik[1], Prashant Bisht[1], Che-Hao Liao[2], Xiaohang Li[2], Bodh Raj Mehta[1] and Rajendra Singh[1]; [1]Indian Institute of Technology Delhi, India; [2]King Abdullah University of Science and Technology, Saudi Arabia

The ever-increasing demand for "solar-blind" (insensitive to photons with wavelengths longer than ~285 nm) photodetectors (PDs) in healthcare, space science, and technology, and the military requires focusing on state-of-the-art PDs. Owing to its appealing properties of tunable wide bandgap (3.4 to 6.2 eV), high-temperature robustness, chemical and radiation hardness, $Al_xGa_{1-x}N$ has emerged as the most suitable candidate for fabricating solar-blind PDs [1]. However, the "5S" requirements of high spectral selectivity, sensitivity, speed, signal-to-noise ratio, and stability for a commercial PD emphasize novel strategies to improve the performance parameters of AlGaN-based solar-blind PDs. In the last two decades, the localized surface plasmon resonance (LSPR) in metal nanoparticles (NPs) has proved to be a promising strategy to enhance the performance of semiconductor PDs [2]. The role of Al NPs has been investigated to improve the performance of AlGaN solar-blind PDs. However, the reported responsivity values were only 0.288 AW^{-1} at 5 V [3] and 2.34 AW^{-1} at 20 V [4]. Therefore, there is a need to explore other metal NPs that may prove better than Al NPs for AlGaN solar-blind PDs.

In this work, we report a significant enhancement in the performance parameters of $Al_{0.4}Ga_{0.6}N$ solar-blind PDs mediated by LSPR in Pd NPs. The interdigitated electrode (IDE) geometry (width and inter-electrode spacing 20 μm) of metal-semiconductor-metal (MSM) PDs was fabricated on MOCVD grown $Al_{0.4}Ga_{0.6}N$ epilayers. Pd NPs were deposited on one of the PDs using an integrated gas-phase setup and then annealed at 500 °C to obtain AlGaN PD with Pd NPs. On decorating the $Al_{0.4}Ga_{0.6}N$ film by Pd NPs, a significant enhancement in the current at 500 nm (visible) and 280 nm (solar-blind) was observed. At −5 V, the photo-to-dark current ratio (PDCR) was found to increase by 99.7% and 71.7% at 500 and 280 nm, respectively. Similarly, at −10 V, the enhancement was 99.6% and 85.0% at the two wavelengths. The observed results are attributed to the increased absorption and hot-carrier generation by LSPR in the Pd NPs. As a result, the performance parameters of the PD, such as responsivity and specific detectivity, were found to improve significantly. At −10 V, the peak responsivity was found to increase by 75%, reaching a maximum value of 2.2 AW^{-1} at 220 nm with an incident optical power of only 1.7 μW, indicating the ability to detect even weak signals. It was observed that the responsivity increased with the increasing bias, and an enhancement by 71% was observed in the responsivity at 280 nm for the PD with NPs. To compare the sensitivity of the PDs, the specific detectivity was calculated, and its variation with the incident wavelength was analyzed. At −10 V, the maximum value of specific detectivity was found to increase by 82%, and a peak value of 3.4×10^{13} Jones was calculated. In conclusion, a significant increase in the PDCR, peak responsivity, and specific detectivity by 85%, 75%, and 82%, respectively, was observed for $Al_{0.4}Ga_{0.6}N$ solar-blind PD on decorating with Pd NPs.

Understanding Dislocation Induced Formation of Nanopipes in III-Nitrides from First Principles Liverios Lymperakis, Su-Hyun Yoo and Jorg U. Neugebauer; Max-Planck-Institut für Eisenforschung GmbH, Germany

Threading dislocations constitute a long standing and highly debated issue in the field of III-nitride materials. Typical dislocation densities in nitride based devices can be as high as of 10^8 to 10^{10} cm^{-2}. These defects have recently attracted considerable interest due to their detrimental role in power electronics. *c*-type screw dislocations are considered to be one of the major limiting factors in achieving the full potential of nitride based power electronic devices. Specifically, screw dislocations as well as the associated V-pits have been proposed to be the root cause of device leakage and breakdown [1,2]. An intriguing feature of these defects is that experimental evidences suggest that they are associated with open core structures, thus forming nanopipes with diameters of a few nm [3]. On the other hand, early as well as recent first principles calculations indicate that the formation of nanopipes is energetically unfavorable under typical growth conditions [4,5]. However, these calculations do not explicitly consider the effect of core and/or do not consider the effect of impurities such as hydrogen that is abundant in MOCVD growth or dopand species such as C and Mg.

In order to resolve the aforementioned discrepancies and provide an understanding on the formation and the properties of dislocation induced nanopipes in III-nitrides we combine first principles with large scale empirical potential calculations within the Implicit Boundaries Multiscale Scheme [6]. Using this approach we investigate the energetics, atomic structure and electronic properties of *c*-type screw dislocations in GaN and AlN. Based on these calculations we construct a screw dislocations' phase diagram which describes the energetically most favorable core structures as function of the species' chemical potentials. We explicitly consider the effect of H, C, and Mg as well as the formation of superscrew dislocations, i.e., dislocations with Burgers vector multiple lattice constants. Although nanopipes exhibit large free surface areas which increase the energy, they can be energetically favorable if the surface energy is compensated by the core and strain energy of the material removed to create the open core screw dislocation. Our calculations indicate that under MBE growth this requirement is not met and the formation of nanopipes is energetically highly unfavorable. However, a general trend that emerges from the aforementioned phase diagram is that nanopipes become energetically favorable at higher H chemical potentials. Indeed, under typical MOCVD or MOVPE growth conditions the cation and anion dangling bonds at the open core inner surfaces are passivated by NH_x molecules and H atoms, respectively. This reduces considerably the surface energy and the formation of nanopipes with hexagonal cross section and equilibrium diameters ranging from approx. 1 to 2 nm are energetically favorable. Based on these results we will discuss the electronic properties of the nanopipes, the diffusion and incorporation of C and Mg dopands at the open core structure as well as implications these defects may have on the efficiency of the electronic devices.

Growth and Optical Characteristics of High-AlN Content AlGaN on AlN Templates by RF-MBE Under Metal-Rich Conditions Mahiro Hayasaki and Takeyoshi Onuma; Kogakuin University, Japan

Recently, UV-C lights are getting explosive attention for UV sterilization. $Al_xGa_{1-x}N$ is a direct bandgap material covering from 3.4~6.0 eV. It is one of the most promising one to realize semiconductor-based UV-C emitter. However, metal-rich growth of high-AlN content AlGaN by RF-MBE has known to be suffered from drawback due mainly to the difference in the bonding energy of Ga-N and Al-N [1,2]. In this study, high-AlN content $Al_xGa_{1-x}N$ films were grown by RF-MBE. Impact of change in group-III to nitrogen supply ratio on their crystallinity and optical property are studied to phenomenologically understand the growth kinetics.

$Al_xGa_{1-x}N$ films were grown on 425-nm-thick *c*-plane AlN on Al_2O_3 templates [3] at substrate temperature of 775°C. Beam equivalent pressures of Al and Ga sources were fixed at 2.0×10^{-7} and 3.0×10^{-7} Torr, respectively. N_2 gas flow rate was varied in between 0.3~2.0 sccm by fixing RF input power of 150 W. Growth time was controlled by the group-III source supply for 1 hour with maintaining the reactive nitrogen source supply during the heating and cooling processes above 300°C. Photoluminescence (PL) spectra were measured at room temperature (RT) using a frequency-quintupled (213 nm) Q-switched YAG:Nd laser. Reflectance spectra were measured at RT using a 25 W Deuterium and a 20 W Tungsten Halogen lamps.

XRD 2q-w pattern for the film with N_2=0.3~0.5 sccm only shows a (0002) diffraction peak of AlN. Diffraction peaks of GaN and AlGaN additionally appeared for the films with 0.7~2.0 sccm. Furthermore, the AlGaN peaks for 0.7~2.0 sccm exhibited a shoulder at higher and lower diffraction angle side, respectively. Al mole fraction x was measured by X-ray reciprocal space mapping to be 0.67~0.88, confirming the growth of high-AlN content AlGaN.

Film thicknesses were assessed by the spectroscopic ellipsometry measurements to be 387~416 nm for AlN overlayers at N_2=0.3~0.5 sccm, 420~653 nm for AlGaN at N_2=0.7~2.0 sccm, and 4~73 nm for GaN grown on top of the AlGaN layer. PL spectra exhibited near-band-edge emission peaks for GaN at around 3.3~3.4 eV and for AlGaN at around 4.3~4.8 eV. Furthermore, the AlGaN peak for 1.0 and 2.0 sccm clearly shows double peaks. The reflectance spectra show the multiple interference fringes in which three periodic oscillations are overlapped, and the averaged effective bandgap energies of AlGaN layers were estimated to 5.09~5.43 eV.
The overall results can be understood by the growth model [1], in which the Al-N bond is favorably formed under the metal rich condition. The additional lower-Al-content AlGaN and GaN overlayers were found to be grown during the cooling process by nitriding the excess Al and Ga metals.

Defect Detection in AlGaN Barrier of AlGaN/GaN Schottky Diodes Philippe Ferrandis[1,2,3], Matthew Charles[2,4], Marc Veillerot[2,4] and Charlotte Gillot[2,4]; [1]Université de Toulon, France; [2]Univ. Grenoble Alpes, France; [3]Innstitut Néel, France; [4]CEA, LETI, France

The AlGaN/GaN heterostructure has been demonstrated to be a promising candidate for high power amplifiers in the microwave communication system and high-voltage power switches [1]. The combination of GaN device performance with the low cost of silicon substrates enhances the interest of this technology. Despite numerous improvements of GaN power components during the last decades, charge trapping effects at deep levels still lead to dynamic on-resistance and switching losses [2]. To detect these deep traps and determine in which part of the device structure they are located, capacitance deep level transient spectroscopy (DLTS) has been applied to GaN Schottky barrier diodes (SBDs) [3].

However, hole-like traps are frequently observed in DLTS spectra of devices with n-type AlGaN/GaN heterojunctions without any minority carriers. Many works refer to previous studies carried out in AlGaAs/GaAs systems to explain the nature of these DLTS signals. Hence, hole-like traps are often associated with surface states at the ungated SiN/AlGaN interface [4]. They are sometimes related to bulk traps in the AlGaN layer [5] or to the transfer of electrons by tunneling effect from the traps in the lower half of the AlGaN bandgap into the states in the GaN buffer [6].

To our knowledge, no deep investigation exists to clearly identify the origin of hole-like traps in AlGaN/GaN heterojunctions. A detailed understanding of the trapping mechanism involved in this anomalous DLTS signal is of fundamental importance to learn which defects affect device performance such as the gate-lag, for instance [5].

This work introduces a deep study on a hole-like signal which appears in DLTS spectra of AlGaN/GaN SBDs. A correlation between the amplitude of the peak and the reverse leakage current of the diode has been demonstrated and a mechanism is proposed to explain the formation of the hole-like signal. During the pulse voltage, electrons move by tunneling conduction from the two-dimensional electron gas (2DEG) towards the AlGaN layer where they are captured on deep donor states. When the temperature is increased and the reverse voltage is applied on the anode, the thermal energy removes electrons from the traps and the 2DEG is refilled by the reverse leakage current of the diode. The hole-like signal results from the return of electrons into the 2DEG.

The simulation of the DLTS peak using a model involving a transient time constant, which takes into account the thermal activation energy of the reverse leakage current of the diode, leads to the extraction of two deep levels in AlGaN. The concentration of the dominant trap depends on the ammonia partial pressure used to perform the AlGaN layer and was calculated at $4.1\text{x}10^{13}$ cm^{-3} and $5.3\text{x}10^{13}$ cm^{-3} for the two tested SBDs. With the help of secondary ion mass spectrometry studies, this trap was assigned to nitrogen antisite defects. The second trap was tentatively associated with Ga vacancy related defects.

The proposed model allows an explanation of the origin of traps reported in the literature. In addition, this work demonstrates that information can be extracted from a hole-like signal in AlGaN/GaN heterojunctions to access features of traps in AlGaN. We also demonstrated that the amplitude of the hole-like signal is an indication of the quantity of electrons which leave the 2DEG. Since the reduction of electrons in the 2DEG directly results in a decrease of device performance, the appearance of a hole-like signal in DLTS spectra of AlGaN/GaN heterojunctions should be thoroughly investigated.

Defect Analysis of a Thin Channel AlGaN/GaN Transistor Julien Bassaler[1], Farid Medjdoub[2], Yvon Cordier[3] and Philippe Ferrandis[4]; [1]Univ. Grenoble Alpes, CNRS, Grenoble INP, Institut Néel, France; [2]CNRS-IEMN, Institute of Electronics, Microelectronics and Nanotechnology, France; [3]Université Côte d'Azur, CNRS, CRHEA, France; [4]Université de Toulon, Univ. Grenoble Alpes, CNRS, Institut Néel, France

AlGaN/GaN high electron mobility transistor (HEMT) are known to be promising devices for high voltage applications. But the voltage range of the commercially available devices is not exceeding 650 V. To achieve operating voltages above kV, several solutions have been tested. One of them is the use of a thinner GaN channel combined with an ultra-wide bandgap material as a buffer in order to reduce its impact on the overall breakdown voltage.
The device studied in this work is an AlN-based HEMT [1] grown by molecular beam epitaxy. It is composed of a 6 µm thick commercial AlN-on-sapphire template, a 190 nm AlN buffer, a 8 nm GaN channel, a 10 nm AlGaN barrier layer with 90% aluminum molar fraction to ensure a high sheet carrier density and a 5 nm in-situ grown SiN_x cap layer. Ti/Al/Ni/Au ohmic contacts are deposited on top of the barrier layer and Ni/Au is used to form the gate metal. Characterization by capacitance deep-level transient spectroscopy (DLTS) has been performed between 77 K and 500 K. A reverse voltage V_R from −1 V to −7 V has been applied between the gate and the ohmic contact. The filling pulse voltage V_P was fixed at −0.5 V.
For a reverse voltage $V_R > -5$ V, the depleted layer is under the gate. A DLTS peak can be observed at T_{max} = 123 K for a period width of T_W = 10 ms. The Arrhenius plot gives an activation energy of E_a = 0.18 eV and a capture cross-section of $\sigma_n = 1.2\times10^{-15}$ cm^2. The amplitude of the peak is saturating for a filling pulse time of t_P = 10 ms, indicating this is a point defect. It could be related to a N-vacancy defect [2][3]. For a reverse voltage $V_R < -5$ V, the depleted area extends under the SiN_x cap layer. At least five new peaks appear on the DLTS spectra at T_{max} = 158, 190, 294, 375, 443 K for the same period width of 10 ms. Their activation energies are consequently higher than the first identified defect. When the negative voltage is applied on the gate contact, the negative charges in the SiN_x are pushed back towards the ohmic contact and let positive charges on the gate side. The electrons of the channel are attracted by these positive charges and are captured by the defects in the AlGaN layer. This leakage mechanism has already been proposed for another

AlGaN/GaN HEMT [4]. The peaks resulting from this phenomenon are not visible on the DLTS spectra for $V_R > -5$ V because the probed area is not under the SiN_x cap layer. It is expected that the large lattice mismatch between AlGaN and GaN layers, resulting from the high aluminum concentration of AlGaN, leads to the formation of defects. Additional levels which appear in DLTS spectra for $V_R < -5$ V could then be related to interface states or border traps in AlGaN.
The DLTS results enabled to highlight defects in the high aluminum concentration barrier layer and the leakage mechanisms occurring between the channel and the barrier. These results will help to improve critical properties of the AlN-based HEMT with a thin channel.

Late News: Revealing Sub-Quantum-Well Effect on Carrier Dynamics in High Efficiency DUV AlGaN/AlGaN-Based Multiple-Quantum-Wells Iman S. Roqan[1], Idris Ajia[1], Sergei Lopatin[1], Dhaifallah Almalawi[1] and Zhiqiang Liu[2]; [1]King Abdullah University of Science and Technology, Saudi Arabia; [2]Institute of Semiconductors, Chinese Academy of Science, China

We reveal the role of the sub-well centers and related carrier dynamics mechanisms in enhancing the DUV emission of AlGaN/AlGaN multiple quantum wells (MQWs) when AlN substrate is grown homoepitaxially using MOCVD, thus eliminating the dislocation effect. As a part of this work, a 400 nm thick AlN layer was initially regrown on a thick (0001) AlN substrate at 1250 °C, followed by a $20\times Al_{0.6}Ga_{0.4}N$/AlN superlattice (SL) layer. Subsequently, a 1 µm thick n-AlGaN layer was grown, followed by a nominal 5-period $Al_{0.4}Ga_{0.6}N/Al_{0.5}Ga_{0.5}N$ (3 nm/12 nm) MQW active layer capped by a 30 nm p-$Al_{0.65}Ga_{0.35}N$ electron blocking layer (EBL). Both plan-view and cross-sectional images obtained via scanning transmission electron microscopy (STEM) reveal dislocation defect-free epitaxial layers of very high crystalline quality, as well as ultra-thin Al-rich sub-quantum barrier layers. Energy dispersive x-ray (EDX) compositional analysis of the STEM cross-sections indicates that the formation of these layers can be ascribed to the diffusion of Al adatoms towards the top of the barriers, creating shallow sub-wells within the barrier regions. Advanced carrier dynamic analyses via photoluminescence (PL), power-dependent time-resolved PL (TRPL) spectroscopy and PL excitation measurements show that these sub-wells/sub-barriers resulted in additional carrier confinement and exciton localization centers. As a result, internal quantum efficiency is enhanced via staggered carrier repopulation into the MQWs to reach its maximum (~ 85%) and remains high (> 60%) after a slight droop at high carrier densities. We show that this slight efficiency droop is due to Auger recombination counteracted by a simultaneous increase in radiative recombination processes at high power density, demonstrating the role of sub-wells/barriers in efficiency enhancement.

Al Flux Control in Growth of AlN on AlN Templates by RF-MBE Tomoya Yamaguchi and Takeyoshi Onuma; Kogakuin University, Japan

The use of deep ultraviolet (DUV) light for sterilization is attracting much attention behind recent global situation regarding COVID-19. AlGaN is the most promising candidate material [1,2]. Recent developments of high quality AlN template [3] as well as AlN bulk substrate [4] acccelerate improvements of perforance of DUV emitters. Nevertheless the develpments of the template and substrate, precise control of conditions is still nessessary for growth of $Al_xGa_{1-x}N$ by RF-MBE. In general, metal-rich condition is preferred to maintain high crystallinity and flat surface. Meanwhile, Al atoms tend to be stronger bonded to the surface, and Ga and N atoms are hardly incorporated into the alloy lattice even if Ga and N are sufficiently supplied [5]. Therefore, controll of Al flux is crucial to eliminate Al precipitation and to supress composition fluctuation in $Al_xGa_{1-x}N$ alloy. In this study, AlN thin films were grown on AlN templates as functions of Al flux and growth temperature. Effects of the parameters on crystallinity and surface flatness are discussed.
AlN templates were 431-nm-thick c-plane AlN prepared on Al_2O_3 by halide vapor phase epitaxy (HVPE) [3]. 181 to 432-nm-thick AlN films were grown for 1 hour with N_2 gas flow rate of 0.3 and RF input power of 150 W. Substrate temperature was varied as T_s=775, 800, and 850 °C, and Al equilibrium vapor pressure was varied as Φ_{Al} =1.0×10^{-7} Torr and 2.0×10^{-7} Torr. The samples were evaluated by atomic force microscopy (AFM), laser microscopy, X-ray diffraction (XRD), and spectroscopic ellipsometry.
All the XRD 2θ-ω patterns predominatly show a (0002) diffraction peak of AlN. The patterns for Φ_{Al} =2.0×10^{-7} Torr additionally show a (111) diffraction peak of Al metal. The peak appeared regardless of T_s, and the intensity decreased with increasing T_s. It was also confirmed by the laser microscope images that the amount of Al precipitaes decreased with increasing T_s. On the contrary, the films grown with Φ_{Al} =1.0×10^{-7} Torr showed no tendency of Al precipitation at all T_s. The results imply that the growths with Φ_{Al} =2.0×10^{-7} Torr were Al-rich conditions, and growths with Φ_{Al} =1.0×10^{-7} Torr were stoichiometric or slightly N-rich condtions. Furthermore, the growth rate decreased for Φ_{Al} =2.0×10^{-7} Torr at the lowest T_s of 775°C. It was suggested that exesss Al supply induced a fomation of Al layer, which are no longer contribute to the growth, and resulted in a decrease in film thickness [6]. Root mean square roughness obtained from the surface AFM images was improved from 3.7 nm at (Φ_{Al} , T_s)=(2.0×10^{-7} Torr, 800°C) to 1.4 nm at (Φ_{Al} , T_s)=(1.0×10^{-7} Torr, 800°C). The results indicate that the Al precipitaion degrade the surface flatness, and it must be elimineted to obtain crystallinity as is the same with the AlN template.

***Ab Initio* Insights into Fundamental Intrinsic Growth and Materials Limitations in Group-III-Nitrides** Su-Hyun Yoo, Liverios Lymperakis and Jorg U. Neugebauer; Max-Planck-Institut für Eisenforschung, Germany

Their large direct bandgap, high thermal stability and surprisingly large insensitivity against even large defect concentrations have made group-III-nitrides the alloy system of choice in manufacturing light emitting devices and make them highly attractive for high-power applications. Despite the amazing progress that has been achieved in understanding, controlling and processing these materials fundamental issues remain unresolved that severely limit device performance. Infamous examples are the efficiency droop in the green region of the optical spectrum, the spontaneous formation of extended defects during epitaxial growth such as V-pits, or the formation of long-range electrostatic fields due to spontaneous polarization.
Understanding the origin of the underlying fundamental mechanisms requires an in-situ observation of atomic-scale phenomena during epitaxial growth, which makes it hard and often even impossible to explore them by experimental techniques. Recent developments and progress in first principles calculations provide now a powerful tool to unravel the mechanisms that are the fundamental cause for limitations in these materials [1,2]. In the presentation a brief overview about key concepts of the novel approaches will be given. It will be further demonstrated how they help to uncover hitherto unknown surface phenomena such as frustrated hybridization [3] that explain the origin of droop as a phenomenon originating at the surface rather than in bulk.

Growth of High-Quality InGaN on N-Polar GaN Substrates by Plasma-Assisted Molecular Beam Epitaxy at High Temperatures Ruby Wellen, Kamruzzaman Khan and Elaheh Ahmadi; University of Michigan–Ann Arbor, United States

In recent years, nitrogen-polar based devices have emerged as a potential source for novel and innovative developments in the field of GaN technology. With a different polarity, surface reactivity, and growth dynamic, N-polar GaN demonstrates notable advantages over Ga-polar GaN. The benefits of N-polar also span the typical compounds grown on Ga-polar GaN substrate. $In_xGa_{1-x}N$ is especially interesting to investigate due to its attractive applications in optoelectronic devices. However, InGaN growth on GaN is challenging for several reasons, one of which concerns the conflicting values for the optimum growth temperatures of GaN and InGaN. To better examine such obstacles, this study explores InGaN growth on N-polar GaN by plasma assisted Molecular Beam Epitaxy (MBE) with high temperature. Samples were grown within a range of temperatures from 600° to 670°C, although typically InGaN films on Ga-polar GaN are grown around 100° less. The resulting N-polar InGaN samples achieved higher indium incorporation compared to Ga-polar growths. With further experimentation, the desirable growth conditions can be established and applied for development of higher performance InGaN devices.

1:45 PM EQ13.16.03
Atomic-Scale Localization Centers in Strain-Compensated In-rich InGaN Architectures for Red Emission Jing-Yang Chung[1,2], Zackaria Mahfoud[3], Govindo Syaranamual[1], Li Zhang[1], Stephen Pennycook[1,2], Silvija Gradečak[1,2] and Bosman Michel[2,3]; [1]Singapore-MIT Alliance for Research and Technology, Singapore; [2]National University of Singapore, Singapore; [3]A*STAR (Agency for Science, Technology and Research), Singapore

A remarkable increase in the quantum efficiency of long-wavelength III-nitride light emitters has been demonstrated by AlN or AlGaN strain-compensating interlayers that cap In-rich InGaN quantum wells (QWs). However, the structural non-uniformity within these strain-compensated heterostructures, and its effect on the local and overall optical properties, has not yet been satisfactorily addressed.

In this work, we use aberration-corrected scanning transmission electron microscopy (STEM) combined with cathodoluminescence (CL) in the STEM to study optical inhomogeneities resulting from various atomic-scale localization centers in red-emitting AlN capped InGaN/GaN QW devices. By probing the spectral response of individual InGaN QWs with nanometer spatial precision, we show that a secondary blueshifted emission originates within the QW near to the AlN interlayer. On the other hand, the presence of criss-crossing inversion domains intrinsically linked to the strain fields surrounding V-pits result in further distinct blueshifts. Finally, high intensity luminescence can be directly correlated to In-rich quantum dots spontaneously nucleated at intersecting V-pit regions. This study highlights the importance of controlling thickness modulation of interlayers and threading dislocation densities to ensure compositional and optical homogeneity in strain-compensated In-rich optoelectronic devices targeted for practical applications. Our results also suggest the nanoscopic origins for the significant emission wavelength shift with injection-current observed in red-emitting devices.

2:00 PM EQ13.16.04
Detection and Suppression of Compositional Fluctuations in InGaN Light Emitting Diodes Tara P. Mishra[1,2], Jing-Yang Chung[1,2], Zeyu Deng[1], Silvija Gradečak[1,2,3], Stephen Pennycook[1,2] and Pieremanuele Canepa[1,2]; [1]National University of Singapore, Singapore; [2]Singapore-MIT Alliance for Research and Technology, Singapore; [3]Massachusetts Institute of Technology, United States

$In_xGa_{1-x}N$ light-emitting diodes (LEDs) with higher In content have reduced efficiency compared to their lower In counterparts. The origin of this reduction in efficiency is still not fully understood, although compositional fluctuations in $In_xGa_{1-x}N$ quantum wells have been linked with the efficiency of LEDs. We combined atomic-resolved electron energy loss spectroscopy (EELS) imaging with first-principles multiscale computational models to obtain a statistical distribution of the compositional fluctuations in $In_xGa_{1-x}N$ LEDs at different indium concentrations. By analyzing a large dataset of EELS data, we obtain the statistical distribution of the compositional fluctuations as a function of the $In_xGa_{1-x}N$ composition. We show that although lower In content $In_xGa_{1-x}N$ with x~18% LEDs mostly show compositional fluctuations in the limit of a random alloy, the distribution of compositional fluctuation drastically changes in $In_xGa_{1-x}N$ LEDs with higher In content (≥24%)[1]. Therefore, a distinctly different mechanism for carrier localization can be expected for $In_xGa_{1-x}N$ LEDs of different In content, which would ultimately affect the performance of the LEDs [2]. Our theoretical approach directly incorporates strain effects in the $In_xGa_{1-x}N$ quantum wells, resulting from the epitaxial growth. Based on our theoretical model, we will showcase a new method to prevent compositional fluctuations in higher In content $In_xGa_{1-x}N$ LEDs.

Identification of Extended Defects in Long Wavelength InGaN Light Emitters Jing-Yang Chung[1,2], Tara P. Mishra[1,2], Govindo Syaranamual[1], Li Zhang[1], Bosman Michel[2,3], Stephen Pennycook[1,2] and Silvija Gradečak[1,2]; [1]Singapore-MIT Alliance for Research and Technology, Singapore; [2]National

University of Singapore, Singapore; [3]A*STAR (Agency for Science, Technology and Research), Singapore

Extended defects in In-rich quantum wells (QWs) hamper the fabrication of efficient long-wavelength III-nitride light emitting diodes (LEDs). A detailed understanding on their nature, formation mechanism, and the resulting properties is crucial for the design of more efficient optoelectronic devices. With the advent of 5th order aberration correctors in scanning transmission electron microscopes (STEMs), the direct imaging of atom displacements becomes possible, allowing an unambiguous interpretation of the atomic structure of defects. However, at the moment there is no broad reference for STEM-based atomic-resolution defect classification such as those which exists for conventional TEM.

We demonstrate high-angle annular dark-field (HAADF) depth-sectioning as a convenient tool to distinguish between various defect types in In-rich QWs. We show that different planar defects – the dominant defect type emerging from the QWs – are identifiable by their unique atomic column overlap configurations. Through this method, we reveal that defects commonly identified as edge type dislocations in conventional QWs are instead isolated sub 5-nm type I_2 basal stacking faults (BSFs). Electron energy loss spectroscopy mapping of the QWs suggests the origins of these small diameter BSFs to be local compositional fluctuations, which have theoretically been predicted to increase in QWs with higher strain. Through the engineering of a strain relaxed architecture, we show that a pathway for defect-free long wavelength InGaN LEDs can be achieved.

2:20 PM EQ13.16.07
Bandgap Energies of Cubic $Al_xIn_{1-x}N_ySb_{1-y}$ Calculated by the Dielectric Method Hiroyuki Naoi, Shion Iwai and Rinko Ohara; National Institute of Technology, Wakayama College, Japan

Group III−V quaternary alloy semiconductors are attractive materials due to their capability of covering a relatively wide wavelength range at least between those values of their constituent binary compounds. These alloy systems are also attractive due to their capability of changing their bandgap energies even under a fixed lattice constant [1]. The latter nature furthermore opens a possibility of fabricating high−quality layers of these alloys lattice−matched to an underlying layer or a substrate with a low density of crystal defects.
Among a number of group III−V quaternary alloys, this study is focused on cubic $Al_xIn_{1-x}N_ySb_{1-y}$ in terms of not only a wide range of its usable light wavelengths spanning from the ultraviolet to infrared regions but also its lattice matching ability to Si, GaAs, and GaN substrates. Furthermore, this alloy system can potentially be grown in the cubic phase over the entire composition range, since each of the four constituent binary compounds of this alloy system can be grown in the cubic phase [2, 3]. The large difference in the atomic radius between N and Sb should cause large energy gap bowing. This may lower the minimum bandgap energy value of this alloy system to below that of InSb, which has the lowest bandgap energy value among the four constituent binary compounds.
It should be noted that Sakai et al. calculated bandgap energies of a number of group III−V quaternary alloy semiconductors incorporating Nitrogen as group V element [4] by means of the dielectric method [5−8] using band parameters of the constituent binary compounds. $Al_xIn_{1-x}N_ySb_{1-y}$ was also included in this pioneering and comprehensive work [4]. The band parameters for cubic group−III nitrides were scant at that time and more substantial data has become available in recent years including drastically revised parameters of InN. Furthermore, bandgap energies of cubic $Al_xIn_{1-x}N_ySb_{1-y}$ have not been calculated by other methods to the best of authors' knowledge.
In this study, direct and indirect bandgap energies of cubic $Al_xIn_{1-x}N_ySb_{1-y}$ were calculated by means of the dielectric method [5−8]. We referred to a review article for the lattice constant and the direct and indirect bandgap values of the constituent cubic group−III nitrides, AlN and InN [3]. In contrast with Sakai et al.'s work [4], we show all energy set of interest: Γ−valley direct (E_Γ), X−Γ indirect (E_X), and L−Γ indirect (E_L) bandgap energies of this alloy system as contour maps. The transition types of this alloy system were also distinguished on the alloy composition space by simply comparing the calculated E_Γ, E_X, and E_L values.
The calculation results showed that cubic $Al_xIn_{1-x}N_ySb_{1-y}$ converted its band structure from direct to indirect transition types by variation of x and y values. The bandgap range covered in the direct transition regime was between − 5.38 [eV] and 4.60 [eV], indicating that cubic $Al_xIn_{1-x}N_ySb_{1-y}$ can be applicable for optical devices over a wide wavelength range longer than 270 [nm]. $Al_xIn_{1-x}N_ySb_{1-y}$ lattice-matched to either Si or GaAs resulted in having only negative bandgap energies at all possible compositions. On the other hand, $Al_xIn_{1-x}N_ySb_{1-y}$ lattice-matched to GaN was of direct transition type at all possible compositions, with bandgap energies ranging between 2.02 [eV] and 3.81 [eV].

Epitaxial Growth and Materials Characterization of Single Crystalline Boron Rich B(Al)N Ternary Alloys Phuong Vuong[1], Adama Mballo[1], Suresh Sundaram[2], Gilles Patriarche[3], Yacine Halfaya[4], Tarik Moudakir[4], Simon Gautier[4], Paul Voss[2], Jean-Paul Salvestrini[1,2] and Abdallah Ougazzaden[2,1]; [1]CNRS, IRL 2958 Georgia Tech, France; [2]Georgia Institute of Technology, France; [3]CNRS, Centre de Nanosciences et de Nanotechnologies, France; [4]Institut Lafayette, France

Hexagonal boron nitride (h-BN) is a unique 2D III nitride material. It is interesting for applications in electronics and opto-electronics because of its properties such as high thermal conductivity and a wide bandgap (~ 6eV), and its graphite-like 2-D structure makes it interesting for convenient lift-off of devices. AlN, on the other hand, is the most studied material for applications in the deep UV regime, but its high crystalline quality and p-type doping are challenging. To date there have been few reports of boron-rich BAlN alloys. These alloys may enable choice of the bandgap and facilitate lattice/strain engineering for applications. They would enhance emission efficiency in the deep UV for UV LEDs and allow for the achievement of an electron blocking layer.
In this work, we report the growth of boron rich BAlN alloys with Al content up to 17% on 2-inch sapphire substrates by Metal-Organic Vapor Phase

Epitaxy (MOVPE). Characterization of the surface morphology of BAlN alloys shows a transition stage from a completely 2D to a 3D granular surface when the Al content is increased. A shift in the position of the 002 plane reflection peak to higher diffraction angles in the 2 theta-omega scan along with a decrease in intensity was observed, evidence of the formation of layered BAlN alloys. Cross sectional transmission electron microscopy (TEM) studies demonstrate the formation of a single BAlN hexagonal phase with the presence of wurtzite Al rich BAlN phases in a matrix of layered hexagonal B rich BAlN. A band-to-band transition around 5.86 eV has been observed, which shifted slightly to lower energy with increasing Al incorporation. The bowing parameter in boron rich BAlN alloy systems was evaluated to be around 0.65 ± 0.05 eV. This is encouraging evidence of boron rich BAlN alloy formation, motivating further exploration of growth conditions and the study of fundamental BAlN properties for applications in deep UV optoelectronics.

Matryoshka Phonon Twinning in *α*-GaN Bin Wei[1,2,3], Qingan Cai[3], Jiawang Hong[1] and Chen Li[3]; [1]Beijing Institute of Technology, China; [2]Henan Polytechnic University, China; [3]University of California, Riverside, United States

Understanding lattice dynamics is crucial for effective thermal management in high-power electronic devices because phonons dominate thermal transport in most semiconductors. This study utilizes complementary inelastic X-ray and neutron scattering techniques and reports the temperature-dependent phonon dynamics of *α*-GaN, one of the most important third-generation power semiconductors. A prominent Matryoshka phonon dispersion is discovered with the scattering tools and confirmed by the first-principles calculations. Such Matryoshka twinning throughout the three-dimension reciprocal space is demonstrated to amplify the anharmonicity of the related phonon modes through creating abundant three-phonon scattering channels and cutting the phonon lifetime of affected modes by more than 50%. Such phonon topology effectively contributes to the reduction of the in-plane thermal transport, thus the anisotropic thermal conductivity of *α*-GaN. The results not only have significant implications for engineering the thermal performance and other phonon-related properties of *α*-GaN, but also offer valuable insights on the role of anomalous phonon topology in thermal transport of other technically important semiconductors.

Spin-Magnon Coupling in Ultra-Low Loss Magnetic Resonators Ezekiel Johnston-Halperin; The Ohio State University, United States

The emergence of coherent magnons as a potential transduction channel for coupling remote spin qubits has generated intense interest in both the theoretical limits for these strategies and the practical barriers to their implementation. Here, we present recent progress on both fronts enabled by the emergence of the molecule-based coordination compound vanadium tetracyanoethylene ($V[TCNE]_x$), an ultra-low loss ferrimagnet with magnetic excitations whose quality factor, *Q*, exceeds 8,000 (corresponding to a linewidth of 0.51 Oe at 9.86 GHz) and whose Gilbert damping (alpha = 4×10^{-5}) is competitive with highly polished spheres of yttrium iron garnet (YIG). In contrast to other molecule-based materials $V[TCNE]_x$ exhibits a Curie temperature of over 600 K with robust room temperature hysteresis with sharp switching to full saturation. Further, since $V[TCNE]_x$ is grown via chemical vapor deposition (CVD) at 50 C it can be conformally deposited as a thin film on a wide variety of substrates and patterned using electron-beam lithography without introducing additional loss [1]. We will discuss how this combination of properties, coupled with an extremely low saturation magnetization (M_s = 100 Oe), allows access to a regime of magnetization dynamics that is theoretically predicted to yield cooperativities in excess of 10 for spin-magnon coupling in realistic device geometries (e.g., micron-scale magnon resonators) [2]. Further, we will present studies of the temperature dependent linewidth that show a modest peak at a temperature of 10 K and a recovery of room-temperature values at 5 K [3]. This behavior is consistent with models of coherent scattering from two level fluctuators (TLF) developed in YIG, but with a sensitivity to TLFs that is roughly 6 times lower. These results indicate the potential for the lowest damping measured in a magnetic system when temperatures are further reduced into the milliKelvin regime. Finally, we will present the results of combined theory-experiment study of the electronic structure of $V[TCNE]_x$ that provides quantitative agreement between density functional theory (DFT) calculations and electron energy loss spectroscopy (EELS) at both the band edge and for core-level atomic

transitions. This study reveals a distinction between apical and planar TCNE for octrahedrally coordinated V^{2+}, and provide insight into the aging mechanisms of this material. Taken together, these results demonstrate the unique application potential of $V[TCNE]_x$ for quantum information technologies and provide clear directions for further development and study.

Noble Metal Underlayer Influence on the Temperature-Dependent Gilbert Damping in $L1_0$ FePd Films with Large Perpendicular Magnetic Anisotropy Dingbin Huang[1], Delin Zhang[2], Jian-Ping Wang[2], Daniel B. Gopman[3] and Xiaojia Wang[2]; [1]University of Minnesota Twin Cities, United States; [2]University of Minnesota, United States; [3]National Institute of Standards and Technology, United States

The moderate bulk perpendicular magnetic anisotropy (PMA, $K_u \approx 1$ MJ/m^3) and low Gilbert damping ($\alpha < 0.01$) make $L1_0$-FePd a strong candidate for energy-efficient, dense spintronic devices with non-volatility down to 10 nm pitch or even lower. Existing applications subject spintronic devices to a wide temperature operating range from –55°C to 150°C. In order to better address the technological viability of FePd based devices, it is of utmost importance to evaluate the anisotropy strength and Gilbert damping of $L1_0$-FePd at elevated temperatures. In this work, we examine the impacts of buffer layers (e.g., Cr/Pt, Cr/Ru, and Cr/Rh) on the Gilbert damping and PMA of FePd at elevated temperatures (up to 150°C) using the ultrafast, laser-based time-resolved magneto-optical Kerr effect (TR-MOKE) metrology. Our initial data suggest Cr/Ru has a weaker spin-pumping contribution to α of the FePd layer at RT compared with Cr/Pt and Cr/Rh. However, the Gilbert damping of Cr/Ru/FePd increases faster with temperature compared with that of Cr/Pt/FePd and Cr/Rh/FePd. The buffer/seed layers also affect the reduction of effective anisotropy field ($H_{k,eff}$) at elevated temperatures, which is presumably correlated with the $L1_0$ ordering of the FePd layers.

Raman Spectroscopy, Aging and Laser Patterning of the Low-Loss Ferrimagnet Vanadium Tetracyanoethylene Hil Fung Harry Cheung[1], Michael Chilcote[1], Huma Yusuf[2], Donley S. Cormode[2], Yueguang Shi[3], Seth Kurfman[2], Andrew Franson[2], Michael E. Flatté[3,4], Ezekiel Johnston-Halperin[2] and Gregory Fuchs[1,5]; [1]Cornell University, United States; [2]The Ohio State University, United States; [3]The University of Iowa, United States; [4]Eindhoven University of Technology, Netherlands; [5]Kavli Institute at Cornell for Nanoscale Science, United States

Vanadium tetracyanoethylene ($V[TCNE]_x$; $x \approx 2$) is an organic-based ferrimagnet with low magnetic damping and compatible with a wide variety of substrates. These properties make it an attractive candidate in the field of coherent magnonics. However, similar to many organic-based materials, $V[TCNE]_x$ is air sensitive. While encapsulation extends its lifetime in ambient conditions from hours to weeks, its aging mechanism is not well understood. Here we use confocal microscopy, microfocused Raman spectroscopy, ferromagnetic resonance, and magnetometry to study $V[TCNE]_x$. We identify key Raman peaks in $V[TCNE]_x$ with C=C, C≡N vibrational modes, which are consistent with *ab initio* theory. We correlate changes in magnetic properties with changes in Raman intensity and in photoluminescence. These results enable optical characterization of local $V[TCNE]_x$ film quality, which is invaluable when local magnetic characterization is not possible. We also find similar changes can be induced by high intensity laser illumination. We utilize this method for laser patterning $V[TCNE]_x$ by selectively removing magnetism and study the damping, anisotropy, and spin wave modes of patterned structures.

2:45 PM EQ14.01.04
First Principles Calculation of the Electronic Structure of $V(TCNE)_2$ Yueguang Shi and Michael E. Flatté; The University of Iowa, United States

Over the past two decades there has been growing interest in organic magnetic materials, due to their potential applications in the field of magnonics and spintronics.[1,2,3,4] Vanadium tetracyanoethylene, $V(TCNE)_2$, is a room temperature ferrimagnetic semiconductor with a $T_c \sim 600$ K [5], which has very low loss ferromagnetic resonance and spin-wave propagation [1,2]. Previous first principles calculations of the electronic structure have indicated an indirect band gap substantially larger (0.8 eV) than experimentally inferred (0.5 eV) [6,7]. The study of Ref. 6 used a local-orbital basis with B3LYP hybrid functional. Here we explore the electronic structure using a plane-wave code VASP [8,9,10] with Perdew-Burke-Ernzerhof (PBE) functionals with Hubbard model corrections, and hybrid functional Heyd-Scuseria-Ernzerhof (HSE06). We confirm that the structure of VTCNE has a triclinic unit cell with each V atom surrounded by 6 organic ligands, as found in Ref. 6. However, in contrast to the previous study we found a direct band gap of 0.4 eV located at a different k-point. This band gap better agrees with the experimental inference from the conductivity activation energy [7]. We also studied magnetic anisotropy, optical properties, elastic properties of $V(TCNE)_2$ and other metal TCNE materials with other metal substitutes. Further studies also involve magnetic dynamics, magnetoelastic properties, and oxidized or doped $V(TCNE)_2$ systems.

We acknowledge funding from NSF Grant No. DMR-1808742.

Corner Spin-Wave Modes of a Tapered V[TCNE] Bar Kwangyul Hu[1], Denis R. Candido[1] and Michael E. Flatté[1,2]; [1]University of Iowa, United

States; [2]Eindhoven University of Technology, Netherlands

Spin-wave excitations may become highly localized near the edges or surfaces of a magnetic material. Confinement to a small mode volume enhances the magnetic oscillations associated with a single magnon, and thus the local fringe fields that can couple to, e.g., localized spin qubits. This enhancement is critical for achieving high cooperativity spin-magnon transduction and high gate to decoherence ratio spin-spin coupling[1,2]. Localized modes at the edges of a finite magnetic structure originate from internal inhomogeneous demagnetization field at the boundaries[3-6]. For this reason, the edge modes are dependent on the shape of the surfaces and it is possible for the edge modes in non-trivial structures to have unusual properties. Furthermore the nature of these modes may depend strongly on the magnetization of the bar, and low-moment materials have not been extensively explored.

Here we present the spin wave edge modes in a micron-scale magnetic bar of a low-moment material that has tapered edges, with magnetic field in-plane, perpendicular to the bar axis. We used the micromagnetic modeling program MUMAX3[7] to simulate the spin wave excitations. The magnetic material was a low loss semiconducting organic ferrimagnet, V[TCNE] that has a saturation magnetization M_s=7560 A/m, an exchange stiffness constant $A_{ex}=2.2\times10^{-15}$ J/m, a Gilbert damping constant $\alpha=4\times10^{-5}$ and a gyromagnetic ratio 2.7×10^{10} Hz/T [8]. The results show that it is possible to excite highly-localized corner modes with resonance frequencies above the uniform mode, in contrast to the well-known edge modes of perpendicular-wall bars which have frequencies below the uniform mode. We also performed analytic calculations and obtained similar results based on a formalism for inhomogeneous systems[9]. Our work extends the understanding of spin wave edge dynamics in non-trivial structures and suggests potential applications of these new corner modes with very small mode volume to quantum information science.

Time-Resolved Optical Detection of Magnetization Vectors Driven by Pulsed Spin-Orbit Torque Young-Gwan Choi[1] and Gyung-Min Choi[1,2]; [1]Sungkyunkwan University (SKKU), Korea (the Republic of); [2]Institute for Basic Science, Korea (the Republic of)

Spin Hall effect (SHE) driven spin-transfer torque facilitates an efficient manipulation of magnetization with flowing charge current. In aspect of experimental technique, electronic measurement methodologies have widely been used for SHE-driven spin-transfer torque analysis, e.g. Hall measurements, spin transfer ferromagnetic resonance, and so on. However, electronics methods usually detect final static states of the magnetization vector of the ferromagnetic layer, and it is difficult to observe detailed dynamic motion during ultrafast precessional process. Here, we demonstrate a time-resolved technique for pulsed electric current and following pulsed spin torque. We investigate the magnetization precession dynamics, driven by pulsed spin current, by using time-resolved magneto-optical Kerr effect with femtosecond laser. A low-temperature-grown GaAs-based photo-switch can convert an optical pulse to charge current pulse that results in pulsed spin-orbit torque (SOT). We argue that this technique is useful for investigating the current-driven SOT effect in ultrafast time-domain regime.

SESSION EQ14.02: Solid-State Spin Qubits I
Session Chair: Mikey Wojnar

Hynes, Level 2, Room 201

10:45 AM EQ14.02.02
Suppression of the Optical Linewidth and Spin Decoherence of a Quantum Spin Center in a p–n Diode Denis R. Candido[1,2] and Michael E. Flatté[1,2]; [1]The University of Iowa, United States; [2]The University of Chicago, United States

We present [1] a quantitative theory of the suppression of the optical linewidth due to charge fluctuation noise in a p–n diode, recently observed in Ref. 2. We connect the local electric field with the voltage across the diode, allowing for the identification of the defect depth from the experimental threshold voltage. Furthermore, we show that an accurate description of the decoherence of such spin centers requires a complete spin–1 formalism that yields a bi-exponential decoherence process, and predict how reduced charge fluctuation noise suppresses the spin center's decoherence rate.

The material is based on work supported by the U.S. Department of Energy, Office of Basic Energy Sciences, under Award Number DE-SC0019250.

Single-Shot Readout and Coherence Protection of Novel Qubit States in Hexagonal Boron Nitride Rohit Babar[1], Gergely Barcza[2], Anton Pershin[2], Oscar Bulancea Lindvall[1], Örs Legeza[2], Igor A. Abrikosov[1], Adam Gali[2] and Viktor Ivady[1,2,3]; [1]Linkoping University, Sweden; [2]Wigner Research Centre for Physics, Hungary; [3]Max Planck Institute for Physics of Complex Systems, Germany

Point defect qubit sensors in semiconductors have demonstrated their outstanding potential for new discoveries in material science and medicine. The

sensitivity and the spatial resolution of these sensors are currently limited by the distance between the qubit and the target, the spin coherence, and the readout characteristics of the qubit. Here, we report on the peculiar magneto-optical properties and on demand creation of a novel point defect qubit on the surface of hexagonal boron nitride (hBN). The electronic structure of the studied point defect enables optical initialization and single-shot readout of the spin states, while the reported large transverse zero-field splitting gives rise to robust clock transitions between the spin states and elongated coherence time at zero magnetic field. The stress absorption capabilities of the microscopic structure enable further tailoring of the properties of the qubit. Our results thus provide an alternative for advancing nano-scale sensing and magnetic resonance imaging utilizing few layer hBN platforms.

11:15 AM *EQ14.02.04
Probing Spin Dynamics on Diamond Surfaces Using a Single Quantum Sensor Nathalie P. de Leon; Princeton University, United States

Understanding the dynamics of a quantum bit's environment is essential for the realization of practical systems for quantum information processing and metrology. We use single nitrogen-vacancy (NV) centers in diamond to study the dynamics of a disordered spin ensemble at the diamond surface. Specifically, we tune the density of "dark" surface spins to interrogate their contribution to the decoherence of shallow NV center spin qubits. When the average surface spin spacing exceeds the NV center depth, we find that the surface spin contribution to the NV center free induction decay can be described by a stretched exponential with variable power n. We show that these observations are consistent with a model in which the spatial positions of the surface spins are fixed for each measurement, but some of them reconfigure between measurements. In particular, we observe a depth-dependent critical time associated with a dynamical transition from Gaussian (n=2) decay to n=2/3, and show that this transition arises from the competition between the small decay contributions of many distant spins and strong coupling to a few proximal spins at the surface. These observations demonstrate the potential of a local sensor for understanding complex systems and elucidate pathways for improving and controlling spin qubits at the surface.

SESSION EQ14.03: Spin-Based Quantum Memories
Session Chair: Daniel Laorenza
Thursday Afternoon, December 2, 2021

1:30 PM *EQ14.03.01
Nuclear Spin Quantum Memories in Silicon and SiC Guido Burkard; University of Konstanz, Germany

Nuclear spins in solids show long coherence times and could therefore be employed as quantum memories in quantum processors or quantum networks. However, their good isolation from the environment also makes it challenging to prepare and measure (i.e., write and read) nuclear spins, or to coherently transfer information to and from electronic or photonic qubits. We have developed and modelled a method for the readout of a phosphorous donor nuclear spin by probing the transmission of a microwave resonator coupled to a silicon quantum dot-donor system subjected to a transverse magnetic field gradient. We have identified optimal readout points with strong signal contrast to facilitate the implementation of nuclear spin readout. Furthermore, we investigate the potential for achieving coherent excitation exchange between a nuclear spin qubit and microwave cavity photons. A different approach is possible for transition metal (TM) defects in silicon carbide (SiC) that represent another promising platform in quantum technology, especially because some TM defects emit in the optical spectrum into one of the telecom bands. We present a theory for the interaction of an active electron in the D-shell of a TM defect in SiC with the TM nuclear spin and derive the effective hyperfine tensor within the Kramers doublets formed by the spin-orbit coupling [2]. Based on our theory we discuss the possibility to exchange the nuclear and electron states with potential applications for nuclear spin manipulation and long-lived nuclear-spin based quantum memories.

Numerical Modeling of Multi-Qubit Spin Dynamics in a Hyperfine Field Christopher Ciccarino and Prineha Narang; Harvard University, United States

Spins in solid state defects represent promising building blocks for quantum information applications. For these purposes, maintaining the desired quantum state of these spins is crucial, however it is generally not straightforward, as spins can interact with various degrees-of-freedom of the solid state host. In many cases, hyperfine interactions between the electronic spin of the defect and the nuclear spins of the host lattice dominate decoherence. In these scenarios, the cluster-correlation expansion (CCE) method [1,2] has proven to be a useful numerical tool in qualitatively and quantitatively capturing the effective spin coherence of the combined spin-bath system, and more recent generalizations have included population dynamics as well [3]. In this work, we discuss extending this generalized CCE method to capture the spin dynamics of two qubit spins coupled with a common bath of nuclear spins [4]. Using this framework, we evaluate the spin dynamics in a variety of defect qubit candidate systems, where we also consider different defect pair separations, magnetic field strengths, and pulse sequence schemes. We study the interplay of the two qubits and the role of the hyperfine spin bath and highlight particularly important quantum-dynamical processes involved in these various regimes.

8:00 AM *EQ14.04.01

Scaling of Quantum Coherence in Solid-State Spin Defects Shun Kanai[1,1,1], F. Joseph P. Heremans[2,3], Hosung Seo[4], Gary Wolfowicz[2,3], Christopher P. Anderson[3,3], Sean Sullivan[2], Mykyta Onizhuk[3], Giulia Galli[2,3,3], David Awschalom[2,3,4] and Hideo Ohno[1,1,1]; [1]Tohoku University, Japan; [2]Argonne National Laboratory, United States; [3]University of Chicago, United States; [4]Ajou University, Korea (the Republic of)

Solid-state defect centers have achieved various quantum functionalities, and further development of their functionalities as well as the expansion of viable qubit material options are critical issues in quantum information science [1-5]. The electron spin coherence time T_2, is one of the most critical material parameters for defect center qubits. Recently, cluster correlation expansion (CCE) calculations have emerged as a promising tool to simulate the T_2 of materials with dilute spinful nuclei *e.g.*, diamond and SiC [6-10]. Here we show a surprising scaling relationship of T_2 on *g*-factor, spin quantum number, and the densities of electron and nuclear spins based on the CCE calculations, constituting a simple new tool for the exploration of qubit materials [11]. We calculate T_2 of the well-known qubit materials (*e.g.*, diamond, SiC, and Si) with second-order CCE calculations which include pairwise transitions of the nuclear spins, and show the CCE result agrees well with the experimentally observed T_2. Especially, the nuclear spin baths are shown to decouple under external magnetic fields typically encountered in experiments (> 30 mT). For a dilute (< 10^{22} cm^{-3}) spinful nuclear bath with a single nuclear species, T_2 is proportional to the nuclear spin density $n^{-1.0}$, which reproduces the previous experimental reports. Furthermore, based on the CCE calculations, we calculate the coefficients of $n^{-1.0}$ for all stable nuclear spin species, and find that T_2 of electron spin with spin $S = 1/2$ and electron *g*-factor $g_e = 1/2$ is expressed by $T_2 = 1.5\times10^{18}\times|g|^{-1.6}I^{-1.1}n^{-1.0}$ (seconds), where g is the nuclear spin *g*-factor and I the nuclear spin quantum number, which we further generalize to the case for the electron spin with $S \neq 1/2$ or $g_e \neq 1/2$, and show that CCE reproduces the experimentally reported T_2 on the known materials. This quantitative and algebraic expression for T_2 offers qubit materials exploration without extensive computations; for example, we obtain the predicted T_2 of over 12,000 qubit host candidates with bandgap > 1 eV, and show that there are more than 700 materials with $T_2 > 1$ ms. Among these, SiC stands out as the only non-chalcogenide [11]. This study will provide a guideline for material exploration and will be an important resource for understanding nuclear spin bath decoherence in lesser-known compounds.

We thank He Ma, Jaewook Lee, and Huijin Park for their help in cross-checking the CCE predictions. Stacking Fault-Qubit Complexes in SiC for Quantum Technology Applications Rohit Babar[1], Viktor Ivády[1,2,3] and Igor A. Abrikosov[1]; [1]Linköping University, Sweden; [2]Wigner Research Centre for Physics, Hungary; [3]Max Planck Institute for the Physics of Complex Systems, Germany

Spin defect qubits in SiC are strong candidates for scalable quantum communication technology. It is possible to encode and manipulate quantum information in a qubit under optical excitation. However, the qubit properties are often compromised by charge-state instabilities and phonon coupling, which result in diminished spin-initialization fidelity and limited room-temperature operation. Engineering of stacking faults in SiC offers a material-based solution towards stabilizing the qubit charge state at room temperature [1]. In this talk, we theoretically investigate stacking fault-qubit complexes in SiC and demonstrate that the local environment within a stacking fault gives rise to distinct qubit configurations. We report zero-field splitting values above 60 MHz for these complexes, that can further improve the coherence protection scheme achieved for basally oriented qubits in SiC [2]. Further, the calculated magneto-optical and hyperfine parameters can assist in identification of previously unassigned PL signals. Our results demonstrate the quantum-well feature of stacking faults can be exploited to develop robust spin qubits in SiC.

Defects in SiC are of significant interest for quantum information and sensing, due to the combination of long spin coherence times, optical spin polarization, and industrial maturity of the material system. The ideal defect system should have long spin coherence times, homogeneous spin and optical transitions, bright emission, and efficient optical initialization and readout. We have characterized many of these spin and optical properties of the V2 silicon vacancy in 4H-SiC for both single defects and ensembles, showing quite promising results as well as some non-ideal behavior. This defect is notable as it is one of the few that shows spin coherence at room temperature and also has an S=3/2 spin system. For single Si vacancies, we have performed low temperature photoluminescence excitation spectroscopy of the spin-dependent optical transitions, showing two sharp lines with linewidths near the radiative lifetime limit, corresponding to the $m_s=\pm1/2$ and $m_s=\pm3/2$ spin states. Time resolved measurements show significant differences between these two transitions that we understand and theoretically model in terms of the intersystem crossing, which occurs at different rates for the two spin states and has implications for spin initialization and readout. Spin coherence in this system is strongly influenced by the presence of nuclear spins, despite the low natural abundance of isotopes with nonzero spin. The nuclear spin environment gives rise to inhomogeneous dephasing and strong effects on spin echo measurements, particularly at low magnetic fields. We have grown isotopically purified SiC with a very low abundance of ^{29}Si and ^{13}C to strongly suppress

the influence of nuclear spins. Our room temperature spin coherence measurements show large improvements in the coherence times, with particular improvement in the inhomogeneous dephasing time T_2^*, reaching 20 μs in the $m_s=\pm1/2$ basis. We consider the prospects of this system for quantum sensing and for an efficient spin-photon interface.

Random-Access Microwave Quantum Memories Joseph Alexander[1], Oscar Kennedy[1], James O'Sullivan[1], Mantas Šimėnas[1], Ana Villanueva Ruiz De Temino[1], Christoph Zollitsch[1], Kamanasish Debnath[2], Akel Hashim[3], Christopher Thomas[4], Irfan Siddiqi[3], Stafford Withington[4], Klaus Mølmer[2], Philippe Goldner[5] and John Morton[1]; [1]University College London, United Kingdom; [2]Aarhus University, Denmark; [3]University of California, Berkeley, United States; [4]University of Cambridge, United Kingdom; [5]Chimie Paris Tech–École Nationale Supérieure de Chimie de Paris, France

Quantum memories capable of faithfully storing and recalling quantum states on-demand are powerful ingredients in building quantum networks and quantum information processors. As in conventional computing, key attributes of such memories are high storage density, long storage lifetimes and random access, or the ability to read from or write to an arbitrarily chosen register. However, achieving such random access with quantum memories in a dense, hardware-efficient manner remains a challenge, for example requiring dedicated cavities per qubit or pulsed field gradients.

In this talk I will introduce a variety of spin systems in different host materials that are particularly promising for the realisation of microwave quantum memories, including various donors in silicon and optical defects in YSO. I will present recent progress in extending the spin coherence lifetimes in such systems, which impacts the timescale over which the microwave quantum memory is able to faithfully store coherent states. I will also present a protocol that uses chirped pulses to encode qubits within the spin ensemble, offering both random access and naturally supporting dynamical decoupling to further enhance the memory lifetime. Finally, I will discuss recent progress on the implementation of this protocol using different spin systems.

Development of a Scalable Quantum Memory Platform—Er Doped TiO_2 Thin Films on Silicon Manish Kumar K. Singh[1], Gary Wolfowicz[2], Jianguo Wen[2], Abhinav Prakash[2], Sean Sullivan[2], Alan Dibos[2], F. Joseph P. Heremans[2,1], David Awschalom[1,2] and Supratik Guha[1,2]; [1]University of Chicago, United States; [2]Argonne National Laboratory, United States

Recent work exploring rare earth ions as qubits has demonstrated key milestones – such as high cyclicity and high Purcell factor in nanophotonic devices (Raha et al, Nature Comm., 2020) – needed for controlling qubits based on rare earth atoms in a solid-state host. However, the material platform (Er-doped bulk crystals) used in these key studies is difficult to scale and integrate with other semiconductor technology. This capability is necessary for the high qubit densities needed in some advanced quantum applications and thin film host materials that enable scalable deployment is a topic of active research. Here we report on our progress in this direction.

Using the synthesis technique of metal-organic molecular beam epitaxy (MOMBE), we report the growth and characterization of Er-doped TiO_2 thin films – both in single crystal TiO_2 (on r-sapphire and strontium titanate), as well as in polycrystalline films (on silicon). Using XRD and TEM we confirm the dependence of the TiO_2 phase (anatase or rutile) on growth substrate and temperature. The lifetime of the first optical excitation (of Er^{3+}) in our films varies with film structure and thickness, ranging from 1 to 1.85 ms in our films. Through low temperature photoluminescence characterization, we obtained an inhomogeneous linewidth of 5.2 GHz (T=3.4 K), which is about an order of magnitude larger than the value of 460 MHz reported on bulk Er-doped TiO_2 crystals (Phenicie et al., ACS Nano, 2019). This linewidth is thermally broadened and should reduce further at lower temperatures. In addition, we find that the linewidth depends on the thickness, and presence of buffer or capping layers, which we describe by an empirical model. Further, measurement of spectral diffusion, which sets the upper limit on the value of T_2^*, is shown to reduce with Er concentration. Altogether, our study explores and presents data that highlight the potential to engineer a solid-state qubit platform using thin film hosts.

Quantum Metrology Using Spins in Diamond Nanostructures and Nanoparticles Helena S. Knowles; University of Cambridge, United Kingdom

Nanoscale quantum probes are a versatile platform for studying solid state and living systems in a non-invasive way. They can be embedded in a sample of interest and can thus provide in situ, nanoscale information, for example from inside thick biological structures such as cells. In this talk, I will present results on using Nitrogen-Vacancy centres (NVs) in diamond nanocrystals and ensembles of NVs in diamond nanobeams for local sensing of magnetic fields and temperature.

First, I will discuss the detection of NMR signals from multiple nuclear species in a $(19\ nm)^3$ volume using a versatile NV-NMR device inside a diamond nanocrystal of ~25 nm diameter. Within this volume, we are able to sense ~1000 molecules[1]. These promising devices are robust to photobleaching and environmental changes, have low toxicity, and an ability to measure multiple spin species with high specificity. While the spin concentration extracted from the measured NMR signal amplitude is subject to errors due to the geometric variability of nanodiamonds devices, this error can be corrected for using an in-situ calibration scheme based on exploiting the signal from a thin layer of reference nuclei on the diamond surface. We are also able to perform nanoscale measurements of temperature inside living cells, a key tool for investigating thermogenesis on a sub-cellular level.

Second, I will present a quantum sensor composed of a dense spin ensemble in a diamond nanobeam that operates as a collection of independent, unperturbed sensors working in parallel[2]. We experimentally demonstrate fault-tolerant decoupling of spin-spin interactions, achieving a five-fold enhancement of spin coherence time. This is made possible by a novel dynamical decoupling sequence that simultaneously suppresses disorder,

interactions, and imperfections in control operations[3]. We utilize the extended coherence time to demonstrate an increase in magnetic field sensitivity of over 40% compared to conventional sensing protocols such as the XY8 sequence. These results demonstrate a significant enhancement by breaking the natural interaction limit of dense ensembles, and reveal the potential of tailored control in complex, interacting ensembles.

Nanoscale Vector AC Magnetometry with a Single Nitrogen-Vacancy Center in Diamond Paola Cappellaro, Guoqing Wang, Yi-Xiang Liu and Yuan Zhu; Massachusetts Institute of Technology, United States

Detection of AC magnetic fields at the nanoscale is critical in applications ranging from fundamental physics to materials science. Isolated nitrogen-vacancy centers in diamond can achieve the desired spatial resolution with high sensitivity. Still, vector AC magnetometry currently relies on using different orientations of an ensemble of sensors, with degraded spatial resolution. Here I will present a novel protocol that exploits a single NV to reconstruct the vectorial components of an AC magnetic field, by tuning a continuous driving to distinct resonance conditions. As an experimental proof-of-principle, I'll show how to map the spatial distribution of an AC field generated by a copper wire on the surface of the diamond.
The proposed protocol combines high sensitivity, broad dynamic range, and sensitivity to both coherent and stochastic signals, with broad applications in condensed matter physics.

11:30 AM *EQ14.05.03
A Programmable Quantum Simulator Based on Spins in Diamond Tim Hugo Taminiau; Delft University of Technology, Netherlands

Spins associated to optically active defects in diamond provide a versatile platform for quantum science and technology. In this talk, I will discuss our recent advances in realizing programmable quantum simulators based on individually controllable carbon-13 nuclear spins in diamond. I will present how one can use a single nitrogen-vacancy (NV) centre to detect, characterize and control a large number of nuclear spins in its environment [1,2]. By controlling the interactions between the spins it becomes possible to create a variety of many-body Hamiltonians with tuneable parameters. As an example, I will discuss our investigation of a discrete-time crystal stabilized by many-body localization, a new out-of-equilibrium phase of matter [3].

Coherent Control of Spin Defects in Hexagonal Boron Nitride Vladimir Dyakonov; University of Wuerzburg, Germany

Optically active defects in solids with accessible spin states are promising candidates for quantum applications. While several candidates in 3D crystals including diamond and silicon carbide have been extensively studied, the coherent control of color centers in 2D materials is still an open issue. We recently investigated a bright 850nm fluorescence in irradiated hexagonal boron nitride (hBN) and found it spin-dependent. Using magnetic resonance techniques such as optically detected magnetic resonance (ODMR), we identify this fluorescence associated with a particular defect, a negatively charged boron vacancy V_B^-, possessing a spin triplet (S=1) ground state and a zero-field splitting D/h of 3.48 GHz. Moreover, we realized a coherent control of these defects by applying pulsed ODMR protocols. In particular, we measured spin-lattice relaxation time T_1 of 18 µs and spin coherence time T_2 of 2 µs at room temperature. T_1 increases by three orders of magnitude at cryogenic temperature following a $T^{-5/2}$ power law, while T_2 remains almost unaffected. Employing electron spin-echo envelope modulation (ESEEM) we were able to separate the quadrupole and hyperfine interactions with the surrounding nuclei. Finally, by applying a two-frequency "hole-burning" technique, we partially decoupled the electronic spin state from its inhomogeneous nuclear environment, which prolonged the spin coherence time by a factor of three. Our results can be important for employment of spin-decorated hBN layers as local probes in hybrid quantum systems, however, requires careful defect and heterostructure engineering.

Quantum Control of Color Center Spins Sophia Economou; Virginia Tech, United States

Color centers such as the NV, SiV and SnV centers in diamond and vacancy centers in silicon carbide are leading qubits for quantum repeater networks. These systems have a spinful ground state, which is used as a qubit to encode information, optical transitions for spin-photon entanglement and long-range quantum communication, and are coupled to nuclear spin qubits which, given their long coherence times, can be used as an additional memory register. This talk will present high-fidelity designs for entangling gates between the defect and nuclear spin qubits which selectively couple one nuclear spin while decoupling the rest. Optical control protocols tailored to SiV and SnV centers in diamond that overcome cross talk and leakage errors will also be discussed.

5:00 PM EQ14.06.03
Theory and All-Electrical Detection of Spin-Coherent Trap State Dynamics at the Si/SiO_2 Interface Nicholas Harmon[1], James Ashton[2], Patrick Lenahan[2] and Michael E. Flatte[3]; [1]Coastal Carolina University, United States; [2]The Pennsylvania State University, United States; [3]University of Iowa, United States

Interfacial traps states have been a subject of study due to the detrimental effect they have on conventional electronic devices (*e.g.* source of leakage currents). The same states also deleteriously impact quantum coherent devices though spin-spin interactions (when the trap state is paramagnetic) or charge fluctuations. Recently, an upside for interfacial trap states has been discovered [1]: interfacial spins may serve as quantum sensors due to how transport or

recombination through the sensors intimately depends on the local field environment.

In this work, we present theoretical and experimental results determining the role that spin-dependent processes at deep levels plays in governing recombination through interfacial traps. For paramagnetic trap states, capture of electrons or holes is limited by spin statistics. For instance, a neutral trap with S = 1/2 only captures spins with opposite orientation (assuming a negatively charged ground state of S = 0). These spin-dependent processes are incorporated into a generalized Shockley-Read-Hall model. Magnetic interactions (*e.g.* hyperfine) at each of the combining spins modify capture efficiency; the probability of capture is determined by solving the stochastic Liouville equation for the spin density matrix. Using this formalism, we calculate magnetoresistance for dangling bond defects at the Si/SiO_2 interface. The results from the model agree well with our experiments measuring recombination current in a Si/SiO_2 MOSFET. Chief among our conclusions is that a large number of nuclei interact with the trap spin which necessitates a semiclassical approximation for the hyperfine interaction. Lastly, we examine how the quantitative theory can be utilized in the service of all-electrical quantum magnetometry using interfacial trap states.

Magneto-Rotation Devices and Spin Current Generation in the Presence of Acoustic Cavities Jorge Puebla[1] and Yoshichika Otani[1,2]; [1]RIKEN, Japan; [2]University of Tokyo, Japan

In this contribution, I present our most recent research on magnon-phonon coupling. A fundamental form of magnon-phonon interaction is an intrinsic property of magnetic materials, the “magnetoelastic coupling.” This form of interaction has been the basis for describing magnetostrictive materials and their applications, where strain induces changes in internal magnetic fields. Unlike magnetoelastic coupling, more than 40 years ago, it was proposed that surface acoustic waves may cause surface magnons via a rotational motion of the lattice in anisotropic magnets [1]. However, a signature of this magnon-phonon coupling mechanism, termed magneto-rotation coupling, has been elusive. We recently demonstrated a nonreciprocal acoustic wave attenuation with an unprecedented ratio of up to 100% rectification, which is understood as a consequence of the magneto-rotation coupling [2]. Considering the broad application of the general acoustic device in sensing, filtering, and information transportation, the intriguing nonreciprocal features of our magneto-rotation devices suggest an extraordinary versatility of acousto-magnetic applications.
As well-known, the coupling of surface acoustic waves with ferromagnetic layers also induces acoustic ferromagnetic resonance, consequently acting as a method of spin current generation [3, 4]. An intriguing scenario is to explore the spin current generation when the strength of magnon-phonon coupling is improved. We have carefully engineered an acoustic wave device in the presence of an acoustic cavity consisting of two acoustic reflectors separated by a distance equal to a multiple of the acoustic wavelength of our device. In our acoustic cavity device, we observed enhancements of up to two times in acoustic ferromagnetic resonance and up to three times more spin current generation than a non-cavity reference device [5]. The apparent discrepancy between the enhancements of energy absorption in acoustic ferromagnetic resonance (two times) and the enhancements of the spin current generation (three times) is an open question. Beyond the enhancement of spin current generation, improvements of magnon-phonon coupling towards the strong coupling regime can have significant consequences such as early on-sets of nonlinear effects, enhancement of magnon propagation length, condensation, and transfer of coherent phase information.

Phase-Field Simulations on Temperature-Related Behaviors of Skyrmions Yu Wang[1], Takahiro Shimada[1], Shizhe Wu[2], Yuelin Zhang[2], Jinxing Zhang[2], Jie Wang[3] and Hiroyuki Hirakata[1]; [1]Kyoto University, Japan; [2]Beijing Normal University, China; [3]Zhejiang University, China

Controlling static and dynamic behaviors of the bubble-like magnetic skyrmion exhibits great potential in the application of spintronics. Especially, as a natural property, temperature plays an important role in the control of skyrmion behaviors. For example, statically, the temperature can lead to the phase transition of the topological magnetic structures (such as skyrmions) by affecting their stability; dynamically, fluctuated or inhomogeneous temperature fields can drive the skyrmion motion. However, due to the limitation of existing hypothesis-based simulation methods, the study of temperature-related behaviors of skyrmions from the perspective of thermodynamic free energy is rare. Here, we developed a temperature-related phase field simulation to predict and explain the skyrmion behaviors in temperature fields. Statically, we demonstrate the skyrmion lattice of a room-temperature ferromagentic thin film lose the thermal stability near the 340 K, and obtain the temperature-magnetic field-strain phase diagrams of topological structures in MnSi thin film, which consists with the experimental results very well. Dynamically, we study the rectilinear motion of the individual asymmetrical skyrmion driven by temperature gradients, and propose a kinematic equation to describe it. Therefore, these works demonstrate the temperature-related phase field simulation is a reliable method to simulate the skyrmion behaviors in temperature fields, and propose the thermodynamics explanation on both static and dynamic

features of skyrmions, which is anticipated to be the theoretical support for further research about temperature-related behaviors of skyrmions and their potential applications in functional devices.

7:15 PM EQ14.07.03
Direct Neutron Scattering Observation of Spin-Phonon Coupling in Nickel Oxide Chen Li[1,1], Qiyang Sun[1], Lin Jiao[2] and Doug L. Abernathy[2]; [1]University of California, Riverside, United States; [2]Oak Ridge National Laboratory, United States

Antiferromagnetic (AFM) materials have great potentials for spintronics applications due to their robustness again disturbance. The physics of mutual interactions between lattice and spin degrees of freedom in AFMs, leading to unusual transport phenomena of spin and heat, has been a subject of continuing interest. In the current work, temperature and field dependent inelastic neutron scattering measurement were performed to investigate the magnon-phonon interactions in AFM nickel (II) oxide. Giant phonon anomalies are observed by inelastic neutron scattering in the first Brillouin zone, showing magnon-like behaviors. Atomistic simulation and scattering simulation attribute such anomalies to strong spin-phonon coupling and the broken symmetry of related phonon modes. Such couplings have important implications on the properties of both phonon and spin dynamics. Additionally, the discover provides a direct approach to quantify such spin-lattice interactions via a revised inelastic neutron scattering formalism.

7:30 PM EQ14.07.04
THz Dynamics of Emerging Low-Dimensional Antiferromagnets Jun Xiao[1,2,3], Chenyi Xia[1], Jake Wisser[1], Yuri Suzuki[1,2] and Aaron Lindenberg[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States; [3]University of Wisconsin–Madison, United States

Antiferromagnets are a type of quantum material where electron exchange interactions result in antiparallel or non-collinear microscopic spin correlations with negligible macroscopic magnetization. Given their low-loss THz magnetic resonance and insensitivity to stray fields, antiferromagnetic spintronics holds great potential in realizing high-speed communications and robust in-memory computing[1]. Emerging low-dimensional antiferromagnets such as nanoscale oxide thin films and van der Waals layered materials[2,3], are expected to further pave the way for ultimate antiferromagnetic device miniaturization. Here we investigate the THz magnetic dynamics of such novel material systems. Using cryogenic THz emission spectroscopy as a direct probe of the time-dependent magnetization, we observed nontrivial THz signals generated by ultrafast optical pumping of NiO thin films and $NiPS_3$ crystals. Their unique THz emission dependence as a function of optical fluence, THz polarization, and temperature, shows direct sensitivity to the magnetic ordering symmetry and picosecond spin dynamics. Our findings will advance the understanding of the underlying physics that governs the dissipation and electrodynamics of low-dimensional antiferromagnetic materials with large tunability for ultrafast and compact spintronic devices.

Revealing the Origin of the Feature-Rich MEL Response of OLEDs Based on Ordered Singlet-Fission/Triplet-Fusion Materials Sebastian Engmann[1,2], Emily G. Bittle[1], Lee Richter[1], Rawad Hallani[3,4], John Anthony[4] and David Gundlach[1]; [1]National Institute of Standards and Technology, United States; [2]Theiss Research, United States; [3]King Abdullah University of Science and Technology, Saudi Arabia; [4]University of Kentucky, United States

Magneto-electroluminescence (MEL) is a powerful tool to study singlet fission and triplet fusion dynamics in organic light emitters as the functional form of the MEL response can be qualitatively attributed to the dominant processes within the device. In this study, we will present a quantitative model for the MEL response, valid over a wide current range, and apply it to devices based on Rubrene, and three solution processable anthradithiophene emitters. By varying the chemical motif, we are able to systematically vary the film structure between highly textured, poly-crystalline to amorphous. We find significant diversity in the MEL, with the textured films showing feature-rich MEL responses. We will show that features in the MEL response coincide with field direction dependent crossings of the projections of the coherent triplet pair state onto the singlet state of the spin-Hamiltonian. Furthermore, we will discuss the effect of the film structure on the observable MEL response.

Effectiveness of Different Heat Treatments in Attaining Very Low Gilbert Constant in Sputtered Co_2FeAl Thin Film on Si (100) Soumyarup Hait[1], Sajid Husain[2], Vineet Barwal[1], Nanhe K. Gupta[1], Lalit Pandey[1], Peter Svedlindh[3] and Sujeet Chaudhary[1]; [1]Indian Institute of Technology Delhi, India; [2]Mixed Unit Of Physics CNRS, Thales, France; [3]Uppsala University, Sweden

The current-driven switching of the magnetization of a ferromagnetic (FM) layer in a multilayer stack continues to be one of the intensively investigated topics of research interest both from the fundamental as well as technological points of view. To achieve the switching with lower (critical) current, it is highly desirable that the FM layer must possess a high value of spin-polarization (such as in Heusler alloys), sufficiently *low* Gilbert damping α_{int} and *preferably low* values of both saturation magnetization M_S and anisotropy energies.
In this work, the effectiveness of two different approaches used in growing sputtered FM films suitable for such current induced switching applications is investigated in detail. In particular, the effectiveness of maintaining high substrate temperature (T_S) during deposition versus *in situ* annealing of the films at high temperature (T_A) after sputtering at room temperature is compared with an objective to obtain thin films of Heusler alloy Co_2FeAl (CFA) having optimally low α_{int} and 12-17% smaller M_S by employing ion beam sputtering technique and Si(100) as substrates. In each of the two series of CFA films, appropriately suitable choices of T_S and T_A (lying in 300-773K range) were explored for optimally tailoring their structural, static and dynamic magnetization properties.
Structural studies revealed that although all the CFA films of the two series were polycrystalline but the post-deposition annealed films were structurally optimal with higher density (6.36±0.09 g/cm^3) and lower interface roughness (0.48±0.03 nm) compared to the CFA films grown at high T_S (6.23±0.06 g/cm^3, 0.61±0.01 nm). While the higher density for the post annealed films is accredited to the removal of the voids at higher T_A, the higher interface roughness of the films grown at higher T_S is attributed to the non-uniform growth of films at higher T_S.
In-plane field-angle dependent longitudinal magneto optical Kerr effect (L-MOKE) study on these CFA films revealed the existence of a coupling between the uniaxial and biaxial magnetic anisotropies, whose origin is attributed to the employed deposition geometry. Contribution of both the anisotropies are separated and the calculations suggest that the uniaxial anisotropy is *dominant* over biaxial anisotropy in all the CFA films.
Ferromagnetic resonance (FMR) spectroscopy measurements, performed in both the field configuration, viz. in-plane as well as out-of-plane, revealed a

lowest value of 1.19 (± 0.08) $\times 10^{-3}$ of α_{int} in the film post-annealed at 773K. In addition, the observed non-linear relation between the α_{int} and the dynamical '*g*'-factor suggests that the contribution of spin-orbit interaction to the damping is far less compared to the damping contribution from the DOS present near the Fermi level. It is remarkable to note that the *as-grown* CFA films sputtered at room temperature exhibited a record lowest value of 1.73 (±0.09) $\times 10^{-3}$ of α_{int}. Attainment of such a small value of Gilbert damping and having moderate magnetization in high spin polarized Co_2FeAl Heusler films sputtered on the Si (100) substrate opens up their great application potential in future spintronics devices.

Robotic Fabrics and Liquid Metal-Based Stretchable Circuits—Two Wearable Technologies for Haptic Interfaces Trevor Buckner, Shanliangzi Liu and Rebecca Kramer-Bottiglio; Yale University, United States

Robotic fabrics and stretchable electronics are broad-category technologies that may play a role in next-generation haptic interfaces. In this talk, we will present two recent works and speculate on their applications to wearables.
First, we will present an implementation of robotic fabrics by integrating functional fibers into conventional fabrics using typical textile manufacturing techniques. We will introduce a set of actuating and variable-stiffness fibers, as well as printable in-fabric sensors, which allow for robotic closed-loop control of everyday fabrics while remaining lightweight and maintaining breathability. By designing actuators, sensors, and structural components that conform to a fiber-based geometry, our methodology shows that simple fabrics can be functionalized to create self-deploying structures, morphing airfoils, and damage-responsive tourniquets, among other wearable and haptic devices.
Second, we will present biphasic Ga–In (bGaIn): a printable, solid–liquid biphasic material that maintains a near-constant resistance under extreme strains; maintains direct, consistent, and stretchable electrical connections with conventional electronic components; and is mechanically stable when applied onto numerous soft materials. bGaIn is produced by thermally treating eutectic GaIn nanoparticles to create a mixture of liquid and crystalline solids. It shows a high initial conductivity of 2.06×10^6 S/m and near-constant resistance at strains over 1,000%. We have employed bGaIn as a stretchable interconnect to interface with commercial electronic components---including resistors, capacitors, light-emitting diodes (LEDs), operational amplifiers, and microcontrollers---by simply pressing the electronics into the bGaIn trace. Using bGaIn vertical interconnect accesses (VIAs) to connect traces on the top and bottom layers, we have converted conventional multilayer PCB designs into stretchable circuit board assemblies (SCBAs) that maintain performance while experiencing large strains. Finally, the applicability of bGaIn stretchable circuits to wearables will be shown with a stretchable signal conditioning circuit integrated into a smart sensing garment.

11:00 AM EQ15.01.03
Measurement of Lateral Force and Slipping Based on Optical Fiber Mechanism Michael Han and Cindy Harnett; University of Louisville, United States

Humans excel at controlling their gripping force during manipulation tasks so that objects don't slip, while avoiding too-strong pressures that damage soft objects. In this presentation, we develop a soft optical sensor for slipping measurement in gripping applications. The principle is micro-bending of a soft optical fiber by lateral forces and its effect on optical transmission from emitter to receiver. The optical fiber deformation is intensified by a stress-concentrating structure. Based on the data, we describe the empirical relationship between intensity and lateral force with a function.

When it comes to robotic grasping, measuring tactile information is critical for human-like performance. In the case of the human grasping process, cutaneous sensory input determines how grasping forces are modulated. Lateral-force tactile sensors for robotic hands, and sensors that can measure lateral forces experienced in human test cases, will help robots emulate human dexterity in manipulation tasks.
Considering the human case, we need to detect both slipping (lateral forces) and grasping forces (normal forces) in real-time, thereby holding objects with optimum forces--not crushing, but also not dropping the object. In that case, lateral forces and the relative slipping amount provide direct and indirect information for determining slippage and grasping normal force respectively. Therefore, it is natural to identify contact mechanisms, which can provide friction force and normal force information. Furthermore, based on the contact mechanism it can make tactile sensors be designed and analyzed in accordance with the situation.
Because our optic fibers are fabricable and elastic, we can make them available to analyze the contact mechanism assuming under Hooke's laws. In particular, we measured lateral force by using an elastomeric optical fiber through the stress concentrating structure that deforms the fiber in response to the shear forces of the surface. In other words, we investigate the relationship between light power intensity variations and lateral forces and figure out its viability to grasping applications. Moreover, based on the stress concentrating structure, we investigate how variables related to surface contact dynamics depend on applied forces. In this study, the regions of lateral force sensing are in the $1 – 5$ cm^2 range and the detected displacements are on the $1 – 5$ mm scale. Although it could be changed by the stress concentrating structure due to its material and configuration, the lateral forces are low under 20N for this displacement range.

11:15 AM *EQ15.01.04
A General Strategy to Impart Electronic Conductivity to Hydrogels Laure V. Kayser; University of Delaware, United States

Human–machine interfaces are increasingly prevalent in society to enhance productivity and performance (e.g., automated driving), aid people with sensory and motor deficiencies (e.g., tactile displays, assistive exoskeletons), and allow remote tasks (e.g., surgery, bomb deactivation). This field, and particularly haptics and robotics, is gradually switching from hard and bulky materials to softer, lightweight, and conformable ones. As such, new electronic materials are needed to enable finer tasks and sensations, more realistic human–machine interactions, and less intrusive assistive devices. Additionally, ionic and electronic conductivity are both required to transduce biological to electronic signals and vice versa. For this purpose, we have developed a general approach to synthesize electronically and ionically conductive hydrogels with tunable mechanical properties. Instead of using rigid metal nanoparticles or stiff conductive polymers, we use a water-soluble derivative of 3,4-ethylene dioxythiophene (EDOT) functionalized with oligo-ethylene oxide side chains (EDOT-DEG) directly polymerized in a range of hydrogels commonly used for biological interfaces. The resulting conductive hydrogels have low impedance and resistance, and similar mechanical properties as the initial—non-electronically conductive—hydrogels. Importantly, the shape and size of the hydrogel is retained after the polymerization of the conductive PEDOT-DEG polymer. In this presentation, I will share our synthetic approach towards these materials, their characterization, and a vision of how they could address challenges in interfacing electronics with the human body.

SESSION EQ15.02: Materials for Haptic Interfaces II

1:30 PM EQ15.02.01
Textile-Based Wearable Haptic Devices Barclay Jumet, Jeffrey Berning, Nicolas Escobar, Mark Schara, Zane A. Zook, Marcia K. O'Malley and Daniel J. Preston; Rice University, United States

Wearable haptic devices use intuitive tactile signals to enable alternative pathways for communication in "noisy" environments and immersive virtual reality experiences. These wearable devices often employ rigid electromechanical components, including onboard motors that require gearboxes for appropriate torques in squeeze cues and rotating eccentric masses for vibration cues [1]; incorporation of these rigid components hinders the construction of unobtrusive, comfortable, and lightweight wearables.

Soft haptic devices overcome this limitation by leveraging intrinsic compliances to apply haptic cues while maintaining flexibility and light weight, with most approaches utilizing either (i) compliant pneumatic systems composed of inflatable bladders or (ii) flexible electronic systems. Focusing on the former, typical pneumatic systems are composed of molded elastomers or bonded thermoplastic sheets which create chambers that can apply kinesthetic or tactile feedback when inflated [2]. However, these materials introduce challenges for seamless and discreet integration into everyday wearable devices, clothing, and other attire.

Here, we present a new approach for soft haptics based on textiles bonded with an adhesive thermoplastic. The adhesive thermoplastic allows tunable actuator geometries and strong bonds between textiles. Textiles are low-profile, ubiquitous, and most importantly, comfortable and conformal to the human body [3], and this approach enables easy and inconspicuous integration into clothing because textiles can be sewn into or bonded onto existing garments.

We selectively bond textiles to each other through heat and pressure to define internal bladders and pathways for flow of pressurized air, driving actuation of the haptic devices. The geometry of the customizable bladders facilitates squeeze, stretch, and vibration cues, while the channels route the pressurized air to the actuators through tailored pathways. The addition of a patterned intermediate layer between textiles permits the formation of these features by preventing adhesion in defined locations. Moreover, fluidic and systematic instabilities can be designed and exploited to provide simpler control [4] than existing pneumatic counterparts that rely on bulky electromechanical regulators for actuation [5].

Soft haptic devices based on textiles and fluidic actuation allow facile fabrication and operation, and the ease of integration into everyday garments and wide array of design possibilities highlight a promising strategy for integration in wearable devices. Our textile-based approach to wearable haptics can supplement the more traditional, yet often saturated, modes of communication (visual, aural, etc.) while delivering salient information to a user in an inconspicuous, lightweight, and comfortable manner.

Materials for Epidermal Haptic Interfaces John A. Rogers; Northwestern University, United States

Immersive systems for virtual and augmented reality (VR/AR) will transform the way that we interact with computer-generated environments and, by extension, with one another. Interfaces that add spatio-temporally controlled physical sensations to well-developed audio and video components of VR/AR systems will qualitatively enhance the user experience. These technologies have myriad potential uses in remote health care, in prosthetic control, in physical rehabilitation, in social media, in entertainment and in training. This talk summarizes our most recent work in this area, with a focus on concepts in materials science and electrical engineering for thin, soft, lightweight sheets that embed wirelessly powered and addressed arrays of high-speed, millimeter-scale mechanical actuators, capable of gently laminating onto the skin. We highlight the capabilities through several example application areas, and we outline frontier opportunities for continued research.

2:15 PM EQ15.02.03
Smart Knit Textiles for Soft Robotic Garments Vanessa Sanchez, Kausalya Mahadevan, Katia Bertoldi and Robert J. Wood; Harvard University, United States

Soft robotic garments represent a promising approach to provide a wearer with mobile assistance for haptic communication, grasping and reaching, and dynamic thermoregulation [1]. For these devices to be as wearable as everyday clothing, it is necessary for them to be created from compliant, lightweight, breathable, and stretchable materials, and textiles satisfy all of these needs. Textile-based soft robotic components, including sensors, actuators, and integration components (which connect to power and control elements) are gaining traction to enable these properties; however, they are traditionally developed separately using different manufacturing processes due to their diverse requirements in terms of mechanical and electrical properties. In order to build a full robotic garment with distributed sensing and actuation, subcomponents must be manufactured discretely and subsequently connected together using cut-and-sew processing. Such manufacturing strategies increase complexity and also reduce durability by adding potential failure points.

To overcome these challenges, we leverage weft knitting as a strategy to create integrated robotic textile materials. Weft knitting is a single additive manufacturing process that can form monolithic 3D shell shapes out of multiple materials [2,3]. Simultaneously, the ability to vary the knit stitch pattern (including changing stitch symmetry and geometry) and material choice enables mechanical diversity, which is necessary to optimize for separate component needs [4,5]. Here, we investigate the ability of weft knitting to create integrated textile actuators and sensors, and we show how the knit architecture, dictated by stitch pattern, leads to tailorable properties required for these components. Specifically, we explore how the stitch pattern changes knit mechanical properties, including stress-strain behavior and Poisson’s ratio, for use in fluidic actuators. We also study how varied knit architectures change the sensitivity, linearity, and range of knit strain sensors. We demonstrate fully integrated robotic textile components (sensors, actuators, and conductive signal lines) based on these strategies.

2:30 PM EQ15.02.04
Materials Control of Tactile Sensations for Haptics and Touch Psychophysics Charles Dhong; University of Delaware, United States

For the sense of sight, we can purchase HD screens to recreate nearly any image or movie. For touch, we are not yet able to recreate the variety of sensations from our everyday experiences. However, an accurate and rich recreation of tactile sensations could have broad implications in human machine interfaces, soft robotics, and disability rehabilitation. While most haptic devices rely on reconfigurable bumps or electrical stimulation, one possible avenue we explore for is creating tactile sensations through materials chemistry.

A challenge behind controlling touch is that touch is a complex mechanical event between the finger—a heterogenous and deformable interface—and an object. During touch, friction generated between the finger and object produces a variety of mechanical vibrations, which ultimately forms a tactile perception. In this talk, we describe our efforts to use materials coating to both control touch and to study touch. In the first part, we will discuss our efforts in using silane-derived monolayers and our findings that humans can perceive single atom substitutions within silane-coated silicon wafers, thus opening the possibility for molecular-scale control over touch. In the second part, we use tools from materials chemistry to enable psychophysical investigations on the perception of softness. By creating samples which react to touch in a known manner, we can perform our investigations with high “ecological validity”, i.e., perform studies in a manner similar to everyday human exploration. We will discuss our key findings that the perception of softness is universal between subjects, and thus is a repeatable and controllable tactile percept.

2:45 PM *EQ15.02.05
Intrinsically Soft Actuators and a Route to High Density Arrays in Small Form Factors Robert Shepherd; Cornell University, United States

Since the modern concepts for virtual reality and augmented reality were first introduced in the second half of the twentieth century, the field has strived to develop technologies that could create realistic experience for the user to immerse themselves in a fully or partially virtual environment. While there has been great progress in visual and auditory technologies, haptics has seen much slower technological advances. The challenge is because skin has densely packed mechanoreceptors distributed over a very large area with complex topography; devising something as targeted as an audio speaker or television where sensory input is made into something as specific as an ear canal or iris seems to be a more difficult task. To compound the difficulty of a somewhat universal haptic solution, the soft and sensitive nature of the organ makes it difficult to apply solid state electronic solutions that cannot address large areas without causing discomfort. The emerging field of soft robotics, where many actuators and sensors are built from materials science innovations, offers potential solutions towards this challenge. In this article, we first provide an overview of haptic output and input technologies to identify opportunities for soft robotics to provide solutions for haptics. We then introduce mechanisms of intrinsically soft actuators and sensors and discuss soft haptic output and input devices categorized by device form of wearable, graspable, or touchable interfaces. We also review the definition and history of virtual and

augmented reality and show examples of soft haptic devices demonstrated in VR/AR environments. Finally, we will introduce an innovative solution to the multiplexing vs. sensory density problem facing haptics.

3:15 PM EQ15.02.06
Multistable Self-Folding Knit Textiles for Deployable Structures Kausalya Mahadevan, Vanessa Sanchez and Katia Bertoldi; Harvard University, United States

The existing familiarity of textiles makes them ideal for lightweight, breathable, wearable soft robots and shape changing deployable garments. These garments are often manufactured by weft-knitting. The weft-knitting process allows us to alter the topology of a manufactured textile through an infinite number of stitch patterns, which allows for precise control of both the tactile and mechanical properties. We harness the existing symmetry in a knit stitch to manipulate the natural curvature of the material into a self-folding pattern. While traditional knit textiles are monostable and return to a single rest state when a load is removed, we leverage this folding to design a textile with multiple stable configurations. This multistable textile is evaluated by mechanical testing and predicted by a finite element model. We investigate how the distribution of stitches affects both the mechanical properties and the energy landscape of the knit. Understanding the relationship between the stitch pattern and the mechanical properties allows us to tune the behavior of these structures; we can select the switching load and design the shape of the structure in each stable state. By fine tuning the geometric parameters in the structure, we exploit the bistability to realize shape changing garments and deployable structures.

3:30 PM EQ15.02.07
Mixed-Conducting Particulate Composites for High Resolution Human-Machine Interfaces Han Yu, Richard Yao, Claudia Cea and Dion Khodagholy; Columbia University, United States

The ability to decode hand gestures is critical for natural human-machine interaction, immersive virtual reality, and creation of effective prosthetics. Although technologies such as video tracking have been applied for hand gesture recognition, they restrict the user's mobility as they need to capture images of the body with several optical devices surrounding the user, and the cameras must maintain clear line-of-sight with all movements. Therefore, bioelectronics that are able to directly acquire and communicate the electrical activity of the human peripheral nervous system to machines have the potential to overcome these limitations. However, it is challenging to non-invasively acquire high-resolution electrophysiology signals that allow representation of ongoing muscle activity in the body. Effective contact and adhesion between conformable high-density electrodes and human skin are essential for the success of this kind of interface. Here we present a novel device that combines conformable electronics and organic mixed-conducting particulate composites (MCPs) to acquire reliable and high-spatiotemporal resolution muscle activity at the level of individual motor neuron action potentials. We demonstrated that MCP can establish anisotropic conduction with the tissue allowing the creation of high-density conformable electronics for the peripheral nervous system. We developed a 10x12 high density conformable array of electrodes combined with mixed conducting particulate composites with similar particle size as skin roughness to cover approximately 500 mm^2 of muscle area. We performed electrophysiological recordings in humans and non-human primates while subjects performed predefined tasks and movements. We are able to cluster the acquired action potentials into a large number of putative single motor units (MUs) using a template matching-based clustering algorithm. The action potential firing pattern was then correlated with the corresponding movement to establish a decoding model to allow construction of gestures. As such, our approach facilitates investigation into the neural mechanics of our sensorimotor system and enables creation of effective bioelectronic interfaces.

SESSION EQ15.03: Materials for Haptic Interfaces III

Hynes, Level 1, Room 110

10:30 AM EQ15.03.01
Hybrid Response Pressure Sensors Nanshu Lu and Kyoungho Ha; The University of Texas at Austin, United States

Soft pressure sensors with high sensitivity over a wide pressure range are required for various applications such as electronic skins for human-mimetic robotics and electronic tattoos for mechanophysiology measurement. In the last decade, most research aiming at increasing the sensitivity of capacitive pressure sensors focused on developing dielectric materials with added air gaps and/or higher dielectric constants. After extensive research, sensitivity has been significantly improved at low pressure range, e.g. 1 kPa, but still decays drastically as the pressure increases. To overcome this challenge, we engineered a soft capacitive pressure sensor based on an electrically conductive porous nanocomposite. The porous nanocomposite was fabricated by molding the mixture of functionalized carbon nanotubes (f-CNT) and Ecoflex out of a nickel (Ni) foam. The nanocomposite was 600-μm thick and 86% porous with open cells and tubular ligaments. With enough f-CNT doping (e.g. 0.25 wt%), the nanocomposite became electrically conductive with both piezoresistive and piezocapacitive characteristics. An ultrathin dielectric layer was added between the conductive nanocomposite and the electrode to ensure the whole device was still capacitive. This hybrid response pressure sensor (HRPS) was measured to have a sensitivity of 3.13 /kPa within 0-1 kPa, 1.65 /kPa within 1-5 kPa, 1.16 /kPa within 5-10 kPa, 0.68 /kPa within 10-30 kPa, and 0.43 /kPa within 30-50 kPa of pressure ranges. The hybrid response was fully understood through a simplified circuit model, which has been validated by experimental measurements and could be used to determine the optimal f-CNT loading. We have successfully applied this sensor to measure very subtle surface pulse waves of the radial artery, the common carotid artery, and the temporal artery, even under large preloads such as a VR (virtual reality) headset.

10:45 AM EQ15.03.02
Late News: Macro-Assembly of Carbon Nanotube Wrapped Textile Yarn for Multifunctional Wearable Electronic Applications Md. Milon Hossain and Philip Bradford; North Carolina State University, United States

Carbon nanotube (CNT) is a promising material for multifunctional wearable electronic applications due to their excellent electrical conductivity, low density, and superior strength. However, the shorter length of CNTs and nanoscale dimension restricts them for macro assembly and bulk scale processing. Therefore, different synthesis methods emerged for the macro-assembly of the CNTs. Here we report a solid-state and straightforward process of producing CNT-wrapped textile yarns for multifunctional wearable electronic applications. Highly aligned and millimeter-tall CNTs were synthesized on a quartz substrate by chemical vapor deposition. Two CNTs arrays were placed on a custom-made spinning device, and the textile yarn was inserted as a core. Both the arrays were wrapped over the textile yarns for producing highly conductive and strong yarn.
The produced yarn has a diameter similar to the conventional textile yarns essential for the bulk production of electrodes. Scanning electron microscope (SEM) showed successful wrapping of CNTs over different textile yarns. The CNT-wrapped yarns are suitable for textile processing such as weaving and

knitting, sewing, and embroidering into apparel and have excellent electrical conductivity. Both the strength and conductivity of the CNT-wrapped yarn can be customized for various applications. A 1% thermoplastic polyurethane nanocoating increased packing density by aligning the fibers along the yarn axis and increasing the strength two folds. We have demonstrated the use of the yarns in different multifunctional applications such as motion sensors, powering LEDs and heating garments. The yarn was seamlessly integrated into 3D knitted gloves and used for finger movement detection. The yarn exhibited a large resistance change when the finger was bent and returned to the initial position in relaxing conditions. When the yarn is connected to a power source, the yarn can transfer the power lighting 12V LED. A knitted wrist band was produced for wearable thermotherapy, and when connected to 3V, it can generate heat higher than skin temperature and reach about 46 degrees Celcius. The yarn can also be used as a flexible electrode for different physiological health monitoring such as electrocardiography and electromyography.

SESSION EQ15.04: Materials for Haptic Interfaces IV
Wednesday Afternoon, December 1, 2021
Hynes, Level 1, Room 110

1:30 PM EQ15.04.01
Liquid Crystal Elastomers with Enhanced Directional Actuation to Electric Field Hayden E. Fowler[1], Philipp Rothemund[2,1], Christoph Keplinger[2,1,1] and Timothy White[1,1]; [1]University of Colorado Boulder, United States; [2]Max Planck Institute for Intelligent Systems, Germany

Liquid crystal elastomers (LCEs) are stimuli-responsive materials. Programming the local orientation within LCEs is a promising route to realize 3-D deformations. Recent demonstrations have shown these materials can exhibit exceptional work capacity of upwards of 40 J/kg. However, the inefficient and slow responses of LCEs to heat and light limit the functional integration of these materials in many applications. Electrical control of LCEs continues to be a preferred stimuli for use in actuation. Recently, electromechanical actuation of LCEs at ambient conditions was realized by exploiting the unique mechanical anisotropy (e.g., association of modulus with orientation) of aligned LCEs. By coating both sides of an aligned LCE with compliant electrodes and applying voltage, the LCE film is compressed in its thickness, leading to deformation in the planar area. However, due to the mechanical anisotropy, the LCE deforms preferentially in the lower modulus direction, leading to directional mechanical response in these actuating elements. Here, we are concerned with understanding the role of materials properties on the electromechanical response of LCEs. Using a newly developed materials chemistry and employing established processing methods, reliable electromechanical actuation is realized in LCEs with high mechanical anisotropy and uniaxial actuation strains up to 17.5%. The uniaxial actuation behavior is closely predicted using previously developed theory and the physical materials properties of the LCEs. Response times of 1 Hz are demonstrated. Furthermore, 3-D deformations from flat sheets to cones are demonstrated.

1:45 PM *EQ15.04.02
Organic Haptics—Soft Materials for Artificial Touch Darren J. Lipomi; University of California, San Diego, United States

Human culture is replete with artifacts that interact with the senses of sight, hearing, taste, and smell. Material objects whose purpose is to produce a thoughtful or emotional response through the sense of touch, however, are rare. In this talk, I present my group's recent work on the intersection between the science of soft materials and the science of touch. This field, which we have named "organic haptics," combines active polymers, contact mechanics, and psychophysics. We are beginning to understand the ways in which stick slip friction, adhesion, and capillary forces between planar surfaces and human skin affect the ways materials produce tactile objects in consciousness as mediated by the sense of touch. This work, which combines human subject experiments, laboratory mockups of human skin, and analytical models accounting for friction, has led to several important observations. In particular, we have elucidated the mechanism by which humans can differentiate hydrophilic from hydrophobic surfaces when bulk parameters such as hardness, roughness, and thermal conductivity are held constant. We examined the role of relief structures in the skin—i.e., fingerprints—in determining the human ability to differentiate between surfaces. We have taken the insights from these psychophysical experiments to design new electroactive and ionically conductive materials to produce "actuator skins" whose goal is to produce realistic sensations for applications in tactile therapy, instrumented prostheses, education and training, and virtual and augmented reality.

2:15 PM EQ15.04.03
Microstructured Materials for Controlling the Pressure Response of Soft Optical Skins Michael Portaro, Rio Brittany and Cindy K. Harnett; University of Louisville, United States

Soft optical pressure-mapping elastomeric skins are an intrinsically stretchable and deformable platform for human-like tactile sensing. In this work, we investigate how the microstructure of an elastomer layer controls its light transmission as a function of pressure. Under pressure, voids in a soft, optically-transmissive material will preferentially compress, making the microstructured material densify. Not only do the voids control the tactile feel of the layer, but shrinking surface voids can increase the solid contact area that the elastomer makes with an underlying waveguide core, causing more light to exit the waveguide at the pressure location. Whether the voids are randomly distributed or deterministically placed by molding, the surface takes on new optical and mechanical properties thanks to its microstructure. Developments in this area will lead to all-polymer surfaces that measure and map deformation on a force scale controlled by the material's design.

Optical waveguiding in a core-clad structure requires a cladding that has a lower index of refraction than the core. The refractive index (RI) describes the speed of light in the material, with higher RI materials having higher optical density, shorter wavelengths for a given frequency, and slower light velocity than in a low RI material. The ideal high-index core, low-index cladding structure enables rays with a sufficiently shallow incidence angle to achieve total internal reflection (TIR) at the core-cladding interface, the principle behind long-distance optical fiber communication. Normally the cladding is a solid material. Here, the cladding is an elastomer with RI between 1.4 and 1.6, containing voids: air pockets with RI close to 1. Voids are created using two methods: molding liquid-cure elastomers on micromachined substrates, and incorporating porogens into liquid-cure elastomers.

Two principles apply to these porous materials at different size scales: 1) for large features (> 0.1 micron relative to the 940 nm sensor wavelength in this research), more of the light escapes the core where the cladding is solid compared to where the cladding has a void. Therefore the light loss increases as pressure increases the solid fraction of the total contact area. Scattering and interference also occur at the interfaces between air and solid. 2) For sub-wavelength features (< 0.1 micron), scattering and interference become less of an issue, and the material behaves as a composite with a refractive index somewhere between solid and air, proportional to the solid volume fraction.

To characterize the optical pressure response of these structured materials, we developed an instrument to measure transmission *vs*. incidence angle as a function of pressure for soft films having thicknesses between 0.5 and 3 millimeters. Applied pressures were in the 0-0.1 MPa (0-15 PSI) range that

humans typically use to manipulate objects. Optical microscopy of molded surfaces, for example a hexagonal array of 180-micron diameter silicone hemispheres (RI=1.41), showed that the solid contact area with a glass slide (RI=1.55) did increase under pressure. We found that increasing pressure on the sample increased the amount of light escaping the glass at incidence angles below the TIR angle for the glass-to-solid elastomer interface.

Changing the designs of the micromachined features might allow one to further tune the pressure response, for example buckling at a threshold pressure or responding to shear forces. The work here was performed on liquid-cure elastomers, but porogens incorporated into 3D printable filaments such as thermoplastic urethane could enable additive manufacturing of microstructured soft optical surfaces without high-resolution printing.

Late News: Multilayered Joints with Adjustable Linear and Rotational Stiffnesses via Electro-Stiction Phenomenon Yuri Cho, Hyun-Ki LEE, Mijin KIM and Seung Tae CHOI; Chung-Ang University, Korea (the Republic of)

The electro-stiction phenomenon provides the frictional force between two contacting electrodes covered with high dielectric media, of which an applied electric field produces the Maxwell force to attract the two electrodes. Such an electro-stiction force is mechanically and electrically simple and has a fast response speed. But it requires a relatively high driving voltage. In this study, we developed robotic joints having adjustable linear and rotational stiffnesses by stacking many electro-stiction layers, composed of dielectric film/electrode/frame/electrode/dielectric film. Polyoxymethylene copolymer (POM-C) is used for the frame of thickness 1 mm, and Au is sputtered onto the POM-C frame as the electrode of thickness 24 nm. A relaxor ferroelectric polymer, poly(vinylidene fluoride-trifluoroethylene-chlorotrifluoroethylene (P(VDF-TrFE-CTFE)), is used as the dielectric film material since the electro-stiction force is proportional to the relative permittivity of the dielectric material. The P(VDF-TrFE-CTFE) film is first dip-coated on the Au electrode and frame, followed by lamination of the 5 μm thick P(VDF-TrFE-CTFE) film, which is fabricated by the adhesion-mediated film transfer technique (AMFTT). The multilayered structure is an effective way to produce high electro-stiction force with low driving voltage, but all layers must be kept at a constant distance to attract neighboring layers with the same force. In this study, by extending the edge of the structure, drilling a hole, and aligning many frames through an elastic string, the multilayered frames can be simultaneously controlled with the same applied voltage. Therefore, two bundles of frames can freely slide each other without applied voltage, while they can experience different linear and rotational stiffnesses when the applied voltage is changed.

EQ15.05.02
Transparent Omni-Directional Stretchable Circuit Lines Made by Junction-Free Grid of Expandable Au Lines Minsik Kong and Unyong Jeong; Pohang University of Science and Technology, Korea (the Republic of)

Although various stretchable optoelectronic devices have been reported, omni-directionally stretchable transparent circuit lines have been a great challenge. We engineer the cracks and fabricate highly conductive patterned metal circuit lines in which Au grids are embedded. Au is deposited selectively in the cracks to form a grid without any junction between the grid lines. Since each grid line is expandable under stretching, the circuit lines are stretchable in all the directions. This study shows that a thin coating of Al on the oxide surface enables precise control of the cracks (crack density, crack depth) in the oxide layer. High optical transparency and high stretchability can be achieved simultaneously by controlling the grid density in the circuit line. We integrate light-emitting diodes (LEDs) directly on the circuit lines and demonstrate stable operation under 100% stretching.

EQ15.05.03
Electroluminescent Liquid Dielectric Actuators Using Silica-Coated ZnS:Cu Jae Rim Lee and Byung Yang Lee; Korea University, Korea (the Republic of)

Multifunctional soft actuators can impart soft robots with diverse properties in a limited space, enabling the integration of several functionalities in a single device. Recently, soft electroluminescent actuators have been reported, where a dielectric elastomer is combined with electroluminescent particles under combined AC and DC driving signals. Here, we present an electroluminescent soft actuator that utilizes a liquid dielectric as the active material with EL phosphor particles dispersed in it. By coating the surface of the ZnS with silica, we solved the problem of agglomeration of the ZnS particles in the dielectric liquid, resulting in uniform luminescence throughout the device active region. The soft actuators showed strain values of 34% and maximum EL values of 25 cd/m^2 for a single actuator and over 34 cd/m^2 for five stacked actuators. The strain values are comparable to previous works. We expect our EL actuator devices will be used as new smart components for soft robotics and interactive sensors where external stimulus can be displayed as color signals.

Semi-Crystalline Polymer Films to Probe the Effects of Crystallinity on Tactile Discrimination Abigail Nolin and Charles Dhong; University of Delaware, United States

Human touch is critical to the human experience, especially those with low vision and sensory impaired disorders. The field of haptics aims to design materials that recreate tactile sensation. Sensations in fine touch derive from the dynamic frictional forces that arise at the interface between human skin and the surface of a material, and these forces depend on both pressure and sliding velocity. Current approaches rely on physical controls such as mechanical vibrations, bumps, or pins, but the mechanical forces in fine touch arise from not only physical surface features, but the chemical properties of the material itself. Crystallinity is a classic material structure property used to control the mechanical forces of a material and has wide applicability in many material systems. Semi-crystalline polymers can have both amorphous and crystalline regions, and the degree of crystallinity can be controlled through many processes including annealing the polymer at an ideal crystallization temperature. Crystallinity has well-defined effects on mechanical forces, most notably an increase in modulus, but also has effects on frictional forces. Increasing crystallinity correlates with higher molecular order and higher shear strengths, resulting in lower coefficients of friction and less sensitivity to contact pressure. To connect tactile perception with degree of crystallinity, chemically similar atactic and isotactic polystyrene films were prepared and then annealed to induce crystallization. Films were compared for tactile distinguishability with an in-house mechanical testing set-up and human testing. We demonstrated that humans could distinguish films which differed by only degree of crystallinity as predicted by frictional force curves and characterized through microscopy and GIWAXS. Connecting tactile

discriminability with degree of crystallinity has immediate use in developing switchable haptics devices with materials such as liquid crystal elastomers or conjugated polymers.

EQ15.05.05
Electrochemiluminescence Skin with Piezo-Ionic Effect and Mass Transport Phenomenon Jong Ik Lee[1,2], Hanbin Choi[3], Ik-Soo Shin[4,2], Do Hwan Kim[3] and Moon Sung Kang[1]; [1]Sogang University, Korea (the Republic of); [2]Graphenide Technology, Korea (the Republic of); [3]Hanyang University, Korea (the Republic of); [4]Soongsil University, Korea (the Republic of)

Electrochemiluminescence (ECL) has been recently exploited to form alternative light-emitting devices. referred to as phenomenon electrochemiluminescence device (ECLD). Unlike conventional light-emitting devices, an ECLD requires mass transfer of oxidants/reductants as well as charge transfer reactions in an electrolytic environment. In this talk, we propose the electronic skin (e-skin) device exploiting the characteristic mass transfer phenomenon within ECLD, as an alternative strategy capable of transducing mechanical stimuli into visual readout rely on ECL. First, we investigate the influence of the mass transfer and electron transfer kinetics on emission of ECLDs. Then, we fabricated an e-skin based on ECL layer employing thermoplastic polyurethane as a matrix polymer. The proposed material platform shows the visco-poroelastic response to mechanical stress, which induces a change in the distribution of the ionic luminophore in the film referred to as the piezo-ionic effect. This piezo-ionic effect is exploited to develop a simple device containing the composite layer sandwiched between two electrodes, which is termed ECL skin. Emission from the ECL skin is examined, which increases with the applied normal-/tensile- stress. Additionally, locally applied stress to the ECL skin is spatially resolved and visualized without the use of spatially distributed arrays of pressure sensors. The simple fabrication and unique operation of the demonstrated ECL skin are expected to provide new insights into the design of materials for human-machine interactive electronic skins.

Reconfigurable 3D Structures of Spatially Programmed Liquid Crystal Elastomers and Their Ferromagnetic Composites Yi Li and Xueju Wang; University of Connecticut, United States

Reversible programming of 3D soft mesostructures is desired for many applications including soft robotics and biomedical devices. The large, reversible shape changes of liquid crystal elastomers (LCEs), which result from the coupling between the alignment of liquid crystal (LC) molecules and the macroscopic deformation of polymer networks, have attracted much attention for such applications. In this talk, I will discuss our recent effort in developing a facile and versatile strategy to create reconfigurable, freestanding 3D mesostructures of LCEs and magnetic LCE composites that are inaccessible with existing techniques via spatially programming LC molecules. Experimental and theoretical results of more than 20 reconfigurable 3D LCE mesostructures of diverse configurations and their large, reversible shape-switching behaviors over multiple cycles will be demonstrated. In addition, an LCE gripper and a robot of ferromagnetic LCE composites that simultaneously responds to magnetic and thermal stimuli for diverse biomimetic behaviors, especially crawling underneath a narrow crack, will be used to illustrate the integration of other functional materials to LCEs for multifunctional systems.

Tactile Sensing and Perception for Human–Robot Systems Veronica Santos; University of California, Los Angeles, United States

The sense of touch is vital for any system in which humans use machines to physically interact with the world. An artificial sense of touch is especially useful when complementary sensory modalities, such as vision, are limited or unavailable. I will highlight past and present work to enhance the functionality of artificial hands in human-robot systems. I will describe our efforts to develop multimodal tactile sensor skins and our experiences with a variety of deformable, low-cost and commercially available tactile sensor designs. I will discuss the use of machine learning to perceive tactile directionality and salient geometric features, along with a tactile perception pipeline for haptically locating objects buried in granular media. Finally, I will present work in which reinforcement learning is used for the tactile-driven manipulation of deformable objects, such as sheets of paper, ziplock bags, and computer cables. Real-time tactile perception and decision-making capabilities could be used to advance semi-autonomous robot systems and reduce the cognitive burden on human teleoperators for applications that include assistive technology, manufacturing, the handling of dangerous materials, and remote healthcare and work in space.

4:45 PM EQ15.06.04
Increasing Performance of Soft Dielectric Elastomer Artificial Muscles via Nanomaterial Composite Electrical Insulators Max Herzog, Maduran Palaniswamy, Chuck Rutledge, Shardul S. Panwar, Michael Jones and Michael P. Rowe; Toyota Research Institute of North America, United States

The fields of soft robotics and human-machine interfaces are rapidly evolving but are still limited by the commercial viability of soft actuator technologies. When compared against other soft actuators (e.g. shape-memory alloys, pneumatics/hydraulics), dielectric elastomers provide a superior balance between performance metrics like actuation frequency, stroke length, and implementation hardware but fall short when comparing force output. Additional benefits of dielectric elastomers are that they are compliant, low profile, lightweight, and scalable, making them ideal in wearable, e-textile, and haptic interface platforms. The force output of dielectric elastomer artificial muscles depends on a few key parameters (e.g. electrode area, dielectric fluid volume, applied voltage, geometry of thin-films); it is well known that increasing the dielectric constant of the electrically insulating materials within the actuator has a nominally linear relationship to force output, but it is challenging to access high-dielectric polymers that can be used in artificial muscle fabrication.

Diverging away from homo- and co-polymers, high dielectric constants can be alternatively accessed through nanomaterial composite films. This methodology allows for the use of high-dielectric inorganic materials (which are typically very rigid) in soft robotic applications. Inorganic nanomaterial composites using titanium dioxide, Fe_3O_4, and barium titanate were formed in a sandwich structure with polymer layers of biaxially-oriented polypropylene and poly(ethylacrylate acrylamide). Composites consisting of conductive, organic nanomaterials (e.g. graphene, carbon nanotubes) and their combinations with inorganic materials were also fabricated. The microstructure, composition, and electrical properties of these nanomaterial composite films were analyzed using scanning electron microscopy (SEM), Raman and FT-IR spectroscopy, and capacitance measurements. Changes in the dielectric constant were measured indirectly through material property analysis and mechanical studies of the artificial muscle actuator performance. These modifications showed artificial muscle maximum force output improvements greater than 2.5x compared to control muscles without nanomaterial incorporation. Actuator performance gains were in spite of any added thickness to the electrical insulators from the addition of nanomaterial. Efforts to decrease dielectric relaxation time and increase the actuator duty cycle by using a graphene-doped titanium dioxide nanomaterial composite found that conductive carbon can have a dramatic impact on performance. These nanomaterial composite advancements are particularly attractive because their drop-in quality allows for application in artificial muscle technologies without impacting existing actuator design. Such fundamental material insights push the field of soft robotics towards improving real-world human-machine interactions.

5:00 PM EQ15.06.05
Effect of the Magnetic Field-Assisted Synthesis of PVB/Fe_2O_3 Magnetic Polymers Films on the Magnetic Properties for Haptic Actuators Sara Gomez, Beatriz C. Lopez-Walle and Edgar Reyes-Melo; Universidad Autonoma de Nuevo Leon, Mexico

Haptic actuator research presents a challenge correlating fundamental knowledge between the properties of the materials and their behaviour on haptic systems. Specifically, the analysis of the magnetic properties of magnetic polymers produced by assisting the synthesis process with a magnetic field is still promising. In this work, magnetic polymer films (thickness: ~0.020 mm) were made by the *in situ* synthesis of iron oxide nanoparticles (Fe_2O_3) in a polymeric matrix of polyvinyl butyral (PVB). This synthesis is performed by applying a constant magnetic field during the nucleation and growth of the Fe_2O_3 nanoparticles. Consequently, an increase in the reaction time was also necessary during this process. Therefore, a change in the magnetic properties (and the magnetic response) of the resulting magnetic polymer films was obtained. The magnetic characterization of the resulting PVB/Fe_2O_3 magnetic polymer films was performed using a vibrating sample magnetometer (VSM). The magnetization curves showed that in samples produced without the magnetic field, the maximum magnetic magnetization is similar (about 0.89 emu/g) and, in samples obtained with the magnetic field, the maximum magnetic magnetization is different (from 0.32 emu/g to 0.66 emu/g). Thereby, the orientation of the magnetic field could have affected the maximum magnetic magnetization. These results will improve the use of magnetic actuators in haptic systems like soft robots for manipulating actuators, aquatic actuators, or mimic animals.

Failure Mechanisms of Embedded Flexible Strain Sensors for Soft Robotics Akshay Kakar, Derrick Banerjee, Edward M. Sabolsky and Kostas Sierros; West Virginia University, United States

Flexible sensors are being used in a variety of applications such as biomedical, textile robotics, and wearable devices. The ability of the sensors to function while deformed proves their adaptability for being implemented into various soft robotic structures, which makes them more desirable than conventional rigid sensors. Therefore, it is important to study the mechanisms through which the sensors reach their functional limits and begin to fail. In this study, we used PDMS as the matrix and silver-based ink for printing linear strain sensors. The sensors with varying vol.% of binder, dispersant, and solvent were embedded using two methods: lay-up and direct-writing. The failure mechanisms of these sensors were then studied based on the electro-mechanical performances, deformation tolerance, and durability while under varying levels of tension and compression using a universal testing machine. The desirable ink composition and fabrication method were evaluated based on the sensor's conductivity, stretchability, bendability, and longevity.

A Soft Neuromorphic Mechanosensor Using Ferromagnets Si Li, Hian Hian See, Aeree Kim, Jingyi Yang, Kelu Yu and Benjamin C. Tee; National University of Singapore, Singapore

Mechanosensors in biological somatosensory system encode mechanical stimuli into electrical pulse (i.e, action potential) for tactile perception and learning. Inspired by the nature of biological action potentials, we present a soft neuromorphic mechanosensor that enable robust tactile application even in aquatic environments. The soft ferromagnetic material in the mechanosensors generates electrical pulses under external stimuli. The decoded responses from the specific pulse sequences exhibit a highly linear function with the mechanical stimuli. Assisted with machine learning algorithms, we achieved high accuracy multi-pixel differentiation and underwater object recognition in robotic and flexible human-machine interface applications. We anticipate that this new soft neuromorphic mechanosensor will potentially enable new forms of robots and human-machine interfaces.

Deciphering Physical Cues and Dimensions that Underlie Our Sense of Compliance Gregory J. Gerling; University of Virginia, United States

Mobile phones, tablets, and watches have become a normal part of everyday life. The next generation of devices will enable touch feedback, become flexible, and extend increasingly rich and immersive interactions into virtual reality. Remote touch interactions will convey an object's compliance, or softness, as with fruits such as plums and tissues such as skin. In addition to applications in entertainment and personal productivity, such interactions will enable surgeons to distinguish gallbladder and prostate tissue and ducts from fat and bone, small children to feel a parent's hand, and consumers to inspect and compare products, clothing, and work pieces. While promising new possibilities, the displays under development do not yet feel natural. They also face severe limitations in terms of weight, power, and actuation range. To inform devices to replicate naturalistic interactions of this sort, we have been working to define how the finger pad must deform in space and time to adequately convey a natural sense of compliance.

Object softness, of which compliance is one major dimension, is thought to be encoded by relationships of force, displacement, and contact area at the finger pad. This talk will describe work to understand how time-dependent cues, or information in the rate of change of skin over a spatial field, govern the

encoding of compliance. To do so, we have first developed experimental devices to control the force, indentation, and or their rates in passive touch. We concurrently developed an ink-based method to measure biomechanical contact of the finger pad. Human-subjects studies show that temporal, force-rate cues are more efficient in discriminating compliances, by reducing the amount of deformation of the finger pad and stimulus, which aligns with ongoing skin remodeling. To further study force-rate cues, but under an active touch paradigm, we developed a compliance illusion by introducing spheres of various elasticities and curvatures, derived from finite element simulations of the finger pad. The illusion is that participants cannot discriminate, in passive touch, spheres that are small and compliant versus large and stiff, which generate equivalent contact areas. In active touch, however, participants easily discriminate these spheres, and may utilize cues tied to proprioceptive joint angle, the rate of change of contact area, or surface penetration depth. This special case tells us that our perception of softness is a product of both sensation and volition, and depends upon both afferents in skin and proprioception. To further evaluate these cues, we developed a stereo imaging technique to capture skin deformation while interacting with objects of varied elasticity. We have also standardized a way to characterize the elasticity of test stimuli used by others in similar studies and begun to study ecological interactions with naturalistic fruits in order to reproduce observed skin deformation with dynamic displays.

OPEN DISCUSSION: Organic Haptics—Soft Materials for Artificial Touch Darren J. Lipomi; University of California, San Diego, United States

Open Discussion

11:30 AM EQ15.07.02
Tactile perception of micro-structured materials Roland Bennewitz; INM - Leibniz Inst for New Materials, Germany

Roughness at the micrometer scale has been identified as a key tactile dimension in the haptic perception of materials. There is a longstanding tradition to create well-defined surface structures with the goal to elucidate mechanisms underlying roughness perception. We will discuss results of two tactile perception studies with micro-structured stimuli.
Randomly rough surfaces were created by 3D printing with independently varied topography and spectral distribution of roughness. We found that the tactile perception of similarity follows the amplitude of roughness at smaller length scale rather than the topographic resemblance. The interaction between surface asperities and fingertip skin led to higher friction for higher microscale roughness. Individual friction data allowed us to construct a psychometric curve which relates similarity decisions to differences in friction [1].
We also produced fibrillar samples from materials with varying elastic modulus. The perception of similarity between samples with different fibril length and different elastic modulus followed the bending of the sub-millimeter scale fibrils, which were arranged in regular arrays on the surface.
[1] R. Sahli, A. Prot, A. Wang, M.H. Müser, M. Piovarči, P. Didyk, R. Bennewitz, Tactile perception of randomly rough surfaces, Scientific Reports, 10 (2020) 15800.

11:45 AM *EQ15.07.03
Self-Healable Soft Materials for Sensing and Actuation Benjamin C. Tee; National University of Singapore, Singapore

Haptic devices can elicit sensations remotely or in virtual environments. Sensing and actuation are required in order to digitize real world interactions and transmit it to an actuation device or system. In this talk, I will discuss strategies to enable soft electromagnetic materials to sense the environment and simultaneously actuate. Such materials can potentially be made self-healable, and allow for mechanical recovery in performance despite mechanical damage. Repair can be effected simply by mechanical contact of the damage areas. It is envisioned that such materials can be useful in the growing field of haptic devices and systems.

12:15 PM EQ15.08.05
Soft Rubbery Electronics and Sensors for Robotics Cunjiang Yu; University of Houston, United States

Soft sensory devices that mimic the human skin with multiple sensors spatially distributed to extract information in a temporal manner are technically challenging yet promising for many emerging applications from haptic interfaces, to medical robotics and to skin prosthesis among others. Although drastic advances already been made in developing various soft devices with various functions, one of the long-lasting challenges is to have biology-similar materials and structures to physically mimic the human skin. This presentation will introduce rubbery electronics, which is a new type of electronics with skin/tissue-like softness and mechanical stretchability, constructed all based on elastic rubbery electronic materials. The innovations in rubbery electronic materials and devices set the foundation for rubbery electronics, integrated system and their broad usages, such as active matrix based tactile sensory skins, soft neurorobotics, etc. This presentation will introduce fully rubbery based active matrix tactile sensory skin that is able to sense the touch spatiotemporally that could be equipped for various robotics and robotic interfaces. This presentation will also demonstrate a soft neurorobots which is constructed with neurologic function integrated skin on soft robotics to decode the external interactions into neurological signals for decision making.

1:00 PM EQ15.08.01
Increased Performance by Matching Electric Fields from Triboelectric and Ferroelectric Charges in Nanogenerators Linards Lapčinskis[1], Kaspars Malnieks[1], Artis Linarts[1], Kaspars Pudzs[2] and Andris Sutka[1]; [1]Riga Technical University, Latvia; [2]Institute of Solid State Physics, Latvia

The field related to triboelectric nanogenerator (TENG) devices is emerging rapidly by continuously presenting new original and creative TENG concepts for convertion of mechanical energy into electricity.[1] The working principle of TENG is straightforward - upon contact-separation or sliding of two triboelectric material (often polymer) coated electrodes surface charges are formed on the triboelectric materials, which induce an electrostatic charge on the conductive electrodes. As electrodes move, a potential difference is created causing a current flow in the external electric circuit. Evidently, TENG devices can be used as excelent self-powered force sensors and haptic sensor arrays.[2,3] Up to now devices have been integrated into a range of objects - fabrics,[4] wearables,[5] interior objects,[6] and even implantable devices.[7]
Additionally embedding ferroelectric dipoles in contacting polymer layers is known to effectively enhance the performance of TENG. However, dipoles can form also between the opposite triboelectric surface charges on the contacting ferroelectric films. Up to now this similarity has been neglected in the

relevant studies. Our research demonstrates that proper attention to the alignment of the distinct dipoles present between two contacting surfaces and in composite polymer/$BaTiO_3$ ferroelectric films can lead to up to four times higher energy and power density output compared with cases when dipole arrangement is mismatched. For example, TENG device based on PVAc/$BaTiO_3$ shows energy density increase from 32.4 μJ m^{-2} to 132.9 μJ m^{-2} when comparing devices with matched and mismatched triboelectric and ferroelectric dipoles. The presented strategy and understanding of resulting stronger electrostatic induction in the contacting layers enable the development of TENG devices with greatly enhanced properties. Greater generated energy allows easier integration with MEMS and since the output signal is stronger - more precise electromechanical response and sensing.

Multi-Stimuli Responsive Reduced Graphene Oxide Patterned Azo-Liquid Crystalline Polymer Networks for Stretchable Electronics with Tailored Morphologies Woongbi Cho[1], Jisoo Jeon[1], Wonsik Eom[2], Tae Hee Han[2] and Jeong Jae Wie[1]; [1]Inha University, Korea (the Republic of); [2]Hanyang University, Korea (the Republic of)

The concept of ‘kirigami’ has been of interest in the field of stretchable electronics because the kirigami patterned structure can increase the degree of freedom for deformation beyond the intrinsic limits of the original material. Furthermore, shape-reconfiguration of tunable electronics can be achieved by the introduction of kirigami-engineered design for programmable materials such as azo-benzene functionalized liquid crystalline polymer networks (azo-LCN). In this presentation, we introduce a facile coating process for patterned reduced graphene oxide (rGO) as well as integration of the patterned rGO along with shape-reconfigurable azo-LCN. The rGO patterned azo-LCN (azo-LCN/rGO) demonstrates about 500 % higher storage modulus of 6.4 GPa than neat azo-LCN (1.3 GPa) and an electrical conductivity of 380 S cm^{-1} at 4 times the number of rGO coating cycles. In addition, multi-stimuli (i.e. UV, NIR, focused solar ray, and direct heat) responsive actuation of azo-LCN/rGO is achieved by photochemical isomerization of azobenzene moiety in conjunction with the coefficient of thermal expansion (CTE) mismatch via photothermal effects. In particular, the convolution of photochemical and photothermal effects provides enhanced actuation performance of the azo-LCN/rGO bilayer from the neat azo-LCN monoliths. Finally, the kirigami pattern allows the azo-LCN/rGO to endure a higher strain beyond the strain capacity of azo-LCN/rGO without permanent damages to its own body or deterioration of electrical performance. The kirigami-engineered azo-LCN/rGO demonstrates passive, active and hybrid types of shape-morphing under mechanical tension, UV, and simultaneous stimuli of UV and tension, respectively. Toward shape-reconfigurable and stretchable electronics, we demonstrate UV-induced shape-morphing of the kirigami-engineered azo-LCN followed by 60 % of mechanical strain by tension without increase in electrical resistance.

1:10 PM EQ15.08.03
Wearable Haptic Feedback Based on Electrohydraulic Actuators Yitian Shao; Max Planck Institute for Intelligent Systems, Germany

Current virtual reality (VR) techniques can provide synthesized graphics and sounds that allow the user to explore the virtual world but permit comparatively limited haptic feedback. One challenge frequently encountered by wearable haptics designers is the dilemma between the need for generating sufficiently large haptic signals and the desire for keeping the device small and lightweight for better wearability. Indeed, a bulky and heavy haptic device may constrain the movement of the user and cause fatigue. Actuators made from smart materials can have high power-to-weight ratio and therefore can provide sufficient haptic feedback with limited size and weight.

Here, we present our recent design of a wearable haptic device made from electrohydraulic actuators [1]. The device consists of a flat dielectric pouch filled with liquid dielectric. Six pairs of hydrogel electrodes are attached to opposite sides of the pouch and enclosed by insulating rubber. Made from soft and compliant materials, the device can be attached to the skin as a body-worn haptic interface. Voltage applied to any pair of hydrogel electrodes generates electrostatic force, which closes the gap and displaces the liquid dielectric between them. Activation of multiple pairs of electrodes can produce both static and dynamic spatial patterns to provide feedback to a large area of the skin. The device is thin (< 3.5 mm), lightweight (< 35 grams), and capable of producing substantial displacement (> 2 mm) and forces (> 0.8 N) for haptic feedback. The wearability of the device allows long-term usage in VR systems. Since the feedback provides a softness feeling, potential applications of the device include wearable interfaces for social haptics and medical training simulators in VR. Currently, in our unpublished work, we further improved the design to enable more complex haptic feedback patterns, larger displacement and force output, and full portability of the whole system.

Haptics—Emerging Material Technologies and Touch Interaction Yon Visell; University of California, Santa Barbara, United States

Haptics refers to our capacities for touch perception and physical interaction with our surroundings. Haptic technologies hold the potential to transform how we interact within environments that are increasingly interwoven with digital information. However, technologies for furnishing tactile information to the skin, our largest sensory organ, are rudimentary when compared with biological capabilities. I will describe the challenges involved in characterizing and engineering for the human sense of touch. I will discuss recent research in my lab that aims to meet these challenges through research on haptics and emerging material technologies, including several projects that elucidate key synergies between materials, mechanics, and capabilities of biological and engineered systems, and how this research is yielding new technologies for haptics and robotics.

1:45 PM BREAK

1:50 PM EQ15.08.08
Spatial Independent Zone for Body-Motion Unaffected Haptic Sensors Chanho Jeong and Tae-il Kim; Sungkyunkwan University, Korea (the Republic of)

Haptic sensors are devices for measuring any physical quantities that can be received from a tactile sense. They measure from temperature, pressure to their advanced concepts such as roughness, vibration, pain, etc. Most haptic sensors are designed to be placed close to the skin for the purpose of haptic. This

can be attributed to the tremendous development of 2D flexible devices. Despite such advanced haptic sensors, haptic sensors always suffer from motion noise. Even though the sensor reads the necessary data, it is mixed with noise and cannot transmit meaningful information. Accordingly, many researchers tried to solve the problem with various ideas such as strain/bending insensitive pressure sensors, uni-directional sensors, decoupled strain-temperature sensors, etc., and published quite meaningful research results. However, another difficulty arises when the different sensors studied in their own methods need to be combined once more to be used in the complex sensing system of the haptic.
Unlike previous studies, we did not focus on the sensor itself, but rather focused on the surrounding environment where the haptic sensors are located. Haptic sensors are mostly in the form of a flexible film in order to be close to the skin, and are affected by the relaxation, contraction, and bending of the skin. Here, we have focused on stress-transformation in this skin. In an environment where only one-way normal force of contraction and relaxation is applied, such as skin, stress transformation shows that there is a region where stress in a specific direction does not exist. At this time, it is necessary to focus on the fact that most flexible sensors are in the form of a 2D film and have little reactivity to normal stress acting perpendicular to the 2D film unless they have a bi-layer structure. From the perspective of research up to now, it was taken for granted that the flexible sensor was located on the same surface as the skin surface due to the morphological factor of the 2D film. This is the most vulnerable positioning method to the force transmitted by contraction and relaxation. However, even though it is a 2D film, it is a different story if it maintains a different angle from the skin surface. The force transmitted from the skin can be made to act in a direction in which the sensor does not respond. Taking advantage of this, we found a specific area that stress from the dynamic motion does not affect the device. In this area, the strain sensor is insensitive to contraction, tension, and bending, but reacts sensitively to the external pressure that must be read as a real tactile sense. Furthermore, since this study is not limited to sensors, it can be applied to universal 2d flexible sensors. Therefore, we performed a measurement experiment with a 2d temperature sensor in the corresponding area. It was possible to measure the desired temperature without being affected by motion noise.
Our research was more about the environment surrounds the strain sensor rather than the sensor itself. It means it is applicable to many other already-made sensors without an additional device.

Chemical Heterogeneity in Grafted Particle Nanocomposites Measured in Rheology Di Wu and Pinar Akcora; Stevens Institute of Technology, United States

Structural and chemical heterogeneity around nanoparticles have strong influences on mechanical properties of nanocomposites. The phase stability of polymer grafted nanoparticles in polymer melt is governed by the mixing of chemically different polymers in the particle-polymer interfacial regions. In this work, poly(methyl methacrylate) (PMMA)-grafted Fe_3O_4 nanoparticles with the same grafting density but with two different chain lengths are synthesized and dispersed in poly(methyl acrylate) (PMA) at different molecular weights. The mechanical responses of the composites are measured in rheometer. The grafted particle composites exhibit the higher rubber plateau modulus than adsorbed samples. This is attributed to the higher number of segments interacting with the matrix chains, and this conformational factor on interfacial layers on nanoparticles tune thermal-stiffening and reinforcement of composites. It was found that intermediate molecular weight of grafted chains reinforces the composite better at high temperatures. For both long and short grafted particles, rubber plateau modulus and entanglement density decreased due to phase separation of grafted particles. Moreover, the interface entanglements recover and re-entangle more with the large deformation experiments with the short graft and matrix chains.

Soft Robotics for Haptics—Industrial Perspective on Challenges and Philosophy Yigit Menguc[1,2]; [1]Facebook, United States; [2]Oregon State University, United States

Our coordination and convergence challenges in industrial soft robotics are defined by task uniqueness (no one has ever tried to do what we do) and expansive multidisciplinarity (...→chemistry→materials→mechanics→design→...). Such an environment makes it hard to scope and align research for the individual scientists, engineers, and designers, and makes prioritizing the work ambiguous for the academic and industrial organization.

The history of scientific discovery highlights certain research teams (Bell Labs, PARC, Rad Lab) that implemented strategic organizational and tactical behavioral innovations that lead to a culture of convergence. All research may be considered on a two dimensional space defined by the axes of Fundamental↔Applied and Curiosity-Driven↔Use-Inspired. Industrial soft roboticists are working in the quadrant of Fundamental, Use-Inspired research — called Pasteur's Quadrant — that is neither pure basic nor pure applied research.

Much like academia, industrial research into soft robotics is based on the fundamental questions that push each subsystem forward. The anatomy of soft robots spans actuators, sensors, control, power, and the mechanical structural (skin, bone, etc). The divergence between academia and industry is in terms of value assigned to system integration and to reliability/replicability. System integration is often considered technical and without intellectual merit, yet the gaps in human knowledge around holistic system design is vast -- especially in soft robotics. Risk assessment, balancing, and mitigation drive much of the industrial research portfolio management -- and a major attribute of this process is assessing the reliability and replicability of novel technology. The current academic incentive for novelty and first-to-press discounts the value of replicability/reliability that drives industrial research. Strengthening the alignment and bridging the divergence between academy-industry must be our goal in soft robotics research if it is to broadly translate its impact to society.

SESSION EQ15.09: Soft Matter Materials and Mechanics in Haptic Interfaces IV

EQ15-Virtual

10:30 AM EQ15.09.01
3D and 4D Printing of Stimuli-Responsive Materials and Actuation Devices Rigoberto C. Advincula[1,2,3]; [1]Case Western Reserve University, United States; [2]The University of Tennessee, Knoxville, United States; [3]Oak Ridge National Laboratory, United States

The use of 3D printing for rapid prototyping of functional and biocompatible polymeric materials enables new functionality of polymeric materials for

devices useful in flexible and wearable electronics. The use of thermoplastics, thermosets, and elastomers
based on their outstanding thermo-mechanical properties have to be married with their 3D printability. In addition, for actual biomedical device applications, their in-vivo or in-vitro functions have to be considered. A number of 3D printing methodologies (FDM, SLA, SLS, VSP)
can make use of new blended or formulated compositions that incorporated stimuli-responsiveness. Herein, we demonstrate the ability to deploy 3D and 4D printing methods of designed (materials and geometry) polymer materials. This will be demonstrated in the following: 1) biomedical grade thermoplastic polyurethanes (TPU) with compatibility to mammalian NIH 3T3 cells and elastomeric response. 2) Shape-memory polybenzoxazine-epoxy polymers that enable T and P response, and 3) Actuator devices to measure mechanical response in motion detection. The 4D printing allows the design of new materials and applications based on integrating the chemistry of conversion with the printing mode. For example, these materials have been printed via viscous extrusion printing (VEP) or VSP and then converted to an elastomeric actuating material with very high cyclic compressibility. Other work based on the use of SLA, SLS, FDM, towards high
strength nanocomposite and biomaterials will also be discussed.

10:45 AM *EQ15.09.02
Active Haptics in Clothing—Approaches and Obstacles for Designing Soft Wearable Systems Lucy Dunne; University of Minnesota, United States

Textile- and clothing-based haptic systems remain a persistent challenge for research and industry. Integrating mechanical actuation into structures with variable and unpredictable geometry and mechanics is a new level of complexity for system design. The field of flexible electronics has afforded a degree of conformability to electronic devices, but does not yet meet the 3D drapability or comfort requirements expected of clothing-like wearability, particularly for systems that require simultaneous access to many parts of the body. Developing effective wearable haptic systems requires accommodating many facets of user and system needs, which are often in conflict. This talk will explore challenges and current approaches related to: haptic modalities in clothing; fabrication and manufacture of soft actuation devices; understanding and affording perceptibility of actuators in clothing systems; sizing and fit across a user population; and balancing the comfort/functionality tradeoffs in system design.

11:15 AM EQ15.09.03
Stretchable Printed Giant Magnetoresistive Sensors for On-Skin Interactive Electronics Eduardo Sergio Oliveros Mata[1], Minjeong Ha[2], Gilbert Santiago Cañón Bermúdez[1], Yevhen Zabila[1,3], Juergen Fassbender[1] and Denys Makarov[1]; [1]Helmholtz-Zentrum Dresden-Rossendorf, Germany; [2]Electronics and Telecommunications Research Institute, Korea (the Republic of); [3]Polish Academy of Sciences, Poland

Printed electronics are expected to be implemented as a set of industrial technologies that will facilitate the on-demand fabrication of imperceptible[1] and shapeable[2] devices. Conductive pastes are typically composed of polymeric matrices with embedded conductive fillers. The properties of the fillers can be exploited to deliver functional devices as printed transistors[3], displays[4], and sensors[5]. The smart integration of such elements will allow task-specific integration in consumer electronics and even personalized wearable devices.

Aiming to develop on-skin printed interfaces, it is necessary to ponder mechanical, performance, and health safety considerations. Integrating magnetic sensors on interactive platforms is attractive due to their touchless, action-at-distance nature, which increases the reliability of the devices[6]. In the past, solution processable magnetic field sensors have been fabricated from composite pastes embedding magnetic particles. Among the previous reports on printable magnetic sensors[7], there are not examples of devices able to maintain high performance sensing during usual skin deformations. Concomitantly, there is a lack of research on skin-compliant printed magnetic sensors able to perform below the 40 mT safety continuous exposure threshold established by the World Health Organization[8].

Here, we will present the fabrication and implementation of stretchable printed magnetic field sensors. They are based on composite pastes with embedded flakes of $[Py/Cu]_{30}$ Giant Magnetoresistance (GMR) thin-film stacks. We demonstrated printed GMR sensors on ultrathin (3-µm-thick Mylar) foils which are skin compliant, and with maximum sensitivity at 0.88 mT. The stretchable sensors maintained stable sensing performance at 16 µm bending radius and 100 % strain which corresponds to two orders of magnitude increase with respect to previous reports. We demonstrate the implementation of the technology on interactive applications after laminating the printed sensors on the user's skin to navigate through digital maps and scroll through text documents. The ability of the sensor to comply with the skin creases and deformations, and to detect field changes in the safe threshold limit, place this technology as a prospective method for fabricating on-demand printed human-machine interfaces[9].

11:30 AM *EQ15.09.04
Haptic Illusions from Soft Wearable Haptic Devices Allison Okamura; Stanford University, United States

Haptic devices allow touch-based information transfer between humans and intelligent systems, enabling communication in a salient but private manner that frees other sensory channels. For such devices to become ubiquitous, they must be intuitive and unobtrusive – properties that can be achieved using soft materials that interface comfortably with the body. The amount of information that can be transmitted through touch is limited in large part by the location, distribution, and sensitivity of human mechanoreceptors. Not surprisingly, many haptic devices are designed to be held or worn at the highly sensitive fingertips, yet stimulation using a device attached to the fingertips precludes natural use of the hands. In this talk, we will explore the design of haptic feedback mechanisms that can be worn on the body, which achieve compelling haptic stimulation using a combination of soft robotics approaches and an understanding of human haptic illusions.

In creating wearable soft haptic devices, one can consider an approach that transmits information through many contacts, taking advantage of “unused real estate” on the surface of the skin to deliver haptic cues over a large area. One example uses a sequence of discrete contacts delivered to the forearm by pneumatic pouches attached to a growing haptic device constructed from flexible low-density polyethylene, called HapWRAP. Controlled air flow through tubes and pouches allows HapWRAP to grow out of a compact housing unit and provide a combination of directional and force feedback to a user. When activated, HapWRAP grows up and around the forearm; its loops form a temporary sleeve. After growth, pneumatic actuators inflate and deflate to stimulate mechanoreceptors in the skin at distinguishable locations, or in sequence to allow the haptic illusion of a traveling contact on the skin.

Alternatively, a wearable haptic device can use a single contact, but apply multi-modal feedback and/or multiple degrees of freedom of simulation to transmit information to the user. We created a multi-modal haptic device with a rigid rotational housing and three soft fiber-constrained linear pneumatic actuators. Soft pneumatic actuators were used because of their compliance, light weight, and simplicity, while rigid components provided robust and precise control. The soft pneumatic actuators provide linear horizontal and vertical movements, and the rigid housing, affixed to a motor, provides rotational movement of the tactor. The device can produce normal, shear, vibration, and torsion skin deformation cues by combining the movement of the soft pneumatic actuators with the rotational housing. The device generates haptic illusions in that the skin deformation, which is inherently tactile in nature, can generate the sensation of a world-grounded force applied to the arm.

Actuation Requirements for Maximizing Information Transmission Through the Skin Hong Z. Tan; Purdue University, United States

This talk will present an information-theoretical approach to maximizing information transmission through haptic displays. While the talk will not focus on soft materials per se, it will provide the engineering specifications for actuation materials and mechanisms based on psychophysical data. Our past research over several decades have provided empirical evidence that the human skin is capable of receiving complex information at a rate of at least 12 bits/s, a rate that is significantly above the demonstrated performance of most haptic displays. A major challenge is the lack of suitable actuation mechanisms for wearable haptic displays.

I will cover the following topics in this talk:
1) The need for an information-theoretical approach to haptic interface research;
2) The derivation of 12 bits/s from natural tactile speech communication methods;
3) Guidelines for maximizing information transmission based on empirical evidence;
4) Recent success in transmitting English words via a tactile sleeve with an embedded array of broadband actuators.

I will conclude the talk with a set of engineering specifications for soft materials and mechanisms capable of delivering broadband actuation on the skin surface to achieve high information transmission rates.

Near-Field Heat Transfer in Non-Hermitian Many-Body Systems Philippe Ben-Abdallah; Université Paris-Saclay, France

In this talk I will discuss some thermomagnetic effects for radiative heat exchanges in non-Hermitian many-body systems [1]. Contrary to Hermitian systems, the non-Hermitian systems are optically non-reciprocal. This breaking of symmetry gives rise to some singular radiative behaviors that we detail in this talk.
The first effect is a thermal analog of Hall effect [2] which exists in magneto-optical networks in presence of an external magnetic field. This effect consists in the appearance of a temperature gradient and therefore a heat flux transversally to the direction of a primary temperature gradient.
The second effect is a giant thermal magneto-resistance [3] within these systems. Similarly to the famous magnetoresistance [4] reported in ferromagnetic/normal metal multilayers, variations of thermal resistance of about 50% has been highlighted in nanoparticle networks with magnetic fields of magnitude of 500mT opening so the way to an ultrafast tunability of heat transfers mediated by an external field.
Next we analyze the radiative heat transfers in Weyl semimetals networks. Contrary to magneto-optical systems these Weyl networks are intrinsically non-reciprocal even without applied magnetic field. Hence an anomalous Hall effect [5] can exist in these media.

To finish we discuss some potential applications for these effects to control heat flux at nanoscale and to cool down solids using an external magnetic field.

Tuning the Spectrum of Near-Field Thermal Radiation Using Quantum Dots Saman Zare and Sheila Edalatpour; University of Maine, United States

Thermal emission observed at sub-wavelength distances from the emitting medium is referred to as the near-field thermal radiation. Thermal radiation in the near-field regime can exceed the far-field blackbody limit by orders of magnitude and be quasi-monochromatic. These unique properties of near-field thermal radiation have attracted significant attention for many potential applications such as waste heat recovery using thermophotovoltaic devices, near-field photonic cooling, and thermal rectification. Most of near-field applications require tuning the spectrum of near-field thermal radiation. So far, the near-field spectra are tuned by engineering materials at the sub-wavelength scale. These sub-wavelength-engineered materials are referred to as metamaterial. Thermal emission by metamaterials, which is significantly different from that of the corresponding bulk materials, can be tuned by modifying the geometry and size of the sub-wavelength features in the material. In this study, we propose tuning the spectrum of near-field thermal radiation by engineering the materials at the quantum scale. We show that modulating the electronic structure of materials by capitalizing on the quantum confinement effect provides a powerful mechanism for tuning the peak location of near-field thermal radiation.
For this purpose, we calculate the local density of states (LDOS) thermally emitted by lead chalcogenide quantum dots (QDs) of various diameters ranging from 3.3 nm to 6.8 nm at a near-field distance from the QDs. To find the thermal LDOS, the size-dependent dielectric function of the QDs is extracted from their measured absorbance spectra using the Maxwell-Garnett effective medium theory, the Kramers–Kronig relation and an optimization technique. The thermal discrete dipole approximation is used for finding the LDOS based on the framework of fluctuational electrodynamics and using the extracted dielectric function data. The thermal LDOS emitted by periodic and random arrays of QDs shows a peak around the bandgap energy of the QDs. The bandgap energy, which is affected by the quantum confinement in the QDs, can be tuned by changing the size and thus the level of quantum confinement of the QDs. The wavenumber of the peak LDOS emitted by PbS QDs can be shifted by up to 4490 cm^{-1} by changing the diameter of the QDs from 3.7 nm to 6.8 nm. It is also demonstrated that the peak location of the near-field radiative heat transfer between two arrays of QDs shows the same level of tuning as the thermally emitted LDOS.

Exploring Near-Field Enhanced Electrical Power Output in an Efficient Thermophotvoltaic Energy Conversion System Rohith Mittapally, Byungjun Lee, Linxiao Zhu, Ju Won Lim, Dejiu Fan, Stephen R. Forrest, Pramod Sangi Reddy and Edgar Meyhofer; University of Michigan, United States

Thermal radiation from a hot body is well described by Planck's law. However, Planck's law is not applicable when the gap size or the characteristic dimensions of the involved objects are much smaller than the thermal wavelength. Specifically, when a hot and a cold object are placed at nanoscale gaps, orders of magnitude enhancement in the radiative energy transfer is expected due to contributions from the evanescent waves. This can dramatically enhance the performance of thermophotovoltaic (TPV) energy conversion, which involves a hot emitter radiating photons that excite electron hole pairs in a photovoltaic (PV) cell. The performance of a TPV system can be characterized by the electrical power density and the efficiency of the radiative energy conversion. Recent TPV studies in the far-field demonstrated impressively high efficiencies (~30%) but at low power densities due to operation in the far-field. Several theoretical proposals have shown that dramatic enhancement in power density can be achieved by reducing the gap to tens of nanometers. However, such demonstrations have been challenging due to difficulties in maintaining nano-gap separations between a hot emitter (>1000 K) and a cold cell (~300 K). In this talk, we will first describe the development of micro-fabricated doped silicon emitters that can be resistively heated to temperatures as high as 1270 K. Next, we will describe how high power (~5000 W/m^2) and high efficiency (~7%) TPV energy conversion can be achieved when the hot emitter is placed at nanometric separations (<100 nm) from a custom fabricated thin-film InGaAs-based PV cell designed for high internal quantum efficiency and for minimized sub-bandgap absorption. Finally, we will present strategies for achieving even larger energy conversion efficiencies.

11:30 AM EQ16.01.04
Near-Field Radiative Heat Transfer Between Time Reversal Symmetry-Breaking Weyl Semimetals with Fermi Arc Surface States Simo Pajovic, Yoichiro Tsurimaki, Xin Qian, Svetlana V. Boriskina and Gang Chen; Massachusetts Institute of Technology, United States

Recently, time reversal symmetry-breaking Weyl semimetals have attracted great attention in the field of thermal radiation because of their strong, intrinsic electromagnetic nonreciprocity in the mid-IR. Previous models have emphasized their potential to realize the breakdown of Kirchhoff's law of radiation (i.e., the inequality of spectral directional emissivity and absorptivity) and highly directional emitters and absorbers. Their far-field nonreciprocity is linked to nonreciprocal surface plasmon polaritons, which suggests even stronger nonreciprocity is possible in the near-field, where surface modes dominate the radiative heat transfer. The effects of Fermi arc surface states (a defining characteristic of Weyl semimetals) on surface modes and near-field radiative heat transfer remain largely unexplored. Here, we model the near-field radiative heat transfer between two planar time reversal symmetry-breaking Weyl semimetals, explicitly including the effects of Fermi arc surface states in Maxwell's equations. We show that the inclusion of Fermi arc surface states creates new surface modes that exhibit strong nonreciprocity and exotic behavior. These modes, which can exist at relatively large wavevectors, contribute non-negligibly to the heat transfer, contrasting our previous studies in which Fermi arc surface states did not significantly affect far-field radiative heat transfer. Our work further points to the applicability of Weyl semimetals in nonreciprocal, tunable radiative heat transfer systems and highlights the importance of Fermi arc surface states beyond as a hallmark of Weyl semimetals. This work is supported by ARO MURI (Grant No. W911NF-19-1-0279) via the University of Michigan.

11:45 AM EQ16.01.05
Near-Field Thermal Radiation from Room to High Temperature—Calibration and Temperature Dependence Christophe Lucchesi[1], Maud Piqueras[1], Ali Alkurdi[1], Jean-Marie Bluet[2], Rodolphe Vaillon[3] and Pierre-Olivier Chapuis[1]; [1]CNRS - INSA Lyon, France; [2]INSA Lyon, France; [3]IES, France

Near-field radiative effects can be observed through two different manifestations. First, the distance dependence of the flux exchanged between two bodies

at different temperatures is different from the prediction from the macroscopic theory. This is now well established for large bodies, such as parallel-surfaces and sphere-plane configurations [1]. Second, the temperature dependence of the flux exchanged is also expected to be different in the near field [2,3], as sizes and temperatures are tightly connected [4]. Only moderate temperature differences (up to 400 K) between emitter and receiver were probed so far, and only few materials were tested. We therefore focus on near-field radiative heat transfer measurements between microspheres and planar substrates [5] for record temperature differences larger than 900 K, with the emitter being heated up to 1200 K [6]. This allows observing the temperature dependence of near-field radiative heat transfer for various materials (SiO_2, graphite and InSb). It is shown that the temperature exponent n of the near-field radiative power, ranging between 2 and 3 in various cases, is lower than that in the far field, which itself can deviate from n = 4 well-known in the Stefan-Boltzmann law. These results are obtained thanks to a careful calibration of thermal cantilevers by combined means of Raman thermometry and FEM simulations. They indicate that power increase due to decreasing distance and rising emitter temperature do not act with equal footing, which has key implications for energy harvesting such as thermophotovoltaics.

1:30 PM *EQ16.02.01
Controlling the Optical Properties of Conducting Oxides for Time-Varying Metasurface Applications Alexandra Boltasseva[1], Vladimir Shalaev[1], Soham Saha[1], Marcello Ferrera[2], Vincenzo Bruno[2], Michael Wood[3], Richard Schaller[4] and Benjamin Diroll[4]; [1]Purdue University, United States; [2]Heriot-Watt University, United Kingdom; [3]Sandia National Laboratories, United States; [4]Argonne National Laboratory, United States

The fast and large optical response changes in transparent conducting oxides (TCOs), namely, ITO and AZO, under external optical excitation have recently led to the demonstration of nonlinearity enhancements and all-optical addition of signal. In this talk, techniques to control the optical responses of TCOs will be discussed as well as nonlinear optical effects enabled by the so-called epsilon-near-zero (ENZ) region of the TCOs. Recent results on extending the ENZ regime from the visible to the mid-infrared wavelength region by utilizing metal- and optical doping will be reported. Specifically, we tailored the ENZ points of cadmium oxide from 11 µm to 5 µm by yttrium doping, to develop fast all-optical switches in the mid-IR regime. Secondly, utilizing undoped zinc oxide, we showed real-time control over the permittivity by interband pumping, achieving unity order refractive index change, and picosecond-speed reflectance modulation in the telecom regime. In addition, by employing titanium nitride with a nanosecond response, and aluminum-doped zinc oxide with a picosecond response, we tuned the switching speed of a metasurface from the nanosecond to the picosecond scale. This results could pave the way to designing novel nonlinear optical devices spanning the telecom to the mid-infrared regime.

2:00 PM EQ16.02.02
Electrolyte-Gated $La_{1-x}Sr_xCoO_{3-\delta}$ (LSCO) for Tunable Infrared Nanophotonics—Fundamental Optical Properties and Applications in Active Metasurfaces Rohan D. Chakraborty, Vipul Chaturvedi, Chris Leighton and Vivian E. Ferry; University of Minnesota Twin Cities, United States

Material systems with tunable optical properties are in high demand for mid- and far-infrared applications, including infrared sensing, thermal imaging, and radiative cooling. Such materials can also enable active metasurfaces, which can serve different optical functions simply by tuning the refractive index of a material layer. Here, we present the perovskite cobaltite $La_{1-x}Sr_xCoO_{3-\delta}$ (LSCO) as a new material candidate for tunable nanophotonics that demonstrates increased light modulation depth and convenient electrical control for infrared applications.

We focus on electrolyte-gated transistors featuring perovskite LSCO at $x = 0.5$ (LSCO50), which is a metallic ferromagnet with a low formation enthalpy and high diffusivity of oxygen vacancies. Using electrolyte gating with ionic liquids/gels, it has been shown that positive gate voltage and resulting oxygen vacancy formation in ~10-nm-thick LSCO50 drives a topotactic transformation from the metallic perovskite phase to an insulating oxygen-vacancy-ordered brownmillerite phase, $La_{1-x}Sr_xCoO_{2.5}$, and thus a metal-insulator transition (MIT).

Here, we show via *ex situ* spectroscopic ellipsometry and Kramers-Kronig consistent dispersion models that this electrochemically-induced MIT produces significant, nonvolatile refractive index changes between the perovskite and brownmillerite phases of LSCO50, both of which are air-stable. In particular, the insulating brownmillerite phase is a high-index, low-loss dielectric ($n > 3$, $k < 0.4$) in the mid-infrared, while the metallic perovskite phase remains highly lossy.

We then implement electrochemically-gated LSCO50 as the active layer in a reconfigurable, mid-infrared plasmonic absorber designed with finite-difference time-domain (FDTD) electromagnetic simulations. In the ungated state, strong optical losses in metallic-phase LSCO50 hinder surface plasmon resonance and yield a spectrum of higher reflectance, but the insulating phase accessed by electrochemical gating allows incident radiation to couple into highly-absorbing resonant modes, significantly lowering the reflectance of the metasurface. Such a device could enable many infrared applications including dynamic thermal imaging and infrared camouflage, and cements electrolyte-gated LSCO50 as a promising vehicle for tunable nanophotonics.

2:15 PM EQ16.02.03
Electrochemically Tunable Mid-IR Metasurface by Conducting Polymers Po-Chun Hsu; Duke University, United States

Metasurface design is a powerful approach to create exotic and desirable properties that do not appear in nature. The quasi-2D and deep-subwavelength structure suggests the device can be made ultrathin, lightweight, and flexible. By coupling the metasurface with mid-IR light, one can enhance performance or create new functionality in the frequency regime of phonons, which has wide applications in molecular vibrational spectroscopy, imaging, and thermal management. In particular, by employing index-tunable materials in metasurfaces, one can modulate the thermal radiation to stabilize the heat balance,

which can be a game-changer for future energy-efficient wearable/portable thermoregulation. This dynamic mid-IR metasurface device is orders of magnitude more efficient than traditional thermoregulation such as thermoelectric devices or resistive heaters because it controls the heat transfer coefficient rather than directly pumping heat. Although there are various ways to achieve tunable mid-IR metasurface, special considerations are needed to optimize the thermoregulation performance in tuning range and switching time.
In this talk, I will introduce our recent research progress in using conducting polymers for mid-IR emissivity tuning and comparative study for ordinary versus metasurface design. Conducting polymers are widely known for their electrochemically tunable optoelectronic properties, and they have the suitable plasmon frequency to work as a mid-IR plasmonic material. The change of carrier density is driven by electrochemical reaction, which implies large contrast. The switching speed is not as fast as electrostatic gating but nevertheless more than enough for wearable technology and room temperature thermoregulation. Despite the potential impacts on applications for personal health and space heating/cooling energy efficiency, mid-IR electrochromic properties of conducting polymers have not been thoroughly studied, limiting their utility for tunable metamaterials. I will share our study on conductive polymer charge transport and optoelectronic properties, hoping to enrich the material palette for tunable mid-IR materials.

Atomic Layer Deposited VO_2 Thin Films for Modulated Optoelectronic Devices Virginia Wheeler[1], Chase Ellis[1], Marc Currie[1], Jason Avila[1], Joshua Caldwell[2], Joseph Tischler[3], Austin Howes[4], Zhihua Zhu[2], David Curie[2], Richard Haglund[2], Ahmed Morsy[5], Romil Audhkhasi[5], Michelle Povinelli[5] and Jason G. Valentine[2]; [1]U.S. Naval Research Laboratory, United States; [2]Vanderbilt University, United States; [3]The University of Oklahoma, United States; [4]Northrop Grumman Corporation, United States; [5]University of Southern California, United States

VO_2 is a phase change material that undergoes a first order crystalline phase transition at a critical temperature (T_c = 68ºC), resulting in significant changes in intrinsic electrical and optical properties, especially in the infrared. Optical changes with this phase transition are of particular interest as passive and active components of optoelectronic devices, specifically for thermal regulation and modulated signaling. Realizing this type of device often requires the integration of thin, conformal VO_2 films with complex, non-planar structures (like metamaterials). Thus, atomic layer deposition (ALD) is an ideal deposition method in these cases. In this work, we will discuss the ALD process optimization and characterization of thin VO_2 films itself and subsequent integration into different optoelectronic structures for active modulation. In particular, we will present a few examples based on nanopillar arrays.

Traditional metal-based plasmonic materials suffer from high optical losses, which has promoted research towards alternative low-loss materials that can support plasmonic-like effects. One such approach employs phonon-mediated collective-charge oscillations (surface phonon polaritons, SPhPs) that are supported by nanostructured polar dielectric materials (SiC, AlN, etc), which inherently are low-loss. Geometric design of the nanostructures enables spectral tuning of resonant features between the longitudinal and tranverse optical phonons of the polar material, typically in the infrared regions. However, the spectral position and amplitude of these resonances remain fixed after fabrication. Integrating phase change materials with these structures provides a way to achieve active modulation of resonances.

As an example, nanopillar arrays were etched into SiC and AlN to create narrowband resonances in the long-wave infrared region. These structures were subsequently coated with ALD VO_2 films with different thicknesses (8-75nm). As-deposited VO_2 films are highly conformal and amorphous, and cause the resonances to shift and broaden due to the different dielectric environment. However, after annealing the films at 525°C in $6x10^{-5}$ Torr, the VO_2 films crystallize resulting in sharper resonances and spectral locations close to the initial uncoated structures. Temperature-dependence reflectance and emission measurements show that by heating through the VO_2 transition temperature, the amplitude of the resonances can be modulated. Full signal modulation (ie. on/off) requires at least a 16nm VO_2 film.

ALD VO_2 films can be applied to other optoelectronic pillar arrays derived from different, non-polar semiconductors, such as Si, to enable active focusing/defocusing or optical limiting [1] using metasurface concepts. Additionally, we have demonstrated the ability to use these in planar stacks for thermal homeostasis [2]. We will briefly go over several of these concepts the advantages and disadvantages of ALD VO_2 films in each.

Dynamic Infrared Metasurfaces Based on Phase Change Media Jason G. Valentine; Vanderbilt University, United States

The use of nano and microstructured metasurfaces provides new freedom in infrared optic design as it allows precise control over the phase, amplitude, and polarization at a surface. Realizing dynamic tuning of these properties is a critical step towards achieving more advanced functionality and improved operational bandwidth. In this talk, I outline several approaches towards achieving dynamic tuning by incorporating metasurfaces with phase change media. I will explore both thermal and electrical activation of these metasurfaces for achieving dynamic tunability in both the infrared regime. The metasurface can be used for a variety of purposes including spectral signature control, thermal management, and adaptive systems.

Full Control of Far-Field Thermal Radiative Properties with Nonreciprocal Materials and Nanophotonic Designs Bo Zhao[1,2]; [1]Stanford University, United States; [2]University of Houston, United States

Objects around us constantly emit and absorb thermal radiation. The basic properties that characterize these two processes are emissivity and absorptivity, respectively. For reciprocal systems, the emissivity and absorptivity for a given direction, polarization, and frequency are tightly restricted to be equal by Kirchhoff's law of thermal radiation [1]. This restriction limits the control of thermal radiation and contributes to an intrinsic loss mechanism in photonic energy harvesting systems.

Existing approaches to violate Kirchhoff's law typically utilize conventional magneto-optical effects in the presence of an external magnetic field. However, these approaches require either a strong magnetic field (~3T) [2] or narrow-band resonances under a moderate magnetic field (~0.3T) [3], because the nonreciprocal effect in conventional magneto-optical materials is usually weak in the thermal wavelength range. The nonreciprocal effect is also only confined in a relatively narrow angular range. Meanwhile, in these designs, the angular distribution of emissivity and absorptivity is symmetric with respect to the normal direction, meaning that the emissivity in the θ direction is always equal to the absorptivity in the -θ direction. This equality significantly restricts the ability to separately control the emissivity and absorptivity in the angular degree of freedom.

In this talk, I will show that the axion electrodynamics in magnetic Weyl semimetals can be used to construct strongly nonreciprocal thermal emitters [4,5]. Such a thermal emitter can near completely violate Kirchhoff's law over broad angular and frequency ranges, without requiring any external magnetic field. Meanwhile, I will introduce a general coupled-mode theory framework for nonreciprocal thermal emitters. I will discuss the necessary conditions for the nanophotonics design to decouple the link between emissivity in the θ direction and the absorptivity in the -θ direction so that one can achieve complete control of emissivity and absorptivity in the angular degree of freedom. Finally, I will present a case study using nanophotonic design and magnetic Weyl semimetal to achieve nonreciprocal thermal emission in semitransparent emitters [6].

Thermochromic Coatings for Energy-Efficient Smart Windows Resulting from Phase Separation of VO_2 in SiO_2 on SiO_2-Coated Float Glass Cindy Yeung[1,2], Roberto Habets[1,2], Luc Leufkens[1,2], Fallon Colberts[3], Kathleen Stout[3], Marcel A. Verheijen[4,5], Zeger Vroon[3,1,2], Daniel Mann[1,2] and Pascal Buskens[1,2,6]; [1]TNO, Netherlands; [2]Brightlands Materials Center, Netherlands; [3]Zuyd University of Applied Sciences, Netherlands; [4]Eurofins Material Science Netherlands BV, Netherlands; [5]Eindhoven University, Netherlands; [6]Hasselt University, Belgium

Vanadium dioxide displays thermochromic properties based on a reversible metal-insulator transition which is caused by the structural phase transition from monoclinic VO_2 (M) to rutile VO_2 (R) and *vice versa*. We developed a single layer coating comprising VO_2 (M) and SiO_2 starting from a mixture of pre-oligomerized tetraethoxysilane and vanadium(IV) oxalate dissolved in an alcohol-water mixture [1,2]. After dip coating and subsequent solvent evaporation under ambient conditions, we obtained a homogeneous mixture of both components as xerocoat on silica-coated float glass. During the thermal anneal at 450°C in inert gas atmosphere phase separation occurred. This yielded coatings comprising V-rich and Si-rich nanodomains, the size and shape of which depended on the V/Si ratio in the starting mixture. Size and shape of the nanodomains were determined by performing scanning transmission electron microscopy – energy dispersive X-ray studies on scraped off coating material. The thermochromic coatings resulting from these experiments combine high visible light transmission $T_{vis} > 60\%$ with a large solar modulation $\Delta T_{sol} \geq 10\%$, as demonstrated via UV-vis-NIR spectrophotometric analyses performed below and above the switching temperature. In addition to T_{vis} and ΔT_{sol}, the switching hysteresis width studied. The relationship between the coating size, shape and concentration of VO_2 domains and the optical properties of the coating was studied in detail. Additionally scraped off coating material has been isolated and measured with differential scanning calorimetry to determine the switching enthalpy and relate that to the amount of VO_2 (M) in the obtained mixture of vanadium oxides. When applied in insulating glass units, the coating has a positive impact on energy savings for heating and cooling of buildings in intermediate climates, which is demonstrated through energy performance simulations. For a typical house in the Netherlands, energy savings up to 24% were forecasted [3]. In addition, we demonstrate a coating life time of > 10 years in insulating glass units through accelerated life time tests, including switching fatigue studies.

Optical Properties of Oxides at High Temperatures Jonathan Kaufman and Keivan Esfarjani; University of Virginia, United States

We present the results of our density functional theory simulations of the optical properties of some oxides at high temperature.
To validate, we simulate the band structure and dielectric constant of one of the archetypal oxides for which many experimental data is available i.e. MgO. To overcome the gap underestimation, we use the GGA+U approximation. At high temperatures, defects affect the optical properties, and therefore we simulate the dielectric constant of this system with O and Mg vacancies as the dominant defects. They induce respectively donor and acceptor levels in the gap and cause interband transitions of lower energies. The change of the dielectric constant as a function of defect concentration will be discussed in this work.

5:00 PM EQ16.03.05
Giant Optical Anisotropy in Quasi-1D Hexagonal Perovskite-Derived Chalcogenide $A_{1+x}TiS_3$ (A=Sr, Ba) Boyang Zhao[1], Jad Salman[2], Guodong Ren[3], Hongyan Mei[2], Shantanu Singh[1], Shanyuan Niu[1], Arashdeep Thind[3], Huandong Chen[1], Rohan Mishra[3], Mikhail A. Kats[2] and Jayakanth Ravichandran[1,1]; [1]University of Southern California, United States; [2]University of Wisconsin–Madison, United States; [3]Washington University in St. Louis, United States

Birefringent and dichroic crystals are critical building blocks for devices such as polarizers, filters, and phase matching elements in optical systems. However, in the mid-wave (MWIR) and long-wave (LWIR) infrared spectral ranges, there is still a shortage of optically anisotropic materials. In this work, we show perovskite-derived chalcogenides—$A_{1+x}TiS_3$ (A=Sr, Ba)—are a platform for achieving giant optical anisotropy across the MWIR and LWIR and can play a key role in next-generation infrared optics. We grew high-quality $A_{1+x}TiS_3$ crystals of various shape and orientation by chemical vapor transport. Electron microscopy studies revealed 1D chains of face-sharing TiS_6 octahedra with a highly anisotropic electronic structure, which infers a large optical anisotropy. We used polarized infrared spectroscopy combined with spectroscopic ellipsometry to extract the optical properties of these materials and discovered refractive-index differences between the ordinary and extraordinary axes of up to two across the MWIR and LWIR, as well as large dichroism. We applied Density Function Theory (DFT) on $A_{1+x}TiS_3$ structure and discovered that such optical anisotropy originates from the structural modulation of TiS_6 octahedral. We anticipate $A_{1+x}TiS_3$ (A=Sr, Ba) and other quasi-1D materials will be useful for next-generation imaging and sensing applications, especially for miniaturized photonic devices. This study also lays ground for material designs towards highly electronic and optic anisotropic materials.

Programable Hyperbolic Polaritons in van der Waals Semiconductors Aaron Sternbach[1], Sanghoon Chae[1], Simone Latini[2], Andrey Rikhter[3], Yinming Shao[1], Baichang Li[1], Daniel Rhodes[4], Brian Kim[1], Peter Schuck[1], Xiaodong Xu[5], Xiaoyang Zhu[1], Richard Averitt[3], James Hone[1], Michael Fogler[3], Angel Rubio[2,6] and Dmitri Basov[1]; [1]Columbia University, United States; [2]Max Planck Institute for the Structure and Dynamics of Matter, Germany; [3]University of California, San Diego, United States; [4]University of Wisconsin–Madison, United States; [5]University of Washington, United States; [6]Center for Computational Quantum Physics (CCQ), Flatiron Institute, United States

Programing materials with light and interrogating their properties within the resultant transient states is an important goal of modern condensed matter physics. Polaritons - where strong dipole active resonances hybridize with photons - are central to transient nano-optical exploration. Infrared nano-imaging can be used to detect these polaritonic waves, yeilding detailed information on the properties of host materials that support these polaritons. The naturally layered class of van der Waals (vdW) materials are particularly intriguing in this regard due, in-part, to their often strongly anisotropic behavior. In materials hosting both strong anisotropy and strong dipole active resonances sub-diffractional polaritonic wave packets, that travel as conical rays with hyperbolic dispersion throughout the materials' bulk, can emerge. We utilized femtosecond photoexcitation to agitate crystals of the vdW semiconductor WSe2 and interrogated these crystals in the transient state with near-field optical microscopy [1]. Our time-resolved nano-imaging data reveals key signatures of optical hyperbolicity, appearing on the sub-picosecond timescale.

1:30 PM *EQ16.05.01
Thermal and Electrical Properties of Some of the Narrow Gap Semiconductors and Topological Conductors Mona Zebarjadi; University of Virginia, United States

Narrow gap semiconductors and topological semimetals/metals are important in infrared applications and can be used for harvesting radiative thermal energy. The band structure of these materials can change with temperature when the material goes through a phase change and it affects the material's thermal, electrical, and magnetic properties. In this talk, I will discuss several materials, their band structure in different phases, and how the band structure and the electron-phonon scattering affect the electrical, and thermomagnetic properties. I will discuss our results on NbSe2 sample, a topological metal/semimetal, that goes through charge density wave (CDW) transition, and superconducting phase at lower temperatures. The band structure of both 1T and 2H phase appears semimetallic in the normal phase while a gap opens up in the CDW phase. I will also discuss the Mo1-xWxTe2 single crystal samples, another topological semimetal, which are going through 2H-1T phase change, and show how the Seebeck and the Nernst coefficients are affected. Finally, I will discuss the case of FeSb2, a highly correlated narrow-gap semiconductor with debates on the effect of phonon-drag as opposed to correlation on its transport properties and specifically on the Seebeck coefficient.

2:00 PM *EQ16.05.02
Metastructure Design for Actively Tailoring Thermal and Nonthermal Radiation Harry A. Atwater; California Institute of Technology, United States

Photonic designs with active elements have the potential to exquisitely tailor the properties of thermal radiation, including modulation of the intensity, phase, linewidth, wavevector and scattered wavefront. We describe the coupling of tunable permittivity graphene elements to resonant nanophotonic structures for i) modulation of emissivity between 10% and 97% by Fermi level modulation, ii) active steering and focusing of thermal radiation, iii) dramatic emission line narrowing of thermal emitters from linewidths characteristic of blackbody emitters to those more closely resembling light-emitting diodes.

Pulsed laser excitation of graphene is shown to exhibit ultrabright non-thermal emission, arising from spontaneous emission of plasmons generated by cooling of the nonequilibrium carrier distribution. Our observation of the non-thermal contribution of Fermi-level-dependent radiation constitutes the first experimental demonstration of hot plasmon emission arising from a photo-inverted carrier distribution in graphene. This previously unobserved mechanism generates bright nonthermal radiation in the far field, as the generated plasmons are outcoupled from the excited graphene by gold nanoantennas, with implications for design of future ultrafast and ultrabright mid-infrared emission processes and light sources.

For the vast majority of materials, Kirchoff's Law dictates that absorptivity and emissivity are equal for any particular wavelength or angle, a property that has fundamental implications for infrared photonics. While previous theoretical work has suggested that Kirchoff's Law could be violated using magneto-optical materials, the required magnetic field strengths were impractically large. We demonstrate in the present work the first definitive experimental observation of Kirchoff Law violated in magnetoelectric heterostructures. We find that the required magnetic field for reciprocity breaking can be reduced by over an order of magnitude, bringing it within the range of practical experiments with simple permanent magnets. By combining the magneto-optical character of doped InAs crystals in the epsilon-near-zero wavelength regime with guided mode resonance waveguides, we have observed violations of Kirchoff's Law as large as 50% in experiment. These results open up new opportunities for the manipulation of thermal radiation in the long wavelength infrared regime.

2:30 PM EQ16.05.03
Ultrafast Polariton Dynamics Following Remote Heating via Mid-Infrared Pump-Probe Spectroscopy John A. Tomko[1], William D. Hutchins[1], Daniel M. Hirt[1], Joseph Matson[2], Katja Diaz-Granados[2], Joshua Caldwell[2] and Patrick E. Hopkins[1]; [1]University of Virginia, United States; [2]Vanderbilt University, United States

The reduced dimensions of electronic devices lends itself toward rapid bottlenecks in thermal dissipation; heat conduction becomes limited due to interface scattering of thermal carriers when material geometries approach the nanoscale. Thus, additional thermal transport pathways are necessary in further developing next-generation RF and power electronics. In this work, we consider two potential means of doing so: i) enhancing interfacial heat transport rates through non-equilibrium processes and ii) accessing polariton-mediated transport mechanisms.

In the first case, we elucidate a novel energy transduction pathway that can efficiently transfer heat across metal-semiconductor interfaces, where traditional thermal boundary resistances greatly mitigate heat flow. This energy transfer mechanism, termed Ballistic Thermal Injection, is demonstrated in gold/cadmium oxide (CdO) heterostructures. We find that under non-equilibrium conditions, photo-excited metals can undergo an electron-mediated ballistic energy transfer process that can remotely modulate the electronic environment of an underlying degenerate semiconductor; namely the plasmonic resonance of this semiconductor. We term this effect 'ballistic thermal injection' (BTI) to distinguish it from the well-studied charge injection effects caused by hot electrons traversing an energy barrier. Our results are explained through transient reflectivity (TDTR) measurements to understand the fundamental carrier dynamics at the Au/CdO interface. Additionally, we perform mid-infrared, ultra-fast pump-probe experiments to obtain spectral, temporal, and ultimately spatial resolution of the electronic environment within the CdO layer following excitation of the Au film. Ultimately, the carrier dynamics derived from the transient spectra fully agree with our TDTR results, and can only be accurately modeled by the BTI process rather than by charge injection.

With regards to polariton-mediated heat transfer pathways, from an experimental perspective, many of the recent advances have been investigated from the perspective of thermoreflectance measurements, such as TDTR or FDTR, where the role of these potential thermal carriers is inferred by trends in thermal conductivity measurements. While certainly of merit, these methods provide an experimental measure of the average temperature of a system rather than a direct probe of the vibrational carrier of interest. In this work, we further employ our tunable-wavelength, mid-infrared ultrafast pump-probe spectroscopy system to perform such a measurement. In particular, we investigate the phonon dynamics of both h-BN and SiC following pulsed excitation of a metal contact, providing a direct measure of the temporal dynamics of the optical phonon mode, the highly-reflective Reststrahlen band, and phonon-polaritons in these material systems during heating. These results demonstrate a unique regime of polariton-mediated heat transfer: the generation of a thermal radiation-induced phonon polariton. In other words, we demonstrate the ability to stimulate phonon polaritons in h-BN via remote heating of a metal contact, thus allowing for enhanced radiative heat transfer in device heterostructures.

2:45 PM EQ16.05.04
Hyperbolic Shear Polaritons in Low-Symmetry Crystals Nickolai Passler[1], Xiang Ni[2], Guangwei Hu[3], Joseph Matson[4], Martin Wolf[1], Matthias Schubert[5], Andrea Alu[2], Joshua Caldwell[4], Thomas G. Folland[6] and Alexander Paarmann[1]; [1]Fritz Haber Institute, Germany; [2]The City College of New York, United States; [3]National University of Singapore, Singapore; [4]Vanderbilt University, United States; [5]University of Nebraska–Lincoln, United States; [6]University of Iowa, United States

The lattice symmetry of a crystal is one of the most important factors in determining its physical properties. Low-symmetry crystals offer powerful opportunities to control light propagation, polarization, and phase. When such materials featuring extreme optical anisotropy, they can support a hyperbolic response, enabling coupled light-matter interactions, also known as polaritons, with highly directional propagation and compression of light to deeply sub-wavelength scales. In this talk we show how low-symmetry crystals can support hyperbolic shear polaritons, a new polariton class arising in the mid- to far-infrared due to shear dissipation in the dielectric response. This feature can emerge in materials where the dielectric tensor cannot be diagonalized, that is, in low-symmetry monoclinic and triclinic crystals where multiple damped oscillators with non-orthogonal relative orientations contribute to the optical response. This results in a non-zero complex off-diagonal terms in the dielectric tensor which cannot be removed by coordinate rotation. Hyperbolic shear polaritons complement previous observations of hyperbolic phonon polaritons in orthorhombic and hexagonal crystal systems, unveiling new features, such as the continuous evolution of their propagation direction with frequency, tilted wavefronts, and asymmetric responses.
As an exemplar case, we will describe the hyperbolic shear polaritons supported by the polar optical phonons of the monoclinic semiconductor β-Ga_2O_3. We will describe an approximate framework for how to classify polaritons in low-symmetry materials with non-orthogonal oscillators, and how this predicts a continuous rotation of the polariton direction frequency. We will then go on to experimentally demonstrate how hyperbolic shear polaritons can be measured using orientation sensitive prism type coupling experiments. Finally, we will show the specific role of the off-diagonal terms play in creating new types of light propagation, and how this influences our treatment of the polaritons. This interplay between diagonal loss and off-diagonal shear dissipation in the dielectric response of these materials has implications for new forms of non-Hermitian and topological photonic states. We anticipate that our results will motivate new directions for polariton physics in low-symmetry materials, which include geological minerals, many common oxides, and organic crystals, significantly expanding the material base and extending design opportunities for compact photonic devices.

Coherent Thermal Emission by Metasurfaces Zongfu Yu; University of Wisconsin--Madison, United States

Engineering the coherent properties of thermal emission plays an important role in many applications, such as energy harvesting, light sources, imaging and remote temperature sensing. Whereas thermal emission from bulk materials is generally incoherent, it has been shown that structured material, which have at least one of its structure parameters comparable with the thermal wavelengths, can greatly modify the coherence of thermal emission due to excitation of optical modes in the photonic structures. Most of existing works so far can only realize simple function such as spectral and directional selectivity. More complex control such as focusing and holography, remains difficult to achieve. The limited control of thermal emission is a result of the simple structures used in most previous works, which are either periodic structures or small structures whose sizes are around the wavelength of thermal photons. They do not offer enough degrees of freedom to accomplish complex control. To overcome this limit, we use large-area emitters with inhomogeneous structures that offer a large design space. Fine tuning the structural features allows us to exploit collective wave effects of thermal photons and to realize sophisticated control of thermal emission such as focused thermal emission and thermal holography.

5:00 PM EQ16.06.03
Beyond Traditional Polyethylene Fibers for Passively Cooling Monomaterial Textiles Volodymyr Korolovych[1] and Svetlana V. Boriskina[1,2]; [1]Institute for Soldier Nanotechnologies, Massachusetts Institute of Technology, United States; [2]Massachusetts Institute of Technology, United States

Considering the adoption of the sustainable circular bioeconomy, polyethylene (PE) fibers produced from green, renewable raw material are becoming more and more critical for everyday clothes, bedding textile and wearables due to their low environmental footprint and combination of material low-cost, durability with lightweight, high UV resistance and infrared (IR) transparency. [1-4] It is not surprising that the unique properties of green PE can be exploited to engineer high-performance sustainable fibers with mechanical properties tunable by design. Here, we explore the role of polyethylene molecular architecture in engineering mechanical properties and surface morphology of fibers based on the traditional fossil sourced raw PE and sugarcane-derived, renewable raw PE material. A range of fibers with different material parameters have been fabricated by a low-cost melt-extrusion method, mechanically and optically characterized, and classified according to their crystallographic structure as well as elongation, strength, recovery properties, and surface morphology. Differential scanning calorimetry and X-ray scattering techniques confirmed that by combining precise engineering of molecular structure we can adjust structural disorder in PE fibers, which results in crystallinity of fibers ranging from ~8% to ~60% and different crystallite orientation along the fiber axis. This tunability of the fiber molecular structure translates into a wide range of elongation at break, specific stiffness and specific strength values as well as tunable infrared transparency and thermal conductivity values. These results demonstrate feasibility of low-cost, large-scale fabrication of green PE fibers with a wide range of mechanical performance, smooth fiber surfaces, and variable cross-sectional shapes, paving the road to engineering mono-material high-performance sustainable textiles. These mono-material textiles can find applications in passive cooling technologies and are 100% recyclable at the end of their lifecycle.

This work was supported by the DEVCOM Soldier Center through the US Army Research Office (W911NF-13-D-0001), the Advanced Functional Fabrics of America (AFFOA) Institute (W15QKN-16-3-0001), the MIT Deshpande Center, and the US Department of Energy (DE-FG02-02ER45977). We thank B. A. Welsh (DEVCOM SC) for help with PE fiber fabrication and Braskem and Dow Chemical Company for providing raw olefin polymers.

5:15 PM EQ16.06.04
Enhancing Passive Radiative Cooling in Solar Modules Using Microstructures with Mie-Like Resonances Evelijn Akerboom[1], Tom Veeken[1], Chris Hecker[2] and Albert Polman[1]; [1]AMOLF, Netherlands; [2]University of Twente, Netherlands

Photovoltaic systems show a strong reduction in conversion efficiency when their temperature rises due to hot carrier cooling and non-radiative recombination in the solar cells. One key factor that determines the steady-state cell temperature is the radiative cooling rate: every solar cell shows spontaneous emission of infrared light. The spontaneous emission is determined by the emissivity, which is linked to the absorptivity by Kirchhoff's law (ε=A=1-R-T). To achieve the maximal radiative cooling rate for a silicon solar cell, and given the absorption spectrum of the earth's atmosphere, the emissivity should be minimal in the spectral range from the Si bandgap at 1.1 to 4 micron and be maximal beyond that range.

Here, we propose two designs based on resonant microstructures; one for bare silicon solar cell and a second for a silica-based solar module glass. Both designs enhance the emissivity, and hence the radiative cooling rate, by reducing the reflection and transmission in a well-defined spectral range beyond 4 micron. They effectively enhance the absorption of infrared light. The design is based on Mie-like resonances in spherical or cylindrical structures that show strong forward scattering of light and thereby decrease the reflectivity. Finite-difference-time-domain (FDTD) simulations are used to optimize the geometry of the radiative cooling microstructures, by minimizing the reflectance in the infrared.

For the bare silicon solar cell, we find an optimized design composed of a close-packed hexagonal array of glass microspheres (diameter 20 micron) that is fabricated by drop casting from an aqueous suspension on silicon. The hemispherical reflectivity of the stack is measured using Fourier Transform Infrared Spectroscopy (FTIR) with an external integrating sphere. The measured reflectivity of bare silicon is reduced from 80 to 10 percent by adding the close-packed monolayer of glass spheres, for wavelengths larger than 7 micron.

To determine the radiative cooling power we measure, using a thermocouple, the temperature of different designs under direct sunlight on a sunny summer day in Amsterdam. The preliminary results of the silicon covered with glass spheres, show a clear decrease in temperature of approximately 5 degrees with respect to the bare silicon reference under solar illumination. Reference reflectivity measurements at wavelength below the Si bandgap show the effect is not due to reduced incoupling of below-gap sunlight into the cell, hence demonstrating a significant radiative cooling effect.

For the silica-based solar module glass, we use a periodic hexagonal array of quartz cylinders (diameter 3.5 micron, height 2.25 micron, pitch 6.13 micron). The cylinders are fabricated into a thin quartz plate with UV lithography and reactive ion etching using C_4F_8/Ar. The micropatterned plate is then placed on top of a silicon sample. The unpatterned stack shows a strong reflection peak at 9 micron, due to a stretching vibration in the quartz crystal. This peak is reduced from 75 to 30 percent, due to the forward scattering of the induced electric dipole in the microcylinders.

The new radiative cooling microstructure design concept can be applied to every kind of solar cell, with or without module glass. The resonant radiative cooling concept can be applied to all devices operating in outside ambient that benefit from a low operation temperature.

Near-Field Thermophotonic Devices with AlGaAs Emitters and Cells Julien Legendre and P.-Olivier Chapuis; CNRS-CETHIL, France

Thermophotonics (TPX) is a technology close to thermophotovoltaics (TPV), where a heated light-emitting diode (LED) is used as the active emitter of the system [1]. By doing so, the emission profile can be tuned: initially in the infrared range, it can be shifted by means of electroluminescence to a spectral range matching better the gap of a photovoltaic cell. With the development of LEDs and the increase of their achievable quantum efficiency, TPX has come out as an attractive concept for both energy harvesting and refrigeration [2]. The many studies on near-field (NF) thermal radiation and their application into efficient NF-TPV devices [3] highlight the possibility to extend the concept to near-field thermophotonics (NF-TPX) [4], where enhanced energy conversion is due to both electric control and wave tunneling.

This contribution analyzes numerically the capabilities of NF-TPX systems. Several methods modelling the charge carriers behaviour for NF-TPV systems [5-6] are compared for NF-TPX in terms of precision and computation time. For both the LED and the PV cell, the capabilities of PN and PIN AlGaAs junctions are analyzed. The results include detailed IV characteristics around the maximum power point, highlighting in particular the advantages in comparison to far-field TPX and NF-TPV. The impact of the doping levels and the thickness of each element are amongst the studied parameters.The capabilities of NF-TPX to harvest energy are assessed for thermal sources of few hundreds of degrees Celsius [7].

Photonic Multilayer Structure for Near-Infrared Blocking as Energy-Saving Window Jiwon Kim[1], Sangwon Baek[1], Jae Yong Park[1], Kwang ho Kim[2] and Jong-Lam Lee[1]; [1]POSTECH, Korea (the Republic of); [2]Pusan National University, Korea (the Republic of)

Blocking near-infrared (NIR) is indispensable for saving energy consumed to maintain an interior temperature in buildings. However, it is hard to achieve both high visible transmittance and high NIR reflectance for energy-saving windows. Here, we demonstrate a TiO_2/Ag/TiO_2/SiO_2/TiO_2 multilayer film on a glass substrate to block the entire NIR ($800 \leq \lambda \leq 2500$ nm) while maintaining high visible transmittance. We first design and optimize the thickness of a TiO_2/Ag/TiO_2 structure; the metal layer reflects NIR and the dielectric layers increase visible transmittance with zero reflection condition. To further enhance NIR-blocking efficiency, we implement a TiO_2 back reflector with a SiO_2 spacer to TiO_2/Ag/TiO_2 structure. TiO_2 layer with high refractive index sandwiched between glass substrate and SiO_2 with low refractive indices can induce additional Fresnel reflection without sacrificing transmittance in visible light. The optimal photonic multilayer film shows solar energy rejection 89.2% (reflection 86.5%, absorption 2.7%) in NIR, visible transmittance 69.9%. Furthermore, the blocking capability in NIR of the designed multilayer film is maintained over a wide range of incident angles of light.

Ultrafast Phonon Polariton Dynamics Resolved via Femptosecond Mid-Infrared Spectroscopy William D. Hutchins[1], Daniel M. Hirt[1], John A. Tomko[1], Patrick E. Hopkins[1], Joshua Caldwell[2], Joseph Matson[2] and Katja Diaz-Granados[2]; [1]University of Virginia, United States; [2]Vanderbilt University, United States

As electronic devices continue to reduce towards nanoscale dimensions, understanding heat transport mechanisms at these scales becomes vital. In most non-metallic materials heat dissipates according to the movements of phonons or phonon-like waves. The efficiency of this phonon-mediated heat transport is dictated by various characteristics of these modes including their lifetime, scattering rate, and velocity. Thus, characterization of these properties is crucial to making more effective devices. From an experimental perspective, the majority of recent advances in such characteristics stems from ultrafast thermoreflectance measurements, namely TDTR and FDTR, where phonon transport is inferred from trends in thermal conductivity of materials. In other words, these methods measure the average temperature of a material following pulsed excitation rather than directly monitoring the individual mode of interest. In this work, we develop a novel ultrafast pump-probe technique that allows us to directly couple to vibrational modes of interest with sub-picosecond time resolution, thus characterizing the aforementioned phonon dynamics.

Our technique relies on a wavelength tunable mid-infrared probe pulse, allowing us to directly resonate with vibrational heat carriers, thus providing a direct measure of phonon dynamics in nanoscale material systems. In particular, we investigate the phonon dynamics in hexagonal boron nitride (h-BN) and silicon carbide; the high frequency optical modes in these materials lends itself to the potential for manipulation of thermal radiation in near room temperature conditions. Thus we investigate the ultrafast temporal dynamics of the transverse optical (TO) modes, the high reflectivity Reststrahlen band, and a unique regime of polaritonic heat transfer: the generation of a thermal radiation-induced phonon polariton.For the first time, we experimentally demonstrate the ability to stimulate phonon polaritons in h-BN through remote heating of a metal contact. Our results open the door for future experiments to manipulate and guide phonons via heterostructures, which could increase thermal efficiency of microelectronics.

Late News: Conduction-radiation Coupling and Slowing-down of Thermal Relaxation Between Two Closely Separated Solids Riccardo Messina, Marta Reina and Philippe Ben-Abdallah; Université Paris-Saclay, France

Two bodies at different temperatures experience a photon-mediated heat exchange, even when separated by vacuum. This radiative heat flux is limited by Stefan-Boltzmann's law in the far field, i.e. when the separation distance between the bodies is large compared to the thermal wavelength. The pioneering works of Rytov, Polder and van Hove and the development of the theoretical formalism of fluctuational electrodynamics allowed to show that in the near-field regime the heat flux can instead exceed this limit even by orders of magnitude for shorter distances. Surprisingly, the huge majority of works exploiting fluctuational electrodynamics neglect the possible existence of a temperature gradient due to the coupling between radiative heat transfer between the bodies and conduction within each body, and assume a perfectly uniform temperature inside each of them. We have recently developed a theory to describe the conduction-radiation coupling between solids of arbitrary size separated by a subwavelength gap [1]. The essence of this approach is based on the combination of Boltzmann's equation to deal with the transport of heat carriers inside the solids (valid for any heat-transport regime) and fluctuational electrodynamics to calculate the radiative power locally dissipated in each body. By means of this approach we show that the interplay between conduction and radiation can indeed result in an observable temperature profile within each solid. Moreover, we show that, as a result of this temperature profile, the radiative heat flux exchanged between two parallel slabs at nanometric distances can be orders of magnitude smaller than the one predicted by the conventional theory. These results could have important implications in the fields of

nanoscale thermal management, near-field solid-state cooling, and nanoscale energy conversion. By exploiting our formalism, we have also highlighted a significant slowing-down of the thermal relaxation process [2] in the extreme near-field regime at distances where the heat flux exchanged between the two solids is comparable or even dominates over the flux carried by conduction inside each solid. This mechanism, leading to a strong effective increase of the system thermal inertia, should play an important role in the temporal evolution of thermal state of interacting solids systems at nanometric and subnanometric scales.

Enhancing Light-Matter Interaction Using Ultrafast Q-Switching Pavel Shafirin; University of California, Los Angeles, United States

Using resonant structures for enhancing light-matter interactions is a popular topic of research. The field localisation that they provide allows to amplify all kinds of processes, such as absorption and nonlinear effects. One limiting factor of resonant structures is their limited bandwidth, especially for the high-Q resonances the bandwidth is too small to effectively interact with short laserpulses. In this work we present a method, that allows to resolve this issue by dynamically switching the Q-factor of the resonance and allowing short pulses to effectively couple to the resonant mode. We demonstrate the effect using a simple theoretical model based on coupled mode theory and then show a potential implementation of the technique using a dielectric metasurface that we model using FDTD. In both models we consider the using our approach to increase the efficiency of third harmonic generation and show a significant increase in the generated harmonic.

Shaping Asymmetric Responses for Infrared Light with Meta-Gratings Stavroula Foteinopoulou; University of New Mexico, United States

Photonic structures with asymmetric responses to impinging light are highly desirable across the EM spectrum, even more so for infrared (IR) light, as they introduce new capabilities for integrated beam manipulation as well as thermal management applications. Here we discuss the key principles leading to extreme asymmetry in reflection or in both reflection and transmission in metagratings comprising building-blocks that lack inversion symmetry along the propagation direction. Although counterintuitive, we explain how such extremely asymmetric responses in these passive systems are entirely consistent with the reciprocity principle. We further showcase examples relevant to highly efficient uni-directional thermal IR sources and directional higher-harmonic generation.

Late News: Configure Phonon Polaritons in van der Waals Materials Siyuan Dai; Auburn University, United States

The manipulation of light at small scales is one of the ultimate goals for nanophotonics. For this purpose, polaritons – hybrid light-matter waves that propagate in a confined length scale – are typically involved. Recent results of polaritons in van der Waals materials reveal a series of advances, including atomic scale localization, dynamic tunability, relative low-loss and topologically protected states. These advances are attributed to the unique physical properties in reduced dimensions and the configurability through van der Waals structuring and stacking. In this talk, I will show new merits of phonon polaritons that can be obtained through van der Waals configuration. I will talk about the tunability implemented into phonon polaritons by van der Waals heterostructuring hexagonal boron nitride with graphene and vanadium dioxide, where the polaritons can be tuned dynamically and reversibly via electrostatic gating and temperature control. I will also talk about the geometry and topology configuration of phonon polariton wavefront by twisting stacked slabs of molybdenum trioxide.

Current Flux Imaging of a Micromagnetic Electrofoil David Mayes[1], Maxwell Grossnickle[1], Farima Farahmand[1], Mark Lohmann[1], Mohammed Aldosary[1], Junxue Li[1], Vivek Aji[1], Jing Shi[1], Justin C.W. Song[2] and Nathaniel Gabor[1]; [1]University of California, Riverside, United States; [2]Nanyang Technological University, Singapore

Individual electrons in conductors are transported via diffusion, yet current-voltage characteristics in a device are governed by the collective flow of current along streamlines. Despite being at the core of our understanding of electronic and optoelectronic charge transport, the intrinsic global pattern of current streamlines - described by the Shockley-Ramo theorem - has never been imaged. Here, we unveil a microscopy method to image the streamlines along which current naturally flows through ultrathin photodetector devices. Combining scanning photovoltage microscopy with a highly uniform, rotating magnetic field, we probe the photoresponse of atomically pristine thermospintronic heterostructures composed of platinum on yttrium iron garnet (YIG). Under focused laser excitation, a local out-of-plane temperature gradient produces a corresponding out-of-plane spin current in the YIG layer by the Spin Seebeck Effect, which, according to the Inverse Spin Hall Effect, scatters electrons in the platinum layer away from an external, saturating magnetic field. Much like tracers in a wind tunnel map the flow of air around an aerodynamic airfoil, we use a scanning laser beam as a source of directional charge current to map the flow around precisely engineered wing shaped devices, or electrofoils. Photocurrent streamlines can be contorted, compressed or expanded by changing the shape and angle of attack of the electrofoil devices. By imaging and manipulating photocurrent streamlines, we demonstrate an intensive imaging technique to visualize and characterize charge flow in quantum materials.

SESSION EQ16.09: Infrared 2D Materials

Infrared s-SNOM Imaging and Spectroscopy of Polaritons at STO-Based Surfaces and Interfaces Yixi Zhou, Weiwei Luo, Margherita Boselli, Adrien Bercher, Adrien Waelchli, Willem Rischau, Stefano Gariglio, Jean-Marc Triscone and Alexey Kuzmenko; University of Geneva, Switzerland

Infrared spectroscopy probes charge, spin and lattice dynamics and therefore is a useful tool to elucidate the physical origin of ordered phases in quantum oxides and interfaces. However, conventional infrared measurements are diffraction limited and do not provide nanoscale resolution. The technique of scattering-type scanning near-field optical microscopy (s-SNOM) based on the near-field interaction between an atomic-force microscope (AFM) tip and the sample, overcomes the diffraction limit, while keeping all the advantages of conventional spectroscopy. We present variable temperature s-SNOM mapping and infrared near-field spectra of surface phonon polaritons in SrTiO3 and coupled phonon-plasmon polariton modes in (nano-)structures realized at LaAlO3/SrTiO3 interfaces [1,2]. We report a long phonon-polariton propagation length exceeding 100 microns, which shows a significant temperature dependence. Our results suggest that strontium titanate and related oxide interfaces are potentially promising for (far-)infrared plasmonic applications.

Multipole-Engineered van der Waals and High-Refractive-Index Nanostructures Viktoriia Babicheva; University of New Mexico, United States

Transition metal dichalcogenides belong to the family of van der Waals materials and exhibit unique optical and electronic properties, including high tunability, strong nonlinearity, and anisotropy stemming from the van der Waals layers of the material [1]. Most importantly, these materials have a high refractive index and small non-radiative losses in the infrared spectral range. One can operate in the regime when the period of the nanoantenna array is comparable to the wavelength of multipole resonance of a single nanoantenna, which results in optical coupling between nanoantenna and the excitation of lattice resonances [2].

We consider various multipole excitations in such van der Waals and high-index nanostructures, and we design metasurfaces with the properties of directional scattering based on the excited multipoles. We take advantage of both the same-multipole couple and cross-multipole coupling of nanoscatterers in the lattice. We show the nanostructure Mie resonances and coupling between nanoantennas and substrate in the van der Waals nanoantenna array. Such nanoantenna arrays with collective excitation and Mie resonances have a high potential to be utilized in infrared metasurfaces and photonic elements.

The computational efforts are supported by UNM Research Allocations Committee, award RAC2022.

Dynamic Spectrum Optoelectronics with Black Phosphorus Hyungjin Kim[1,2] and Ali Javey[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Optoelectronics devices operating at different wavelength ranges require materials with different bandgaps. Although varying chemical compositions or integrating materials with different bandgaps could tailor the operating wavelength range depending on their target applications, increased complexity of their fabrication and necessity for precise control of thickness and/or compositions of materials have made it impractical for realization of actively tunable optoelectronics. Strain is an effective method to modulate the electronic and optical properties of semiconductors by mechanically altering their structure. Reversible and controllable tuning of bandgap in semiconductors can be achieved even within a single device *via* application of elastic strain. While bulk crystalline materials possess a limited maximum amount of strain, two-dimensional (2D) layered materials, such as graphene and transition metal dichalcogenides (TMDCs), can sustain much larger elastic strain, thus allowing for wide tuning of their optical bandgap using strain.
Black phosphorus (bP) has shown unique response upon strain, including anomalous strain dependence of bandgap, tunable van der Waals interactions, and piezoelectricity. These unprecedented strain-dependent characteristics are attributed to a puckered lattice structure of bP, of which bandgap has extraordinary sensitivity to strain. To fabricate devices where reversible strain application is viable, semiconductor materials are required to be in a form of thin membrane. As opposed to bulk crystalline semiconductors, this is readily achievable in bP due to its thin-membrane nature and by mechanical exfoliation to obtain the desired thickness of the bP membrane. Especially, bP with thickness greater than 6 layers has its bandgap spanning over near-infrared (NIR), short-wavelength infrared (SWIR), and mid-wavelength infrared (MWIR) ranges where there is a rapidly increasing demand for optical communications, thermal imaging, health monitoring, spectroscopy, and gas sensing. Strain-induced bandgap modification in bP has recently been studied by several studies and they have shown potentials of bP as tunable optical materials. However, despite the considerable interest in IR regime for optoelectronic applications, such as light-emitting diodes and photodetectors, a device-compatible approach towards tunable optoelectronics with high performance at room temperature is yet to be demonstrated.
Here, we present bP with strain-tunable bandgap and its applications for room-temperature infrared optoelectronic devices with actively variable operating wavelength ranges. Covering from 2.3 μm to 5.5 μm, we demonstrate wide-range tuning of bP bandgap with a combination of compressive and tensile strain. Repeatable and continuous tuning of electrically-pumped MWIR light emission is achieved by utilizing a strained bP-MoS_2 heterostructure on a flexible substrate. Moreover, the low Auger recombination velocity of bP offers much higher theoretical limit of the quantum efficiency in our tunable bP-LED, compared to other materials with similar bandgaps (e.g. InAs and PbSe). We further exploit strain-tunable bandgap of bP to develop a spectrally variable photodetector with high responsivity that can extend its cutoff wavelength by applied strain. Finally, by leveraging the tunable light emission properties of strained bP, we demonstrate multiplexed non-dispersive infrared (NDIR) gas sensing, where multiple gases (e.g. CO_2, CH_4, and H_2O) are detected using a single light source. Our approach bridges the existing technological gap in optoelectronics at infrared wavelength regimes, where III-V and II-VI materials have limited their widespread utilization due to their high cost and stringent requirement for fabrication process by epitaxial growth. Also, our solution decouples the complexity in the device structure and tuning capability in the operating wavelength range without the necessity for sacrificing its performance.

11:35 AM EQ16.09.05
Mid-Infrared Polarization Manipulation via Natural In-Plane Hyperbolic van der Waals Crystals Nihar R. Sahoo, Saurabh Dixit, Anuj K. Singh and Anshuman Kumar; Indian Institute of Technology Bombay, India

Mid-infrared (IR) spectral range has significant potential application in thermal imaging, free-space communication, molecule sensing and others. Thus mid-IR sources, detectors and other opto-electronic components have a vast demand in this era. Furthermore, polarized IR light is a valuable addition in IR imaging techniques as it can distinguish various features of an object. However, conventional wire grid mid-IR polarizers are bulky, designed using complex lithography techniques and exhibit form birefringence. Hence, the integration of conventional mid-IR polarizers with chip-scale devices is challenging. Recently, van der Waals (vdW) materials exhibiting natural in-plane hyperbolicity in the mid-IR spectral region, like α-MoO_3, have garnered research attention. These vdW single crystals demonstrate several benefits over conventional devices, e.g., non-lithographic fabrication approach, facile integration with nano-scale platforms and room temperature operation. In this work, we investigate the infrared optical response of α-MoO_3 thin film for the application of a reflecting type polarizer.

We fabricate the α-MoO_3 using the thermal physical evaporation technique and transfer the as grown α-MoO_3 flakes to a silicon substrate using the mechanical exfoliation method. XRD, HRTEM and SEED confirm the orthorhombic nature of MoO_3 flake. Further, polarization-dependent Raman studies reveal the in-plane anisotropic nature of α-MoO_3. Moreover, the optical response of α-MoO_3 thin film in the mid-IR spectral region displays anisotropic reflectance for p- and s- polarized incident light, which can be exploited as a reflecting type mid-IR polarizer. We explain our results as a manifestation of strong in-plane hyperbolic anisotropy of α-MoO_3 single crystals in the mid-IR spectral region. We verify these experimental results using full-wave numerical simulations and using semi-analytical model based on the transfer matrix method. We perform extensive device optimization and the optimized thickness of α-MoO_3 thin film lies between 1500 nm to 2500 nm where it shows an extinction ratio of more than 5 dB over a bandwidth more than (200 cm^{-1}) with reflectance above 60%. We further experimentally evaluate the temperature resilience of our device and discuss our findings in the context of polarizer performance metrics. This work opens up new avenues for naturally hyperbolic vdW thin-films to be utilized to realize sub-wavelength optical devices with ease of fabrication and chip-scale integration.

A Photothermal Generator via Solar Harvesting Through Spectral Selective Multilayer Transparent Thin Films Mengyao Lyu[1], Jou Lin[1], John Krupczak[2] and Donglu Shi[1]; [1]University of Cincinnati, United States; [2]Hope College, United States

To address the critical energy issues, the utilization of solar energy has been one of the main approaches to produce clean energy for many technical, environmental, and ecological advantages. Conventional solar harvesting has been limited to 2D surfaces such as photovoltaic (PV) solar cells. We report solar harvesting via multiple layers of thin films which are spectral-selectively rendered transparent. In this fashion, solar harvesting is transformed from 2D to 3D with much greater energy density. The key requirements are that these films must not only exhibit strong UV and NIR absorptions for harvesting sufficient solar photon energies, but also high average visible transmittance (AVT) for permitting light passing through many layers. We have designed and synthesized photothermal materials from two families of materials: iron oxide (Fe_3O_4@$Cu_{2-x}S$) and porphyrin compounds (chlorophyllin), both are optically characterized with significant UV and NIR absorptions and high AVTs. Analogous to multilayer capacitors, we have constructed a photothermal generator (PTG) with parallel multilayers of transparent thin films of Fe_3O_4@$Cu_{2-x}S$ and chlorophyllin sealed in a cuboid. As simulated solar light passing through these transparent films, they are photonically activated to generate sufficient heat on each layer, raising the maximum temperature to 76.1 °C. The thermal energy generated has increased from 5074.3 J (one layer) to 55, 465.8 J (ten layers) for the Fe_3O_4@$Cu_{2-x}S$ system, and increased from 3826.3 J (one layer) to 56, 143.9 J (ten layers) for the chlorophyllin system, both have more than tenfold of increase. The solar photothermal conversion efficiencies of the PTG have reached greater than 60% for both systems. Also discussed is the mechanism underlying the structural effects on optical absorption and photothermal heating.

Use of Time-Dependent Refractive Index Modulation to Achieve Strong Violation of Kirchhoff's Law Alok Ghanekar[1], Jiahui Wang[2], Shanhui Fan[2] and Michelle Povinelli[1]; [1]University of Southern California, Los Angeles, United States; [2]Stanford University, United States

Many naturally occuring materials obey Kirchoff's Law, the statement that the absorptivity and emissivity of a material are equal for any given wavelength and solid angle. This fundamental property both underlies and limits a variety of applications, from energy harvesting to remote sensing. In the last several years, there has been growing interest in strategies for breaking Kirchoff's Law, with effort focused on strategies using magneto-optical materials. However, these strategies require use of an external magnet for implementation. Here, we consider an alternate method, which instead uses time-dependent modulation of the material refractive index. This approach would eliminate the need for an external magnet, potentially allowing the violation of Kirchoff's Law in electronically modulated, semiconductor systems. In this work, we use numerical simulations to design a nonreciprocal infrared thermal emitter with strong Kirchoff violation.

We start with a dielectric grating that supports guided-mode resonances and impose a spatially- and time-varying index modulation. We calculate the conversion of incoming light to sideband frequencies using a coupled finite-element method (FEM) simulation formalism. For the lossless system, as in previous work, we find that modulation gives rise to nonreciprocal reflection effects. In the forward direction, mode conversion due to index modulation significantly reduces the reflection. In the reverse direction, the absence of mode conversion results in much higher reflection. We thus observe a strong direction-dependence to the reflected signal.

We then introduce loss into the system to create a material capable of thermal emission. We observe continued direction-dependence in the reflectivity, along with the emergence of a resonant reflection dip in the reverse direction. We then use a generalized coupled-mode formalism valid for time-modulated systems to relate the absorptivity and emissivity at a given angle and frequency to the scattering matrix of the modulated material. In the weak-modulation limit, we choose the modulation to correspond to the maximum conversion rate of the lossless system. In this case, we predict a large contrast between absorptivity and emissivity at wavelengths in the mid-infrared, using realistic modulation frequencies of 10's of GHz. In the strong-modulation limit, we further increase the modulation strength to observe directional Rabi splitting. In this case, we observe even higher contrast between emissivity and

absorptivity.

Our results thus suggest the feasibility of achieving violations of Kirchoff's Law without the use of magneto-optics, providing a route to the use of nonreciprocal emissive effects in a variety of novel energy conversion and sensing applications.

Room-Temperature GeSn Nanowires SWIR and MWIR Photodetectors Lu Luo, Simone Assali, Mahmoud R. Atalla, Sebastian Koelling and Oussama Moutanabbir; Polytechnique Montréal, Canada

Abstract: During the last decade, the opto-electronic properties of direct bandgap and metastable GeSn semiconductors have been intensively investigated from short-wave IR (SWIR: 1.5-3 μm) to mid-wave IR (MWIR: 3-8 μm) wavelengths.[1] By engineering materials properties a plethora of infrared photonic devices have been developed, such as lasers, LEDs, and photodetectors[2,3,4,5] However, GeSn thin films are typically under compressive strain due to the large lattice mismatch with Ge interlayer used in the growth on Si substrate. And plastic relaxation during lattice-mismatched growth results in the formation of defects and dislocations, thereby reducing device performance. By exploiting nanowire (NW) morphology, elastic strain can be relaxed due to the compliant nature of the nanoscale core, thus avoiding the formation of structural defects and resulting in a higher crystalline quality compared to thin film materials, without compromising optoelectronic properties.[6]
With this perspective, we discuss in this work discuss the opto-electronic devices made of Ge/GeSn core/shell NWs and operating at room-temperature across SWIR-MWIR wavelengths. NWs with a tunable Sn content ranging from 8 at.% to >20 at.% were grown in a CVD reactor using either a Si or Ge (111) substrate and their structural properties will be discussed down to the atomic level by combining Transmission Electron Microscopy (TEM) and Atom Probe Tomography (APT). Single Ge/$Ge_{0.92}Sn_{0.08}$ NW SWIR photodetectors that were fabricated on a SiO_2/Si substrate exhibit excellent light detection performance at room temperature, with a responsivity of 2.7 A/W under 1550 nm illumination at 1 V and an extended cutoff wavelength of 2.1 μm compared to the 1.6 μm typical to Ge. Moreover, the single NW photodetector shows a degree of polarization with the polarization ratio up to 32%. The back-gated single NW FET geometry allows to estimate the mobility in the Ge/$Ge_{0.92}Sn_{0.08}$ core/shell NW at 50 , which is two times higher than that in Ge NWs. The tunability of the cutoff wavelength of the NW photodetector from 2.1 μm to higher wavelengths up to 6 μm will be demonstrated using NWs at Sn content of 20 at.% and higher .and their performance will be discussed by combining temperature-dependent responsivity measurements The broadband tunability of GeSn NWs across the infrared range has a tremendous potential for the development of on chip data communication and sensing devices using scalable, Si-compatible fabrication processes.

Extended X-Ray Absorption Fine Structure Spectroscopy (EXAFS) Studies of Sn-Vacancy Defect Complexes in Optoelectronic Ge/Ge-Sn Core/Shell Nanowires John Lentz[1], Michael Braun[1], Apurva Mehta[2], Ryan Davis[2] and Paul McIntyre[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

Germanium-tin alloys may provide a path toward efficient mid-infrared (IR) wavelength optoelectronics in a materials system that is all group IV, and therefore chemically compatible with silicon-based complementary metal oxide semiconductor (CMOS) technologies. They, therefore, hold promise as a potential IR source for on-chip optical interconnects, and for monolithic integration of IR detectors with silicon circuitry. A direct bandgap can be achieved in Ge by incorporating a metastably high Sn composition of about 8–10 at%. However, the optoelectronic properties of these materials have been limited to date, which is thought to be caused largely by a high concentration of grown-in vacancies and vacancy-containing defect clusters. Isolated vacancies act as acceptor-type defects and are present due to the low-temperature at which these alloys are grown[1]. Moreover, complexing of Sn atoms and vacancies is theoretically predicted and can create trap levels near mid gap[2], thus promoting non-radiative carrier recombination. In order to measure the presence and behavior of these complexes in largely strain-free[3] single crystal Ge-Sn shells grown by reduced pressure chemical vapor deposition around Ge nanowires, we have used extended x-ray absorption fine structure spectroscopy (EXAFS). EXAFS is one of the few techniques able to probe the detailed local structure of point defect complexes. We report measurements sensitive to the presence and concentration of Sn-vacancy complexes in Ge/Ge-Sn core/shell nanowires, to provide clearer understanding of how these defects affect the material's optoelectronic properties.

The Origin of Intraband Optical Transitions in Ag_2Se Colloidal Quantum Dots and Their Utilization for Infrared Detectors Ayaskanta Sahu; New York University, United States

In the past 30 years, material scientists have largely capitalized on the grand appeal of utilizing quantum confinement to obtain size-tunable inter-band optical transitions and implement colloidal quantum dots (CQDs) in optoelectronic applications throughout the electromagnetic spectrum. The infrared region is particularly exciting with applications in telecommunications, night-time surveillance, and satellite imaging for agricultural water conservation. While most progress with CQDs in the infrared (IR) has been achieved using inter-band transitions in Pb- and Hg-based heavy metal compounds, intra-band optical transitions originating from external- or self- dopants can potentially expand the library of materials to generate IR-optoelectronic devices with non-toxic materials. In this talk, I will focus on my group's work on recently discovered silver chalcogenide (Ag_2Se) quantum dots that exhibit distinct optical absorption in the mid wave-IR wavelength spectrum. These CQDs demonstrate a narrow bandgap metastable tetragonal phase, not available in bulk, and contain excess electrons in the lowest level of the conduction band. This allows for intra-band optical transitions between the first and the second conduction energy level which can significantly decrease Auger recombination rates and avoid the need for cryogenic cooling. I will present a detailed study of the size-dependent inter-band to intra-band optical transition and compare the competing effects of quantum confinement, environmental Fermi level and particle stoichiometry to provide guidelines for stable electron occupation of the $1S_e$ state and obtaining tunable mid wave IR absorption.

Far-Infrared (THz) Applications of Ultrafast Semiconductor Metasurfaces Igal Brener; Sandia National Laboratories and Center for Integrated Technologies, United States

Semiconductor metasurfaces have become attractive for applications in nonlinear optics, control of light emission and switching. In particular, metasurfaces made from direct bandgap semiconductors with low carrier lifetime combined with design concepts that include topology and symmetry can lead to new ways to emit and detect far-infrared radiation.

Ultrafast photodetection with semiconductor devices typically requires structures with fast photoresponse with minimal volume of the photodetection active area. In particular, photoconductive (PC) detectors for far-infrared (THz) pulses rely on devices made from semiconductors exhibiting sub-picosecond lifetime, high absorption of a short gating pulse and high on-off photoconductive contrast. These simultaneous requirements have been extremely difficult to meet using standard and uniform photoconducting semiconductors. However, perfect absorption in semiconductor metasurfaces has created a new path to a new family of photoconductive detectors with unmatched performance. Perfect absorption in dielectric metasurfaces require overlapping two resonances of opposite symmetry in the meta-atoms, critically coupled to the intrinsic absorption of the semiconductor. Moreover, in order to collect the photocurrent, the metasurfaces should provide a continuous current path to the collecting electrodes. Using these concepts, we show a new family of THz photoconductive detectors that can operate with ultralow gating powers (tens of uW) and exceed most other performance parameters of conventional PC detectors. These highly efficient PC detectors are applicable to a wide range of THz spectroscopy and imaging systems, particularly those where low power operation is required such as detector arrays and cryogenic environments.

Finally, I will also present our latest results on THz emission from these ultrafast semiconductor metasurfaces.

2:45 PM EQ16.10.06
A Comparative Study on the Switching Kinetics of W/VO_2 Micron-Sized Powders and Nanoparticles Lavinia Calvi[1,2], Luc Leufkens[3,4], Cindy Yeung[3,4], Roberto Habets[3,4], Romy van Geijn[3,4], Janique Hupperetz[3,4], Daniel Mann[3,4], Ken Elen[1,2], An Hardy[1,2], Marlies Van Bael[1,2] and Pascal Buskens[1,3,4]; [1]Hasselt University, Institute for Materials Research (IMO), DESINe Group, Belgium; [2]IMEC Vzw, IMOMEC Associated Laboratory, Belgium; [3]The Netherlands Organisation for Applied Scientific Research (TNO), Netherlands; [4]Brightlands Materials Center, Netherlands

Monoclinic vanadium dioxide VO_2 (M) is a thermochromic material based on its reversible metal-insulator transition (MIT). The MIT results from the underlying structural phase transition (SPT) from monoclinic VO_2 (M) below to rutile VO_2 (R) above the transition temperature (T_0) and *vice versa*. The SPT and associated MIT are of great interest for the implementation in energy efficient glazing as VO_2 (M) exhibits a high transmission for solar infrared (IR) radiation below T_0 while above T_0 IR light is blocked. This can lead to significant reduction in energy consumption for heating and cooling of buildings in intermediate climates.
In order to apply VO_2 (M) in thermochromic energy efficient glazing, dopants are required to lower T_0, from 68°C to 20-30°C. Another challenge is the preparation of high quality doped VO_2 nanoparticles for use in coatings and polymer films. To obtain such nanoparticles, we prepared W-doped VO_2 powders and subsequently subjected them to bead milling. We investigated the switching kinetics of undoped and W-doped VO_2 (M) micron-sized powders [1] and nanoparticles. These studies were carried out using data obtained from differential scanning calorimetry, and isoconversional methods were applied for the kinetic analysis. Undoped and W-doped VO_2 (M) powders were prepared via solution-phase reduction of V_2O_5 with oxalic acid followed by solvent removal and thermal annealing. Nanoparticles were obtained through wet bead milling of the powders dispersed in 2-propanol.
The results show that the activation energy of the SPT is temperature dependent and decreases when the difference between the material temperature and T_0 increases. Additionally, the activation barrier for both VO_2 (M) to VO_2 (R) and *vice versa* is similar for undoped and W-doped VO_2 (M) powders, and ranges between 138-563 kJ mol^{-1}. This indicates that similar defects are involved in the SPT of VO_2 (M) to VO_2 (R) and vice versa [1]. Wet bead milling effectively decreased the VO_2 particle size from 10-50 µm in powders to 50-500 nm for nanoparticles dispersed in 2-propanol. This leads to a decrease in switching enthalpy from 47 to 28 J g^{-1}, amongst others caused by partial loss of crystallinity during bead milling. The activation energy decreases with decreasing particle size. Simultaneously an asymmetry in the switching kinetics occurs and increases with progressive milling. This suggests that the defects introduced into the crystal structure by bead milling affect the transitions VO_2 (M) to VO_2 (R) and *vice versa* differently.
In conclusion, W-doping of the VO_2 was successful in tailoring the transition temperature and from the kinetic studies we find that the switching temperature selected should be 2-3°C below the desired in order to facilitate a rapid SPT and MIT. Additionally, wet bead milling was successfully applied to achieve VO_2 nanoparticles. Milling induces asymmetry in the switching kinetics. The produced particles can be further used for the implementation in coatings and films for studying the relationship between the particle size and switching enthalpy and the optical properties of the resulting coatings and films for smart window applications.

EQ16-Virtual

9:00 PM EQ16.11.02
Late News: Two-Dimensional Ti3C2Tx with Low Infrared Emissivity for Thermal Management and Energy Harvesting Yang Li and Baoling Huang; Hong Kong University of Science and Technology, Hong Kong

In nature, the infrared emissivity of most materials and surfaces are quite large (>0.8), such as woods, glasses, stones, human body surfaces, many plastics, and so on. Apart from polished metals, low-emissivity materials and surfaces (<0.2) are relatively scarce, especially among those dark color materials with high visible absorption. However, those materials and surfaces with low infrared emissivity but high visible absorption are highly demanded for many specific applications, such as visible and IR camouflage, solar thermal harvesting, and thermal management. For instance, even with higher surface temperatures, the low emissivity endows those materials/surfaces with the counter-intuitive ability to conceal themselves from IR detection due to the limited thermal radiation, showing great potential in IR camouflage. Moreover, owing to their dark color, they can easily blend themselves with the environment at night or under weak light. In other words, these visible black but infrared white materials are attractive in multispectral (visible-IR) camouflage. In additional, in solar thermal areas, such low-emissivity black materials can achieve high solar-thermal conversion efficiency due to the

suppression of radiative heat losses. However, the lack of such ideal intrinsic materials has been a long-standing challenge for decades. For this reason, great efforts have been made in developing subwavelength photonic crystals and metamaterials/metasurfaces using complicated and costly nanofabrication methods. It is preferable if there was a flexible intrinsic material with strong, broadband solar absorption but low mid-IR emissivity.
In this study, for the first time, we discovered that the black 2D $Ti_3C_2T_x$ MXene film shows strong reflection up to 90% for the mid-IR wavelengths, resulting in a quite low emissivity of ~0.1. Associated with its high solar absorption (90%), it achieves a record-high spectral selectivity (8.2) among reported black materials to the best of our knowledge. Excellent intrinsic spectral selectivity is offered by the $Ti_3C_2T_x$ MXene in a free-standing form as well as coatings on versatile substrates, even on porous, rough surfaces, showing much wider applications than metamaterials. The great potential of 2D $Ti_3C_2T_x$ in visible-IR camouflage was demonstrated. Further studies also reveal that some other commercially available MXenes are also potential IR white materials.

Human Hand as a Powerless Infrared Light Source for Multilevel Information Encryption Shun An, Wen Shang and Tao Deng; Shanghai Jiao Tong University, China

The utilization of man-made, electricity-powered light sources as external stimuli for anti-counterfeiting and other applications is limited by the cost, energy consumption, and lack of human-compatibility. In this work we explore the use of human hand as a natural and powerless infrared (IR) light source and demonstrated the integration of human hand into the anti-counterfeiting systems to enhance the human-compatibility of the system. This hand-based IR anti-counterfeiting approach enables both multilevel information encryption and unclonable coding. We also demonstrate the simultaneous decoding of both the visible code and the IR code overlaid on a flexible label without interference, which makes it promising for high level dual- or multiple-mode anti-counterfeiting. A smartphone-based IR camera is also integrated into this anti-counterfeiting system, which offers the possibility of instantly uploading the coding data to the database to further enhance the effectiveness of the anti-counterfeiting process. Compared to traditional passive light sources and other external stimuli, using human hand as active stimuli enhances the security level of the system, as well as the portability and accessibility of the anti-counterfeiting system, which will help further open up the possibility of integrating not only human hand, but also potentially other human components into the functional systems and processes.

Infrared Emissivity of Polyurethane/Al Composite Coating with Different Floating Position of Al-Particles Juyeong Nam, Injoong Chang, Junesoo Lim and Hyung Hee Cho; Yonsei University, Korea (the Republic of)

During the decades, the infrared survivability of aircraft has been an important issue for ally's air force enhancement in the modern battlefield. In the development of IR sensors, the signature from airframes in the long-wave infrared (LWIR, 8-12 μm) band could be used for target aircraft tracking. Infrared seekers detect aircraft using the contrast radiant intensity between target aircraft and background. For this reason, we thought that we could reduce contrast signature intensity for infrared camouflage. When the background is the sky, because the infrared signature of the sky is low, many studies have been conducted to lower the surface emissivity of the target in the detection wave band. However, when the background is ground, soil, or forest such as look-down situation, we confirmed that there is an optimal emissivity to minimize the contrast signature. Because the polyurethane (PU) based paint is applied to aircraft, in general, through spray coating, we developed PU/Al composite coating that can be applied to aircraft with the same coating method. Polyurethane (PU)/Al composite coating with low infrared emissivity was prepared via spray coating method using PU paint, Al-particles, and ethanol as adhesive, functional pigment, and agent for spraying, respectively. The effect of floating position and amount of Al-particles on infrared emissivity has been discussed. In order to uniformly spray Al-particles, we mixed particles with ethanol at a weight percent of 0.5% and sprayed them using an air-spray gun. The vertical position of Al-particles in a thin PU paint layer was controlled by varying the drying time of PU paint, which takes 48 hours to completely dry. Also, the amount of Al-particles on the coating surface was controlled by varying the number of spraying. To analyze optical properties, we measured the optical emittance and reflectance using FT-IR, and also the apparent temperature using IR camera in infrared band. The results show that the reflectivity increases, therefore, the surface emissivity decreases in the LWIR band, as the vertical floating position is closer to the top surface. Also, the surface emissivity decreases when there are more particles in the coating, and especially, this effect is greater when the floating position of the particle is on the top surface.

9:25 PM EQ16.11.05
Tunable Multiband Coloration Metamaterial for Visible to Infrared Optical Confusing Applications Injoong Chang[1], Taehwan Kim[2], Namkyu Lee[3], Junesoo Lim[1], Juyeong Nam[1], Maroosol Yun[1] and Hyung Hee Cho[1]; [1]Yonsei University, Korea (the Republic of); [2]Samsung Electronics, Korea (the Republic of); [3]Forschungszentrum Juelich GmbH, Germany

Optical confusion refers to a creature's camouflage technique by which it assimilates itself with the surroundings through manipulation of its colors and patterns. Inspired by these coloration and patterning strategies, artificial tunable materials to control their visible colors or infrared signatures have researched in display, energy, and military application fields. With the development of multiband imagery sensors, optical confusing camouflage must not only be able to control the signature intensity but also be able to mimic patterns of surroundings. Moreover, it must have multiband characteristics. Conventional visible camouflage mimics the colors and patterns of the surroundings and, therefore, creates pixelated digital camouflage patterns. However, conventional infrared camouflage has been focused on reducing signature of target by assuming averaged background signature. Therefore, optical confusion by patterning the colors and signatures in the visible and infrared ranges simultaneously is the most appropriate approach to developing advanced multispectral camouflage.
Herein, we propose a tunable multiband coloration metamaterial (TMCM) devised by arranging pixelated silicon nanowire fractal structures (SiNW-FSs). In this study, we fabricated SiNW-FSs by using one of the wet etching methods, which is metal-assisted chemical etching (MaCE). We calculated the fractal properties of the SiNW-FSs to verify their fractality. As a result, we found that the SiNW-FSs exhibited constant fractal dimension values and a 39% increase in lacunarity, which quantified their morphological heterogeneity with etching time increase. Moreover, we measured their multispectral optical properties, namely, reflectivity and emissivity in the visible and infrared ranges, respectively. we concluded that we could tune the reflectivity and emissivity in each waveband. Finally, through imagery measurements, we confirmed the superior multiband optical confusing effect of the TMCM against a modeled background, which imitates the real environment, compared with that of conventional single-spectral camouflage surfaces. The TMCM is expected to help improve the understanding of the multispectral characteristics of randomly distributed nanostructures and aid the development of state-of-the-art stealth technology.

9:30 PM EQ16.11.06
GeSn/Ge Core-Shell Nanowire Photonic Crystals for Resonant Infrared Photonics Siying Peng[1,2], Michael Braun[1], John Lentz[1], Andrew C. Meng[1], Zhengrong Shang[1], Alberto Salleo[1] and Paul McIntyre[1]; [1]Stanford University, United States; [2]Westlake University, China

Mid-infrared light sources are key components for future chemical sensing, on-chip optical interconnect and LIDAR technologies. GeSn alloys can be synthesized under silicon CMOS compatible conditions. Therefore, GeSn can open pathways for miniaturization of mid-infrared devices such as on-chip

molecular sensors, optical interconnects and thermal cloaking devices. Most importantly, direct band gap GeSn is a promising material for on chip integration of light emitters. Previous research on GeSn films has shown mid-infrared lasing at increasing temperatures, initially (in 2015) at less than 90K and, in more recent reports, at or near room temperature. It has also been shown that GeSn nanowires with high-Sn content exhibit strong direct-gap photoluminescence at room temperature. Compared to GeSn thin films, GeSn nanowires are less constrained to lattice match with misfitting (e.g. Ge, Si) substrates and therefore may achieve higher Sn contents without strain and defects that promote non-radiative recombination. Additionally, unlike in a planar GeSn film where the emission angle is limited to $< 13^0$ by its high refractive index (n>4), GeSn nanowires provide a platform to design the optical density of states for highly efficient light extraction directly from the light emitting material. GeSn nanowires may also constitute a superior medium for absorption and generation of photocarriers.
We demonstrate room temperature mid-infrared photodetection using resonantly absorbing GeSn/Ge core-shell nanowire photonic crystals. We have synthesized GeSn/Ge core-shell single crystal nanowires with up to 6% Sn that exhibit strong direct-bandgap photoluminescence at room temperature, with a fixed periodic, varying radius and Sn compositions. To synthesize the nanowire device, gold catalysts were patterned on Ge [111] substrate and then two step VLS growth was performed to synthesize Ge core and GeSn shell. The vertical nanowire photodetection device consists of arrays of nanowires in-filled with PMMA insulating layer, an ITO top contact (electron selective) and an aluminum bottom contact (hold selective). We performed selective area FTIR reflectance characterization, which indicates the reflectance maximum changes predictably as the radius and composition of the photonic crystal arrays varies. Reflectance data are in agreement with FDTD full wave simulation of resonant wavelengths and band structures of photonic crystal arrays. We performed photocurrent characterization with an FTIR spectrometer at room temperature. The photocurrent spectrum of Ge/GeSn nanowire photonic crystals have absorption edges up to 2.4μm, a many-fold enhancement due to resonant absorption, and a photocurrent spectrum that is tunable by varying the photonic crystal geometry.

9:45 PM EQ16.11.07
Thermal Hysteresis Loop in IR Reflectivity of Nanostructured Phase-Change-Material VO_2 Kazutaka Nishikawa, Masamichi Yoshimura and Yoshihide Watanabe; Toyota Technological Institute, Japan

Vanadium dioxide (VO_2) shows a metal-insulator phase transition around 70 °C (T_c), and is drawing attention due to the anomalous physical properties. The optical property in infrared (IR) light region is drastically changed with the transition due to increased free carrier by 4 digits. The VO_2 at metal state (over T_c) has high reflectivity in IR region, and low reflectivity at insulating state (below T_c). Also, it is well known that the transition temperature is modified by the additional elemental doping such as W and Mg.
VO_2 is a promising material to realize future devices such as “smart glass” and “thermal memory” due to temperature-switchable IR properties. Typically, VO_2 shows a temperature hysteresis during heating and cooling processes. The “smart glass” requires narrow temperature-hysteresis-width. In contrast, the “thermal memory”, which can record and read information with temperature states, requires broad temperature-hysteresis-width to store thermal information. Thus, it is essential for realizing such future devices to control the hysteresis width in optical properties of VO_2. In this study, we have fabricated nanostructured VO_2 with different morphologies and measured the temperature width of the hysteresis by IR reflectivity measurements. We found that the hysteresis width is highly dependent on the VO_2 nanostructures [1].
We fabricated VO_2 nanostructures by sputtering deposition and subsequent lamp annealing. For the sputtering deposition, we used a V metal disc as a sputtering target, and deposited V thin films on Si substrates at 350 °C. For the lamp annealing, the samples were annealed at 600 °C by changing the annealing times (1-90 min) and O_2 pressures (2-15 Pa). We observed the morphology of VO_2 by SEM, and recorded IR reflectivity changing the sample temperature in both heating and cooling processes. We found that the fabricated samples were formed by VO_2 nanoparticles on the Si substrates, and that the aggregation of VO_2 nanoparticles was changed by controlling the annealing times and the O_2 pressure during annealing. The isolation of VO_2 nanoparticles progressed with annealing time, and the long-time annealing (90 min) induced highly isolated VO_2 nanoparticles. From the temperature-dependent IR reflectivity measurements, we estimated the hysteresis width ($\triangle$T) at the wavelength of 2.5 μm. For the highly aggregated VO_2 nanoparticles, which were fabricated by short-time annealing (1 min) and low O_2 pressure (2 Pa), the values of $\triangle$T were small. The value of $\triangle$T increased with the decrease of aggregation of VO_2 nanoparticles. We have fabricated VO_2 nanostructures with the different $\triangle$T of 17 °C and 61 °C by changing the annealing conditions. Also, in cooling process, two-step decreases in reflectivity were observed for the slightly aggregated VO_2 nanoparticles. Such two-step decreases in IR reflectivity were not observed for highly aggregated or highly isolated VO_2 nanoparticles.

Three-Dimensional Construction from Two-Dimensional Glassy Polymers via Photothermal Effects Jae Gyeong Lee, Sukyoung Won, Jeong Eun Park and Jeong Jae Wie; Inha University, Korea (the Republic of)

Photothermal heating method has been emerged as a contactless shape manipulating system in materials community. Although numerous methods are documented to achieve 2D to 3D construction, photothermal method has an advantage of using inexpensive near infrared (NIR) light and uniform stimulus with contactless system. The common photothermal method uses black ink patterned hinges on shape memory polymers (SMP) with local light absorption. However, remaining hinges could induce further undesirable actuation after 3D construction. In this study, we employed adhesive tape patterns instead of black ink patterns to achieve transparent 3D structures. The black adhesive tape patterns were irradiated with NIR light to induce local light absorption. When the temperature of the black adhesive patterned area exceeds the polymer’s glass transition temperature, biaxially-stretched polymeric chains recover its conformation to random coils, resulting in contraction. We present the 3D complex structures from radial and chiral 2D tape patterns to control the curvature. We also demonstrate sequential folding by distinct light absorption time. Furthermore, we will discuss shape-morphing with multi-material including papers and conductive paste to reconfigure the 3D structures and conductivity.

10:05 PM EQ16.11.10
Development of a Drift-Free Transmission Infrared Spectroscopy System for Long-Term Stable Measurement of Reactions in Aqueous Solutions Yuta Kurokawa, Takumi Goto, Takuji Ube and Takashi Ishiguro; Tokyo University of Science, Japan

Transmission infrared (IR) spectroscopy is one of the best methods for quantitative detection of chemical species with high accuracy. However, the evaluation of chemical reactions in aqueous solutions is usually difficult due to the strong IR absorption of water itself. We avoided this difficulty by fabricating an optical cell with an optical path length of about a few micrometers: the thickness of water through which IR rays can penetrate[1,2]. To evaluate the absorbance: A using a single optical cell, we measure the transmitted light I_0 and I_s for the empty cell and the cell filled with a specimen, respectively, and calculate $A = -\log(I_s/I_0)$. However, since the measurement times of I_0 and I_s are different, stable quantitative measurement is difficult due to instrument drift (e.g., temperature change of the interferometer or detector) or accidental fluctuations. In this study, we fabricated a microfluidic cell with two adjacent channels and developed a transmission IR spectroscopy system that can simultaneously measure I_0 and I_s using a linear array detector.
A two-channel microcell was fabricated by photolithography technique on a CaF_2 substrate and sealed with a CaF_2 window plate. This was mounted on a transmission IR spectroscope (IRT7000, Jasco Inc.) equipped with a linear array (16 parallel detectors). The linear array detectors were cooled by a 5L

liquid nitrogen tank, allowing continuous measurements for about a week. One channel was filled with dry nitrogen gas, while the other channel was filled with ethanol solution (20 mass%) for simultaneous measurement of I_0 and I_s. Simultaneous measurements were made 512 times during 100 seconds, and data was transferred in 20 seconds, which was repeated as one cycle.
When the measurements were made at the same time: t, the time variation, or drift, of $I_0(t)$ and $I_s(t)$ was fluctuated synchronously. In order to evaluate the stability of this IR measurement system, we calculated the time variation of the ratio of $Int(I_s(t))/Int(I_0(t))$. Here, $Int(I_0(t))$ and $Int(I_s(t))$ were calculated by integrating the respective spectra of $I_0(t)$ and $I_s(t)$ in the range of 2000 to 2250 cm^{-1} after sensitivity correction. For example, in the case of simultaneous measurements, $Int(I_s(t))/Int(I_0(t))=0.98733\pm0.00012$. In a normal measurement, i.e. using one cell, it takes about one hour to change the cell contents. Therefore, the time difference of $Int(I_s(t+\tau))/Int(I_0(t))$ was evaluated as τ=1 hour. The error in this case was ±0.00150. In other words, the stability of the measurement was improved by a factor of 12.5.
The system was found to be capable of stable quantitative absorbance measurements over a long period of time, even in the presence of external disturbances. As a result, this system can be applied to the measurement of slow chemical reactions in aqueous solution, such as photosynthesis, photocatalysis, and cellular metabolism.

SESSION EQ16.13: Metasurfaces and Metaplatforms for Infrared
Session Chairs: Sheila Edalatpour and Georgia Papadakis
Wednesday Afternoon, December 8, 2021
EQ16-Virtual

1:00 PM *EQ16.13.01
Mid-Infrared Metasurfaces for Biosensing and Tunable Optical Control Hatice Altug; École Polytechnique Fédérale de Lausanne, Switzerland

Metasurfaces have recently emerged as a breakthrough platform for manipulating light at the nanoscale with the use of engineered dielectric and plasmonic nanostructures. They can be tailored to operate over a broad spectrum ranging from terahertz to middle-infrared (Mid-IR) and ultraviolet. Mid-IR metasurfaces are particularly important for the wavelengths between 3 to 20 μm because this range includes two atmospheric windows and fundamental absorption bands of chemicals and biomolecules. Infrared absorption spectroscopy taps into these absorption bands, so called “fingerprints”, for label-free and chemical-specific biosensing. Nevertheless, conventional infrared absorption suffers from several limitations such as low signal levels, difficulty to operate in aqueous environment and bulky and expensive instrumentation. In this talk I will present our recent work with plasmonic and dielectric Mid-IR metasurfaces for realizing novel Mid-IR biosensors through surface enhanced infrared absorption spectroscopy (SEIRA) and incorporation of dielectric metasurfaces with phase change materials for programmable phase control [1-4]. I will also present a versatile nanofabrication process enabling wafer-scale and CMOS-compatible manufacturing of efficient dielectric and plasmonic mid-infrared metasurfaces [5].

With metallic nanoantennas our lab has been developing ultrasensitive SEIRA based biosensors. Most recently, we introduced a deep learning-augmented Mid-IR nanoplasmonic metasurface, which provides a universal platform to study dynamic biological processes involving analytes from all four major biomolecular classes [1]. The optofluidic device incorporating multiresonant plasmonic metasurface and microfluidics enabled to collect a vast amount of spectrotemporal data, which is then used to construct a deep neural network for accurate analyte discrimination. The capabilities of the new method are demonstrated by dynamically monitoring a multistep bioassay containing sucrose- and nucleotides-loaded liposomes interacting with a small, lipid membrane-perforating peptide.

In low-loss dielectric metasurfaces, we harness their high-Q resonances to implement compact Mid-IR biosensors. One of our devices utilizes large-area imaging with a 2D pixelated metasurface to detect Mid-IR molecular fingerprints without the need for spectrometry and frequency scanning [2]. The metasurface is designed to provide strong near-field enhancement, where the resonance positions of individual metapixels are varied over a target Mid-IR range. With this one-to-one mapping between spectral and spatial information, enhanced absorption signatures of analytes are sampled at multiple spectral points and translated into a 2D barcode-like spatial absorption map for imaging-based detection. In another device, we expanded the operational spectral range of dielectric metasurfaces for spectroscopy by using angle scanning and polarization aspect together. The system provided an impressively wide spectral coverage from 1100 cm-1 to 1800 cm-1 at 1.4 cm-1 resolution [3].

Current metasurfaces are often locked to a fixed functionality due to their static constituent materials. Extending into tunable metasurfaces can enable active optical elements such as tunable lenses, dynamic holograms and spatial light modulators for key application areas including adaptive spectroscopy. Recently, we introduced a tunable all-dielectric Mid-IR Huygens’ metasurface consisting of multi-layer Ge meta-units with strategically incorporated phase change material [4]. Through hyperspectral imaging measurements we showed optical programming of a light phase profile into the metasurface with single meta-unit precision and a maximum light phase tunability of 81% of full 2π phase shift.

Light-Absorption in Nano-Antennas—From Self-Heating to Reconfigurable Metasurfaces Giulia Tagliabue; École Polytechnique Fédérale de Lausanne, Switzerland

By engineering light absorption in dielectric nanoantennas, we explore new opportunites for the manipulation of temperatures at the nanoscale as well as

the design of reconfigurable metasurfaces.
In the last decade, optical nanoantennas have revolutionized light manipulation and control at the nanoscale. Light absorption was initially considered a purely detrimental process, reducing the efficiency of optoelectronic devices. Recently, however, it has attracted growing interest, enabling novel light-energy conversion pathways and offering intriguing opportunities for reconfigurable systems. In particular, going beyond metallic nanostructures, I will introduce the opportunities offered by dielectric nanoantennas for thermonanophotonics and, more specifically, for thermo-optical reconfigurable devices. In the first part of the talk, I will discuss self-induced optical heating effects in highly absorbing Silicon (Si) and Germanium (Ge) nanoresonators. In particular, I will show recent calculations demonstrating that, due to thermo-optical effects, self-heating can give rise to a complex, non-linear relationship between illumination intensity and temperature, even for moderate illumination intensities relevant for applications such as Raman scattering [1]. Subsequently, I will discuss how self-induced optical heating could be employed in optical devices and metasurfaces. In particular, I will present our recent efforts in the design of thermally reconfigurable metalenses [2].

Near-Field Infrared Optical Characterization Techniques of Twisted and Indirectly Nanostructured 2D Material Heterostructures Frank Koppens; ICFO - The Institute of Photonics Sciences, Spain

Two-dimensional (2D) materials offer extraordinary potential for control of light and light-matter interactions at the atomic scale. In particular, twisted 2D materials has recently attracted a lot of interest due to the capability to induce moiré superlattices and discovery of electronic correlated phases [1,2]. In this talk, we present nanoscale optical techniques such as near-field optical microscopy and photocurrent nanoscopy, and reveal with nanometer spatial resolution unique observations of the infrared and photothermal properties of twisted 2D materials.
We report on the photo-thermoelectric nano-imaging within the Moire unit cell of small-angle twisted graphene [4] and interband collective modes in charge neutral twisted-bilayer graphene near the magic angle [3]. The freedom to engineer these so-called optical and electronic quantum metamaterials [1] is expected to expose a myriad of unexpected phenomena. As an example for indirectly patterned polaritons, we introduce and demonstrate a novel multimodal reflection mechanism of the ray-like optical excitations in hyperbolic materials, such as hBN.

Towards Complete Optical Coupling to Localized Optical Modes Javier Garcia de Abajo[1,2]; [1]ICFO, Spain; [2]ICREA, Spain

The large mismatch between the free-space light wavelength and the spatial extension of localized optical modes, particularly at infrared frequencies, results in a poor light-mode coupling, which poses a serious problem in the design of practical structures for light and thermal radiation management. As a possible way to address this issue, we propose the use of perfect scatterers, which enable complete coupling between free space radiation and arbitrarily small localized modes when they are placed at suitable positions and the external light is also optimally structured in the far field. We discuss quantum perfect scatterers consisting of two-level atomic/molecular systems, as well as classical perfect scatterers provided by Mie-mode-supporting dielectric cavities. Our results open a practical route to circumvent the long-standing photon-polariton wavelength mismatch problem in nanophotonics.

Nanophotonics with Phonon Polaritons in 2D Materials Rainer Hillenbrand; CIC nanoGUNE BRTA, Spain

Phonon polaritons - light coupled to optical lattice vibrations - in 2D materials exhibit ultra-short wavelengths, long lifetimes and strong field confinement, which allow for manipulating infrared light at the nanometer scale. Here, we discuss real-space nanoimaging studies of ultra-confined infrared phonon polaritons, essentially in thin hexagonal boron nitride layers and nanostructures, using scattering-type scanning near-field optical microscopy (s-SNOM) and nanoscale infrared Fourier transform (nano-FTIR) spectroscopy. We visualize and analyze phonon polaritons in nanoscale waveguides and resonators. Particularly, we will demonstrate that phonon polaritons can be utilized to achieve vibrational strong coupling with nanoscale amounts of organic molecules.

Highly Broadband Spectral Control of Thermal Radiation by Exploiting Air as a Functional Element Andrej Lenert, Tobias Burger, Dejiu Fan, Zachary J. Berquist, Andrew J. Gayle, Neil P. Dasgupta and Stephen R. Forrest; University of Michigan, United States

Air can play a key role within photovoltaic and photothermal materials, owing to its non-absorbing, low-index, low-thermal-conductivity properties. However, exploiting these unique properties is challenging because it requires an approach that accommodates the undesirable properties of air, namely the lack of structural support. Here, I discuss our recent progress in realizing thermophotovoltaic (TPV) cells[1] and refractory solar thermal absorbers[2,3] that incorporate air in a way that does not compromise their functional stability. In doing so, we overcome key limitations in TPV and solar thermal conversion, namely a lack of broadband spectral control, and realize record-high efficiencies. With such high-efficiency approaches, TPV-based thermal batteries can serve as a solution to the long-duration electricity storage problem, while concentrated solar thermal can access a high-temperature regime and, in turn,

provide efficient, on-demand power generation and industrial process heat.

Radiative Properties of Optically Clear Mesoporous Silica Films and Monoliths Laurent Pilon and Refet Yalcin; University of California, Los Angeles, United States

This talk presents new synthesis methods and characterization of optically transparent mesoporous silica thin films and monoliths with tunable infrared properties. The material featured porosity that can be adjusted from 50 to 90% with narrow pore size distribution varying between 5 and 20 nm and silica building blocks between 2 and 10 nm. As a result, the materials are transparent in the visible while their infrared properties can be tuned to achieve very high and/or spectrally selective thermal emission at room temperature. The material optical behavior observed across the spectrum is interpreted thanks to numerical simulations of electromagnetic wave transport through realistic computer-generated mesoporous materials. Particular attention is paid to the effects of dependent scattering, absorption, and fractal architecture of the mesoporous structure. The novel materials investigated could be used for passive thermoregulation of buildings.

SESSION EQ16.15: On-Demand
Sunday Morning, December 5, 2021

8:00 AM EQ16.03.03
High-Temperature Photonics with Refractory Metals Margaret A. Duncan[1], Mariama Rebello Sousa Dias[2] and Marina Leite[1]; [1]University of California, Davis, United States; [2]University of Richmond, United States

The continuous growth of the field of photonics over the last several decades has led to a myriad of groundbreaking applications, from ultrafast quantum computation to long-distance data transmission to energy conversion. However, most of the current research in photonics is performed at room temperature in an ambient environment. Determining the optical behavior of materials in different environments and at higher temperatures is crucial to understanding their properties and thus the performance of devices in the real world. Similarly, certain materials with advantageous mechanical and thermal properties such as refractory metals remain minimally explored in the optical regime. Because of this, refractory metals have for the most part been overlooked for photonic applications, even though their refractive indices may prove highly useful to many situations, e.g. thermophotovoltaics (TPV). We resolve the effects of environment (air, N_2, and Ar) and temperature (25 – 600°C) on the complex refractive index of seven refractory metals (Cr, Hf, Mo, Ru, Ta, Ti, and W) as well as TiN by performing *in situ* ellipsometry, where all thin films are fabricated via sputtering. Our *in situ* ellipsometry experiments suggest a reaction at high temperatures between certain refractory metals and an N_2-rich environment. For example, we show a maximum change of 38% for the refractive index and 24% for the extinction coefficient in Mo, and a maximum change of 23% for the refractive index and 47% for the extinction coefficient in W. This change remains even after the temperature is lowered. We note that TiN has the added benefit of including nitrogen, making it less likely to react when placed in an N_2-rich environment at high temperatures. When exposed to an inert Ar environment, many of the refractory metals showed similarly substantial changes in refractive index beginning around 500°C. We complement the optical measurements with morphological and chemical analyses of the films' surface by combining atomic force microscopy, transmission electron microscopy, and X-ray photoelectron spectroscopy of the substrates before and after being held at high temperatures, to analyze the possible physical and surface changes that have occurred. With these experimentally obtained temperature-dependent refractive indices, we provide an example application, quantifying the performance of these refractory metals in an example TPV absorber/emitter. Here, we find a 3-fold increase in efficiency by using refractory metals when compared to other current state-of-the-art absorber/emitters, proving their value for modern photonic applications.

Incandescent Metasurface Modulated Beyond 10 MHz Leo Wojszvzyk, Anne Nguyen, Cheng Zhang, Anne-Lise Coutrot, Benjamin Vest and Jean-Jacques Greffet; Institut d'Optique, France

Incandescent sources such as hot membranes and globars are widely used for mid infrared spectroscopic applications. The emission properties of these sources can be tailored by means of resonant metasurfaces: control of the spectrum, polarization and directivity has been reported. For detection or communication applications, fast temperature modulation is desirable but is still a challenge due to thermal inertia. Reducing thermal inertia can be achieved using nanoscale structures at the expense of a low absorption and emission cross section. Here, we introduce a metasurface that combines nanoscale heaters to ensure fast thermal response and nanophotonic resonances to provide large monochromatic and polarized emissivity. The metasurface is based on platinum and silicon nitride and can sustain high temperatures. We report a peak emissivity of 0.8 and an operation up to 20 MHz, six orders of magnitude faster than commercially available hot membranes.

11:00 AM *EQ16.12.02

Near-Field Heat Transfer and Energy Conversion in Nanoscale Gaps Pramod Sangi Reddy; University of Michigan, United States

Understanding radiative heat transfer in nanoscale gaps and devices is of considerable interest for creating novel energy conversion devices. In this talk, I will first describe ongoing efforts in our group to experimentally elucidate nanoscale radiative heat transfer. Specifically, I will present our recent experimental work where we have addressed the following questions: Can existing theories accurately describe radiative heat transfer in single nanometer sized gaps? Can radiative thermal conductances that are orders of magnitude larger than those between blackbodies be achieved? In order to address these questions we have developed a variety of instrumentation including novel nanopositioning platforms and microdevices, which will also be described. Further, I will discuss possible applications of near-field thermal radiation for energy conversion and photonic cooling. Finally, I will briefly outline how these technical advances can be leveraged for future investigations of nanoscale heat transport and near-field thermophotovoltaic energy conversion.

11:30 AM EQ16.12.03
Exploring Phonon Polariton Heat Transfer Channels Across Nanoscale Gaps Using an Electron Beam Isobel C. Bicket[1,1], Connor Wong[1], Yao-wen Yeh[2], Joshua Tefal[1], Nabil Bassim[1,1] and Maureen Joel Lagos[1,1]; [1]McMaster University, Canada; [2]Rutgers, The State University of New Jersey, United States

Understanding near-field radiative heat transfer (NFRHT) underpins the management of thermal energy for the development of novel heat-control technologies. Evanescent near-fields couple across nanoscale gaps, making these platforms a classic case study for NFRHT phenomena. Most studies on NFRHT in gaps provide limited spectral information, with the exception of scanning probe microscopies [1], in which the spatial resolution is limited to tens of nm. Spectral information can also be obtained using far-field IR probes, in which case much of the spatial sensitivity is lost and optically dark modes are unreachable. Challenges remain in understanding the spectral and spatial properties of NFRHT channels provided by bright and dark surface phonon polaritons (SPhP) in dielectric-based nanogaps. Detecting all of the available SPhP modes present in a gap and their spatial distribution; understanding the role of gap size and shape in tuning the spectral response; and nanoscale imaging of the local temperature profile across the gap is needed to further our understanding of NFRHT limits and nanoscale thermal emission.
We study the near-field spectral response of SiC nanogaps as small as 5 nm, with different temperature gradients across the gap. We use an atom-sized electron beam in a monochromated transmission electron microscope to conduct electron energy loss spectroscopy (EELS) measurements of the IR response [2]. We image the spatial distribution of both bright and dark SPhP modes, providing rich spectral information with nm spatial resolution [3]. For temperature measurements, we use a recently-developed method to locally measure thermal profiles across the gap using phonon EELS signal [4].
We fabricate SiC nanogaps between two rods using a focused ion beam, producing gaps ranging from 40-280 nm. Under heating, the gaps may shrink, down to 5 nm. Our EELS data reveals a broad spectral peak: the amalgamation of a rich spectrum of SPhP modes. We notice that the shape, intensity, and maximum of the EELS peak depends on the gap size and shape, and on the probe location in the gap. For example, the high energy modes within the peak are stronger in the centre of the gap than near the open sides, indicating strong high energy near-fields at the gap centre due to the formation of highly localized modes in these narrow gaps (<50 nm). Our results suggest that spectral tunability can be obtained even with small gaps, potentially affecting spectral heat flux and thermal emission. To gain further insight into the variety of SPhP in the gap, we conduct boundary element simulations of coupled nanorods with varying cross-sectional geometries. We find that a large variety of coupled modes exist, including new face-type modes with extremely localized near-fields, dependent on the cross-sectional shape. Our results provide relevant information on channels for NFRHT beyond the traditional coupled dipolar modes.
Our fabricated gaps are designed to exhibit different temperature profiles; some gaps have the same temperature on either side while other gaps have hot and cold sides, according to our local temperature measurements. In thermally symmetric gaps, the near-field intensity drops towards the centre, but is symmetrically distributed on either side and increases under heating. In thermally asymmetrical gaps, the near-fields near the hotter rod are stronger, due to an increase in thermal phonon population [4]. Our work studying the spatial distribution and temperature gradients present in coupled SPhP represents progress towards understanding the available channels for NFRHT and thermal emission in nanogaps.

Analysis of Nano-Resistor Light Emssion Areas in Solid State Incandescent Light Emitting Devices Yue Kuo and Jia Quan Su; Texas A&M Univ, United States

The Solid State Incandescent Light Emitting Device (SSI-LED) was reported recently (1,2,3). It emits the warm white light from visible to near IR wavelength range, which is similar to that emitted from a conventional incandescent lamp or that of the sunlight in the same wavelength range. The principle of the light emission of this kind device is the thermal excitation of nano-resistors formed from the breakdown of a MOS capacitor with a metal oxide high-k gate dielectric. It can be operated continuously for more than 20,000 hours in air without failure. The electrical, optical, and material properties of the SSI-LED have been investigated. In general, the intensity and spectrum of the emitted light is related to the material and structure of the nano-resistor, i.e., the original gate dielectric properties, and the applied voltage. In this paper, authors investigated the relationship between the (light emission area/whole gate area) ratio and the operation condition as well as th gate dielectric material using the J Mapping method. The cause of the high light emission density on the edge of the device will also be discussed.

12:00 PM *EQ16.12.05
μEngineering the Spectrum of Near-Field Thermal Radiation Using Thermal Metamaterials Sheila Edalatpour; University of Maine, United States

The near-field effects of radiative heat transfer arise when at least one of the characteristic lengths of the system, i.e., the size of the objects and their separation distance, is smaller than the dominant thermal wavelength (approximately 10 μm at room temperature). Radiative heat transfer in the near field can be quasi-monochromatic, polarized, coherent, and it can exceed the far-field blackbody limit by several orders of magnitude. These unique properties are highly promising for many advanced and state-of-the-art technologies in waste heat recovery, nanoscale-resolution imaging, photonic cooling, thermal management of electronic devices, and thermal rectification through a vacuum gap. The quasi-monochromatic nature of near-field radiative heat transfer

plays a central role in these technologies. For example, quasi-monochromatic thermal emission has been reported to improve the performance of nano-gap thermophotovoltaic devices which are proposed for waste heat recovery. Another example is a thermal diode, which allow heat to flow only in a preferred direction. In this case, thermal rectification is achieved by capitalizing on temperature dependence of the resonance frequency of thermal emission. Development of the near-field applications requires materials with designer near-field thermal spectra. Materials with designer near-field spectra are rarely found in nature. As such, metamaterials that are engineered at the sub-wavelength scale have been proposed for controlling the spectral distribution of near-field thermal radiation.
Achieving customized near-field spectra using metamaterials requires reliable and computationally efficient theoretical models for designing the material as well as robust experimental techniques for characterization of the designed materials. This talk starts with an overview of near-field thermal radiation, its significance and applications, and it continues with a discussion of various metamaterials, including nanopillars, gratings, and Mie-resonance based metamaterials, proposed for tuning the spectrum of near-field thermal radiation. Next, the numerical and approximate models used for designing metamaterials is reviewed, and an experimental technique for characterizing the spectrum of near-field thermal radiation is presented. Finally, the measured near-field and far-field thermal radiation spectra for metamaterials made of silicon carbide nanopillars are presented and discussed.

Interfacial Electronic Properties in Organic Solar Cell, a Two Study Case—Fullerene vs Non Fullerene Acceptor at TiO2 Surface and 4P-NPD as Exciton Blocking Layer in Inverted Solar Cell Architecture Nadine Witkowski[1], Dylan Amelot[1], Hervé Cruguel[1], Mariam Ahmad[2], Mehrad Ahmadpour[2] and Morten Madsen[2]; [1]Sorbonne University, France; [2]University of Southern Denmark, Denmark

Solar energy is by far the most abundant and widespread renewable energy resource, which is maintenance-free and envisioned to play a key role in the energy transition needed for the next decades. Organic photovoltaics (OPVs) technology, offering now power conversion efficiency of over 18%, is expected to provide alternative implementation technologies such as large area flexible panels for urban compatible exploitation with cost-effective printing techniques.
Organic solar cells architectures have become increasingly complex with stacking of both organic and inorganic materials optimized to provide largest efficiency in the final device. The rational design of electronic levels at the organic/organic interfaces or at the organic/inorganic interfaces is of fundamental importance in the transport of charges for improved efficiency. The use of electron spectroscopies carried out using synchrotron radiation allows an in-depth investigation of the electronic interplay at the interface evidencing charge transfer, band bending or chemical bonding together with a detailed picture of the band alignment.
In this context, we have used electron spectroscopies to investigate metal oxide interfacial layers acting as electron-transport layer (ETL) in organic solar cells, namely TiO2, in connection with acceptor molecules. During past twenty years, fullerenes have been dominant as electron accepting materials for designing high performance organic solar cells, however their drawbacks mainly in terms narrow absorption spectra have motivated their replacements by non-fullerene electron acceptor molecules. The comparison between C70 and non-fullerene acceptor, namely ITIC molecule, at the interface with low temperature sputtered TiO2 ETL will be presented. It will be shown that resonant photoemission is a powerful technique capable in revealing the role of defects states present at the TiO2 interface.

In the second example presented, we will focus our interest on organic/organic interfaces. It has been evidenced that the efficiency of organic solar cell suffers from the recombination of photo-induced electron-hole pair or excitonic state at the interface between the electron donor and the hole transport layer (HTL) or electrode. One of the strategies to limit this recombination consists in introducing an exciton blocking layer (EBL) at the interface between the electron donor and the HTL. Such strategy has been recently used successfully in an inverted solar cell design, in which a molecule commonly used in OLED, 4P-NDP has demonstrated its abilities as EBL in a planar heterojunction of 4P-NDP/DBP. Surprisingly, the optimal thickness of the EBL giving higher power conversion was found to be less than one nm. Our investigation of interfacial electronic properties in 4P-NDP/DBP heterojunction reveals the

strong influence of DBP in term of band alignment on ultra-thin layer of 4P-NDP favoring the charge transport across the device.

The presented work is a join study by Sorbonne Université and University of Southern Denmark and supported by Danmarks Frie Forskningsfond, DFF FTP project 'React-PV', Danish Ministry of Higher Education and Science project 'SMART', Horizon2020 project CALIPSOplus.

11:00 AM EQ17.01.03
Novel Solution-Combustion Technique for the Synthesis of Impurity-Free $BaSnO_3$ Nanoparticles at 130 °C Sushobhita Chawla[1], Garima Aggarwal[1], Akash Kumar[2] and Balasubramaniam Kavaipatti[1]; [1]Indian Institute of Technology Bombay, India; [2]Gachon University, Korea (the Republic of)

Conventionally, thin-film synthesis of the high mobility, high figure of merit $BaSnO_3$ is achieved *via* cost-intensive, high temperature, high vacuum methods. *Chimie-douce* techniques for nanoparticle synthesis of this material are often accompanied by impurity phases such as $BaCO_3$, SnO_2 and Ba_2SnO_4, necessitating high annealing temperatures, consecutively rendering it impractical for numerous applications. Lowering the synthesis temperature to obtain phase pure $BaSnO_3$ can expand the horizons for its optoelectronic applications, with an obvious reduction in the thermal budget.

In this work, we have developed a novel solution combustion technique for the synthesis of $BaSnO_3$ nanoparticles. A peroxo/superoxo precursor to the nanoparticles is first synthesized by co-precipitation of the tin and barium salts *via* the H_2O_2 assisted route. We find that the crystallization temperature of $BaSnO_3$ is significantly reduced by adding an organic solvent to the precursor; temperatures as low as 130 °C lead to phase pure $BaSnO_3$ nanoparticles. The role of the organic solvent is established as the component responsible for an exothermic reaction occurring around 130 °C, that leads to crystalline $BaSnO_3$ formation. Importantly, this method allows for facile incorporation of dopants. Such low synthesis temperatures enable $BaSnO_3$ to be used in devices having temperature limitations during device processing, such as perovskite-based solar cells in an n-*i*-*p* architecture or heterojunction Si solar cells.

11:15 AM DISCUSSION TIME

11:30 AM EQ17.01.05
Late News: Transferrable Ag Nanogrid Electrodes by Unidirectional Electrospinning for Semitransparent Perovskite Solar Cells Jieun Lee, Beomjune Shin, Seongheon Kim, Seong Ho Cho, Yonghoon Jung, Ki-Tae Park, Changgyun Son, Young Ho Chu, Da Gil Ryu, Sunggun Yoon, Munkyeong Choi, Ho-Young Kim and Yun Seog Lee; Seoul National University, Korea (the Republic of)

Semitransparent solar cells are used in diverse energy-related applications, such as Building Integrated Photovoltaics (BIPV), automobile windows, and wearable electronic devices. Perovskite is fairly attractive as an active layer in semitransparent solar cells. When this material is used, the thickness of the light absorption layer can be easily controlled based on a solution-based process. On the contrary, the fabrication of a transparent electrode layer in film solar cells with great performance remains a challenge so far. Since the layers of perovskite solar cells are substantially thin, the transparent electrode should be manufactured with the low surface roughness to prevent a detour current path between the different layers. In addition, the transparent electrode should be fabricated in low-temperature, moreover, the use of polar solvents is not beneficial because the active layer of solar cells can be damaged.
In this contribution, the Ag nanogrid electrode is fabricated by using directional electrospun polyethylene oxide (PEO) nanofibers as an etching mask in the wet etching process. Because polar solvents are not used, and high temperature is not required in this process, electrodes can be fabricated on Polydimethylsiloxane (PDMS) substrate; hence, electrodes can be transferable to various surfaces or shapes. In addition, when this method is applied, the high scalability can be achieved, such as for the roll-to-roll process for large-area substrates. The fabricated transferrable Ag nanogrid transparent electrodes has the transmittance of 92.7% (at 550 nm) and the sheet resistance of 18.0 Ω/sq. Furthermore, the $MAPbI_{2.5}Br_{0.5}$ based perovskite semitransparent solar cell with Ag nanogrid electrode attached as the top electrode was manufactured. And the performances, such as J-V characteristics, quantum efficiency, and transmittance, were investigated. Consequently, we report a semitransparent solar cell with an average visible wavelength transmittance (AVT) of 25.2%, and a power conversion efficiency (PCE) of 12.7%. Therefore, the light utilization efficiency rates (LUE) of 3.21%, which is the highest value in the conventional perovskite semitransparent solar cells, can be identified.

SESSION EQ17.02: Perovskite and Organic Solar Cells
Session Chair: Nadine Witkowski
Tuesday Afternoon, November 30, 2021
Hynes, Level 2, Room 203

1:30 PM EQ17.02.01
Think Small—Hole-Selective Monolayers for Solar Cells Artiom Magomedov[1], Ernestas Kasparavicius[1], Amran Al-Ashouri[2], Eike Köhnen[2], Yuanbao Lin[3], Yuliar Firdaus[3], Bor Li[2], Thomas D. Anthopoulos[3], Tadas Malinauskas[1], Steve Albrecht[2] and Vytautas Getautis[1]; [1]Kaunas University of Technology, Lithuania; [2]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [3]King Abdullah University of Science and Technology, Saudi Arabia

Several emerging technologies from the field of organic electronics have a great promise to disrupt our everyday lives. To achieve this goal, new materials need to be developed, that would meet the high expectations of the market.
Traditionally, self-assembled monolayers (SAMs) were widely used in material sciences for the modification of the interfaces of various semiconducting oxides. However, there were not many examples, where the SAMs would have an individual role, rather than that of the "assisting" or "improving". The most significant demonstration of the power of the SAMs is dye-sensitized solar cells. There, in a combination with the mesoporous scaffold, a single layer of the dye molecules was sufficient to ensure efficient absorption of the light. Nevertheless, there were still only several examples of the other types of semiconducting SAMs demonstrated over the years.
Recently in our work, we have introduced carbazole-based phosphonic acids into the p-i-n perovskite solar cell architecture. It was used instead of the traditional hole-transporting materials, formed by a spin-coating method. Instead, the layers were formed on top of the indium tin oxide electrode by a simple dipping procedure.
Initially, phosphonic acid with dimethoxydiphenylamine-substituted carbazole chromophore was used for the construction of the proof-of-concept devices, showing a promising efficiency of over 17%. Eventually, the structure was simplified, and the devices with the [2-(9H-carbazol-9-yl)ethyl]phosphonic acid (**2PACz**) have demonstrated over 20% efficiencies, outperforming polytriarylamine (PTAA) standard. In further work **2PACz** was used as a starting compound for the structural modifications, leading to some exceptional results.
The first example is a material called **Me-4PACz** ([4-(3,6-dimethyl-9H-carbazol-9-yl)butyl]phosphonic acid), which was used to fabricate record-breaking silicon/perovskite tandem solar cell, with 29.2% efficiency [1]. Another example is **Br-2PACz** ([2-(3,6-dibromo-9H-carbazol-9-yl)ethyl]phosphonic acid),

which was used in bulk-heterojunction solar cells, to give 18.4% efficiency, which is one of the highest reported values in the literature [2].
The incorporation of the monolayers into devices as a functional layer is leading to a breakthrough in several aspects. First, due to the ultimately low thickness of the layer, the amount of the required material is significantly reduced. Next, the defined orientation of the molecule ("anchor" attached to the surface, while "head" staying on the surface), gives a promise for the more rational design of the materials. Finally, conventional synthetical procedures are allowing the creation of large libraries of the materials, making it possible to fine-tune the properties of the layer.

Indium Oxide Grown by Atomic Layer Deposition as Impermeable Top Electrode in Semi-Transparent Perovskite Solar Cells Florian Zimmermann, Tobias Gahlmann, Manuel Theisen, Kai O. Brinkmann, Cedric Kreusel and Thomas Riedl; Bergische Universität Wuppertal, Germany

The efficiency of perovskite solar cells (PSCs) almost reached that of silicon photovoltaics. Owing to the facile band-gap tunability of halide perovskites, partially see-through, i.e. semi-transparent, solar cell architectures with appealing colour impression become attractive. This opens up innovative areas of application, such as window integration, house facades, and in vehicles. Another essential challenge for PSCs is the susceptibility of the perovskite material to the effects of outside gases, such as moisture and oxygen.

A key element of semi-transparent cells is the semi-transparent top electrode. Previously, we have shown that networks of silver nanowires [1] or thin metal layers, such as Ag [2], can be used to realize such electrodes. Both concepts are based on metals that are easily corroded by halide containing species potentially leaking from the perovskite (e.g. at elevated temperature). To mitigate this issue, an impermeable ALD grown SnO_x electron transport layer is typically inserted to prevent halide migration and to protect the perovskite against subsequent deposition processes.

While the SnO_x is highly transparent and an excellent permeation barrier, it lacks the intrinsic electrical conductivity (5×10^{-3} S cm^{-1}) to qualify as a stand-alone semi-transparent top electrode without the requirement of additional metals.

In this work we propose ALD grown In_2O_3 from Cyclopentadienylindium(I) (CpIn) as semi-transparent top electrode with a high electrical conductivity of 2×10^3 S cm^{-1}, which is six orders of magnitude higher than that of SnO_x and on par with that of sputtered indium tin oxide (ITO). Even at growth temperatures as low as 80°C and without any post deposition annealing, our In_2O_3 layers provide a high charge carrier density in the order of 10^{21} cm^{-3} and an electron mobility up to 23 cm^2/Vs. In stark contrast to sputter deposited ITO the ALD grown In_2O_3 provides outstanding properties as diffusion barrier, exemplified by a low water vapor transmission rate (WVTR) of 4.8×10^{-4} g (m^{-2}d^{-1}) at 70°C/70%rH, which is orders of magnitude lower than number typically quoted for sputtered ITO [3].

Finally, a high optical transmittance of over 80% in the wavelength range from 400-1000 nm for layers with a thickness of 100 nm and a sheet resistance of 45 W/sq, qualifies the In_2O_3 as an excellent semi-transparent electrode to realize semi-transparent PSCs. Details of the growth conditions using oxygen and water as co-reactants in the ALD process as well as the requirement of a proper seed layer for the In_2O_3 on top of the perovskite will be discussed. In first experiments, we applied our In_2O_3 as semi-transparent top electrode in semi-transparent PSCs, which afford notable efficiencies up to 16.5%.

Engineering the Interfaces of Highly Efficient Perovskite/Organic Multi-Junction Solar Cells Thomas Riedl; Wuppertal University, Germany

Hybrid halide perovskites have overwhelmed the field of photovoltaics with unprecedented progress and skyrocketing efficiencies. Their facile bandgap tunability renders perovskite solar cells excellent building-blocks for multi-junction architectures, that provide the prospect to overcome fundamental efficiency limits of single-junctions. While perovskite/silicon or all-perovskite tandem cells have shown some remarkable progress, as of yet, perovskite/organic tandem cells show subpar efficiencies of ~20 per cent, limited by the low open circuit voltage of wide-gap perovskite cells, and serious optical/electrical losses introduced by the interconnect between the sub-cells.
Organic and perovskite semiconductors share similar processing technologies, which makes them attractive partners in multi-junction architectures. More importantly, the introduction of non-fullerene acceptors has boosted the efficiency of organic solar cells to levels beyond 18 per cent.
Here, we demonstrate perovskite/organic tandem cells with an efficiency up to 24 per cent, setting a new milestone for perovskite/organic tandem devices, which now for the first time outperform the most efficient single junction perovskite cells in *p-i-n* architecture. In an optimistic scenario, we envision that perovskite/organic tandem architectures bear a realistic prospect to reach efficiencies above 31 per cent.
This progress is not least based on significant improvements on the most critical interfaces in such a device:
Firstly, we managed to overcome interfacial losses, that are the predominant reasons limiting the performance of wide-gap perovskite cells. This allows us to access previously unreached territory of combined high open circuit voltage and fill factor. At the same time, our findings evidence that the proper choice of charge extraction layers allows to mitigate the detrimental halide segregation typically encountered in mixed-halide perovskites.
Secondly, we introduce a novel recombination interconnect for the two sub-cells, that is based on an ultra-thin (~1.5 nanometers) metal-like indium oxide layer. This interconnect offers unprecedented low optical and electrical losses, which unlocks the exploitation of the full potential of the two sub-cells without any discount. It can be foreseen that the applicability of this novel interconnect is not limited to perovskite/organic tandem cells but we expect that it will likewise revolutionize other tandem architectures.

Defect Characterization and Passivation in Printable Electronic Materials—An Electrochemical and Spectroscopic Perspective Linze Du, Michel

De Keersmaecker, Joshua Hill, Neal R. Armstrong and Erin L. Ratcliff; University of Arizona, United States

This talk will focus on the combined use of photoelectron spectroscopy and electrochemical methods as a unique feedback loop to i) characterize the origin of defects in printable electronic materials; ii) quantify the energetics and effective density of states within the gap under applied voltage conditions; and iii) assess the validity of different passivation strategies using ionic liquid (IL) layers.

Defects and near-surface mid-gap states are a fundamental challenge in semiconductor materials. For example, in photovoltaic devices, controlling defects of charge selective layers and photoactive layers is critical to energy level alignment, functionality, and overall performance. For printable semiconductor materials and devices, a number of factors can increase the concentration of mid-gap defects, which can be coupled to complex Lewis and/or Bronsted acid/base chemistries, and redox reactions. We have recently shown that we can electrochemically quantify defect density and energetics in thin film opto-electronic materials using solid electrolytes, where the electrolytes act as transparent top contact in the dark and under illumination. Operando diffraction and spectroscopic tools can then be used under device-relevant conditions to probe changes in lattice spacing and band energetics.

Herein we expand on this to consider layer-by-layer vacuum deposition of IL films on prototype opto-electronic materials. Interfaces are characterized using photoemission spectroscopies (XPS/UPS) primarily to elucidate changes in band edge energetics at the electronic material/IL heterojunction. Striking differences are seen in the energetics and composition of these heterojunctions depending on the type of semiconductor substrate and type of IL deposited, which enhances our understanding of the electrostatic interactions between ILs and printed semiconductor materials which impact on both defect characterization and defect mitigation.

3:00 PM *EQ17.03.02
Metal Halide Perovskite Interface Reactivity—Towards Understanding Doping and Degradation Barry P. Rand; Princeton University, United States

Metal halide perovskite semiconductors have captured significant interest in the thin film optoelectronics community. As one example, certified photovoltaic efficiencies of metal halide perovskite solar cells currently exceed 25%, making them competitive in the laboratory with well-established technologies like multicrystalline-Si, CdTe, and CIGS. Also recently, gains have been made in perovskite-based light emitting devices (LEDs), with external quantum efficiency (EQE) of approximately 20% realized for bromide (green) and iodide (red/near-infrared) based perovskite emission layers. But in order to better understand the physics of device operation as well as degradation, we need to understand what can occur at interfaces of halide perovskites with other materials. For example, we have determined that metal halide perovskites not only feature mixed ionic-electronic motion but are also considerably chemically reactive, for example via redox or acid-base reactions. In addition, it may be possible to exploit this reactivity to allow for charge transfer doping, as we have shown perovskite systems with the ability to illustrate charge transfer states as well as doping with important implications on perovskite optoelectronic devices.

SESSION EQ17.04: Nanowire and Semiconductor Coatings
Session Chair: Elvira Fortunato

Hynes, Level 2, Room 203

10:30 AM EQ17.06.04
Spotlight Talk—Transparent Amphiphobic Surfaces from Metal-Organic Frameworks Vikaramjeet Singh and Manish K. Tiwari; University College London, United Kingdom

Transparent amphiphobic surfaces (repelling water and other low surface tension liquids) are of great interest in applications such as self-cleaning, anti-icing, anti-fouling, condensation and water harvesting etc. Current state-of-the-art in highly liquid repellent surfaces highlights several limitations on their use in practical applications. For example, superhydrophobic surface (SHS) suffer from instabilities/collapse of air pockets/cushion responsible for high liquid contact angles. Similarly, the retention of slippery behaviour in lubricant infused surfaces (SLIPS) and other smooth surfaces (SS) are restricted by eventual lubricant depletion and mechanical susceptibility of short molecular chains, respectively. Herein, we present a way to overcome these challenges by combining a robust nanohierarchical morphology with long flexible alkyl chains and achieve high drop mobility (~10 times than SLIPS) and amphiphobicity (Singh et al., Nano Lett. 2021, 21, 8, 3480–3486). High drop mobility comparable to superhydrophobic surfaces is achieved due to nanohierarchy i.e. reduced solid fraction (= 0.4). Precisely controlled nanohierarchy is obtained from surface grown metal-organic frameworks (MOFs) via layer-by-layer method. Covalently attached zirconium-based MOFs (OH-UIO-66) on glass substrate are used for demonstration due to their highly stable framework structure and easy synthesis. We observed a free sliding of vegetable oil, alcohols or other polar liquids at <15°. In addition to the excellent optical transparency and robustness, our surface enables a unique combination of additional desirable properties, e.g., resistance to high-speed liquid impact due to high capillary pressure generated from MOF nanopores (V = 35 m/s, We_l = 42,500), thermal stability up to 200 °C, and mechanical stability of scratch resistance. Moreover, benefiting from inherent porous structure of MOFs, our surface is able to absorb carcinogenic pollutants such as dyes and volatile organic compounds (VOCs) from water. These features endow the usage of the presented nanohierarchical MOF coating in applications such as windows, hand-held displays, goggles, wind screens, optoelectronics and so on.

10:35 AM EQ17.06.13
Spotlight Talk—3D Printing of Transparent Polysiloxanes Using Direct Ink Writing Michael Ford, Colin Loeb, Lemuel Pérez Pérez, Stuart Gammon, Steven Guzorek, Hawi Gemeda, A. Golobic, August Honnell, Justin Erspamer, Eric Duoss, Thomas Wilson and Jeremy Lenhardt; Lawrence Livermore National Laboratory, United States

Mixtures of silica and polysiloxane form thixotropic inks useful for 3D printing. However, 3D printed structures of these inks have typically been opaque due to the refractive index mismatch between the base polysiloxane and silica. By tuning the composition of the base polysiloxane, we matched the refractive index to formulate transparent inks. The transparent inks transmit up to ca. 90% of 700 nm light through 1 cm and remain transparent when solidified. We observed and characterized a thermochromic effect, where the inks change in opacity depending on refractive index mismatch and temperature. We also observed that the rheological properties of the ink depend on the distribution of silica particles, which is dictated by silica functionality, weight content, and processing. We demonstrate utility of these inks by printing encapsulants for LEDs, scintillators, and microfluidic mixing devices.

10:40 AM EQ17.06.15

Spotlight Talk—Late News: Large Area, Multi-Pulse Laser Lifetime of Purified Nematic Liquid Crystals at Near Infrared Wavelengths Selim Elhadj[1], Andy Bayramian[1], Stavros Demos[2] and Kenneth Marshall[2]; [1]Seurat Technologies, Inc., United States; [2]University of Rochester - LLE, United States

Nematic liquid crystals (LC's), ubiquitous in high information density displays, are typically composed of rod-shaped molecules that can exhibit large dielectric anisotropy, high birefringence and excellent transparency. These properties make them well suited for use in many optical components in high power laser systems, including polarization controllers and optoelectronic devices for beam shaping in 3D metal printing ["*A new era In metal part production"*, available at www.seuratech.com]. Recently, the single shot laser damage threshold of both saturated and un-saturated nematic LC's revealed an intrinsic relationship between the degree of chemical bond saturation within LC molecules and laser damage [Kosc *et al*, *Scientific Reports* 2019, 9 (1), 16435]. Extrinsic factors such as alignment layer material selection and preparation, particulate contamination and LC chemical purification can also play an important role in determining the optical response and durability of the liquid crystals. In this study we investigate the efficacy of several absorption-based purification methods and their impact on the laser damage behavior of nematic LC'S. We focus on the lifetime of purified and as-prepared LC'S when exposed to multiple laser pulses at kW's average power, over cm^2 areas, at near infrared wavelength and 20 to 40 Hz rep rates. Numerical simulations are used to estimate the degree of heat accumulation during exposure to rationalize the LC lifetime results.

10:45 AM EQ17.04.07
Interfacing Silicon with Doped Coatings for Band Modulation and Improved Light Emission Sufian Abedrabbo[1], El Mostafa Benchafia[1], Ahmad Al-Qawasmeh[1], Anthony T. T. Fiory[2] and Nuggehalli M. Ravindra[3]; [1]Khalifa University of Science and Technology, United Arab Emirates; [2]Integron Solutions, United States; [3]New Jersey Institute of Technology, United States

The recent report of a breakthrough in light emission in silicon-germanium alloys has renewed interest in light emission in silicon related materials and structures. The ability to tailor solid-solid interfaces, for a desired functionality, is of enormous interest in a vast variety of applications in materials science and engineering. In this work, engineered doped coatings catalyzed by several acids are deposited on silicon to introduce random interfacial stresses that can modulate the silicon bandgap. This modulation has been demonstrated to be beneficial by adding two functionalities to ordinary Czochralski-Si. It has appreciably improved bandgap radiative recombination of carriers by over two folds which leads to the possibility of engineering silicon-enabled absorber by circumventing Auger recombination processes, i.e. better light emitter and photovoltaic candidate at the same time. This talk will brief properties of the films that lead to light emission enhancement and will present the room-temperature photoluminescence results as well as the nature of the interfacial strains and will quantify bandgap modulations. Theoretical interpretation of these interesting results will be presented along with some comparative studies of stressed and alloyed silicon.

11:00 AM EQ17.04.06
De-Densifying Metallic Nanowire Networks Using Betweenness Centrality Adam Trebach[1], Evan Toth[2], Woo Hyun Chae[1], Jatin Patil[1], Ki-Jana Carter[1], Thomas Sannicolo[1] and Jeffrey C. Grossman[1,1]; [1]Massachusetts Institute of Technology, United States; [2]Northeastern University, United States

Silver nanowire networks show great promise as transparent conductors, but many nanowires in these materials participate only meagerly in conduction. Using graph theoretic measures to rank the importance of different nanowires, we show that simulated networks can be strategically de-densified to below the percolation threshold while maintaining low resistance. We achieve performance reaching 63% of the theoretical maximum, a roughly 91% gain over the performance predicted by percolation theory. Furthermore, the mathematical methods applied here are sufficiently general to apply to any networked material in which there is a non-monotonic relationship between density and performance.

11:15 AM EQ17.04.05
Encapsulation of Silver Nanowires *via* Metal-Oxynitride Reactive Sputtering for Highly Stable Transparent Electrodes Jatin Patil, Maya Reese, Eric Lee and Jeffrey C. Grossman; Massachusetts Institute of Technology, United States

Silver nanowire networks (AgNWs) are a promising candidate for transparent electrodes due to their high transparency, low sheet resistance, flexibility, and potential for low-cost implementation, owing to their high DC-to-optical conductivity ratio and low metal loading. These properties make it suitable for applications such as transparent heaters and solar cell electrodes. Unfortunately, AgNWs are susceptible to electrical, thermal and chemical degradation, which have largely stifled their implementation; effective encapsulation strategies are needed. To ensure the encapsulation approaches are scalable, industrial scale, high throughput deposition methods should be targeted. Moreover, encapsulation methods should use low cost, high-abundance elements with low-temperature processing. A variety of encapsulation approaches have been considered in the past, but physical vapor deposition approaches are the most promising for these criteria.

In this work, reactive pulsed DC and RF magnetron sputtering at room temperature are demonstrated as a promising approach to encapsulate AgNWs with thin films. Since using O_2 as a reactive gas can significantly oxidize and damage the AgNWs and active layer surfaces, N_2 is used as a reactive gas under moderate base chamber pressures (0.5×10^{-4} Torr). Low- to moderate- cost metal sputtering targets (Al, Ti, Zr) are then used to deposit as little as 20 nm of oxynitrides using mixed Ar and N_2 gas flow with high deposition rates. Oxynitride-encapsulated AgNW films show exceptional electrothermal stability, surviving at temperatures of 100°C more than unencapsulated AgNWs (>250°C). They also show exceptional chemical stability, where the electrical properties of Al oxynitride encapsulated wires stay nearly unchanged after >7 days under modified Damp Heat testing conditions (80°C, 80%RH). This work demonstrates a versatile approach to encapsulating AgNWs with sputtering, which can be extended to encapsulate lithographically patterned electrodes and other solar cell device architectures.

SESSION EQ17.05: Oxide Electronics and Transparent Conductive Oxides
Session Chair: Anna Regoutz
Wednesday Afternoon, December 1, 2021
Hynes, Level 2, Room 203

1:30 PM *EQ17.05.01
The Past, Present and Future of Oxide Electronics Elvira Fortunato, Emanuel Carlos, Rita Branquinho, Pedro Barquinha and Rodrigo Martins; NOVA University Lisbon, Portugal

Oxide electronic materials is one of the most promising technologies for electronic devices, as distinct from the traditional silicon technology. The fact that

circuits based on conventional semiconductors such as silicon and conductors such as copper can be made transparent by using different materials, the so-called transparent semiconducting and conducting oxides (TSOs and TCOs, respectively), is of great importance and allows for the definition of innovative fields of application with high added value.
Oxide electronic materials are becoming increasingly important in a wide range of applications including transparent electronics, optoelectronics, magnetoelectronics, photonics, spintronics, thermoelectrics, piezoelectrics, power harvesting, hydrogen storage and environmental waste management. Synthesis and fabrication of these materials, as well as processing into particular device structures to suit a specific application is still a challenge. Further, characterization of these materials to understand the tunability of their properties and the novel properties that evolve due to their nanostructured nature is another facet of the challenge.
In this paper we will present the most important landmarks achieved by these stimulating scientific area as well as some insights to emerging applications.

2:00 PM EQ17.05.02
Enhancement in Photo-Absorbing Performance of Hafnium–Indium–Gallium–Zinc Oxide Based Optoelectronic Devices by Reduction Treatment with Sodium Dithionite Min Seong Kim[1], Joohye Jung[1,2], Hyung Tae Kim[1], Dong Hyun Choi[1], Sujin Jung[1] and Hyun Jae Kim[1]; [1]Yonsei University, Korea (the Republic of); [2]Samsung Display, Korea (the Republic of)

During the last decade, the constant growth of interest in the field of optoelectronic devices has been observed in almost every commercial electronic device. Advances in interdisciplinary researches and industrial approaches have practically improved the optical characteristics of optoelectronic devices comparable with conventional silicon-based photodiodes. Among these extensive ranges of studies, transparent metal oxide semiconductors such as indium–gallium–zinc oxide or indium-zinc oxide have emerged as an important candidate owing to the wide variety of their electronic and optical properties, for instance, high field-effect mobility, low off-state current, optical transparency, high uniformity in large area deposition and processing versatility. However, the wide bandgap above 3 eV of metal oxide layer fundamentally restricts its light absorption range under about 420 nm which is the spectrum of ultraviolet and blue light. In this regard, more detailed researches about metal oxide semiconductors-based optoelectronic devices are required, which focus on how to engineer them for excellent responsivity upon the visible light and stability concurrently. Studies focusing on expanding the absorption range of metal oxide semiconductors-based phototransistors have been conducted by inserting a visible light absorption layer such as nanomaterials, quantum dots, perovskite, or two-dimensional materials. Although these results manifested the feasibility of metal oxide semiconductors-based optoelectronic devices, they still have some inherent barriers for practical large-scale devices due to the high cost and complicate fabrication process. In this work, we introduce a facile method to control the photoresponse characteristic of oxide semiconductor under visible light using a reducing agent, sodium dithionite ($Na_2S_2O_4$), that is able to compensate for the aforementioned limitations. $Na_2S_2O_4$ exhibits strong reducing properties due to its weak S-S bond. Photoresponse characteristic of hafnium–indium–gallium–zinc oxide (HIGZO) thin-film was enlarged to absorb visible light by modulating sub-gap states and oxygen vacancy of HIGZO through reduction treatment, immersing in $Na_2S_2O_4$ solution. Moreover, we revealed that photoresponsivity of HIGZO thin-film is easy to control substantially depending upon the molarity of $Na_2S_2O_4$. This controllability plays a key role in widening its potential applications and fine adjustment of performance from phototransistor to photo memory such as neuromorphic devices using persistent photoconductivity (PPC). Specifically, we achieved HIGZO phototransistors with photoresponsivity of 626.32 A/W, photosensitivity of 3.32×10^7, and detectivity of 7.18×10^{11} Jones under 10 mW/mm^2 of red light using 0.1 M of $Na_2S_2O_4$. In addition, HIGZO photomemory-based neuromorphic devices with a paired-pulse facilitation index of 142.6% under the input pulse of red light with 1 mW/mm^2 intensity were fabricated by increasing the molarity of $Na_2S_2O_4$ to 0.5 M. As a result, we successfully demonstrated the facile method for improving the performance of HIGZO optoelectronic devices by controlling the photoresponse characteristic which makes it possible to be applied in various optoelectronic applications.

2:15 PM EQ17.05.03
Unravelling the Chemical Conversion of Sub-10 nm Metal Oxide Thin–Film Precursors—An IRSE Study Christina Koutsiaki, Demosthenes Koutsogeorgis and Nikolaos Kalfagiannis; Nottingham Trent University, United Kingdom

The last decade has witnessed a remarkable development in thin film technologies, the application of which has marked a new era in electronics research and industry. To this end, thin film-based optoelectronic devices have created the foundation of outstanding technology applications, from flexible displays to smart window coatings, to name a few. Whilst the demand for improvement in device performance is increasing, Metal Oxides (MOs) have lately emerged as a prominent class of optoelectronic materials, whilst gathering a plethora of unique features such as increased carrier mobility, high optical transparency and mechanical stability. Besides their advantages, MOs present an excellent compatibility with solution processes, thus providing the opportunity of a novel, high-throughput manufacturing scheme of MO-based high-performance optoelectronic devices.
“Sol-gel” is established as one of the currently favourable solution processes, as it uniquely links MOs to solution processing. This deposition of organometallic precursors *via* wet techniques, followed by a subsequent thermal treatment, enables the formation of high-quality MOs, while accommodating essential advantages such as ambient processing conditions and composition tuning. The growing implementation of sol-gel ultra-thin MO layers (<10 nm) in optoelectronic devices renders the assessment and control of their optoelectronic properties essential. However, the cost and time-consuming features of current characterization techniques such as XPS and TEM hinders their implementation in a high-throughput production line. In addition, their “destructive” character (Pt deposition in TEM, Argon etching in depth-profile XPS) allows only for final product analysis, thus restricting the possibility of *in situ* monitoring during fabrication. Therefore, the presence of non-invasive, highly-sensitive characterization techniques could introduce a remarkable upgrade of MO thin film manufacturing.
To address this challenge, we propose Infra-Red Spectroscopic Ellipsometry (IRSE) as an alternative and novel approach towards the clarification of the sol gel precursor conversion stages, the control of which leads to high quality MO ultra-thin films. Particular focus is being paid in the role of substrates, as their optoelectronic properties may tune the presence of spectral features, thus allowing the detection of vibrational modes in ultra-thin films (~ 1 nm). In this study, $In(NO_3)_3$ dissolved in 2-Methoxyethanol ($C_3H_8O_2$) is converted into an ultra-thin In_2O_3 film (<10 nm), a popular MO semiconductor, widely used as a Transparent Conductive Oxide (TCO) host. The individual stages are captured by IRSE, aiming to shed light into the sol gel reaction conversion. For this, various substrates are being utilized (Al, TiN, Au and Si (including highly doped)), aiming to enhance the IRSE sensitivity, thus provide a clear monitoring of the conversion process through vibrational mode detection. We thus identify the intermediate products during transition towards In_2O_3. This introduces IRSE as a new route towards the detection of sol-gel stages in ultra-thin films, with its implementation in solution processing technologies being potentially essential. The suggested methodology can also be employed in the non-destructive characterization of an expanded material palette, such as 2-D materials. This approach could constitute a novel tool in thin film industry, thus boosting the new generation of optoelectronic devices.

2:30 PM EQ17.05.04
Solid Phase Epitaxial Growth of the Transparent Conducting Oxide $SrVO_3$ Samuel Marks, Lin Lin, Peng Zuo, Patrick Strohbeen, Ryan Jacobs, Dongxue Du, Jason Waldvogel, Rui Liu, Donald Savage, John Booske, Jason K. Kawasaki, Susan Babcock, Dane Morgan and Paul Evans; University of Wisconsin–Madison, United States

$SrVO_3$ thin films with a high figure of merit for applications as transparent conductors were crystallized from amorphous layers using solid phase epitaxy (SPE). Epitaxial metal oxides incorporating multivalent ions can be formed with thermodynamics and kinetics derived from crystallization processes that are initiated at buried amorphous/crystalline interfaces. We report crystallization methods allowing control of the ionic valence during crystallization and

the synthesis of epitaxial $SrVO_3$ on $SrTiO_3$. The $SrVO_3$ layers exhibited room temperature resistivity as low as 2.5×10^{-5} Ω cm and visible light transmission ranging from 0.89 to 0.52 for thicknesses from 16 to 60 nm. Amorphous $SrVO_3$ was deposited at room temperature using radio-frequency sputtering and crystallized by heating in a gas environment with selected oxygen activity. The lattice parameters and mosaic angular width of x-ray reflections from the crystallized films are consistent with partial relaxation of the strain resulting from the epitaxial mismatch between $SrVO_3$ and $SrTiO_3$ in the 60 nm layer while the 16 nm layers were found to be fully strained. A reflection high-energy electron diffraction study of the kinetics of SPE indicates that crystallization occurs via the thermally activated propagation of the crystalline/amorphous interface, similar to SPE in other perovskite oxides. Thermodynamic calculations based on density functional theory predict the temperature and oxygen partial pressure conditions required to produce the $SrVO_3$ phase and are consistent with the experiments. The separation of deposition and crystallization processes used in this work are scalable to large areas and can form the basis of technologies incorporating complex oxide electronic materials in emerging devices.

2:45 PM EQ17.05.05
CaCuP—A Degenerate Wide Band Gap Phosphide for Transparent Conducting Applications Joe Willis[1,2], Andrea Crovetto[3] and David O. Scanlon[1,2]; [1]University College London, United Kingdom; [2]Diamond Light Source, United Kingdom; [3]Helmholtz-Zentrum Berlin, Germany

In modern day life, transparent conducting materials (TCMs) are ubiquitous, playing an integral role in touch and display screens, solar cells and smart windows. P-type TCMs have often been overshadowed by n-type TCMs, due to the increased difficulty in synthesis, poorer stability and inferior opto-electronic properties. With technologies such as pop up windshield displays and fully transparent touch-display screens on the horizon, there is an impending need for the development of a high performance p-type TCM, in turn allowing the fabrication of a transparent p-n junction.

In 2017, CaCuP (and MCuP where M = Mg, Sr, Ba) was identified as a potential p-type TCM by Williamson et al, owing to its large valence band dispersion and optical absorption onset at around 2.7 eV.[1] Powders were synthesised and pressed into pellets, which were shown to be phase pure from XRD analysis, to possess a strong absorption onset of around 2.7 eV, and to display p-type conductivity of around 2×10^{-3} S cm^{-1}, with the origin of this conductivity suggested to be Cu vacancies. For a nominally undoped pressed powder sample, this was an impressive level of conductivity, and served as the motivation for this work.

Formation energies for the intrinsic defects in CaCuP have been calculated using hybrid density functional theory within VASP. The Cu vacancy possesses extremely low formation energies under cation poor growth conditions, and is stable into the valence band giving rise to degenerate semiconducting behaviour. The resulting hole charge density is delocalised through the Cu-P layers of the material, indicating high charge carrier mobility and conductivity.

Phase pure thin films have been successfully grown across a Cu gradient via the pulsed laser deposition technique. The measured room temperature conductivity is 1040 S cm^{-1}, a vast improvement over the pressed powder samples. Hall measurements indicate a mobility of 36 cm^2 V^{-1} s^{-1} and a carrier concentration of around 1.8×10^{20} cm^{-3}, supporting the defect calculation results and indicative of a degenerate semiconductor. Temperature dependent charge transport calculations are being performed using the AMSET code[2] to assess if this is the intrinsic material limit, or if improved electronic properties could be achieved with a better optimised deposition process. The optical behaviour of these films is not straightforward, with a larger absorption coefficient than expected seen at the indirect band gap value of around 1.2 eV – optical defect transition calculations are being performed in order to understand this further.

Late News: Solution-Processed Cathode Interfacial Layers for Efficient Energy Level Alignment in Organic Photovoltaics Jisu Hong[1,2], Zhang Dongbo[1], Hyeok-jin Kwon[2], Chan Eon Park[2], Soon-Ki Kwon[1] and Yun-Hi Kim[1]; [1]Gyeongsang National University, Korea (the Republic of); [2]Pohang University of Science and Technology, Korea (the Republic of)

Organic Photovoltaics (OPVs) have now attained high power conversion efficiencies (PCEs) over 15%, and research on OPV fabrication via solution processes on flexible substrates, and replacement of toxic halogenated solvents by environmentally benign solvents, is underway, as are extensive efforts to improve the PCEs. In this work, we synthesized solution processable cathode interfacial materials and used in OPVs. Two small-molecule interfacial materials with phosphine oxide and benzoimidazole groups were designed to induce strong interface dipoles and chelate with the metal electrodes. We used isopropanol, an environmentally benign solvent, to dissolve the small-molecule materials and spin-coated solutions onto photoactive layers. The interfacial materials formed ohmic contacts between the electron acceptor materials and the OPV cathodes due to the strong interface dipoles. As the highest occupied molecular orbital (HOMO) energy level of the interfacial materials is -7.05 eV, hole carriers cannot travel toward the cathode. The appropriate energy levels of the interfacial materials and the efficient energy level alignment facilitated charge extraction at the cathodes and increased the PCEs of OPVs. Of the two, BIPO (with two benzoimidazole groups) more efficiently formed smooth interfacial layers on active layers that allowed of better energy level alignment between the electron acceptor materials and the cathodes.

EQ17.06.02
Helical Self-Assemblies of Pt(II) Complexes Exhibit Strong Circularly Polarized Luminescence Emission Dong Yeun Jeong[1], Seung Yeon Yu[2], Jong Jin Park[3], Jong Hyun Kim[3] and Youngmin You[1]; [1]Ewha Womans university, Korea (the Republic of); [2]Ewha Womans University, Korea (the Republic of); [3]Ajou University, Korea (the Republic of)

Circularly polarized luminescence (CPL) refers to the differential photoemission between left- and right-handedly polarized lights. The polarity of CPL provides a unique principle for photonic applications, including three-dimensional displays and quantum encryption. However, previous CPL-active materials have suffered from a trade-off between a photoluminescence quantum yield (PLQY) and a luminescence dissymmetry factor (g_{lum}). We recently

discovered that helical co-assemblies of square-planar cycloplatinated complexes could overcome the intrinsic limitation. This strategy exploited an asymmetric exciton coupling and the magnetically allowed metal-metal-to-ligand charge-transfer (MMLCT) transition within the Pt(II) complex co-assemblies. However, utility of this strategy is limited because it inevitably requires chiral guest molecules to form helical co-assemblies.
In this research, we have developed a combined top-down and bottom-up strategy which enables strong CPL emissions without chiral guest molecules. Our strategy takes advantage of the chiral induction effect exerted by counter anions of charge-cationic Pt(II) complexes. The Pt(II) complexes stack in a face-to-face fashion to form helical self-assemblies, where the helical sense is dictated by the point chirality of counter anions. We tailored the chemical structures of the counter anions, including (*R*)-/(*S*)-tetrahydrofuran-2-carboxylates ((*R*)-/(*S*)-TC), L-/D-dipivaloyl tartarate (L-/D-PT), and L-/D-dibenzoyl tartarate (L-/D-BT).
The Pt(II) complex self-assemblies could be grown by in-situ anion metathesis between [(2-phenylpyridinato)(4,4′-bis(nonyl)-2,2′-bipyridine)platinum]ClO_4 ([PtN]ClO_4) and tetrabutylammonium (TBA) salts of the chiral anions in 1,2-dichloroethane (1,2-DCE):CH_3CN (8:2, wt/wt). The formation of PtN self-assemblies were supported by an emergence of the MMLCT absorption at 500 nm and the strong MMLCT phosphorescence at 613 nm (PLQY = 0.19 for the $[PtN]_2$BT self-assemblies). The MMLCT transitions of the self-assemblies were chiroptical, as seen from strong couplets at 500 nm in electric circular dichroism. Among the tested anions, BT having the -2 charge and the elongated π-conjugation structure resulted in the most tight and helical stacking of PtN. As expected, helical supramolecular structures were absent for the self-assemblies of [PtN]ClO_4.
To further enhance the CPL activities, we allowed the self-assembly formation within microchannels with a 28 μm width which were formed by a conformal contact between a glass substrate and a poly(dimethylsiloxane) mold. The self-assemblies of $[PtN]_2$BT formed within the microchannels exhibited a two-fold improvement in PLQY (0.32) over that (0.19) of the self-assemblies formed onto the planar glass substrate. In addition, an order of magnitude enhancement in $|g_{lum}|$ was also found; g_{lum} (572 nm) were -0.12 and 0.13 for the self-assemblies of $[PtN]_2$L-BT and $[PtN]_2$D-BT, respectively, grown within the microchannels, whereas g_{lum} (572 nm) were -0.027 and 0.037 for the dropcasted self-assemblies of $[PtN]_2$L-BT and $[PtN]_2$D-BT, respectively. The notable improvement in $|g_{lum}|$ was attributed to the tight and ordered supramolecular packing structures. Our approach is valuable as it does not rely on chiral guest molecules. The successful combination with soft-lithographic techniques will stimulate the future research to construct CPL-active materials.

EQ17.06.03
High-Efficiency Thermally Activated Delayed Fluorescence Emitters with High Horizontal Orientation and Narrow Deep-Blue Emission Youngnam Lee and Jong-In Hong; Seoul National University, Korea (the Republic of)

Highly efficient 10-(5,9-dioxa-13*b*-boranaphtho[3,2,1-de]anthracen-7-yl)-10*H*-dispiro[acridine-9,9′-anthracene-10′,9″-fluorene] (OBOtSAc) and 10-(2,12-di-*tert*-butyl-5,9-dioxa-13*b*-boranaphtho[3,2,1-de]anthracen-7-yl)-10*H*-dispiro[acridine-9,9′-anthracene-10′,9″-fluorene] (tBuOBOtSAc) emitters, comprising almost perpendicularly linked rigid 5,9-dioxa-13*b*-boranaphtho[3,2,1-de]anthracene (OBO) electron acceptors and a rigid and linear tri-spiral acridine electron donor, are reported here. OBOtSAc and tBuOBOtSAc show deep-blue emission (λ_{max} = 452 and 446 nm) with narrow full width at half maximum (FWHM) values of 50 and 48 nm, respectively. Due to the rigid and twisted structures, and the appropriate singlet and triplet energy levels of both emitters, 10 wt% doped films of OBOtSAc and tBuOBOtSAc in a bis[2-(diphenylphosphino)phenyl]ether oxide (DPEPO) host show efficient thermally activated delayed fluorescence (TADF) emission and photoluminescence quantum yields (PLQYs) of 97% and 90%, respectively. Moreover, linear-shaped OBOtSAc and tBuOBOtSAc lead to excellent horizontal emitting dipole orientations (88% and 90%, respectively). Consequently, organic light-emitting diode (OLED) devices using OBOtSAc and tBuOBOtSAc exhibit maximum external quantum efficiencies (EQEs) of 31.2% and 28.2%, respectively, and Commission Internationale de l'Éclairage (CIE) coordinates of (0.147, 0.092) and (0.149, 0.061), respectively.

EQ17.06.04
Spotlight Talk—Transparent Amphiphobic Surfaces from Metal-Organic Frameworks Vikaramjeet Singh and Manish K. Tiwari; University College London, United Kingdom

Transparent amphiphobic surfaces (repelling water and other low surface tension liquids) are of great interest in applications such as self-cleaning, anti-icing, anti-fouling, condensation and water harvesting etc. Current state-of-the-art in highly liquid repellent surfaces highlights several limitations on their use in practical applications. For example, superhydrophobic surface (SHS) suffer from instabilities/collapse of air pockets/cushion responsible for high liquid contact angles. Similarly, the retention of slippery behaviour in lubricant infused surfaces (SLIPS) and other smooth surfaces (SS) are restricted by eventual lubricant depletion and mechanical susceptibility of short molecular chains, respectively. Herein, we present a way to overcome these challenges by combining a robust nanohierarchical morphology with long flexible alkyl chains and achieve high drop mobility (~10 times than SLIPS) and amphiphobicity (Singh et al., Nano Lett. 2021, 21, 8, 3480–3486). High drop mobility comparable to superhydrophobic surfaces is achieved due to nanohierarchy i.e. reduced solid fraction (= 0.4). Precisely controlled nanohierarchy is obtained from surface grown metal-organic frameworks (MOFs) via layer-by-layer method. Covalently attached zirconium-based MOFs (OH-UIO-66) on glass substrate are used for demonstration due to their highly stable framework structure and easy synthesis. We observed a free sliding of vegetable oil, alcohols or other polar liquids at <15°. In addition to the excellent optical transparency and robustness, our surface enables a unique combination of additional desirable properties, e.g., resistance to high-speed liquid impact due to high capillary pressure generated from MOF nanopores (V = 35 m/s, We_l = 42,500), thermal stability up to 200 °C, and mechanical stability of scratch resistance. Moreover, benefiting from inherent porous structure of MOFs, our surface is able to absorb carcinogenic pollutants such as dyes and volatile organic compounds (VOCs) from water. These features endow the usage of the presented nanohierarchical MOF coating in applications such as windows, hand-held displays, goggles, wind screens, optoelectronics and so on.

EQ17.06.05
Improved Charge Injection in Metal-Polymer Interfaces of Inverted Organic Electronic Devices Using Dithiolane-Based Self-Assembled Monolayers Sneha Sreekumar, Marzieh Hydari, Zhongkai Cheng, Hemanth Maddali, Elena Galoppini and Deirdre O'Carroll; Rutgers, The State University of New Jersey, United States

The fabrication of polymer-based organic light-emitting diodes (OLEDs) using the inverted method, where the device is built on top of a metal back electrode has advantages over more conventional OLED fabrication methods. For example, the inverted method provides a way to control the structure and morphology of the metal electrode. This, in turn, enables improved light management by control of the photonic and plasmonic behavior within the OLED devices. Ag is a good option as a back metal electrode in OLEDs because of its low optical loss, high reflectivity and high conductivity. However, Ag has a work function (~4.4 eV) which is not compatible with the band gap of many polymeric organic semiconductors.
Poly(9,9-dioctylfluorene-alt-benzothiadiazole) (F8BT) is a conjugated polymer commonly used in OLED prototypes that has high electron affinity (~3.3 eV), large ionization potential (~5.9 eV), and high fluorescence quantum yield. Combining F8BT with an Ag back electrode results in a high barrier height for charge injection, which results in poor device performance and a high turn on voltage. A method to overcome this, as some studies on organic field-effect transistors (OFETs) have, used self-assembled monolayers (SAMs) of sulphur compounds like thiols to reduce the work function of Ag and the barrier height for charge injection into the polymer.
Here, we have extended this methodology in using the more commercially available lipoic acid (LA) and its derivatives to form SAMs in between Ag back electrodes and F8BT thin films. By selecting LA, we can tailor the functional groups at one end of the compound by converting the acid to an ester,

allowing the influence of difference alkyl chains as well as chain lengths to be investigated. We have studied how having two sulphur linkages instead of one in the case of conventional thiols like 1-decanethiol(1-DT), as well the dipole orientation of the molecules can change the work function of Ag and improve the contact at the metal-polymer interface. X-ray photoelectron spectroscopy and Raman spectra reveal the binding properties of the SAMs, while current density-voltage and ultraviolet photoelectron spectroscopy measurements show that (±)-α-lipoic acid and (±)-4-phenylbutyl 5-(1,2-dithiolan-3-yl)pentanoate improve the charge injection greatly by changing the work function of the Ag and by altering the morphology of the semiconducting polymer. The results obtained gave us valuable insight into the effect of chain length and functional groups of the SAMs in engineering morphological and electronic properties of the metal-polymer interface.

Facile and Rapid Fabrication of p-type Copper Iodide Nanowire Networks and Utilization in UV Photodetectors Muhammed A. Calasin[1], Serkan Koylan[1], Loay Madbouly[1], Sensu Tunca[1], Yusuf Tutel[1], Sahin Coskun[2] and Husnu E. Unalan[1,1,1]; [1]Middle East Technical University, Turkey; [2]Osmangazi University, Turkey

Semiconductors industry necessitate p-type materials in a wide range of applications like photovoltaics, light-emitting diodes, detectors, transistors and thermoelectrics. Copper iodide (CuI) has received significant interest as an alternative beyond silicon. Intriguing optoelectronic properties of CuI include but not limited to, direct and wide bandgap (3.1 eV measured as thin film), high hole mobility (in excess of 40 $cm^2/V.$ s) and large exciton binding energy (62 meV). Direct iodination of copper thin films allows production of CuI films even at room temperature, which makes CuI a suitable candidate for flexible and transparent electronics. In this study, γ-CuI nanowire networks were fabricated through direct vapor iodination of copper nanowire (Cu NW) networks. Cu NWs were synthesized and purified by solution means and deposited onto glass substrates by spray coating [1,2]. A house-made setup was used for the vapor iodination of Cu NW networks. The transformation of Cu to γ-CuI was monitored through investigating morphological, structural, chemical and optoelectronic properties of the fabricated γ-CuI NW networks. Upon 120 seconds exposure to iodine vapor, initially smooth Cu NW surface became rough, indicating transformation to γ-CuI with a zinc-blende structure. γ-CuI NWs were found to consist of only Cu^+ and I^{-1}. Hall-effect measurements revealed a mobility and resistivity of 12 $cm^2/V.s$ and 19.9 ohm-cm, respectively. Optical transmittance of γ-CuI NW networks was over 68% in the wavelength range of 300-1200 nm, while that of Cu NWs was 85%. The direct optical band gap value was determined as 3.2 eV with the help of Tauc's plot. Following materials characterization, UV-photodetectors in metal-semiconductor-metal structure were fabricated using γ-CuI NW networks. A three times increase in current was registered in response to UV light illumination (with a wavelength 365 nm) under 5 V.

Polyimide Doped Indium-Gallium-Zinc Oxide Based Transparent and Flexible Phototransistor for Visible Light Detection Kiseok Kim[1,2], Min Seong Kim[1], Jusung Chung[1], Dongwoo Kim[1], I Sak Lee[1] and Hyun Jae Kim[1]; [1]Yonsei University, Korea (the Republic of); [2]LG Display Co., Ltd., Korea (the Republic of)

Nowadays, displays are evolving as a way of interacting with users rather than simply conveying information. Interactive display is one of the new high-value-added display technologies and means a display that enables interaction between users and display devices through interface technology with transparent display panels that incorporate various sensors. These interactive displays can perform various roles, such as providing new experiences to users through interaction with users and responding to emergency situations through real-time environment awareness. For the implementation of these interactive displays, research on transparent and flexible phototransistors for embedding in transparent display panels is essential. The phototransistor is an essential element to perform various functions such as user's touch, motion, and gaze recognition. To apply it to transparent displays, it is also essential to ensure transparency, to facilitate processing for large-area substrates, and to have low off current for high photosensitivity. Therefore, oxide semiconductors with high transparency, large area processability, and reasonable mobility (~ $10cm^2/Vs$) are suitable candidates for the channel layer of phototransistors. However, oxide semiconductors cannot absorb visible light with large bandgap energy of ~ 3.0 eV. For fabricate an oxide semiconductor-based phototransistor that can absorb the full range of visible light, one of the most widely used methods is to add absorption layer such as chalcogenides, organics, perovskites, and nanodots. However, in the case of the materials that can absorb visible light, it is not transparent due to a small bandgap. Thus, it is difficult to fabrication transparent phototransistors.
In this work, we propose a method for fabricating polyimide (PI) doped single layer (PSL) phototransistor that is transparent and can absorb visible light. Amorphous indium-gallium-zinc oxide (IGZO) and PI can be deposited using co-sputtering process for the channel layer itself to absorb visible light. The PI is well known in the display industry as a flexible substrate and can be made into a sputter target, so it can be used in sputter equipment. We used a SiO_2/p^+-Si substrate in which SiO_2 is thermally oxidized on a p^+-Si wafer; the p^+-Si and SiO_2 were used as gate and gate insulator, respectively. On the SiO_2/p^+-Si substrate, the PSL phototransistor was deposited as a channel layer using a co-sputtering process; a shadow mask was used for patterning. The powers of IGZO and PI were set to 150 W and 0 to 30 W, respectively. After that, thermal annealing was performed at 300 ºC for 1 hr. Finally, aluminum was deposited as a source/drain using a shadow mask for patterning. When fabricating the PSL phototransistor, it was optimized by controlling the sputter power of the PI target. We confirmed that the PSL phototransistor fabricated with sputter power of PI 10 W featured excellent optoelectronic characteristics compared with other PSL phototransistors. In addition, when compared with the IGZO phototransistor, the optoelectronic characteristics of the PSL phototransistor also improved in red lights at $1mW/mm^2$ intensity. Specifically, photoresponsivity improved from 14.43 to 623.79 A/W, photosensitivity improved from 2.30×10^0 to 9.89×10^6, and detectivity improved from 8.92×10^6 to 5.83×10^{11} Jones. Furthermore, as the bending test was conducted 10,000 times, the flexible PSL phototransistor exhibited stable optoelectronic characteristics.
As the phototransistors can be fabricated with an organic material, this manufacturing method shows mechanical flexibility and reliability, which enables its usage in the display industry in the future.

EQ17.06.09

Silver Nanoparticles-Decorated Titanium Oxynitride Nanotube Arrays for Enhanced Solar-Assisted Hydrogen Generation Nageh K. Allam; American University in Cairo, Egypt

We demonstrate, for the first time, the synthesis of highly ordered titanium oxynitride nanotube arrays sensitized with Ag nanoparticles (Ag/TiON) as an attractive class of materials for visible-light-driven water splitting. The nanostructure topology of TiO2, TiON and Ag/TiON was investigated using FESEM and TEM. The X-ray photoelectron spectroscopy (XPS) and the energy dispersive X-ray spectroscopy (EDS) analyses confirm the formation of the oxynitride structure. Upon their use to split water photoelectrochemically under AM 1.5 G illumination (100mW/cm2, 0.1M KOH), the titanium oxynitride nanotube array films showed significant increase in the photocurrent (6mA/cm2) compared to the TiO2 nanotubes counterpart (0.15mA/cm2). Moreover, decorating the TiON nanotubes with Ag nanoparticles (13±2nm in size) resulted in exceptionally high photocurrent reaching 14mA/cm2 at

1.0VSCE. This enhancement in the photocurrent is related to the synergistic effects of Ag decoration, nitrogen doping, and the unique structural properties of the fabricated nanotube arrays.

EQ17.06.10
Experiments and DFT Calculations of DTO Crystal Iskander G. Batyrev and Rosario C. Sausa; DEVCOM U.S. Army Research Laboratory, United States

X-ray diffraction (XRD) and Raman spectroscopy measurements of relatively new energetic crystal DTO [N-(1,7-dinitro-1,2,6,7-tetrahydro-[1,3,5]triazino[1,2-c][1,3,5]oxadiazin- 8(4H)-ylidene)nitramide] are accompanied by DFT calculations. Calculated XRD and Raman spectra are in reasonable agreement with experiments. Calculated vibrational spectra identified in terms of atomic movements help us determine the `weakest link` in the molecular crystal, whereas DFT partial charge density calculations related with N, C, and O atoms are used to find most chemically active atoms in crystal decomposition. In addition, the calculations show that the cage-containing N atoms provide the main contribution near the bottom of the DTO valence band. The DTO band gap calculated with hybrid function is compared to the band gap of several other energetic materials with regards to impact sensitivity.

EQ17.06.11
Investigation of the Electronic Structure and Triplet Emission Energy of $Ir(azp)_2(acac)$—an Organometallic Infrared Emitter Nasir Javed, Jinyu Chong and Deirdre O'Carroll; Rutgers, The State University of New Jersey, United States

Infrared (IR) emitting phosphorescent materials have unique photophysical properties which make them useful for applications in optoelectronic devices. $Ir(azp)_2(acac)$ (Bis(1-monoazaperylene)iridium(acetylacetonate)) is a promising phosphor for IR emitting applications; however, little information is available about the frontier orbitals and triplet states of this molecule. Here, density-functional theory (DFT) is used to calculate the singlet and triplet electronic structure of $Ir(azp)_2(acac)$, and the triplet emission energy. Typically, DFT calculation results of organometallic phosphors, especially of iridium-based emitters, are reported with varying accuracy compared to experimental results. Therefore, first a calculation method is established by carrying out DFT calculations of two well-known organometallic phosphorescent materials: FIrpic (Bis[2-(4,6-difluorophenyl)pyridinato-C^2,N](picolinato)iridium) and $Ir(ppy)_3$ (tris(2-phenylpyridine)iridium). A set of different hybrid functionals that are a mixture of Hartree-Fock exchange with DFT exchange-correlation (e.g., B3LYP, M05, M06), or a long-range correlation functional (e.g., CAM-B3LYP), are used with different basis sets including double-zeta (such as LANL2DZ) and polarized triple-zeta basis sets (such as DEF2TZVP) to optimize the ground state and triplet state geometries of the molecules in solvents (using polarizable continuum model) and in the gas phase. It is determined that the B3LYP functional performs better as compared to other functionals in terms of performance as well as accuracy; most likely because it uses non-local correlation, which works better with large molecules. From the DFT calculations of FIrpic and $Ir(ppy)_3$, and comparing the calculation results with relevant literature, it is determined that the LANL2D basis set gives results within less than 0.2 eV of error. The DEF2TZVP, being a bigger basis set used with the B3LYP functional, gives the most accurate energy levels; however, it requires much longer computational time. Later, the B3LYP functional and DEF2TZVP basis set are used to carry out geometry optimization of $Ir(azp)_2(acac)$ in the ground state and in the first triplet state in dichloromethane and in the gas phase. Energy levels of the highest occupied molecular orbital (HOMO), lowest unoccupied molecular orbital and first triplet level (T_1) are determined from the optimized geometry. Finally, the triplet emission energy is calculated from the difference in energy level of T_1 and HOMO. This study not only provides useful information about the frontier orbitals and triplet states of $Ir(azp)_2(acac)$ but also will help researchers working in the field in selecting appropriate functionals and basis sets for DFT calculations of the similar molecules.

EQ17.06.12
Optimization of Indium Oxide Thin Films by Molecular Beam Epitaxy Erika V. Ortega Ortiz, Johanna Nordlander, Margaret Anderson, Charles Brooks and Julia Mundy; Harvard University, United States

Transparent conducting oxide (TCO) thin films play an important role in the development of optoelectronic devices. To fulfill their function as contacts and interfaces in optoelectronics, these materials need to perform well in terms of electronic conductivity, while at the same time maintaining their optical transparency. The most widely-used TCO is indium tin oxide. However, a remaining long-standing challenge in the synthesis of such indium-oxide-based thin films is achieving a sufficiently high crystalline quality and smooth surface morphology, which has complicated their integration into next-generation nanoscale devices. Here, we use oxide molecular beam epitaxy to explore the optimal growth parameters for both undoped and doped indium oxide on various technologically relevant substrates. By combining in-situ electron diffraction during thin-film growth with post-deposition X-ray diffraction and atomic-force microscopy, we achieve improved epitaxy and smoothness of our films as an important step to facilitate their integration in nanoscale optoelectronic devices.

EQ17.06.13
Spotlight Talk—3D Printing of Transparent Polysiloxanes Using Direct Ink Writing Michael Ford, Colin Loeb, Lemuel Pérez Pérez, Stuart Gammon, Steven Guzorek, Hawi Gemeda, A. Golobic, August Honnell, Justin Erspamer, Eric Duoss, Thomas Wilson and Jeremy Lenhardt; Lawrence Livermore National Laboratory, United States

Mixtures of silica and polysiloxane form thixotropic inks useful for 3D printing. However, 3D printed structures of these inks have typically been opaque due to the refractive index mismatch between the base polysiloxane and silica. By tuning the composition of the base polysiloxane, we matched the refractive index to formulate transparent inks. The transparent inks transmit up to ca. 90% of 700 nm light through 1 cm and remain transparent when solidified. We observed and characterized a thermochromic effect, where the inks change in opacity depending on refractive index mismatch and temperature. We also observed that the rheological properties of the ink depend on the distribution of silica particles, which is dictated by silica functionality, weight content, and processing. We demonstrate utility of these inks by printing encapsulants for LEDs, scintillators, and microfluidic mixing devices.

EQ17.06.14
AZO/TiO_2 Core-Shell Heterojunction Nanorods for Dye-Sensitized Solar Cells Hiroto Ando, Mahito Yamamoto and Mitsuru Inada; Kansai University, Japan

It is well known that increasing the surface area and reducing the electrical resistance of the photoanode electrode are important factors for realizing a highly efficient dye-sensitized solar cell. Long and dense nanorods are a suitable structure for obtaining a large surface area. However, in long nanorods, the photoexcited carriers tend to recombine before reaching the electrode, which causes a decrease in photoelectric conversion efficiency. Therefore, a low resistivity material is desired as the nanorod material. ZnO possess higher electron transport properties than traditional anode material, TiO_2, and thus improve the conversion efficiency of the solar cell. However, bare ZnO nanorods are prone to chemical etching. In this point, the ZnO/TiO_2 core-shell heterojunction is candidate for the nanodot, because TiO_2 shell can prevent both the chemical eiching and material corrosion caused by the external

environment such as acid and/or alkali solutions. Nevertheless, the conversion efficiency of present ZnO/TiO_2 nanorod dye-sensitized solar cells is not sufficiently high. In this study, we adopted Al-doped ZnO (AZO) as the core nanorod material. This is because the resistivity of AZO is lower than that of ZnO, so higher conversion efficiency can be expected.

AZO/TiO_2 core-shell heterojunction nanorods are prepared by a combination of hydrothermal method and successive ionic layer absorption and reaction (SILAR) method. Fluorine-doped tin oxide (FTO) sheet glass was used as substrate. AZO seed layer was deposited on the FTO glass substrate by sputtering. AZO nanorods were prepared by immersing the substrate in a mixtured solution of zinc nitrate hexahydrate, aluminum nitrate hexahydrate, hexamethylenetetramine and polyethyleneimine at 90°C for 3 hours. TiO_2 shell layer was then prepared by SILAR method, repeatedly dipping three kinds of solution, "titanium tetraisopropoxide + diethanolamine + IPA", "IPA" and "deionized water", in this order. From SEM observations, the typical length and diameter of the nanorods were 1.6μm and 60 nm, respectively.

Comparing the performance of our dye-sensitized solar cells using AZO nanorods and that of ZnO nanorods, the short-circuit current increased by 12% and the photoelectric conversion efficiency improved by 43% by using AZO nanorods.

EQ17.06.15
Spotlight Talk—Late News: Large Area, Multi-Pulse Laser Lifetime of Purified Nematic Liquid Crystals at Near Infrared Wavelengths Selim Elhadj[1], Andy Bayramian[1], Stavros Demos[2] and Kenneth Marshall[2]; [1]Seurat Technologies, Inc., United States; [2]University of Rochester - LLE, United States

Nematic liquid crystals (LC's), ubiquitous in high information density displays, are typically composed of rod-shaped molecules that can exhibit large dielectric anisotropy, high birefringence and excellent transparency. These properties make them well suited for use in many optical components in high power laser systems, including polarization controllers and optoelectronic devices for beam shaping in 3D metal printing ["*A new era In metal part production"*, available at www.seuratech.com]. Recently, the single shot laser damage threshold of both saturated and un-saturated nematic LC's revealed an intrinsic relationship between the degree of chemical bond saturation within LC molecules and laser damage [Kosc *et al*, *Scientific Reports* 2019, 9 (1), 16435]. Extrinsic factors such as alignment layer material selection and preparation, particulate contamination and LC chemical purification can also play an important role in determining the optical response and durability of the liquid crystals. In this study we investigate the efficacy of several absorption-based purification methods and their impact on the laser damage behavior of nematic LC'S. We focus on the lifetime of purified and as-prepared LC'S when exposed to multiple laser pulses at kW's average power, over cm^2 areas, at near infrared wavelength and 20 to 40 Hz rep rates. Numerical simulations are used to estimate the degree of heat accumulation during exposure to rationalize the LC lifetime results.

Probing Buried Interfaces in Device Heterostructures Using Soft and Hard X-Ray Photoelectron Spectroscopy Anna Regoutz; University College London, United Kingdom

Interfaces govern the behaviour of all electronic devices. Herbert Kroemer coined the famous phrase "the interface is the device" in his 2000 Nobel Prize lecture, and we are still applying tremendous effort to understand interfaces in new material generations, with transparent and wide band gap materials being no exception. Understanding gained for the bulk behaviour of materials can often not be extended to their behaviour in structured film stacks, where interfaces play a vital role.

This talk will give an overview of analytical strategies to probe buried interfaces between metallisation, dielectrics and semiconductors using both soft and hard X-ray photoelectron spectroscopy (XPS and HAXPES). It will contrast opportunities and limitations of these techniques to qualitatively and quantitatively explore heterostructures both in the laboratory and at synchrotron sources. It will explore how the different types of spectral features, such as shallow and deep core levels, Auger lines, and valence spectra, can be used to understand aspects of device critical interfaces such as elemental distributions, local chemical environments, intermixing and interdiffusion, and interface defects.

To illustrate the capabilities of PES techniques to address device interfaces and their structure and electronic structure, application examples including bulk Ga_2O_3, transparent conducting oxide (TCO) based transistors and diodes and copper-based industrial metallisation schemes will be used.

Understanding the Surface Chemistry of Tin Dioxide Gas Sensors Luisa Herring Rodriguez[1], Chris Blackman[1] and David O. Scanlon[1,2,3]; [1]University College London, United Kingdom; [2]Diamond Light Source, United Kingdom; [3]Thomas Young Centre, United Kingdom

Tin dioxide (SnO_2) is one of the most studied and used metal oxide semiconductors and is often used in gas sensors. Despite the extensive research into SnO_2 and its wide range of uses, its surface chemistry is still not fully understood. A detailed literature search of previously proposed surface structures and gas adsorption mechanisms for SnO_2 reveals many conflicting models with zero consensus. This disparity between different mechanistic theories demonstrates the need for a more thorough investigation into SnO_2 if we are to design new gas sensing materials in a methodical way in the future.

In this work, we use levels of accuracy within a Density Functional Theory (DFT) framework which have hitherto been inaccessible due to their computational expense. We initially calculate the optoelectronic properties of bulk SnO_2 and systematically investigate the effect of slab and vacuum thickness on surface model validity. We go on to calculate the energetics and electronic structures for a range of proposed surface defects, as well as for various proposed gas adsorption sites.

Our initial results show that larger slab models than those previously used are required to accurately represent the SnO_2 crystal structure. Overall, this work highlights how modern first-principles methods can elucidate surface phenomena in well-studied materials and paves the way for the rational design of new inorganic compounds for gas sensing applications.

Rapid Recombination by Cadmium Vacancies in CdTe Seán R. Kavanagh[1], Aron Walsh[2] and David O. Scanlon[3]; [1]University College London & Imperial College London, United Kingdom; [2]Imperial College London, United Kingdom; [3]University College London, United Kingdom

The ability to accurately model, understand and predict the behaviour of crystalline defects would constitute a significant step towards improving photovoltaic device efficiencies and semiconductor doping control, accelerating materials discovery and design.[1] In this work, we apply hybrid Density Functional Theory (DFT) including spin-orbit coupling to accurately model the atomistic behaviour of the cadmium vacancy (V_{Cd}) in cadmium telluride (CdTe).[1] In doing so, we resolve several longstanding discrepancies in the extensive literature on this species.

CdTe is a champion thin-film absorber for which defects, through facilitation of non-radiative recombination, significantly impact photovoltaic (PV) performance, contributing to a reduction in efficiency from an ideal detailed-balance limit of 32% to a current record of 22.1%. Despite over 70 years of experimental and theoretical research, many of the relevant defects in CdTe are still not well understood, with the definitive identification of the atomistic origins of experimentally observed defect levels remaining elusive.[2–4]

In this work, through identification of a tellurium dimer ground-state structure for the neutral Cd vacancy, we obtain a single negative-U defect level for V_{Cd} at 0.35 eV above the VBM, finally reconciling theoretical predictions with experimental observations. Moreover, we reproduce the polaronic, optical and magnetic behaviour of V_{Cd}^{-1} in excellent agreement with previous Electron Paramagnetic Resonance (EPR) characterisation.[5,6] We find the cadmium vacancy facilitates rapid charge-carrier recombination, reducing maximum power-conversion efficiency by over 5% for *untreated* CdTe—a consequence of tellurium dimerisation, metastable structural arrangements, and anharmonic potential energy surfaces for carrier capture.

The origins of previous discrepancies between theory and experiment, namely incomplete mapping of the defect potential energy surface (PES) and approximation models, are highlighted and discussed. Importantly, these results demonstrate the necessity to include the effects of both metastability and anharmonicity for the accurate calculation of both charge-carrier recombination rates in emerging photovoltaic materials and the efficiency limits imposed by both native and extrinsic defect species.

1:00 PM *EQ17.10.01
Thin-Film Solar Cell Structures as Revealed by Electron and X-Ray Spectroscopies Marcus Baer[1,2,3]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie GmbH, Germany; [2]Helmholtz-Institute Erlangen-Nürnberg for Renewable Energy, Germany; [3]Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany

The multitude of layers, interfaces, elements, impurities, defects, etc. contributing to the structure, function, and performance of optoelectronic devices means that characterization and fundamental understanding of the chemical and electronic structures of each component, as well as their interactions at interfaces, are crucial to support technical progress. The deliberate combination of complementary electron and x-ray spectroscopies can reveal crucial information that open routes to insight-driven strategies to improve device performance.
To showcase the power of this approach, several examples from the field of photovoltaics will be presented. In particular, the chemical and electronic structures (including energy level alignment) of the emitter/absorber and absorber/back contact interfaces for $Cu(In,Ga)Se_2$ (CIGSe) thin-film solar cell absorbers and how they are modified by different alkali post-deposition treatments will be presented and discussed against the background of the respective device performances.

1:30 PM EQ17.10.02
Strong Fermi-Level Pinning at Metal Contacts to Halide Perovskites Kootak Hong[1,2], Ki Chang Kwon[2], Kyoung Soon Choi[3], Carolin M. Sutter-Fella[1] and Ho Won Jang[2]; [1]Lawrence Berkeley National Laboratory, United States; [2]Seoul National University, Korea (the Republic of); [3]Korea Basic Science Institute, Korea (the Republic of)

The performance of halide perovskite-based electronic and optoelectronic devices is often related to interfacial charge transport. To shed light on the underlying physical and chemical properties of $CH_3NH_3PbI_3$ ($MAPbI_3$) in direct contact with common electrodes Al, Ti, Cr, Ag, and Au, the evolution of interfacial properties and Fermi level pinning is systematically studied. Given a unique experimental facility, pristine interfaces without any exposure to ambient air were prepared. We observe aggregation of substantial amounts of metallic lead (Pb^0) at the metal/$MAPbI_3$ interface, resulting from the interfacial reaction between the deposited metal and iodine ions from $MAPbI_3$. It is found that the Schottky barrier height at the metal/ $MAPbI_3$ interface is independent of the metal work function due to strong Fermi level pinning, possibly due to the metallic Pb^0 aggregates, which act as interfacial trap sites. The charge neutrality level of $MAPbI_3$ is consistent with the energy level of Pb^0-related defects, indicating that Pb^0 interfacial trap states can be nonradiative recombination sites. This work underlines that control of chemical bonding at interfaces is a key factor for designing future halide perovskite-based devices.

1:45 PM *EQ17.10.03
Making Contact with Emerging Photovoltaic Materials Aron Walsh; Imperial College London, United Kingdom

Device architectures for high-performance solar cells have evolved over decades to maximise current collection and to minimise voltage losses. The two main challenges caused by moving to new systems is the change in crystal structure and the variation in electron energies (ionisation potential and electron

affinity). These issues are magnified for non-cubic crystals where anisotropic materials properties can result in a mistmatch between the ideal orientations for absorption and transport verses the preferred orientation for crystal growth. I will discuss our development and application of computational tools to accelerate the design process including the electron-lattice-strain (ELS) descriptor[1] and its extension to systems including Sb2Se3, SnS, and CuBiS2 [2,3].

Optical Properties of OLED Materials by TDDFT Nobuhiko Akino; Hosei University, Japan

Organic light emitting diodes (OLEDs) have been of great interest for display and lighting applications during decades and they have recently been utilized in smartphones and flat-panel displays. After the development of fluorescent materials, the phosphorescent materials have been introduced and have achieved high efficiency. However, phosphorescent materials require expensive heavy metal such as Ir and Pt. Recently, thermally activated delayed fluorescence (TADF) materials have been developed as a new class of light emitting material where triplet excitons are converted into singlet excitons without heavy metals in phosphorescent materials.[1] Theoretically, an internal quantum efficiency of 100%, the same as for phosphorescent materials, can be expected.
In order to study the optical properties of materials, we have employed the time dependent density functional theory (TDDFT), which is one of the most prominent and widely used methods for calculating excited states of various molecules, and it is recognized as a powerful tool for studying their electronic transition. In our calculations, the real-time and real-space (RSRT) techniques are employed in solving time dependent Kohn-Sham equation by the finite difference approach [2,3] without using explicit bases such as plane waves and Gaussian basis. Within the frame work of this approach, we can solve for the wave functions on the grid with a fixed domain, which encompasses the physical system of interests.[4]
In this study, we have focused on the spectrum of OLED materials. For material design, it is highly desirable to simulate the spectral profile, not only the peak wavelength of absorption and/or emission, but also its spectrum shape. RSRT-TDDFT is applied to analyze some typical organic materials to study their spectrum profiles. In adition to the convensional fluorescent materials, phosphorescent and TADF materilas are studied. Although the research is in an early stage, current results show that this approach may be able to simulate the spectrum profile reasonably well and to apply the material design.

Experimental Realization of P-Type Transparent Conductive Phosphides Andrea Crovetto[1,2], Thomas Unold[1] and Andriy Zakutayev[2]; [1]Helmholtz-Zentrum Berlin, Germany; [2]National Renewable Energy Laboratory, United States

Despite long-standing research efforts to develop p-type transparent conductive materials (TCMs), the current generation of optoelectronic devices still relies exclusively on n-type TCM contacts due to their much better trade-off between conductivity and transparency. An important issue in oxide-based p-type TCMs is the deep energy and localized nature of the 2p oxygen states in the valence band, which has negative consequences on both hole dopability and hole mobility in most oxides.

Recent computational work [1,2] has identified several earth-abundant phosphides (particularly BP and CaCuP) that could potentially outperform the existing p-type TCMs. These phosphides have shallow, disperse valence bands that are ideal for high hole dopability and mobility. Although their indirect band gaps are rather low (around 2 eV), their direct band gaps are much wider and could ensure transparency in thin film samples. However, thin films of CaCuP have not been made yet, and previously reported BP thin films have not been thoroughly evaluated as transparent contacts [3].

Using a unique combinatorial sputter chamber with reactive PH_3 gas, we have synthesized BP and CaCuP films as a function of various process parameters. Last year we gave a preliminary report of their properties at this conference. This year, we will discuss their suitability as p-type TCMs in much greater detail.

In particular, we have found that the electrical conductivity of CaCuP under optimized growth conditions is almost on par with the conductivity of state-of-the-art n-type TCMs such as ITO and FTO, even in the absence of any extrinsic dopant. However, CaCuP films are only moderately transparent in the visible region due to unexpectedly high absorption strength above the indirect band gap.

We have also found that BP can be doped p-type up to remarkably high hole concentrations by using extrinsic dopants combined with off-stoichiometry. However, it is challenging to obtain BP films of high crystal quality by sputter deposition. This issue has so far prevented us from reaching high hole mobilities.

Despite the experimental challenges, we confirm that both CaCuP and BP could be outstanding transparent conductors if their growth processes could be further improved. More generally, the field of metal phosphides appears to be a fertile search space for potential p-type transparent conductors.

Ultrafast, Low-Noise Solution-Processed Quantum Dot Photodetectors with Amorphous Selenium Transport Layer Haripriya Kannan[1], Atreyo

Mukherjee[2], Triet Ho[2], Jann Stavro[3], Adrian Howansky[3], Neha Nooman[2], Dragica Vasileska[4], Wei Zhao[3], Amirhossein Goldan[3] and Ayaskanta Sahu[1]; [1]New York University, United States; [2]Stony Brook University, College of Engineering and Applied Sciences, United States; [3]Stony Brook University, United States; [4]Arizona State University, School of Electrical, Computer and Energy Engineering, United States

Effective sensing of optical signals by a solid-state detector that convert photons to electricity are widely used in digital imaging, optical communications, remote-sensing, spectroscopy, and astronomy. These photodetectors should possess high sensitivity, i.e., the ability to differentiate signal from noise, especially at low light intensities down to single-photon level. In recent years, colloidal quantum dots (CQDs) have gained significant attention in optoelectronics due to their wide spectral tunability, high absorption coefficients, and large oscillator strengths. Colloidal quantum dots also allow facile solution-processing that enables an easy room-temperature integration onto variety of substrates, rigid or flexible, including read-out integrated circuits with near-unity fill factor. In semiconductor optoelectronics, fast and sensitive photodetection is achieved when photocarrier recombination is limited by physically separating holes and electrons through electron/hole-transport layer. In our work, we developed vertical-stack photodetectors, which uses a solution-processed nanocrystal photoconversion layer coupled to an amorphous selenium wide-bandgap avalanche charge transport layer, in the desired p-i-n fabrication sequence that enables compatibility with active-matrix readout circuitry. Amorphous-selenium detectors have gained significant attention due to their single-carrier hole impact ionization phenomenon achieving high gains (~1000) with a very low excess noise factor and are suitable for a large-area deposition at room-temperature without damaging the underlying read-out circuits. Here, in our recent work on colloidal quantum dot/glass avalanche transport layer heterostructures, optical absorption and electrical transport are physically separated which enables increased flexibility for spectral tuning and increased charge extraction reaching high specific detectivity (5x10^12 Jones), fast photoresponse with megahertz 3-dB electrical bandwidth (~ 25 Mhz), ultra-low dark current density (~ 10 pA/cm2), low noise current (~ 20 fW/Hz1/2), and high linear dynamic range (~ 150 dB).

Space-Resolved Photoelectron Spectroscopy to Probe Heterostructures Dipankar Das Sarma; Indian Inst of Science, India

X-ray photoelectron spectroscopy has played an enormous role in developing our understanding of a range of interesting materials over the last five decades, primarily arising from its ability to energy-resolve electrons ejected from any sample due to its interaction with sufficiently high energy photons, thereby defining one of the most powerful spectroscopic techniques. However, when combined with space-resolution to achieve a microscopy based on this spectroscopy, it can provide us with unique information, not available otherwise. In my presentation, I shall describe two qualitatively different ways[1,2] to achieve such a space-resolution to provide complementary insights into diverse systems.

In the first part of the presentation, I shall focus on an elusive metastable phase, existing only as small patches in chemically exfoliated few-layer, thermodynamically stable 2H phase of MoS_2 that is believed to critically influence properties of MoS_2 based devices. Its electronic structure is little understood in absence of any direct experimental data and conflicting claims from theoretical investigations. I shall present data[3,4] to conclusively resolve this issue based on probing the electronic structure of chemically exfoliated few layer systems using lateral-space-resolution in photoemission spectroscopy.

In the second approach, I shall explore the rapidly expanding field that deal with emergent properties at a variety of interfaces formed in heterostructured materials, including optically active nanomaterials. It is in general difficult to probe directly the nature of such interface states since these are typically buried under a depth and represent a very small volume fraction of the entire sample. We have shown over the years[2,5-10] that x-ray photoelectron spectroscopy with a widely tunable photon energy from synchrotron sources can be used very effectively to obtain vertical-space resolution leading to layer-resolved electronic structure information; This makes this technique an ideal probe to investigate interface properties in diverse heterostructured systems. I shall illustrate this by discussing electronic properties of a few interesting systems, such as $LaAlO_3$-$SrTiO_3$, magnetic tunnel junctions with CoFeB and MgO, and optical properties of highly luminescent semiconductor nanoparticles with integrated internal interfaces.

Organic Electronics with Solution-Processed Electron Transport Layers Based on ZnO and MgO Ioannis Ierides[1,2], Kunping Guo[1,2], Isaac Squires[3], Giulia Lucarelli[4], Thomas M. Brown[4] and Franco Cacialli[1,2]; [1]University College London, United Kingdom; [2]London Centre for Nanotechnology, United Kingdom; [3]Imperial College London, United Kingdom; [4]Università degli Studi di Roma Tor Vergata, Italy

Electron transport layers (ETLs) have been instrumental in breaking the efficiency boundaries of optoelectronic devices. A key ETL for organic electronics is ZnO, however, depending on its preparation it can be a sub-optimal ETL suffering from surface defects. The application of a thin interlayer between ZnO and the active layer of optoelectronic devices has proven to be a successful method to achieve performance enhancements. Ultrathin MgO in combination with metal oxides such as SnO_2 and TiO_2 to form effective ETLs has afforded tremendous success in various solution-processed systems, such as perovskite photovoltaics. However, its application to improve ZnO based ETLs for organic electronics is limited.[1]

In our work, we investigate MgO as a modifying interlayer on top of a ZnO ETL formed by simple solution-processing and low temperature annealing and

apply it to organic photovoltaics (OPVs). We show that the modified ETL enhances the performance of OPV devices with respect to a single ZnO ETL without significantly affecting the photon capture rate and blend morphology. The ZnO/MgO ETL is shown to have a more uniform top surface with a root mean square roughness decreasing from 4.5 ± 0.2 nm to 3.2 ± 0.4 nm and a lower work function (by 0.11 ± 0.05 eV) compared to the single ZnO ETL, which is expected to be beneficial to electron extraction. We demonstrate that insertion of the thin MgO interlayer in devices leads to a reduced leakage current and an increase in the shunt resistance. The power conversion efficiency of OPVs employing the ZnO/MgO ETL is enhanced by ≈ 10% (relative increase) as a result of a boosted short circuit current density and fill factor.[2]

Late News: Transfer of Oxide Electrode Sheet with Wide Bandgap of 4.6 eV Lizhikun Gong, Mian Wei, Hiromichi Ohta and Tsukasa Katayama; Hokkaido University, Japan

Transparent conductive oxides (TCOs) are essential for optoelectronic devices. Among TCOs, ITO is widely utilized due to its high electrical conductivity (~10000 S cm^{-1}[1]) and easy synthesis. However, the bandgap of ITO (~3.5 eV) is insufficient compared to the requirements of electrodes for deep-ultraviolet light-emitting diodes (DUV-LEDs) ($h\nu$ > 4.1 eV). As the electrode, La-doped $SrSnO_3$ (LSSO) is promising due to its both wide bandgap (~4.6 eV) and high electrical conductivity (~3000 S cm^{-1}[2]). Nevertheless, there is a problem that single-crystal LSSO epitaxial film requires high deposition temperature, which is beyond the heat resistant temperature of the DUV-LEDs. In order to solve this problem, we proposed a lift-off and transfer method, which enables preparation of LSSO sheet on many kinds of substrates at room temperature.
The LSSO thin films were heteroepitaxially grown on the water-soluble $Sr_3Al_2O_6$ (SAO)[3,4]-buffered $SrTiO_3$ (STO) substrate by pulsed laser deposition method. Then, we removed the SAO layer with water. The LSSO sheet was further transferred on glass or PET substrates.
The out-of-plane X-ray diffraction (XRD) patterns of the LSSO/SAO bilayer film and transferred LSSO sheet clearly exhibited the LSSO peaks without any impurity peaks. In addition, the sheet exhibited coexistence of high electrical conductivity (~1600 S cm^{-1}) and wide bandgap (~4.6 eV) at room temperature. The single-crystal LSSO sheet with lateral size of 5 mm × 5 mm was successfully obtained.

4:50 PM EQ17.11.04
Carbon Based Materials for Hole- Extraction in Perovskite Solar Cells G.R.A. Kumara[1], D.G.B.C. Karunarathne[1], A.D.T. Medagedara[1], R.M.G. Rajapakse[2], Dhayalan Velauthapillai[3], Punniamoorthy Ravirajan[4], A. G. U. Perera[5], Ajith DeSilva[6] and K. Tennakone[1,5]; [1]National Institute of Fundamental Studies, Sri Lanka; [2]University of Peradeniya, Sri Lanka; [3]Western Norway University of Applied Sciences, Norway; [4]University of Jaffna, Sri Lanka; [5]Georgia State University, United States; [6]University of West Georgia, United States

Performance of perovskite solar cells (PSCs) are largely determined by the nature of the hole -collector material and its interface with the perovskite. The molecular solid Spiro-OMeTAD; inorganic p – type semiconductors such as CuSCN, CuI and NiO; conducting polymers; metals and forms of carbon have been used as the hole -collector materials. PSCs based on metals and carbon are often referred to as hole- collector free perovskite solar cells. A misleading statement, because it is not clear how the hole extraction property has arisen, as the of nature of the true interface remain uncertain. Metals are often coated with oxide layers and in many instances different forms of carbon had been blended other substances and reported as carbon electrodes without empathizing role of the binder.
Compared to metals, carbon and its blends turn out be more suitable to understand mechanism by which the holes photo-generated in perovskite are transferred to the cathode of the solar cell. Carbon when perfectly purified contains no solid surface layers; but liable to be populated with surface groups. Therefore in the case of carbon; the grain structure, grain size and surface groups are the main relevant parameters, characterizing the material.
An extensively studied carbon material which can be easily purified is coconut shell charcoal. In the present work; the rectification properties of the perovskite/carbon interface and IV characteristic of cells are examined in detail by pressing coconut shell derived carbon powder on the perovskite surface deposited on TiO_2 by the usual procedure. Results indicate that the grain electrical conductivity, grain size and pressure applied are the crucial factors determining the cell efficiency. Experimental details and possible electron-hole separation mechanisms at the perovskite/carbon will be discussed.

4:55 PM EQ17.11.05
Strategies to Enhance the Capability of Carrier Injection to the Effective Channel for Bottom-Gated Amorphous Oxide Thin–Film Transistors Mingyuan Liu[1], Hyeonghun Kim[1], Han Wook Song[2] and Sunghwan Lee[1]; [1]Purdue University, United States; [2]Korea Research Institute of Standard and Science (KRISS), Korea (the Republic of)

Over the two decades, amorphous oxide semiconductors (AOSs) and their thin film transistor (TFT) channel application have been intensely explored to realize high performance, transparent and flexible displays due to their high field effect mobility (μ_{FE}=5-20 cm^2/Vs), visible range optical transparency, and low temperature processability (25-300 °C).[1-2] The metastable amorphous phase is to be maintained during operation by the addition of Zn and additional third cation species (e.g., Ga, Hf, or Al) as an amorphous phase stabilizer.[3-5] To limit TFT off-state currents, a thin channel layer (10-20 nm) was employed for InZnO (IZO)-based TFTs, or third cations were added to suppress carrier generations in the TFT channel. To resolve bias stress-induced instabilities in TFT performance, approaches to employ defect passivation layers or enhance channel/dielectric interfacial compatibility were demonstrated.[6-7]

Metallization contact is also a dominating factor that determines the performance of TFTs. Particularly, it has been reported that high electrical contact resistance significantly sacrifices drain bias applied to the channel, which leads to undesirable power loss during TFT operation and issues for the measurement of TFT field effect mobilities. [2, 8] However, only a few reports that suggest strategies to enhance contact behaviors are available in the literature. Furthermore, the previous approaches (1) require an additional fabrication complexity due to the use of additional treatments at relatively harsh conditions such as UV, plasma, or high temperatures, and (2) may lead to adverse effects on the channel material attributed to the chemical incompatibility between dissimilar materials, and exposures to harsh environments. Therefore, a simple and easy but effective buffer strategy, which does not require any additional process complexities and not sacrifice chemical compatibility, needs to be established to mitigate the contact issues and therefore achieve high performance and low power consumption AOS TFTs.

The present study aims to demonstrate an approach utilizing an interfacial buffer layer, which is compositionally homogeneous to the channel to better align work functions between channel and metallization without a significant fabrication complexity and harsh treatment conditions. Photoelectron spectroscopic measurements reveal that the conducting IZO buffer, of which the work function (Φ) is *4.37 eV*, relaxes a relatively large Φ difference between channel IZO (Φ*=4.81 eV*) and Ti (Φ*=4.2-4.3 eV*) metallization. The buffer is found to lower the energy barrier for charge carriers at the source to reach the effective channel region near the dielectric. In addition, the higher carrier density of the buffer and favorable chemical compatibility with the channel (compositionally the same) further contribute to a significant reduction in specific contact resistance as much as more than 2.5 orders of magnitude. The improved contact and carrier supply performance from the source to the channel lead to an enhanced field effect mobility of up to 56.49 cm^2/Vs and a threshold voltage of 1.18 V, compared to 13.41 cm^2/Vs and 7.44 V of IZO TFTs without a buffer. The present work is unique in that an approach to lower the potential barrier between the source and the effective channel region (located near the channel/dielectric interface, behaving similar to a buried-channel MOSFET [9]) by introducing a contact buffer layer that enhances the field effect mobility and facilitates carrier supply from the source to the effective channel region.

5:00 PM EQ17.11.06
Improvement of Light-Harvesting in Perovskite Solar Cells by Post-Modification with a Fluorescent Layer Timur Atabaev; Nazarbayev University, Kazakhstan

Perovskite solar cells (PSCs) with a standard sandwich structure suffer from optical transmission losses due to the substrate and its active layers. Developing strategies for compensating for the losses in light-harvesting is of significant importance to achieving a further enhancement in device efficiencies. In this work, the down-conversion effect of carbon quantum dots (CQDs) was employed to convert the UV fraction of the incident light into visible light. For this, thin films of poly(methyl methacrylate) with embedded carbon quantum dots (CQD@PMMA) were deposited on the illumination side of PSCs. Analysis of the device performances before and after application of CQD@PMMA photoactive functional film on PSCs revealed that the devices with the coating showed an improved photocurrent and fill factor, resulting in higher device efficiency.

Fabrication and Characterization of Wrinkle Free Nanometer Rigid Thin Film on Soft Substrate Maryam Jalali-Mousavi[1] and Jian Sheng[1,2]; [1]Texas A&M University, United States; [2]Johns Hopkins University, United States

Flexible electronics and electro-optics have drawn a significant attention in recent years. Successful fabrication of flexible mirrors or transparent electronics will require deposition of relatively rigid thin films on soft compliant substrates. However, direct deposition of a rigid film on soft substrates often suffers from wrinkling or buckling due to the interfacial instability arising from the substrate compression beyond a critical strain. Wrinkled surfaces cause severe reduction in reflectivity and low transmittance. In this work, we report a novel technique to fabricate wrinkle free deposited rigid thin films on soft substrate by suppressing the instability with a nm-layer of jamming nanoparticles. The thickness of the jammer can tailor the wrinkle periodicity and the roughness of the surface. The technique is robust and readily applicable to wide variety of materials. For demonstration system, we selected Poly(dimethylsiloxane) (PDMS), poly(monochloro-p-xylylene) (parylene C) as jammer and various metals (*e.g., Cu, Al, Ti*). Different jammer layers varying from 40nm to 2um are deposited on 1mm PDMS substrate followed by sputter deposition of 50nm thin metal film. The surface morphology of the samples was analyzed by atomic force microscopy (AFM). The results showed that as the jammer thickness increases, the wrinkle wavelength increases accordingly and when the thickness exceeds a threshold (*e.g.*, ~150nm), wrinkles are suppressed. Nanoindentation measurements also show the interfacial stiffness increases by two orders of magnitude as the jammer thickness increases. When the layer reaches 150nm, the metal-jammer-PDMS composite becomes increasingly elastic and deviates substantially from viscoelastic behavior. A dual power law emerges in Young's relaxation modulus.

Computational Fermi Level Engineering and Doping-Type Conversion of Mg:Ga_2O_3 via Three-Step Processing Anuj Goyal[1], Andriy Zakutayev[1], Vladan Stevanovic[2,1] and Stephan Lany[1]; [1]National Renewable Energy Laboratory, United States; [2]Colorado School of Mines, United States

Ga_2O_3 is being actively explored for optoelectronic (phosphorus, and electroluminescent devices, solar-blind photodetectors) application due to its ultra-wide bandgap and low projected fabrication cost of large-size and high-quality crystals. Efficient *n*-type doping of Ga_2O_3 has been achieved, but *p*-type doping faces fundamental obstacles due to compensation, deep acceptor levels, and the polaron transport mechanism of free holes. However, aside from achieving *p*-type conductivity, plenty of opportunities exists to engineer the position of the Fermi level for improved design of Ga_2O_3 based devices. We use first principles defect theory and defect equilibrium calculations to stimulate a 3-step growth-annealing-quench synthesis protocol for hydrogen assisted Mg doping in beta Ga_2O_3, considering the gas phase equilibrium between H_2, O_2, and H_2O, which determines the H chemical potential. We predict Ga_2O_3 doping-type conversion to a net *p*-type regime after growth under reducing conditions in the presence of H_2 followed by O-rich annealing, which is similar process to the Mg acceptor activation by H removal in GaN. We show there is an optimal temperature that maximizes the Ga_2O_3 net acceptor density for given Mg doping level. After quenching to operating temperatures, the Ga_2O_3 Fermi level drops below mid-gap down to +1.5 eV above the valence band maximum, creating significant number of uncompensated neutral Mg_{Ga}^0 acceptors. The resulting free hole concentration in Ga_2O_3 is very low due to deep energy level of these Mg acceptors, and hole conductivity is further impeded by the polaron hopping mechanism. However, the Fermi level reduction down to +1.5 eV and suppression of free electron density in this doping type converted Ga_2O_3 material is of significance and impact for the design of Ga_2O_3 based optoelectronic devices.

Solar-Blind Photodetectors Based on Gallium Oxide and Their Performance Analysis Against Swift Heavy Ions Damanpreet Kaur and Mukesh Kumar; Indian Institute of Technology Ropar, India

The UV-C (< 280 nm of wavelength) part of the solar spectrum is highly dangerous to living organisms, with exposure often causing changes in their genetic make-up. Thankfully, the ozone layer in the atmosphere absorbs almost all of this radiation, thereby providing us with natural protection. The complete absorption leads to a very low background signal of UV-C on earth. This unique characteristic can be exploited in the fabrication of highly sensitive photodetectors which are responsive to UV-C only from other sources on earth, leading to the development of the so-called solar-blind photodetectors (SBPD). Solar-blind photodetectors are deep-UV photodetectors that show sensitivity to only UV-C radiation. They show no response when placed in natural sunlight and thus have applications ranging from ozone-hole monitoring, missile tracking, flame detection, space exploration, UV sterilization systems, non-line-of-sight communications, etc. Traditionally, SBPDs were fabricated using mature technologies such as silicon. However, a

band gap of 1.1 eV renders the devices to have a broadband photoresponse, thus necessitating the use of costly optical filters. Wide band gap semiconductors offer a solution to this problem by removing the need for any filters due to their suitable band gap. Gallium oxide is a new, ultra-WBG material with properties that are promising for its use as a functional material in the fabrication of SBPDs. It has an apt band gap of 4.6-5.3 eV (depending on the polymorph) making it intrinsically solar-blind. Moreover, it is highly chemically and thermally stable (M.P. ~ 1730°C), has a high breakdown voltage and is extremely radiation hardened and hence it can be employed for use in extreme environment applications (high temperature and high radiation conditions). Some of these applications include employment in nuclear, geothermal or space exploration, which require the material to be immune (at least partially) to all sorts of radiation. This requires extensive studies to investigate the effect that each type of radiation might have on the material as well as on the performance of its devices.
We have undertaken such a study on the radiation hardness and device performance of amorphous and polycrystalline gallium oxide thin film against heavy ion (Ag^{7+}) irradiation with a high energy of 100 MeV. We found that the amorphous thin film shows better resilience to the radiation as compared to the polycrystalline film. Changes in the morphology and crystal structure of the material were thereby investigated. There occurs recrystallization and formation of nano-pores in the amorphous film while the polycrystalline film shows destruction of the larger crystallites. The photodetectors fabricated on the irradiated films exhibit good device integrity albeit with a decrease in performance. The change in performance is linked to the change in the material's defect density which is confirmed by photoluminescence study. The optical defects, which are responsible for the high photoconductive gain in gallium oxide, undergo ionization-induced defect annealing and thus lead to an overall decrease in performance. The radiation-damaged performance of the photodetectors is recovered by annealing at moderate temperatures in air ambient, so much so that the amorphous based photodetector not only recovers but shows a two order of magnitude increase in its responsivity. This study not only shows the high radiation hardness of gallium oxide against Swift Heavy Ions but may also serve as a stepping stone for the use of high energy irradiation as a tool for defect engineering in gallium oxide based devices.

Theoretical Investigation of Electronic Structure Properties of $ZnO_{1-x}Se_x$ for Photoanode Applications Arini Kar, Gurudayal Behera, Balasubramaniam Kavaipatti and Dayadeep S. Monder; Indian Institute of Technology Bombay, India

Despite high chemical stability in an aqueous environment, application of ZnO as a visible light photoanode in photoelectrochemical cells (PECs) is limited due to its large bandgap. Alloying ZnO with ZnSe reduces the electronic bandgap of ZnO, as observed experimentally at low alloy compositions. In this work, we have performed density of states and electronic band structure calculations using DFT to determine the band gap of wurtzite solid state solutions of $ZnO_{1-x}Se_x$ over the entire composition range to develop deeper insight into the system. The band gap calculated using the delta-sol method shows a bowing behaviour, with a minimum bandgap at x=0.5, as predicted by the band anticrossing (BAC) model. Difference in the electronegativities of O and Se atoms in the lattice leads to hybridization of O-2p and Se-4p electronic states which can be clearly observed from the projected density of states and band structure plots. Interaction between these electronic states also leads to a split in the valence band edge at O-rich end and a split in the conduction band edge at the Se-rich end. These are observed as dips in the density of states plot at the respective band edges. In addition, the curvature of the valence band maxima and conduction band minima reduce at the O-rich end and Se-rich end, respectively. This implies an increased effective mass of the charge carriers and hence a decreased mobility. These fundamental insights will help in employing suitable alloy compositions in PECs for optimal photocurrent density.

5:25 PM EQ17.11.12
Excimer Laser Crystallization and Doping of Epitaxial Ga_2O_3 Thin Films for Ultraviolet Optoelectronics Devices Kazuki Watanabe[1], Ryoya Kai[1], Naho Kaneko[1], Shohei Hisatomi[1], Tomoaki Oga[1], Satoru Kaneko[2,1], Akifumi Matsuda[1] and Mamoru Yoshimoto[1]; [1]Tokyo Institute of Technology, Japan; [2]Kanagawa Institute of Industrial Science and Technology, Japan

Ultraviolet optoelectronics devices have attracted much interest for a variety of applications to use photolithography, biochemical and so on. Among the wide-bandgap semiconductors, Ga_2O_3 with the bandgap of about 5 eV is considered as one of the eco-friendly candidates used for ultraviolet optoelectronics devices. The development of the Ga_2O_3-based devices relies on the feasibility of growing impurity-doped p-type conductive Ga_2O_3 thin films .[1] It has been reported that n-type Ga_2O_3 semiconductors have been prepared via impurity doping of 4+ cations like Si^{4+} .[2] On the other hand, to fabricate p-type Ga_2O_3 semiconductors, potential dopants like Mg^{2+} and Zn^{2+} are presented. [3] However, as far as we know, there is no report on fabrication of impurity-doped p-type Ga_2O_3 thin films.
So far, we have investigated the pulsed excimer laser-induced room-temperature epitaxial crystallization of β-Ga_2O_3 thin films on the NiO-buffered sapphire substrates. [4,5] Different from the conventional high-temperature growth of β-Ga_2O_3 thin films, crystallization of amorphous Ga_2O_3 thin films via excimer laser annealing at room-temperature is expected to suppress phase separation and precipitation, and also to induce unusual impurity doping. In this study, for the purpose of controlling the electrical properties such as p- or n-type of β-Ga_2O_3 thin films by laser-induced impurity doping, we evaluated the effects of laser irradiation conditions and/or thin film compositions on the crystal growth and conductivity of the impurity-doped amorphous Ga_2O_3 thin films.
In the experiment, Li element was used as one of impurity dopants because Li is expected as monovalent p-type dopant .[6] The amorphous 5 at% Li-doped Ga_2O_3 thin film (50-80 nm-thick) was grown on the atomically stepped α-Al_2O_3 (0001) substrates with about 2 nm thick MgO (111) buffer layer by pulsed laser deposition (PLD) equipped with pulsed KrF excimer laser (λ=248 nm, d=20 ns, and E~1.2 J/cm^2) at room-temperature in ultra-high vacuum (~10^{-6} Pa) using a sintered 5 at% Li-doped β-Ga_2O_3 target. The obtained amorphous Ga_2O_3 thin film were subsequently crystallized in the solid-phase by excimer laser annealing (ELA), in which KrF excimer laser beam (not focused, E~175 mJ/cm^2) was irradiated from the substrate side at room-temperature in air. As a result, it was verified from the XRD and RHEED analyses that 5 at% Li-doped β-Ga_2O_3 (-201) epitaxial film was obtained on the MgO (111) (2 nm thick) buffered α-Al_2O_3 (0001) substrate. Li inclusion in the β-Ga_2O_3 thin film after ELA was confirmed from TOF-SIMS measurements (operated by the Open Facility Center of Tokyo Inst. Tech.). These results indicate that ELA process induces solid-phase epitaxy at room-temperature and suppress re-evaporation of Li in Ga_2O_3 crystallization. In addition, TOF-SIMS measurements also indicate the possible diffusion of Al^+ and Mg^+ elements into the thin film. The optical property of the epitaxial 5 at% Li-doped β-Ga_2O_3 thin films were evaluated by UV-vis measurements, which revealed a transmission over 90% of light in the visible region (360-830 nm) and rapid absorption in the UV region (~360 nm). In addition, the optical bandgap of the 5 at% Li-doped β-Ga_2O_3 thin film was estimated about 4.81 eV, being about 0.1 eV smaller than that of the non-doped β-Ga_2O_3 thin film (4.9 eV). It is suggested that the impurity Li atoms have been largely activated as acceptors in the β-Ga_2O_3 film to modify the energy level of the valence band top. The electrical properties are also reported in the presentation on the day.

Vacuum-Ultraviolet Excimer Light Derived Conductivity and Structural Modification of Pure NiO Epitaxial Thin Films Kenta Kaneko[1], Tomoaki

Oga[1], Hiroki Shoji[1], Shohei Hisatomi[1], Satoru Kaneko[2,1], Mamoru Yoshimoto[1] and Akifumi Matsuda[1]; [1]Tokyo Institute of Technology, Japan; [2]Kanagawa Institute of Industrial Science and Technology, Japan

Recently, perovskite solar cells have attracted interests, and are of significance in photovoltaic energy conversion. Nickel oxide (NiO) with wide-bandgap of E_g~3.4 eV is one of the p-type semiconductors utilized as hole transport layers in the devices [1]. Aliovalent doping of such as Li^+ have commonly applied to enhance its p-type conduction according to improved carrier concentration. Meanwhile, there are some researches of uv-ozone treatment of polycrystalline NiO films using mercury lamps, that altered resistance and electronic states was reported [2,3]. Modification of p-type conduction without impurity doping would advance development and properties of multilayered optoelectronic devices; although it still requires further research on the influence of film structure as well as illuminance and ambience of the irradiation. Application of vacuum-ultraviolet (VUV) light with larger photon energy and efficient production of active oxygen species would contribute to further modification of properties. In this study, noticeable conductivity improvement of epitaxial NiO thin films by excimer VUV-light irradiation was verified, and the effect of the treatment on structure and morphology of the films was investigated.
The epitaxial NiO (111) thin films were grown on atomically stepped α-Al_2O_3 (0001) single crystal substrates by pulsed laser deposition (PLD) technique using a KrF excimer laser (λ=248 nm, E~1.2 J/cm^2) and a pure NiO sintered target. The thin film growth took place at room-temperature (not-heated intentionally) in 1×10^{-3} Pa O_2 (base pressure ~3×10^{-6} Pa). The NiO thin films were subsequently introduced to VUV-light treatment procedure using a Xe_2 excimer lamp (λ=172 nm, E~65 mW/cm^2 at lamp surface). The VUV-light was irradiated to thin film surfaces in air, vacuum, or inert gas at the distance of 0.5–2.0 mm. The electric property of NiO (111) thin films was measured by four-probe DC method. The resistivity of the PLD-grown 40 nm-thick epitaxial NiO (111) thin film was ~7×10^3 Ωcm, although VUV-light irradiation in air at 0.5 mm drastically reduced the value by three-digits, that ~4×10^0 Ωcm and ~2×10^0 Ωcm were obtained after the treatment for 60 and 120 minutes, respectively. The epitaxial structure was retained even after VUV-light irradiation of 120 min according to the XRD and RHEED results, while observed slight reduction of the (111) plane spacing suggested redox reaction of the film. Thus, the demonstrated conductivity improvement of NiO (111) thin films due to VUV-light irradiation would advance optoelectronic application of the material. In addition, influence of conditions of thin film preparation and VUV-light treatment on the structures and properties would also be presented.

Unusual Epitaxy of Nd:ZnO Thin Films on c-Cut Sapphire Under Oblique Incidence Magdalena Nistor[1], Eric Millon[2], Christophe Cachoncinlle[2], Corneliu Ghica[3], Christian Hebert[4] and Jacques Perrière[4]; [1]NILPRP, Romania; [2]Université d'Orléans, France; [3]NIMP, Romania; [4]Sorbonne Universités & CNRS, France

ZnO thin films typically grow with the c-axis normal to the substrate leading to a columnar microstructure with the (002) ZnO planes parallel to the substrate surface. Tuning the incident angle of the species reaching the substrate changes the morphology and microstructure of the film. In this work Nd-doped ZnO thin films were grown by pulsed-electron beam deposition (PED) on c-cut sapphire substrates under oblique angle incidence, at 10^{-2} mbar oxygen pressure and for a substrate temperature of 500°C. Transmission electron microscopy, X-ray diffraction and pole figures analyses were performed to obtain the film microstructure together with their electrical and optical properties. The Nd-doped ZnO thin films were smooth, compact and constituted with columnar grains inclined at about 17°±4° from the normal to the substrate surface. From X-ray diffraction and transmission electron microscopy experiments, the wurtzite phase of Nd-doped ZnO thin films was observed with the c-axis inclined around 35° with respect to the normal axis of the substrate, with a three-fold azimuthal symmetry. Epitaxial relationships between Nd-doped ZnO films and sapphire substrate were determined from the pole figures and compared with those obtained for the films grown under non-oblique angle incidence. Classical in-plane epitaxy with a 30° rotation between the two hexagonal unit cells of ZnO and c-cut sapphire was observed under non-oblique incidence [1, 2]. For the films grown under oblique incidence, the 35° angle tilt of the ZnO c-axis from the normal to the substrate is explained by the epitaxy of the (229) ZnO plane on the (002) sapphire plane. This particular orientation, which has never been reported previously, is obtained from the rotation of the [001] ZnO direction around the [1-10] ZnO one, which allows the (229) ZnO plane to be parallel to the (002) sapphire substrate one [2]. A new well-defined epitaxial relationship was observed between the (229) ZnO on (002) Al_2O_3 plane although the large lattice mismatch and symmetry mismatch. This unusual epitaxy will be discussed, as well as the effect of tilted growth on the electrical and optical properties of Nd-doped ZnO films. These epitaxial c-axis tilted Nd-doped ZnO thin films are also interesting for sensitive and disposable biosensors working as film bulk acoustic resonators in the shear acoustic mode for biological and medical applications. Rapid Vapor-Phase Deposition of Oxide Overlayers on Thermally-Sensitive Device Stacks for Optoelectronics Rob Jagt[1], Virgil Andrei[1], Solène Béchu[2,3], Motiar Rahaman[1], Leonardo Lari[4], Ravi D. Raninga[1], Tahmida N. Huq[1], Weiwei Li[1], Mark Nikolka[1], Muriel Bouttemy[2,3], Mathieu Fregnaux[2,3], Vlado Lazarov[4], Philip Schulz[2,5], Erwin Reisner[1], Judith L. MacManus-Driscoll[1] and Robert Hoye[6]; [1]University of Cambridge, United Kingdom; [2]Institute Photovoltaïque d'Île de France, France; [3]Institut Lavoisier de Versailles (ILV), France; [4]University of York, United Kingdom; [5]CNRS, France; [6]Imperial College London, United Kingdom

Oxides play a critical role in a wide range of optoelectronic devices as the charge-selective layer. Whilst the electronic properties of oxides generally improve with increasing growth temperature, the processing window is limited when depositing over device stacks, owing to the thermal sensitivity of the active layer. A prominent example of a thermally-sensitive active layer is methylammonium lead iodide ($MAPbI_3$) perovskite.[1] This talk explores the use of atmospheric pressure chemical vapor deposition (AP-CVD) as a means to broaden the processing window of oxide overlayers on optoelectronic device stacks. AP-CVD produces oxide films with similar uniformity, density and conformality as films grown by atomic layer deposition (ALD), but with orders of magnitude higher growth rates, and without the need for a vacuum chamber. We investigate the growth of TiO_2 over $MAPbI_3$ films. We show that

growth rates of 1.19±0.04 nm s^{-1} are achievable, which allows 7 nm TiO_2 films to be grown in 6 s (compared to >30 min for ALD). The rapid processing allows us to deposit TiO_2 directly onto $MAPbI_3$ films at 150 °C without any structural, chemical or electronic damage, as found from X-ray diffraction, X-ray photoemission spectroscopy and time-resolved photoluminescence measurements. In $MAPbI_3$ photovoltaic devices, we show that TiO_2 growth temperatures can exceed 180 °C without any drop in efficiency. This is >70 °C larger than achievable with ALD or solution-based methods for growing oxide overlayers, resulting in more conductive TiO_2 films which lead to increases in device performance. We show that these results can be generalised to triple-cation perovskites, as well as to AP-CVD SnO_2 overlayers. In particular, we show that the high density of the oxide overlayers improves fill factors by reducing dark currents, reaching up to 84% (with 19.4% steady-state power conversion efficiency) for triple-cation perovskite devices covered with 60 nm SnO_2.[1]

More broadly, we demonstrate the wider applicability of AP-CVD to grow oxide electron transport layers on the perovskite-inspired material bismuth oxyiodide (BiOI). We show through transmission electron microscopy that AP-CVD ZnO films are highly conformal to the textured BiOI surface, resulting in photovoltaic devices with external quantum efficiencies reaching 80% at 450 nm wavelength.[2] We demonstrate the benefits of this oxide-based device structure for achieving improved performance and stability across multiple light-harvesting applications.

Towards Lead-Free Perovskite Device Architectures—Interface Simulations of Tin-Based Heterostructures Pedesseau Laurent[1], Pingping Jiang[1], Boubacar Traore[2], Mikael Kepenekian[2], George Volonakis[2], Claudine Katan[2] and Jacky Even[1]; [1]FOTON Institute - INSA Rennes, France; [2]ISCR CNRS, France

Following the emergence of lead halide perovskites as record-breaking materials for emerging photovoltaic applications, lead-free perovskites are gaining interest as novel materials which are compatible with inkjet-printing based technologies[1,2,3]. Bulk properties are of the prime importance, but charge transport can be rapidly altered across the interface of perovskite/ (hole or electron) transport layer (HTL or ETL). Yet, due to the size and complexity of the interface systems, a thorough ab initio modeling of the interfaces remains elusive to-date. Within this work, to explore the atomic-scale details of the structural and electronic properties of these materials, we employ state-of-the-art density functional theory (DFT) based calculations of model tin-based heterostructures. We investigate in particular three-dimensional corner-sharing Sn-based perovskites, their surface and interface properties and calculate the interaction of the materials with charge transport layers (CTLs). Our approach reveals the electronic band alignments and dielectric mismatches between perovskite layers and the most important hole and electron transport layers that have been used in prototype thin film device architectures[4,5]. In an effort to understand the fundamental physico-chemical mechanisms that govern the interactions between the photo-active absorber material and CTLs, we also probe the influence of surface termination on structural and electronic properties at $FASnI_3/C_{60}$ (as ETL) interfaces and $FASnI_3/NiO_x$ (as ETL) interfaces. Our findings give a detailed insight into the interface engineering necessary for optimizing the next generation of environmental-friendly high-performing opto-electronic devices.

Indirect Excitation and Luminescence Activation of Tb Doped Indium Tin Oxide and Its Impact on the Host's Optical and Electrical Properties Paul Llontop, Miguel Piñeiro, Carlos Torres, Erik Perez and Jorge A. Guerra; Pontificia Universidad Catolica del Peru, Peru

The effect of terbium doping on the electrical, optical and light emission properties of sputtered indium tin oxide thin films was investigated. The films were prepared by radio frequency dual magnetron sputtering maintaining a high optical transmittance in the ultraviolet and visible spectral regions and an electrical resistivity ranging from 5E-3 to 0.3 Ωcm . Terbium-related luminescence is achieved after thermal treatments at 470 °C in air at atmospheric pressure. Electrical resistivity and optical transmittance were registered after each annealing step to evaluate the compromise between the achieved light emission intensity, electrical and optical properties. Additionally, Tb-related luminescence thermal quenching is assessed by temperature-dependent photoluminescence measurements, from -190 °C to 300 °C, under non-resonant excitation. Thermal quenching activation energies suggest an effective energy transfer mechanism from the ITO host to the rare-earth ions. This indirect excitation mechanism is tentatively modeled using a spherical potential well, as well as a tight-binding one-band approximation, approach for a short-range charge trapping process and subsequent formation of bound excitons to rare-earth ion clusters.

ALD-Oxide Materials and Surface Modification for Next-Generation PV Devices Nathanaelle Schneider[1,2]; [1]CNRS, UMR-IPVF 9006, France; [2]Institut Photovoltaïque d'Ile de France (IPVF), France

Zinc oxide is an extensively studied n-type semiconductor for various applications such as light emitting devices, detection of chemicals or solar cells,[1] which often needs to be doped, modified or protected.

Doped-ZnO films can replace conventional transparent conductive oxides (TCO), especially in high aspect ratio structures. For example, radial junction silicon nanowire (Si NW) based solar cells, which allow to decouple light absorption and charge carrier collection, are highly interesting but challenging to top contact.[2] Use of ALD-Ti:ZnO (TZO) as the top electrode has proven the applicability of ALD-TZO as TCO and the unique capabilities of ALD, showing superior optoelectrical properties, conformally covering the Si NWs, and yielding a PV diode behavior with external quantum efficiency response surpassing the conventional ITO top electrode.[3]
In other cases, it is beneficial to modify the properties of the ZnO surface, for instance by the grafting of organic molecules.[4] ALD-ZnO surfaces were modified by phosphonic acid derivatives with different spacer and functionalizing groups (2-aminoethylphosphonic acid, 2-AEPA ; 4-aminobenzylphosphonic acid, 4-ABzPA; and 4-fluorobenzylphosphonic acid, 4-FBzPA). The resulting ZnO surfaces were characterized, used as a mean to passivate the reactive interface between ALD-ZnO and a hybrid organic inorganic metal halide perovskite, and complete solar cell devices were prepared.[5]
Finally, ZnO-based films often need to be protected to prevent their degradation. Al:ZnO (AZO) window layer is reported as the primary component responsible for the degradation of CIGS solar cells. The feasibility to prevent AZO degradation and encapsulate module-level (10×10 cm^2) CIGS solar devices by a 10 nm ALD-Al_2O_3 barrier layer was demonstrated.[6] However, solar panels in field operation are also exposed to various chemical air pollutants such as in $(NH_4)_2SO_4$ in rural, and NaCl in marine environments. Their effects were studied by placing AZO w/ and w/o encapsulation in specific climatic test conditions. This demonstrated the necessity to consider atmospheric chemistry when evaluating barrier protection capacities of encapsulants and assessing the durability of PV materials and devices.[7]

Charge-Selective Contacts in Energy Conversion Photoelectrochemistry Joel W. Ager[1,2] and Rajiv R. Prabhakar[2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Solar photovoltaic (PV) and photoelectrochemical (PEC) energy conversion share the same fundamental requirements of photon absorption, charge separation, and selective carrier collection [1]. In addition, in order to produce storable chemical energy, PEC systems must drive multi-electron transfer reactions, i.e. water oxidation (OER, a 4 electron process) for a photoanode and hydrogen evolution (HER) or carbon diode reduction (CO_2R) for a photocathode (2-18 electron processes) [2]. In a small number of cases it has been possible to have a single material perform all of the requisite steps and remain stable under operation: water oxidation photoanodes composed of TiO_2 or Fe_2O_3 are examples. However, in the vast majority of cases, it has been beneficial to construct multi-material PEC systems, with different components chosen for optimal light absorption, selective carrier collection/passivation, and catalysis.

In this context, the choice of electron transfer layers (ETLs) for PEC CO_2R reduction will be discussed. While it is attractive to design semiconductor absorbers based on the position of their conduction band relative to the standard state redox potentials of a given CO_2 reaction, e.g. CO_2/CO, CO_2/HCOOH, CO_2/CH_4, etc., this analysis neglects the fact that these multi-electron reactions occur via a series of elementary proton coupled electron transfers, with each step having its own redox potential [3]. For this reason, either solid state or molecular CO_2R co-catalysts are usually integrated with the absorber in PEC CO_2R studies [4,5].

These concepts will be illustrated through the design and operation of Si-based CO_2R photocathodes. Adroit use of charge selective contacts allows for considerable flexibility in design. For example, in contrast to conventional photocathode designs which employ p-type absorbers, we used a back illumination geometry with an n-type Si absorber to permit the use of absorbing metallic catalysts which would otherwise block the light. Hole collection was enabled by p^+ implant on the illumination side while TiO_2 as applied as an ETL on the catalyst side. Selectivity to C-C coupled products was achieved by using hierarchical Au- Ag-Cu nanostructures as electrocatalysts. The photovoltage, 550- 600 mV under simulated 1-sun illumination, and photocurrents exceeding 30 mA cm^{-2} confirm the carrier selectivity and passivation of the front and back interfaces. Under simulated diurnal illumination conditions, over 60% faradaic efficiency to C_{2+} hydrocarbon and oxygenate products (mainly ethylene, ethanol, propanol) is maintained for several days [6].

As further examples of the PEC design space for CO_2R, use of other oxides as ETLs (e.g. Al_2O_3 and TaO_x) and the prospects of achieving cascade CO_2R [7] on the PEC surface will be discussed.

Cascade Photoelectrochemical CO_2 Reduction Using Spatially Patterned Tandem Photovoltaics Adele Tamboli[1], Ann L. Greenaway[1], Calton J. Kong[2], Fry Intia[1], Myles A. Steiner[1], Grace A. Rome[1], Talysa R. Klein[1], Rajiv R. Prabhakar[2], Emily Warren[1] and Joel W. Ager[2]; [1]National Renewable Energy Laboratory, United States; [2]Lawrence Berkeley National Laboratory, United States

One of the primary challenges facing solar conversion of CO_2 to fuel is the selectivity of the CO_2 reduction reaction to a single, ideally liquid, product. One method for improving selectivity is to use a cascade approach, where sequential steps of the multi-step reduction reaction are driven in series using different catalysts and adjacent microenvironments[1]. Each of these catalysts should be supplied with the ideal photocurrent and photovoltage to drive its respective reaction step. As a model system, we are considering the conversion of CO_2 to ethylene using a patterned, multi-terminal photovoltaic device as a photocathode. This two-step reaction (CO_2 to CO, then CO to C_2H_4) can be driven by two terminals of a three-terminal tandem (3TT) photovoltaic cell, where the third terminal drives the oxidation reaction. We have previously demonstrated 3TTs for photovoltaic applications[2], and will present the operational principles of these devices as well as experimental results using III-V semiconductors as a model system. We show that we can achieve the necessary photovoltages and photocurrents from the rear "R" and middle "Z" contact of these devices to drive the two CO_2 reduction reactions, using the top "T" contact to drive oxidation[3]. Then, we will present a model for how this device is expected to operate in an integrated photoelectrochemical cell[4]. Finally, we will discuss surface protection schemes using a transparent, conductive encapsulant[5] with embedded catalysts to protect the semiconductor from degradation, while providing the required electrical conduction and catalyst integration.

This material is based on work performed by the Liquid Sunlight Alliance, which is supported by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences, Fuels from Sunlight Hub under Award Number DE-SC0021266.

Achieving High Product Selectivity in Silicon Photocathodes by Cascade Catalysis for CO_2 Reduction RajivRamanujam Prabhakar and Joel W. Ager; Lawrence Berkeley National Laboratory, United States

In this work, a sequential catalysis approach by light was employed to achieve high product selectivity for CO_2 reduction. By employing light, regions with high photovoltage and low photovoltages was achieved by using photo-absorbers with different opto-electronic properties. In the low photovoltage region, CO_2 would be reduced to CO and at the high photovoltage region, CO would be reduced to useful products such as ethylene and ethanol with high selectivity. Different photovoltage regions was achieved on Silicon photocathodes by tuning the band edge of Silicon using surface dipoles. The surface dipoles were fabricated on Silicon photocathodes using a solution processed technique like spin coating. The regions of different photovoltages were investigated using surface photovoltage (SPV) and kelvin probe force microscopy (KPFM). SPV shows the increase in the photovoltage of Silicon photocathode upon deposition of the surface dipole. KPFM measurements also reveal an increase in the surface potential with the dipole on Silicon. By accomplishing voltage tunability using this strategy, high product selectivity could be achieved by sequential catalysis using light. The results and outcome of this work would bring a paradigm shift in the methodology of obtaining high product selectivity in CO_2 reduction research.

Investigation of Ni/Au/Ni Ohmic Contact and Dry Etch Mask to p-type GaN for Vertical Top-Down Nanowire Optoelectronics Matthew Seitz, Bryan Melanson, Matthew Hartensveld and Jing Zhang; Rochester Institute of Technology, United States

Vertical GaN nanowires have emerged over the past decade as promising candidates for next-generation optoelectronics, which are of great importance for applications such as novel display systems, micro-LEDs, and nanowire LEDs. The small footprint of these nanowire devices allows for increased device scaling and three-dimensional (3D) integration. Typically, GaN nanowires can be formed through either bottom-up or top-down fabrication processes. Metal organic chemical vapor deposition (MOCVD) or molecular beam epitaxy (MBE) are often used to grow nanowires in the bottom-up approach, however these techniques have many drawbacks, including complex growth conditions and non-uniformities in nanowire diameter, height, and spacing, which can only be partially corrected using expensive selective area epitaxy. Top-down fabrication on the other hand, makes use of the well-developed processes to form nanowires from a monolithic, planar epitaxial stack. Our previous works have explored top-down fabrication approaches for GaN nanowires extensively, for device applications such as vertical nanowire LEDs and vertical transistors. Our top-down fabrication approach consists of patterning a 200 nm thick Ni hardmask on top of a 300 nm thick layer of SiO_2 which has been deposited on the GaN epistack. The Ni layer is then used to mask Cl-based dry etches of the underlying SiO_2 and GaN to form approximately 3 µm tall nanowires with diameters of approximately 1 µm down to 20 nm. Following and hydroxyl-based wet etch and deposition of the n-metal contact at the base of the nanowires, an HF-based wet etch is used to remove the Ni etch mask from the tops of the nanowires by etching the SiO_2 to allow for formation of a Ni/Au p-contact. Ni/Au is typically preferred as a p-contact as it exhibits superior contact resistance to Ni, due to the high work function of Au (5.1 eV). While this process has proved successful, the use of a SiO_2 liftoff layer adds complexity to the fabrication process in the form of additional deposition, dry etch, and wet etch steps. It is therefore desirable to develop a method of embedding an ohmic contact beneath the Ni dry etch mask so that it does not require a lift-off process. This can be achieved through exploration of a novel metal stack which acts as both an ohmic contact to p-GaN as well as an effective etch mask for dry etching of higher aspect ratio GaN nanowire structures.
In this work, we have developed a process to embed the low-resistance ohmic contact with the dry etch hard mask, which leads to the realization of vertical GaN nanowire transistors with promising current injection. This novel structure is composed of a 20 nm Ni layer deposited via electron beam evaporation, a 20 nm Au layer directionally deposited via thermal evaporation. This metal stack was then annealed at 500°C for 10 minutes under oxygen. After this anneal, the bottom Ni/Au layers form a low resistance ohmic contact with the p-GaN through diffusion and the formation of NiO. Following the anneal step, a final and conformal 200 nm Ni capping layer deposited via electron beam evaporation. Electrical performance of this full contact stack was measured via the transmission line model (TLM) using 10 µm x 30 µm contact pads at separation distances ranging from 25 µm to 75 µm. Our measurements indicate that the inclusion of this additional capping layer still provides a good ohmic contact with GaN, showing a specific contact resistance as low as 0.14 Ω/cm^2. By including an additional capping layer in our electrical contacts, the metal stack can serve both as a low resistance ohmic contact and additionally as a hard mask for Cl-based inductively coupled plasma (ICP) etching. These promising results suggest that our proposed process could be used for the successful fabrication of high aspect ratio vertical GaN nanowire optoelectronic devices.

III-V Semiconductor Solid-State Design and Interface Engineering for High-Efficiency Photoelectrolysis Todd G. Deutsch, Myles A. Steiner and James L. Young; National Renewable Energy Laboratory, United States

Photoelectrochemical (PEC) water splitting, which is the direct electrolysis of water with one of the half-reactions occurring on an immersed semiconductor electrode, has made good progress in solar-to-hydrogen (STH) efficiency in the last several years. III-V semiconductor materials have demonstrated the highest STH efficiencies mostly due to their excellent optoelectronic properties, bandgap tunability, and ease of monolithic multijunction fabrication. Many unique semiconductor layers must work in harmony to achieve a device that can spontaneously split water upon illumination. The layers that constitute the solid-state device establish the current and voltage generated under illumination while the strata closer to the electrolyte greatly influence the electrochemical performance.
During this talk we will describe the process of designing and testing a multijunction semiconductor structure optimized for maximum STH efficiency. We grew III-V semiconductors with metalorganic vapor phase epitaxy using the inverted metamorphic approach to obtain non-lattice-matched absorber junctions. We used over a dozen distinct III-V layers to achieve a tandem absorber with a 1.8 eV band gap top junction and 1.2 eV bottom junction. While the photovoltaic performance of these devices was exceptional, they were unable to perform photoelectrolysis without a bias due to an unoptimized interface with the electrolyte. We grew a highly doped emitter layer on the wide band gap material to create a buried junction which improved the open-circuit voltage of the PEC structures by > 500 mV. This configuration achieved 14% STH efficiency, which was short of our target efficiency (15%), so we grew a solid-state, surface-passivating “window layer” that is latticed matched to the wide band gap material. While this device structure had improved voltage and current, the window layer is chemically unstable in our acidic electrolyte. We grew a thin, highly-doped, lattice-matched capping layer to protect the underlying window layer. Finally, we sputtered PtRu nanoparticulate cocatalysts on the photoelectrode surface to lower the kinetic overpotential of the hydrogen evolution reaction. We rigorously benchmarked the STH efficiency of the resulting device and observed greater than 16% conversion of sunlight into hydrogen fuel [1]. Still more work remains to be done to engineer the semiconductor/electrolyte interface to address insufficient stability.

Dopant-Free Hybrid Silicon Heterocontacts—Interface Energetics and Solar Cell Performance Steffen Duhm; Soochow University, China

Dopant-free heterocontacts are frequently utilized as charge-carrier selective contacts of hybrid silicon solar cells with high power conversion efficiencies. Although these interfaces are well characterized from a device perspective, the physics and chemistry of contact formation mechanisms are still not well understood. We use X-ray photoelectron spectroscopy (XPS) to track core-level shifts upon contact formation and accessing the built-in potential. Furthermore, vacuum-level shifts are measured by ultraviolet photoelectron spectroscopy (UPS). By spin-coating ultrathin layers of the conducting polymer PEDOT:PSS on hydrogen-terminated n-Si we can track the Si core-levels upon contact formation and get direct evidence for inversion layer formation. In addition, our XPS and UPS data allows us to speculate that PEDOT passivates Si surface states. Furthermore, we demonstrate that the built-in potential measured with XPS correlates well with the open-circuit voltage of model solar cells. The same holds for devices with dopant-free MoO_x/n-Si or LiF/p-Si heterocontacts as main building blocks. Strikingly, the insulator LiF forms a Schottky contact with p-Si and facilitates an ohmic contact in n-Si.

Efficient Electron Injection into Various Organic Semiconductors Utilizing Superbase Tsubasa Sasaki[1], Munehiro Hasegawa[2], Kaito Inagaki[3], Taku Oono[1], Katsuyuki Morii[2,4], Takahisa Shimizu[1] and Hirohiko Fukagawa[1]; [1]NHK Science & Technology Research Laboratories, Japan; [2]NIppon Shokubai Co., Ltd., Japan; [3]Tokyo University of Science, Japan; [4]Nippon Shokubai Research Alliance Laboratories, Osaka Univ., Japan

Tuning the carrier injection barrier between organic semiconductors and electrodes in organic optoelectronic devices is of pivotal importance for their future development. The electron affinity (EA) of materials used in organic light-emitting diodes (OLEDs) is smaller than that of materials used in other organic devices. Therefore, chemically reactive alkaline elements such as Li/Cs have been essential for fabricating the electron injection layer (EIL) near the cathode. Because such alkali elements are highly chemically reactive and easily oxidize in the presence of ambient oxygen and moisture, there is a strong desire to eliminate reactive materials from devices, especially flexible optoelectronic devices.
The method of fabricating a low-work-function (WF) electrode that eliminates reactive alkali elements, which are widely used for electron injection, from organic devices has been the subject of intense study in recent years. Zhou et al. reported electrodes with a WF of about 3 eV by utilizing polyethyleneimine, and some organic devices without reactive alkali elements have been demonstrated [1]. Very recently, an electrode with a WF of 2.4 eV has been reported by Tang et al. [2]. However, alkali elements are still essential in most OLEDs to achieve a barrier-free contact between the cathode and the organic layer, since the EA of materials used in OLEDs is about 2.0 eV.
Here, we succeeded in injecting electrons into various organic materials owing to the discovery of an EIL that can significantly reduce the WF around the cathode [3]. The novel electron injection material found in this study is the superbase 2,6-bis(1,3,4,6,7,8-tetrahydro-2H-pyrimido[1,2-a] pyrimidin-1-yl)pyridine (Py-hpp_2), which can reduce the WF near an Al cathode from 4.3 to 2.0 eV by utilizing both a coordination reaction [4] and the formation of hydrogen bonds [5]. To investigate the correlation between the EA of the electron transport materials and the electron injection properties, OLEDs were fabricated using 17 different materials for the electron transport layer (ETL). The actual EA of these materials was measured by low-energy inverse photoemission spectroscopy (LEIPS). We found that the operating voltage was low when the actual EA was above 2.0 eV, even if the molecular structures were different, such as a compound with nitrogen-containing heterocycles and aromatic hydrocarbons. A compound with nitrogen-containing heterocycles has conventionally been considered to be essential for delivering electrons from the cathode to the light-emitting layer in OLEDs. However, by tuning the WF near the cathode to about 2.0 eV using a superbase, it is possible to deliver electrons from the cathode to the light-emitting layer independent of the molecular structure. On the basis of these results, we fabricated a simple-structure blue OLED with 9-(naphthalen-1-yl)-10-(naphthalen-2-yl)anthracene (1-2ADN) as the emitting host material, and we also used it as the ETL. Then, an OLED with low operating voltage, high efficiency and high operational stability was realized in spite of the simple device structure. This liberation of the materials used in OLEDs by utilizing superbases can enable the realization of device structures that was previously impossible.
Our breakthrough discovery represents a departure from the conventional wisdom and is expected to contribute to significant progress in the development of various devices such as OLEDs, perovskite LEDs, organic/perovskite solar cells, organic semiconductor laser diodes, and organic transistors.

8:45 AM EQ17.15.03
Perylene Diimides (PDIs) as Cathode Interlayer in Organic Solar Cells Julien Leoni[1], Alison Campbell[1], Tom Raeber[2], Mei Gao[2], Anthony Chesman[2] and Girish Lakhwani[1]; [1]University of Sydney, Australia; [2]CSIRO Manufacturing, Australia

Owning to their good photophysical properties, perylene diimides have shown great potential in many fields, such as photo-redox catalysis, bio-imaging and optoelectronic devices. In fact, imine functionalized PDI derivatives have recently been used as cathode interlayers in organic solar cells (OSCs) significantly improving their efficiency. To create the most suitable interface between the bulk heterojunction (BHJ) and the electrode, these materials are processed with an alcohol-based solvent. This combination enables multiple properties that were examined to understand the full extent of how this cathode enhances charge carrier dynamics as well as the exciton dissociation in the OSC's active layer.

A PTQ10:IDIC conventional organic solar cell was reproduced and used as a reference for this project. Several OSCs were fabricated under different conditions and studied through a series of standard PV and spectroscopic characterizations. Indeed, pristine BHJ, alcohol treated BHJ and the addition of a PDI based interlayer were compared. However, one of the key characterization methods used was light intensity variation measurements that were conducted to enlighten us on the types of recombination. This method enables the extraction of the ideality factor through various approaches and can greatly expand our knowledge of the OSC's inner workings.

9:00 AM EQ17.15.04
A Metal-Free Synthetic Protocol for Blue POSS(R)$_8$ Materials for OLED Applications Rina Mahato, Parvez Akhtar, Madhusudan Singh and Chinmoy K. Hazra; Indian Institute of Technology Delhi, India

Polyhedral oligomeric silsesquioxane (POSS)[1] based organic light-emitting devices (OLEDs) have significant potential applications in displays and solid-state lighting[2], based on favorable charge transport, light absorption, and emission, resulting high efficiency OLEDs[3]. The conventional method of attaching the emitters with the POSS core is metal-assisted hydrosilylation, which often involves the use of expensive metals, such as Pt. Since metal incorporation in POSS(R)$_8$ affects the cost of the device, and also increases the environmental footprint of the synthetic process, a metal-free synthetic strategy is highly desirable. In this work, we propose a highly efficient, easily accessible, metal-free Lewis acid-catalyzed hydrosilylation process for the synthesis of POSS(R)$_8$ under very mild conditions, and report on initial results for a blue emitter. A Lewis acid, B(C_6F_5)$_3$ [tris(pentafluorophenyl)borane], is used to activate the Si–H bond group as a constituent of frustrated Lewis pairs (FLP). For the blue emitter[2,4], we have modified the traditional diphenyl group with a more conjugated pyrene moiety. The characteristic peaks of alkenes at δ 5.74 (ddt, J = 17.1, 9.6, 6.8 Hz, 1H), 4.96 – 4.84 (m, 2H), 2.19 – 2.09 (m, 2H), the methyl group at δ 1.36 – 1.24 (m, 3H) ppm from 1H-NMR and the quaternary carbon peak at δ 40.56 ppm from 13C-NMR confirms the successful synthesis of the emitter. Currently, we are optimizing the reaction conditions for the synthesis of different types of POSS(R)$_8$ starting from different emitters where B(C_6F_5)$_3$ can be used as a metal-free catalyst. This reaction will be monitored by using thin-layer chromatography (TLC) and FT-IR spectroscopy. The synthesized products will be characterized by 1H-NMR, 13C-NMR, 29Si-NMR, high-resolution mass spectrometry (HRMS), FT-IR, and
thermogravimetric techniques. The newly developed protocol would provide a more industrially relevant and more environmentally benign process, and contribute significantly to commodity chemical production of [POSS(R)8] due to their significant applications in OLEDs. Characterization data of blue emitter (B2): Yellow fluorescent solid (125 mg, 89% yield). 1H-NMR (500 MHz, $CDCl_3$) δ 8.38 – 8.23 (m, 4H), 8.23 – 7.96 (m, 14H), 7.73 – 7.66 (m, 3H), 5.74 (ddt, J = 17.1, 9.6, 6.8 Hz, 1H), 4.96 – 4.84 (m, 2H), 2.19 – 2.09 (m, 2H), 1.97 (q, J = 7.4 Hz, 2H), 1.53 (s, 2H), 1.36 – 1.24 (m, 3H) ppm; 13C-NMR (101 MHz, $CDCl_3$) δ 152.62, 140.25, 139.08, 138.87, 138.25, 131.57, 131.04, 130.60, 129.67, 128.65, 127.74, 127.49, 127.42, 126.05, 125.39, 125.25, 125.14, 125.00, 124.83, 124.70, 119.93, 40.56, 33.47, 30.92, 29.31, 26.86 ppm.

Morphology- and Surface Chemistry-Controlled $NaTaO_3$ as Highly Efficient Electron Extraction Layer for Halide Perovskite Solar Cells Kootak Hong, Finn Babbe, Guosong Zeng, Francesca M. Toma and Carolin M. Sutter-Fella; Lawrence Berkeley National Laboratory, United States

Lack of stability is one of the major limitations towards halide perovskite solar cell (HPSC) commercialization. As charge transport layers are critical for device performance and stability, the development of charge transport layers with excellent chemical stability and good energy level alignment for efficient charge transfer is of high research interest. TiO_2 and SnO_2 are widely employed as electron transport layers. However, HPSCs with TiO_2 layer suffer from poor stability due to ultraviolet (UV) light-induced O^{2-} desorption leading to degradation of halide perovskites. SnO_2 shows temperature-induced degradation and exhibits a lower conduction band compared to halide perovskites resulting in a voltage loss. To achieve better stability and efficiency of HPSCs, it is essential to identify alternative wide band gap materials that are UV-stable and show favorable energy level alignment.
Here, we report on the flux-mediated synthesis of morphology- and surface chemistry-controlled $NaTaO_3$ thin films and their application as an electron transport layer for HPSCs. The synthesized $NaTaO_3$ films have a band gap of ~ 4 eV, which makes them more chemically robust under UV illumination and slows down the degradation of halide perovskites, leading to enhanced stability of HPSCs. By varying the precursor chemistry, the resulting microstructure of $NaTaO_3$ films can be varied from smooth thin films to nanocubes. The latter is possibly useful to increase photon recycling. More efficient photoluminescence quenching of the halide perovskite emission, as a measure for charge extraction efficiency, is observed with the $NaTaO_3$ in comparison to the SnO_2 layer. In addition, the precursor chemistry can be used to tune the charge extraction ability of $NaTaO_3$ thin films via surface chemistry modifications.

Interfacial Engineering Enables Efficient and Stable All-Perovskite Flexible Tandem Solar Cells Fan Fu, Yannick Zwirner, Huagui Lai and Ayodhya Tiwari; Empa-Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Single-junction perovskite solar cells (~ 1.5 eV) have reached certified efficiency of 25.5%, on par with c-Si technology. Due to the broad bandgap

tunability of perovskites, all-perovskite tandem solar cell (TSC), which consists of a wide-bandgap (WBG, 1.75-1.85 eV) perovskite top subcell and a narrow-bandgap (NBG, 1.2-1.3 eV) perovskite bottom subcell, hold great promise to break the Shockley-Queisser limit of single-junction solar cells via reduced thermalization loss. With only a few years' developments, efficiencies over 25% have been demonstrated in both 4-terminal and 2-terminal all-perovskite TSCs. Despite the promising progress, all-perovskite tandems are still far from reaching their practical efficiency potential (>30%), and the long-term (>1000 hours) stability under operational conditions remains a major concern.
All-perovskite TSCs are complex multilayer devices featuring over 10 thin film layers. Each of these layers has its own functionality, such as charge extraction and transport, defect passivation, broadband transparent conducting electrode, etc., and are equally important to achieve high efficiency and stability. In this contribution, we present comprehensive studies on factors limiting the efficiency and stability of WBG and NBG perovskite subcells. We use advanced materials and device characterizations, including scanning transmission electron microscopy, time-of-flight secondary ion mass spectrometry, time-resolved photoluminescence (TRPL), (hard) X-ray photoelectron spectroscopy, thermal admittance spectroscopy, etc., to gain insights on optical, compositional, structural, and electronic properties in WBG and NBG perovskite absorbers and at interfaces to adjacent layers. We will present interfacial engineering (such as tuning band alignment and implementing surface passivation strategies) tailored for WBG and NBG perovskite layers and associated interfaces to mitigate the photovoltaic performance and stability loss mechanisms. With this approach, we demonstrate over 22% all-perovskite TSCs on flexible polymer foils with promising operational stability. In the end, we will discuss the opportunities and challenges towards 25% flexible all-perovskite TSCs on both 4-terminal and 2-terminal architecture.

Photo-Engineered Optoelectronic Properties of Transparent Conductive Oxides *via* Reactive Laser Annealing (ReLA)—The Consequence of Defects James Hillier, Demosthenes Koutsogeorgis and Nikolaos Kalfagiannis; Nottingham Trent University, United Kingdom

Transparent conductive oxides (TCOs) are appealing materials for electronic and photonic applications as, amongst other advantages, their properties can be modulated by engineering their defects. Optimisation of this adjustment is, however, a complex design problem. In this work we address this problem following two ways: (i) establishing new high-throughput methods to selectively tune these properties towards the requirements of the application and (ii) developing better insights into the optoelectronic properties of TCOs. Specifically, we investigated the selective modification of the optoelectronic properties of sputtered tin-doped indium oxide (ITO), aluminium-doped zinc oxide (AZO) and gallium doped zinc oxide (GZO) thin films *via* laser annealing (LA) within an environmental cell containing a wide set of reducing and oxidising reactive gas mixtures.
In order to elucidate the precise mechanisms behind the ReLA process, the optical properties modifications were related to the structural, compositional, and electronic properties. In one case, where the sputtering conditions were optimised to produce an ITO thin film with low resistivity (4×10^{-4} Ωcm), infrared-visible (0.034-3.4 eV) spectroscopic ellipsometry and Hall Effect measurements revealed a modulation of the optoelectronic properties that is dependant upon the ambient gas mixture. Explicitly, reducing environments (5% H_2 in N_2) promoted a greater enhancement of the carrier concentration. Examination of the X-ray diffractograms and cross-sectional Transmission Electron Microscopy images did not reveal any ReLA-induced structural modifications. However, X-ray photoelectron spectroscopy and energy-dispersive X-ray concluded that the modification of the optoelectronic properties of the ITO films arose from purely compositional changes (creation/filling of oxygen vacancies and activation of substitutional Sn dopants). The precise ReLA induced modifications were not identical for all TCO thin films. In the case of ITO thin films grown with “un-optimised” sputtering conditions (with a higher resistivity of 7×10^{-3} Ωcm), the alteration of the optoelectronic properties was more significant and did not arise from changes to the composition alone. Instead, the depth-dependence of the laser annealing process was uncovered *via* a combination of advanced ellipsometric modelling and cross-sectional transmission electron microscopy. For the AZO and GZO films that form distinct grains even for room-temperature sputter depositions, the role of the grain boundary scattering on the optoelectronic properties is more significant. Therefore, we focussed our attention on the crystal structure in this case. By carefully considering the interplay between the compositional alterations and crystal structure changes for a wide range of TCO films, we revealed the influence of both the intra-grain and inter-grain carrier transport properties for doped ZnO and ITO thin films.
Altogether, we demonstrate that ReLA can be utilised to target specific defects within the TCO films and engineer them to achieve specific alterations to the optical and electronic properties. Hereby, ReLA is established as a novel and versatile tool to tailor the properties of TCO films towards the requirements of potential electronic and photonic applications.

SESSION EQ18.01: Semiconductor Qubits I
Session Chairs: Kyungjean Min and Rick Silver
Tuesday Afternoon, November 30, 2021
Hynes, Level 1, Room 109

1:30 PM *EQ18.01.01
Solid–State Atom-Based Devices for Analog Quantum Simulation Rick Silver[1,2], Xiqiao Wang[2], Jonathan Wyrick[1], Fan Fei[2], Ranjit Kashid[1], Pradeep Namboodiri[1], Ehsan Khatami[3], Albert Rigosi[1] and Garnett Bryant[1]; [1]National Institute of Standards and Technology, United States; [2]University of Maryland, United States; [3]San Jose State University, United States

NIST is using atomically precise fabrication to develop devices for use in quantum information processing. We are using hydrogen-based scanning probe lithography for deterministic placement of individual dopant atoms with atomically aligned gates to fabricate single/few atom transistors, few-donor/quantum dot devices for spin manipulation, and arrayed few-donor devices for analog quantum simulation.

In this talk I will discuss the analog quantum simulation of an extended Hubbard model using arrays of few atom structures in silicon. These atomic clusters form the sites of a Hubbard model array in the strong interaction regime, where we vary the tunnel coupling with atomic precision between nearby dots from a weakly to strongly tunnel coupled regime.
Using an extended Hubbard model we explore the impact of site-by-site disorder on charge occupation and the Hubbard band structure. Numerical simulations of the model reveal the nature of charge distributions and magnetic correlations for different parameter sets. We quantify the electron addition energy spectrum through Coulomb blockade and charge stability analysis and demonstrate tuning of the array's energy spectrum using gates. We map the Hamiltonian parameters to the physical system to tune the charge occupation, the spatial distribution of the eigenstates, localization/delocalization transition, and Hubbard band structure. We identify resonant and inelastic conductance paths and extract coherent tunnel coupling strength.

Details of the STM-fabrication will be described as well as quantum transport measurements from several arrays of few atom clusters ranging from 1x2 double dots to a multi-gate 3×3 dot array to explore the rich Hubbard physics of quantum dot-arrays.

2:00 PM EQ18.01.02
Sequential Atomic-Scale Placement and Alignment of P and B for Bipolar APAM Devices James H. Owen, Robin Santini, Ehud Fuchs and John Randall; Zyvex Labs LLC, United States

The ability to place both *n*-type and *p*-type dopants relative to each other with atomic precision is crucial to the application of Atomically Precise Advanced Manufacturing (APAM) beyond quantum computing. While PH_3 and $AsH_3$are highly selective precursors for donor dopants [1-3], the direct equivalents for B and Al are unstable. However, diborane has been used to create a p-n junction[4], and halide precursors, BCl_3 and $AlCl_3$ are proving promising for acceptor dopants[5].
In this work, we have developed an APAM process for the sequential placement of P and B using PH_3 and BCl_3. First, Hydrogen Depassivation Lithography is used to create patterns on a H:Si(001) substrate. PH_3 is dosed onto the sample and adsorbs selectively into these patterns. An incorporation anneal then drives the adsorbed P into the top layer of the substrate. The sample is repassivated with atomic H before returning to the STM for the second dopant step. A similar process of patterning, dosing with BCl_3 and incorporation completes the bipolar device. The P regions are patterned, dosed and incorporated first, as the incorporation anneal temperature for PH_3 is higher than for BCl_3.
Alignment marks on the sample allow rapid relocation of the device area, and we have developed a high-speed dI/dV imaging method[6] to locate surface or buried dopants. The dI/dV imaging provides much higher contrast of the dopants than the topographic image, so that dopant patches can be relocated quickly in the STM using low-resolution, large-area scans. It also allows for precise alignment of new patterns to existing dopant patches. After both dopants have been incorporated, the surface is repassivated, and the presence of both dopants is confirmed in the STM. The dopant device can then be buried in epitaxial silicon. After burial, dI/dV imaging is then used to confirm the location of the bipolar device for electrode deposition.

2:15 PM EQ18.01.03
Experimental Measurements of Atomic Scale Decoherence Mechanisms in Planar Germanium Quantum Wells Brian Gorman[1], Megan Holtz[1], Edwin Supple[1], Chomani Gaspe[2] and Christopher Richardson[2]; [1]Colorado School of Mines, United States; [2]Laboratory for Physical Sciences, United States

Holes in compressively strained germanium quantum wells is an emerging spin qubit system to overcome the challenges associated with valley degeneracy in silicon. The local electrostatic potential is critical to control the qubit state, and through the deformation potential there is a need to understand the local strain environment. Nanometer-scale experimental assessment of the strain in the quantum well is lacking due to the high spatial resolution and nearly single atom detectability required. Using combined Transmission Electron Microscopy and Atom Probe Tomography, strain variations are herein shown to be experimentally accessible in Ge quantum wells grown via MBE on SiGe buffer layers. Using 4-D STEM, anisotropic strain in the Ge layer was mapped in real space to better than 1 nm and lattice parameters measured to better than 0.1 Å in multiple crystallographic directions. The Ge quantum well was found to be tetragonally strained in defect-free regions and partially relaxed near threading dislocations. Combining TEM with APT, the SiGe/Ge internal

interface structure was mapped in 3-D and shown to have sub-nm interfacial roughness. Individual ^{73}Ge atoms with non-zero nuclear spins are uniquely identified within the Ge quantum well in order to provide another metric that quantum wells can be characterized in order to explore potential interactions between nuclear and hole spins.

2:30 PM *EQ18.01.04
Modeling SiGe Heterostructures and Devices for Si-Based Qubits Mark Gyure; University of California, Los Angeles, United States

A current bottleneck for the development of semiconductor-based qubits is the need for high fidelity simulations that can assist in the device design process and minimize expensive and labor-intensive fabrication cycles. This need is largely unmet – there are very few publicly or commercially available simulation tools that are well suited for this task and, as devices get more complex and time consuming to fabricate, the need only continues to grow.

UCLA has developed simulation capabilities over the last several years to meet this need. We have developed and implemented grid-based software components that can be combined to create very accurate simulations of localized quantum mechanical systems. These software components support the construction of simulations that can be used to model everything from the properties of semiconductor heterostructures to the behavior of multiple interacting electrons.
This talk will describe how our simulation tools, which model realistic devices features including gate geometries and dielectric layers, can be used to design SiGe heterostructures and devices for Si-based qubits. We will show that full configuration interaction (FCI) methods can be used to generate highly accurate energy spectra for multi-electron and coupled few-electron quantum dots including important quantities like the exchange interaction between electrons in nearest neighbor dots including the effects of magnetic fields and valley physics. The exchange interaction is the foundation of most two qubit gates in semiconductor dots and being able to predict its behavior as a function of gate geometry and bias is critically important to optimizing the design of qubit devices.

3:00 PM EQ18.01.05
Impact of Ti/Pd Gates on the Stability of Si/SiO_2 Quantum Dots Kyungjean Min[1,2] and M. D. Stewart, Jr.[2]; [1]University of Maryland, College Park, United States; [2]National Institute of Standards and Technology, United States

Gate-defined Si/SiO_2 based single electron devices (SEDs) are a promising platform to implement spin qubits and a quantum standard of the Ampere. Noise can limit the performance and integrability of devices for each of these applications. One of the measures of low-frequency charge noise control is known as charge offset drift. The device stability at low frequencies is usually attributed to the presence of defects which are influenced by materials choices, fabrication processes and device design. Poly-Si gated silicon SEDs are known to have smaller charge offset drift (0.01e) than the metallic gates SEDs as observed in the charge offset drift measurement of Al gates SEDs (0.15e). The reactivity of the Al can produce defective AlO_x formation as the inter-gate dielectric as well as underneath the gate, increasing charge offset drift and degrading device performance. However, Pd gates which are much less reactive than Al, may induce fewer defects while preserving the benefits of metal-gated devices such as simplified fabrication, reduced parasitic resistances, and reduced grain size. To assess the impact on stability of Pd gates. we fabricate and measure SEDs with a combination of Ti/Pd and poly-Si gates with thermally grown SiO_2 as the inter-gate dielectric. This choice preserves a high level of tunability and functionality in the devices provided by overlapping gate design, while also avoiding defects associated with a deposited inter-gate dielectric. Our latest measurement results and the implications for device performance will be discussed.

3:15 PM EQ18.01.06
Antisite Defect Qubits in Monolayer Transition Metal Dichalcogenides Jeng-Yuan Tsai[1], Jinbo Pan[1], Hsin Lin[2], Arun Bansil[3] and Qimin Yan[1]; [1]Temple University, United States; [2]Academia Sinica, Taiwan; [3]Northeastern University, United States

Like the classical bit that launched the modern electronic age, the quantum bit or qubit lies at the heart of the ongoing quantum information revolution that is expected to transform science and society in previously unimaginable ways. Although solid-state defects such as the diamond-NV centers in three-dimensional hosts have been demonstrated as promising qubits, atomically-thin two-dimensional (2D) materials offer an exciting new paradigm for qubit fabrication and operation at room temperature. Using data-driven approaches and a symmetry-based hypothesis for qubit discovery, we show that neutral anion-antisite defects in six transition metal dichalcogenide (TMD) monolayers as viable spin qubits. We show how the optical transitions and triplet-singlet intersystem crossing paths in the qubit provide a complete cycle for initialization, manipulation, and readout of the qubit. The operational principles of the qubit are illustrated through an in-depth discussion of the antisite qubit in WS_2. Our study opens a new pathway for creating spin-qubits and multi-qubit platforms for quantum information technologies based on defects in 2D solid-state systems.

SESSION EQ18.02: Superconducting Qubits I
Session Chair: William Strickland
Wednesday Afternoon, December 1, 2021
Hynes, Level 1, Room 109

1:30 PM EQ18.02.01
Long-Lived Transmons with Different Electrode Layouts Kungang Li, Sudeep Dutta, Zachary Steffen, Dylan Poppert, Shahriar Keshvari, Jeffery Bowser, Ben Palmer, Christopher Lobb and Frederick Wellstood; University of Maryland, United States

The relaxation time T_1 of superconducting qubits has increased by orders of magnitude over the last two decades. To test whether quasiparticles are a significant contributor to the loss, we have repeatedly measured T_1 in Al/AlO_x/Al transmons with electrodes with different superconducting gaps. In one device, the first layer electrode was formed by deposition of nominally pure aluminum, while the counter-electrode was formed by deposition of oxygen-doped aluminum. The superconducting energy gap of the electrode depends on the grain size, which depends on the oxygen doping as well as the layer thickness. The device showed relatively large fluctuations in T_1, varying from about 100 μs to just over 300 μs at 20 mK. In other transmons, we formed the first layer electrode by deposition of oxygen-doped aluminum, while the counter-electrode was formed by deposition of nominally pure aluminum. These devices showed a similar range of large fluctuating T_1 values, as well as a maximum T_1 over 300 μs. Measurements of the T_1 of these transmons as a function of temperature shows similar temperature dependence, with the relaxation time at high temperature dropping due to the thermally-generated quasiparticles.

1:45 PM EQ18.02.02

Structural Characterization of Nitride Josephson Junctions Grown via Molecular Beam Epitaxy Using Scanning Transmission Electron Microscopy and Atom Probe Tomography Edwin Supple[1], Megan Holtz[1], Christopher Richardson[2,3] and Brian Gorman[1]; [1]Colorado School of Mines, United States; [2]University of Maryland, United States; [3]Laboratory for Physical Sciences, United States

Current implementations of superconducting qubits have short decoherence times attributed, in part, to losses to two level systems. These two level systems reside in dielectric materials and at interfaces in the device. Josephson junctions made of (Nb,Ti)N superconductors and AlN junction barrier grown via molecular beam epitaxy on sapphire have the potential to eliminate the amorphous material hosting two level systems and thus potentially improve qubit coherence times. Here, we utilize 4-D scanning transmission electron microscopy (STEM) to determine nanometer-scale changes in crystallographic structure, cation ordering, and orientation of the superconductors in a NbTiN / 2 nm AlN / NbTiN device stack grown on c-sapphire. We find that the NbTiN is rock salt structured and highly oriented towards <111> but with rotations about that axis corresponding to step edges in the c-sapphire. The AlN structure, orientation, roughness and thickness were investigated using correlative 4-D STEM and Atom Probe Tomography (APT). Under these growth conditions, the AlN can exhibit island growth on the lower NbTiN, leading to nm scale changes in thickness and shorts across the barrier junction. As a result, the top NbTiN has randomly oriented crystallographic structure. APT was also utilized to determine local changes in point defect chemistry at the internal interfaces. Changes in the nitrogen stoichiometry are observed near the AlN barrier, leading to negatively charged vacancies that may be a source of decoherence.

2:00 PM EQ18.02.03
Transparent Superconductor Candidates—Intercalated ITO Emma K. Batson[1], Marco Colangelo[1], John Simonaitis[1], Mayuran Saravanapavanantham[1], Madison King[2], Johanna Nordlander[3], Margaret Anderson[3], Erika V. Ortega Ortiz[3], Vladimir Bulović[1], Stephanie K. Hurst[2], Julia Mundy[3], Phillip D. Keathley[1] and Karl Berggren[1]; [1]Massachusetts Institute of Technology, United States; [2]Northern Arizona University, United States; [3]Harvard University, United States

There are an increasing number of circuit architectures that put optical modes on-chip with superconducting microwave electronics, such as microwave-to-optical transducers which could help link quantum networks.[1, 2] However, such devices are frequently limited by absorption of the optical field in the superconducting electronics. This loss leads to a reduction in the quality factor of the optics, and may also induce quasi-particle generation which reduces the performance of the superconducting material. Although fine-tuning the geometry of the circuit can decrease optical absorption in the superconductor, the absorption could be further reduced if the electronics were made of a superconductor which was transparent to visible light.

In this work, we study sodium-doped ITO as a potential transparent superconductor. ITO, which has previously been studied as a transparent conductor with a low carrier concentration and a high mobility, has recently been shown to superconduct when electrochemically doped via intercalation of sodium ions.[3] However, the doping is also associated with a visible change in the optical properties of the material that has not previously been quantitatively measured. We develop an electrochemical cell for doping ITO and study how the process affects its electrical and optical properties. We use ITO on different substrates, including glass and silicon, with different doping levels set by intercalation time. We measure how doping changes the optical properties of the ITO using ellipsometry and spectrophotometry across the visible spectrum and near infrared. We also measure the room temperature resistivity and superconducting transition temperature, and their relationship to the optical properties. Based on these measurements, we evaluate the suitability of sodium-doped ITO as a transparent superconductor.

2:15 PM EQ18.02.04
Late News: Microwave Absorption of Near-Surface InAs Quantum Wells on Pseudomorphic III-V Buffer Layers William M. Strickland, Joseph O'Connell Yuan, Aminatou Dabokemp, Mehdi Hatefipour, Dylan Langone and Javad Shabani; New York University, United States

Qubits on solid state devices could potentially provide the rapid control necessary for developing scalable quantum information processors. Materials innovation and design breakthroughs have increased the functionality and coherence of qubits substantially over the past two decades. Here we show by improving the interface between InAs and Al, one can reliably fabricate voltage-controlled Josephson junction field effect transistors (JJ-FET) to be used in tunable qubits, resonators, and couplers. We find that band gap engineering is crucial in realizing a two-dimensional electron gas near the surface. In addition, we show that coupling between the semiconductor layer and the superconducting contacts can affect qubit properties.
We analyze materials systems with varied growth conditions on the pseudomorphic buffer layer and quantum well active region for the purposes of making JJ-FET devices. In samples with a high indium content graded buffer layer, we find that surface roughnesses decrease drastically with the graded buffer layer growth temperature. We also find that samples with isotropic roughnesses along the 〈110〉 and 〈1-10〉 directions show a higher mobility than those with anisotropic roughnesses. We study the effects of the quantum well growth temperature over a range of 445°C to 465°C on 2DEG mobility. We grow a thin 1-6 nm $In_{0.81}Al_{0.19}As$ capping layer in order to discern the effects of surface scattering on the quantum well and measure density and mobility as a function of the $In_{0.81}Al_{0.19}As$ layer thickness. We compare the measured densities to those calculated by solving the Schrödinger and Poisson equations self-consistently, where the presence of a thin $In_{0.81}Al_{0.19}As$ top layer causes the density and mobility increase, due to the decreasing conduction band energy of InAs and to separation from surface scattering sites.
We test these structures in coplanar waveguide (CPW) resonator devices using microwave transmission measurements, we study the quality factor on each device at high and low power and extract TLS losses in each materials combination. We also present anharmonicity and coupling strengths measured from one and two-photon absorption in a quantum two-level system engineered in a fabricated JJ-FET.

2:30 PM EQ18.02.05
Ultra-High Vacuum Electron-Beam Evaporated Niobium for Low-Loss Superconducting Coplanar Waveguide Resonators Daria Kowsari[1], Kaiwen Zheng[1], Jonathan Monroe[1], Nathan Thobaben[2], Xinyi Du[1], Patrick Harrington[1,3], Erik Henriksen[1,1], David Wisbey[2] and Kater Murch[1]; [1]Washington University in St. Louis, United States; [2]Saint Louis University, United States; [3]Massachusetts Institute of Technology, United States

Material losses limit the performance of superconducting qubit processors. Recent advances in the fabrication techniques and materials science have reduced the majority of decoherence sources such as quasiparticles, magnetic vortices, and radiation, leaving two-level system (TLS) defects as the most prominent source of loss. Due to its high transition temperature and critical field, niobium is one of the common materials used to achieve highly coherent devices. Conventional niobium deposition methods, such as DC magnetron sputtering can result in a damaged substrate-metal interface during the deposition due to the presence of high energy argon ions. To eliminate this source of damage, here we report on a refined growth technique for extremely low-loss niobium thin films using an electron-beam evaporator. The films are deposited in a ultra-high vacuum pressure environment (< 5 nTorr) with deposition rates as low as 1.2 nm/min. The resulted films exhibit a superconducting transition temperature of 9.2 K and residual-resistivity ratio as high of 5.1 for a film with a thickness of 200 nm, proving the absence of any trace of impurities, despite the low deposition rate. To further study the sources of

loss in our films, we fabricated the films into coplanar waveguide (CPW) resonators to extract the TLS loss tangent of the niobium using microwave measurements. Notably, we utilized a CPW gap of 2 μm to maximize coupling to the TLSs at the interfaces, and thereby gain a more reliable estimate of the defects in the films. Our results show that after passivating the niobium surface using a buffered oxide etch, we achieve TLS loss tangents as low as 1×10^{-7}, well below the previous limits.

2:45 PM EQ18.02.06
Niobium Coplanar Waveguide Microwave Resonators with Nitrogen Plasma Passivated Surface Kaiwen Zheng[1], Daria Kowsari[1], David Wisbey[2] and Kater Murch[1]; [1]Washington University in St. Louis, United States; [2]Saint Louis University, United States

The quality factor of superconducting coplanar waveguide resonators correlates strongly with the coherence properties of planar superconducting qubits. Recent works have shown that the microwave loss of niobium microwave resonators is dominated by an oxide layer of approximately 5 nm thick at the metal-air interface. Although the microwave loss can be reduced by removing the oxide layer using buffered oxide etch, the oxide regrows in a time frame of several hours. Our work demonstrates a novel method of preventing the regrowth of surface oxide by passivating the metal surface using nitrogen plasma. We will present data of surface and microwave characterizations of resonators passivated using this method.

SESSION EQ18.03: Topological Qubits I

Thursday Morning, December 2, 2021
Hynes, Level 1, Room 109

10:30 AM *EQ18.03.01
Progress in Realizing Topological Superconductivity in Planar Josephson Junctions Javad Shabani; New York University, United States

Recently the drive to understand and control the order parameter characterizing the collective state of electrons in quantum heterostructures has attracted great interest. New physical behavior can emerge that is absent in the isolated constituent materials. With regards to superconductivity this has opened a whole new area of investigation in the form of topological superconductivity. Topological superconductivity are expected to host exotic quasi-particle excitations including Majorana bound states which hold promise for fault-tolerant quantum computing. Recent theory predicts in superconductor-semiconductor devices, Majorana bound states can emerge and are accompanied by a topological phase transition. We study epitaxial Al/InAs Josephson junctions in presence of Zeeman field where we find a transition between trivial and topological superconductivity. We observe a minimum of the critical current at the topological transition, indicating a closing and reopening of the superconducting gap induced in InAs, with increasing magnetic field. By embedding the Josephson junction in a phase-sensitive loop geometry, we measure a π-jump in the superconducting phase across the junction when the system is driven through the topological transition. These findings reveal a versatile two-dimensional platform based on epitaxial superconductors and semicondcutors.

11:00 AM EQ18.03.02
InAs Nanowires on Nanomembranes—Growth and Device Aspects Didem Dede[1], Kristopher Cerveny[2], Chunyi Huang[3], Valerio Piazza[1], Nicholas P. Morgan[1], Martin Friedl[1], Lucas Güniat[1], Jean-Baptiste Leran[1], Jaime Segura Ruiz[4], Valentina Bonino[4], Lincoln Lauhon[3], Dominik Zumbuhl[2] and Anna Fontcuberta i Morral[1]; [1]Ecole Polytechnique Federale de Lausanne, Switzerland; [2]Universität Basel, Switzerland; [3]Northwestern University, United States; [4]European Synchrotron Radiation Facility, France

Even though many advances have been made in the field of quantum computing, Majorana fermions, the exotic mystery of topological qubits, have yet to be conclusively identified and are thus still waiting to be explored.[1] Materials science is still the bottleneck of this progress; high-quality semiconductor nanowires (NWs) in a precise configuration are required, as well as a deeper understanding of their structural, electrical, and transport properties. Previously, selective area growth of horizontal In-based NW networks by molecular beam epitaxy has been proposed for these systems due to the scalability of the process, inherent properties of the material, and the cleaner environment of the machine.[2,3]Growing NWs on defect-free GaAs templates or nanomembranes (NMs) results in high crystal quality, eliminating undesired impurity incorporation coming from the substrate. As a result, these NWs show field-effect gating, quantum coherence, and induced superconductivity.[3,4] Moreover, the carrier concentration of the In(Ga)As NW branches can be enhanced by quasi-remotely doping the (111)B GaAs NMs. This results in the observation of weak anti-localization, an indication of strong spin-orbit interaction (SOI), and enhanced coherence length and mean free path.[5] However, the maximum achievable In concentration on these NMs is 50%, and Si dopants accumulate at the NW/NM interface contributing to the donor interface scattering. Thus, advancements are still necessary to achieve the optimal material design for efficient quantum transport.
In this study, we address several challenges related to the design, growth, and exploitation of horizontal NWs grown epitaxially on NMs. First, we explore the crystal orientation of the GaAs substrate as a design parameter for changing the morphology of the In(Ga)As NWs. Since growths on (111)B, (100), and (110) are all governed by both thermodynamics and kinetics, the GaAs NMs have different morphologies and facets depending on the surface energy. Consequently, the NW geometry and the amount of In incorporation in the wire change depending on the substrate orientation. We demonstrate that growth on (100) substrates results in NWs that grow conformally around a low-aspect-ratio NM. These nanowires can be nearly pure InAs and exhibit only a narrow-intermixed region. For growth on (110) substrates, the NWs have a trapezoidal cross-section with a moderate In concentration. Subsequently, we explore the possibility to modify the morphology of the NMs by adding a small amount of Sb during the epitaxial growth (less than 5 at%). Sb acts as a "morphactant" in the system, favoring the formation of a flat top facet. This provides a smoother growth surface for the InAs NW, helping to decrease the scattering at the NM-NW interface. We also investigate new routes to suppress Si dopant diffusion in remotely-doped structures by two different approaches: (i) suppressing dopant mobility during the growth by decreasing the temperature and (ii) introducing a few-nm thick trapping layer after the doped layer growth. Dopant displacement was characterized by atom probe tomography. Finally, we investigate the magnetotransport properties of some of the quasi-remotely doped NWs. By fabricating a dual gated architecture at each side of the NW, we aim to keep carrier density constant while changing the electric field across two gates. This novel device design would make it possible to tune the SOI present in these NWs.

Breakdown of Induced p±ip Pairing in a Superconductor-Semiconductor Hybrid Duc Phan[1], Jorden Senior[1], Areg Ghazaryan[1], Mehdi Hatefipour[2], William M. Strickland[2], Javad Shabani[2], Maksym Serbyn[1] and Andrew P. Higginbotham[1]; [1]IST Austria, Austria; [2]New York University, United States

Superconductor-semiconductor hybrids are platforms for exploring the rich phenomena that can emerge from effective p-wave superconductivity. Spin-orbit coupling, combined with the proximity effect, causes the two-dimensional semiconductor to inherit p±ip intraband pairing, and application of magnetic field can then result in transitions to the normal state, partial Bogoliubov Fermi surfaces, or topological phases with Majorana modes. Experimentally probing the hybrid superconductor-semiconductor interface, however, is challenging due to the shunting effect of the conventional superconductor. Consequently, the nature of induced pairing remains an open question.

I will discuss the use of planar superconducting resonators to probe induced superconductivity in a two dimensional Al-InAs hybrid system. We have observed a strong, anisotropic suppression of superfluid density and enhanced dissipation driven by magnetic field, which cannot be accounted for by the depairing theory of an s-wave superconductor. These observations are explained by a picture of independent intraband p±ip superconductors giving way to partial Bogoliubov Fermi surfaces. Within this picture, we provide the first characterization of key properties of the hybrid superconducting system, with implications for routes to Majorana physics. In addition, this work raises questions surrounding the stability of Bogoliubov Fermi surfaces.

Remote Doping in Nanowires for Quantum Computing Chunyi Huang[1], Didem Dede[2], Martin Friedl[2], Valerio Piazza[2], Anna Fontcuberta i Morral[2,2] and Lincoln Lauhon[1]; [1]Northwestern University, United States; [2]EPFL, Switzerland

The manipulation of Majorana zero modes in networks of semiconductor nanowires is a promising route to quantum computing. A central challenge to this approach is to achieve control of both nanowire morphology and network topology. We have previously demonstrated wafer-scale growth of high mobility branched InAs nanowires (NWs) supported on GaAs nanomembranes (NMs) by molecular beam epitaxy (MBE).[1] Here we address the challenge of controlling the NW morphology and dopant incorporation simultaneously. Modulation of growth temperature and III-As ratios can be used to determine the nanowire morphology by controlling anisotropic growth in these non-planar heterostructures. However, the incorporation kinetics of the dopants are generally facet-dependent, such that the ideal growth conditions for self-assembled NWs may not match the conditions needed to achieve the ideal doping profile. We have used atom probe tomography (APT)[1] to make 3D compositional measurements at the atomic scale to understand the relationship between nanowire faceting and dopant incorporation under a range of growth conditions.

In our initial work, atom probe tomography analysis found that Si dopants accumulate at the top of the (111) facet of InGaAs nanowires,[3] which will produce scattering from the ionized donors. Follow-up work was successful in introducing Si below the NW/NM interface, but with strong facet dependent doping and with incomplete control of morphology. The talk will describe strategies to mitigate facet dependent doping while maintaining precise dopant positioning beneath a well-defined channel. We visualized buried growth interfaces by introducing dilute Al marker layers during growth, providing new insights into of how faceting varies with temperature and III-As ratios in a continuous manner. Si diffusion can be suppressed by doping at reduced temperatures, leading to dopant profiles that are less diffuse both along the growth axis and along the growth interface. However, the growth interface shape changes as the temperature is increased for the definition of the InAs nanowire grown. The precise determination of the nanowire morphology and dopant distribution by atom probe tomography lays an essential foundation to understanding the origin of transport properties, and provides new strategies to mitigate Si segregation and facet-dependent doping.

Reversed Phase Transformation of β→α-Sn at Elevated Temperatures Towards Quantum Material Integration on Silicon Shang Liu, Alejandra V. Covian, Xiaoxin Wang and Jifeng Liu; Dartmouth College, United States

α-Sn and SnGe alloys have recently attracted much attention as a new family of topological quantum materials [1,2]. Depending on strain, they can be topological insulators or topological Dirac semimetals (TDS), the latter being a 3D counterpart of graphene with the Dirac cone protected by crystal symmetry and spin-orbit coupling. Recently, theoretical predictions have also shown that SnGe alloys with >40% Sn composition can be a TDS under compressive strain [2]. If verified experimentally, the wide range of SnGe alloys could greatly enrich the family of 3D TDS since only a few of them have been discovered so far [1,3,4]. They are also naturally compatible with Si-based integrated circuits as alloys based on Group IV elements. However, bulk α-Sn is stable only at <13ºC. High Sn composition SnGe alloys have been rarely studied experimentally since they are well beyond the equilibrium solubility limit [5]. Moreover, the integration of α-Sn on silicon has also been hindered by a large lattice mismatch, and epitaxial α-Sn is limited to InSb substrates so far. To address these challenges, we demonstrate that ~4 at.% Ge-doped α-Sn microdots can be grown on native oxide on Si substrate via a *reversed* phase transformation from β to α-Sn at 300-500°C, seeded by Ge-rich GeSn nanoclusters in the as-deposited materials instead of heteroepitaxy from the Si substrate. This result is exactly opposite to the bulk phase diagram that says α-Sn cannot be formed at >13ºC. It also shows that Ge-doped α-Sn can be stabilized at elevated temperatures without the help of coherent epitaxial interface as in the common case of α-Sn growth on InSb substrates. The size of α-Sn dots reaches up to 280 nm in diameter and 150 nm in thickness, ~10x larger than the upper size limit for α-Sn formation reported before. Raman spectroscopy, X-ray diffraction (XRD), Energy-dispersive X-ray spectroscopy (EDS), and high-resolution transmission electron microscopy (HRTEM) have been used to confirm the formation and determined the Ge composition in α-Sn. A compressive strain of ~-0.6% is introduced to Ge-doped α-Sn, which makes it one of the few candidates for 3D TDS according to theoretical predictions. This work presents the first instance of α-Sn grown at relatively high temperature on Si without epitaxy, breaking through the long-existing constraints in substrate selection, size/thickness limit, and thermal stability of α-Sn growth towards topological quantum material integration on Si. These TDS microdots could be coupled through graphene towards quantum device applications [6]. Furthermore, since we found that Ge-rich GeSn nanoclusters can effectively seed the growth of Sn-rich α-SnGe in this study, this process could potentially be scaled up using selective epitaxial growth on GeSn virtual substrates on Si for high-quality quantum device integration.

Atomic-Scale Material Insights for Silicon Based Qubits Sven Rogge; Univ of New South Wales, Australia

Spins bound to electronic dopant atoms in silicon are promising qubits since they interact weakly with their environment, resulting in exceptional coherence times of the order of seconds. Characterising and controlling their properties and interactions is essential to fulfil the prerequisite for accurate quantum state manipulation needed to build scalable quantum computers. An extra challenge in silicon originates from the indirect bandgap that leads to a spatial modulation of the qubit's wavefunction at the atomic scale that is incommensurate with the host lattice. This presentation will cover innovative methods to probe the quantum states encoded of individual and interacting atom qubits in silicon, including single electron-tunnelling in nanoscale transistors, scanning tunnelling microscopy to directly image the wave-function at the atomic scale and radio frequency reflectometry. Together with the development of atomistic simulations of realistic devices, these methods bring new insights to the understanding of the impact of the valley degree of freedom in silicon to accelerate the engineering of atom-based quantum processors.

Bridging the Classical-Quantum Divide with Implanted Ions—Engineered Donors in Enriched Silicon David N. Jamieson[1,2]; [1]University of Melbourne, Australia; [2]Centre for Quantum Computation and Communication Technology, Australia

We have developed a strategy to implant near-surface donor atoms into silicon that form the components of quantum computer devices employing the donor nuclear and electron spins. Our devices address the challenge of bridging the internal donor quantum states to read-out circuitry and hence the classical observer. One and two atom devices can be engineered by implanting a small number of ions, subject to Poisson statistical distributions, then finding optimally located donors by sweeping surface control gates to induce electron exchange with an adjacent single electron transistor. Enriched 28-Si substrates, depleted in the nuclear spin ½ 29-Si isotope, give long donor nuclear and electron spin coherence times. For large scale devices we have developed a strategy integrating a plasma ion source, which produces donor ions with random arrival times, together with an active substrate that signals the implantation of each ion. The ion implantation site is defined by a nanostencil incorporated in an AFM cantilever that also allows for non-destructive, in-situ imaging of location markers to align the implanted donors to sub-100 nm precision. The signals are generated from the e-h pairs induced in the substrate using high sensitivity readout electronics which has also provided insights into the physics of the ion stopping process for near-surface doping. We have developed the capability to implant molecules of 31-PFx (x=1,2,3,4), Sb isotopes and 209-Bi all within a mean 20 nm of the silicon surface. In the case of PFx molecules, the F bystander ions generate e-h pairs, then diffuse away during post-implantation annealing for donor activation. Signals from the ion-induced electron hole pairs also show that discrete ion impacts suffer much lower levels of charge recombination in the substrate compared to continuous ion irradiation. In parallel we have demonstrated a method to locally deplete the non-zero nuclear spin isotope 29-Si to 250 ppm using high fluence ion implantation. Electron Spin Resonance measurements of near-surface 31-P donors material with 29-Si depleted to 3000 ppm with this method produced a T2-Hahn electron coherence time of 285 μs which is commensurate with previous work on enriched silicon. Also, the signal amplitude as a function of time showed a single component exponential decay without the need for a third order term imposed by residual 29-Si. For a large-scale device, this would potentially allow both 29-Si depletion and donor array construction in the same ion implantation system.

Charge Noise in Semiconductor Quantum Dot Spin Qubits John Nichol; University of Rochester, United States

Electron spins in semiconductor quantum dots are a leading platform for quantum computing because they have extremely long coherence times and are compatible with advanced semiconductor manufacturing techniques. However, most two-qubit gates between spins rely on electric fields to manipulate the wavefunctions of the electrons. Spurious electric-field noise, or charge noise, can cause decoherence of multi-spin systems and is a significant obstacle to large-scale quantum computing with electron spins. I will describe what we know about charge noise in semiconductor quantum dots and potential strategies to mitigate its effects.

Qubits Made by Advanced Semiconductor Manufacturing Anne-Marije Zwerver[1], Tobias Krähenmann[1], Thomas Watson[2], Lester Lampert[2], Hubert George[2], Ravi Pillarisetty[2], Stephanie Bojarski[2], Payam Amin[2], Sergei Amitonov[1], Jelmer Boter[1], Roman Caudillo[2], Diego Corras-Serrano[2], Juan Pablo Dehoillain[1], Gabriel Droulers[1], Eric Henry[2], Roza Kotlyar[2], Mario Lodari[1], Florian Lüthi[2], David Micalak[2], Brennen Mueller[2], Samuel Neyens[2], Jeanette Roberts[2], Nodar Samkharadze[1], Gouji Zheng[2], Otto Zietz[2], Giordano Scappucci[1], Menno Veldhorst[1], Lieven Vandersypen[1] and James Clarke[2]; [1]QuTech and Delft University of Technology, Netherlands; [2]Intel Components Research, Intel Corporation, United States

Spin qubits that are hosted in electrically-controlled, silicon quantum dots are promising candidates for implementing quantum technology. Due to their small size, relatively long coherence times and their compatibility with the semiconductor industry they offer great promises, both for qubit performance and for scaling. To pave the road towards large-scale quantum computing, making use of common CMOS fabrication techniques, like optical lithography and chemical-mechanical polishing is key. Spin qubit devices to date, however, still rely on the flexibility of e-beam lithography and mostly lift-off

techniques.

Here, we present the first qubits in isotopically enriched 28 Si-MOS fabricated entirely with optical lithography in an industrial 300 mm process line. These devices are fully fabricated with optical lithography and chemical-mechanical polishing techniques for patterning, compatible with state-of-the-art fabrication. This leads to an extremely high nanofabrication yield across the full wafer. Furthermore, due to the large number of devices characterized, we can study correlations between room-temperature and low-temperature device behavior. In these devices, we demonstrate well-controlled single and double quantum dots in the multi-electron regime, which is also reproducible across the wafer for several wafers. Moreover, we demonstrate charge sensing with a signal-to-noise ratio high enough for single shot readout. With this, we form high-quality qubits in the single-electron regime, comparable to qubits in academic devices, but with much better prospects for scaling.

10:30 AM EQ18.05.01
Steps Towards Homogenous Transition Metal Nitride Thin Film Growth for Josephson Junctions Using PAMBE Austin Thomas, Nicholas Grabon, Alan Kramer and Christopher Richardson; University of Maryland, United States

Nitride superconductors are attractive materials for superconducting quantum circuits. This work investigates methods of growing an isolated phase of NbN_x to create a materials platform that can be used for an epitaxial Josephson junction (JJ) that may perform better than existing platforms by eliminating interface defects. NbN_x has been used for JJ fabrication due to its high critical temperature, along with its mechanical and chemical stability when compared to pure Nb JJ layers. However, our work has shown that when growing NbN_x with Plasma Assisted Molecular Beam Epitaxy (PAMBE), several distinct crystallographic phases of the nitride are present, and isolation of an individual phase for JJ fabrication proved to be difficult.
Isolation of the rock salt δ-NbN phase is necessary for growing $Nb_xTi_{1-x}N$ films where the (111) plane has the same atomic spacing as the (0001) plane of AlN. These lattice-matched, abrupt interfaces may reduce defects at the insulating barrier, reducing energy loss in Josephson junction devices. The composition of $Nb_xTi_{1-x}N$ can be adjusted to the correct lattice constant for lattice matched growth. These transition metal nitrides are mechanically and chemically stable, with high critical temperatures, making them ideal for superconducting devices.
PAMBE grown NbN_x and $Nb_xTi_{1-x}N$ films on Al_2O_3 (0001) are investigated regarding phase stabilization with varying substrate temperature, buffer layers, and alloyed composition. The rock salt phase of NbN_x is desired for heterostructure growth, and this phase is verified using high-resolution x-ray diffraction (HRXRD) and electron backscatter diffraction (EBSD). Atomic force microscopy (AFM) and electrical characterization of the normal and superconducting states are used to determine suitability for $Nb_xTi_{1-x}N(111)||AlN(0001)||Nb_xTi_{1-x}N(111)$ and $NbN_x(111)||AlN(0001)||NbN_x(111)$ Josephson junction heterostructures.
Samples were grown using a custom DCA M600 MBE system with a base pressure better than 1e-10 Torr. Samples were grown on 2” C-plane sapphire wafers, which were degreased and thermally cleaned before growth. A RF plasma generator is used for nitrogen incorporation, while Nb is deposited using an electron beam evaporator. Ti is deposited using a high-temp effusion cell. Nitrogen flux was set at 0.6 sccm at 500W, and Nb flux was kept between 0.5E17 and 3.5E17 $m^{-2}s^{-1}$. Substrate temps during growth were set at between 800°C and 1000°C by thermocouple.
δ-NbN grows predominantly at 1000°C with our growth technique, though phases γ-Nb_4N_3 and ε-NbN are still present in our films. To isolate the rock salt phase further, we investigate the effects of TiN buffer layers, along with alloying NbN_x with Ti. We have also observed that Ti incorporation in NbN_x films at lower temperatures increases the rock salt phase stability. For δ-NbN, XRD and EBSD results show uniform, single phase growth, while AFM results show a smooth, striated surface with a roughness of < 1nm, ideal for JJ fabrication. Internal quality factors of these thin films are investigated by way of superconducting coplanar microwave resonator measurements.

10:45 AM EQ18.05.02
Suppression of Nb Suboxides via Oxygen Scavenging by TiN Deposition Mahmut Sami Kavrik[1], Shaul Aloni[1], Frank Ogletree[1], Irfan Siddiqi[1,2] and Adam Schwartzberg[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

Quantum computers are an inevitable need for energy efficiency in large scale computation and absolute information security demanded in both military and civil applications. Among the proposed platforms, superconducting qubit-based processors are leading candidates because of its scalability, gate speed, and microwave control. However, the realization of feasible quantum processors is inhibited prominently by the decoherence processes emerging from materials-inherent defects such as suboxides on Nb based superconducting qubits. In recent work, microwave losses scaling inversely with NbO_x thickness in Nb resonator devices has been demonstrated indicating the impact of the suboxides on coherence time. DFT calculations by Griffin et. al., shown that sub-stoichiometric Nb_2O_5 has paramagnetic phase that can be a source of the decoherence. In this work we investigated impact of Nb_2O_5 on coherence time by selectively eliminating Nb_2O_5 via oxygen scavenging by TiN deposited on resonators by atomic layer deposition. In comparison to Nb resonators with native oxide, TiN passivated resonators shows traces of Nb_2O_5 while NbO and NbO_2 persist on the Nb according to photoemission spectroscopy. Controlled selective reduction of Nb_2O_5 to NbO on Nb resonators hence mitigation of the associated defects with TiN passivation suggest a viable step towards development of the large-scale fault tolerant quantum processor.

11:00 AM EQ18.05.03
Using Superconductive Resonators to Characterize Charge Noise in Oxides Sueli Skinner Ramos, Rupert Lewis, William Kindel, Tzu-Ming Lu and Tom Harris; Sandia National Laboratories, United States

Solid state quantum information technologies are highly sensitive to material defects. In particular, charge centers at oxide interfaces have been shown to cause charge noise in electron-spin quantum dot qubits and negatively impact device yield, long-term stability, qubit coherence, and measurement fidelity. Semiconductor spin qubits are typically fabricated using standard metal-oxide-semiconductor gates to accumulate or deplete the two-dimensional electrons regions and localize single electrons in a quantum dot. These gates require an oxide layer, giving rise to two material-oxide interfaces that may contain charge defects that adversely affect the qubit performance. As such, thorough characterization of defects in an oxide layer interface is crucial for optimizing the behavior of quantum information devices. Several measurement techniques using operational qubits have already been established, however these techniques are limited in bandwidth and require long measurement times to fully characterize the charge noise spectrum of a single device. In this work we develop superconductive coplanar waveguide (CPW) resonators as a potentially much faster, scalable, and less expensive alternative charge-noise characterization technique to quantify the quality of oxides. To calibrate our technique, we present measurements of two different oxides, a high-quality

gate oxide and an oxide with intentional defects.

Lessons Learned While Seeking Superconducting Al Doped Silicon Joshua Pomeroy, Ke Tang, Karen A. DeRocher and Frederick Meisenkothen; National Institute of Standards and Technology, United States

Single crystal silicon, super-saturation doped with aluminum, has the promise of realizing superconductivity within a semiconductor with a transition temperature above 4 K, a substantial increase over similar demonstrations with boron and gallium, but is yet to be realized. In this talk, the process of saturation doping a clean silicon surface, overgrowing it with an encapsulating silicon layer and electrically activating the dopants is presented. Emphasis will be put on the determination of the surface-saturation doping density, found to be 3.4×10^{14} atoms/cm^2, which involves comparative measurements from scanning tunneling microscopy (STM), secondary ion mass spectroscopy (SIMS) and atom probe tomography (APT). Additional discussion on the electrical activation efficiency, low temperature transport modelling and prospects for increase the stable dopant atom density will be presented.

11:30 AM EQ18.05.05
Probing Sources of Decoherence at Interfaces in Superconducting Qubit Systems Akshay A. Murthy, Mattia Checchin, Alexander Romanenko and Anna Grassellino; Fermi National Accelerator Laboratory, United States

Superconducting qubits have emerged as a potentially foundational platform technology for addressing complex computational problems deemed intractable with classical computing. Despite recent advances enabling multiqubit designs that exhibit coherence lifetimes on the order of hundreds of μs, material quality and interfacial structures continue to curb device performance. When niobium is deployed as the superconducting material, two-level system defects in the thin film and adjacent dielectric regions introduce stochastic noise and dissipate electromagnetic energy at the cryogenic operating temperatures. In this study, through a combination of correlative electron microscopy imaging and diffraction methods and secondary ion mass spectrometry, we conduct a detailed investigation to disentangle the role specific fabrication procedures play in introducing such dissipation mechanisms in these complex systems. From these measurements, we find that during film deposition, oxide and silicide layers form at metal/substrate and metal/air interfaces and can reduce coherence times. Additionally, we observe that impurity species such as resistive niobium hydrides and carbides are incorporated within the niobium layer through the subsequent lithographic patterning steps, which impact the superconducting properties of the thin film. Armed with these findings, we seek to intelligently fabricate superconducting qubits and extend coherence times.

11:45 AM EQ18.05.06
Evolution of Tunneling Density of States in Nb/Al Based N/I/S Junctions with Al Thickness Zachary Barcikowski[1,2] and Joshua Pomeroy[2]; [1]University of Maryland, United States; [2]National Institute of Standards and Technology, United States

Nb/Al bilayers are of great interest for applications such as X-ray detectors or Josephson junctions where Al enables high-quality tunnel barrier fabrication and can be used to modify the Nb superconducting state. To investigate the evolution of the superconducting bilayer states with Al thickness, we fabricated a series of Nb/Al/AlOx/normal metal tunnel junctions with different Al thicknesses and measured the tunnel junction properties. Tunneling density of states spectra are presented in the regime of $T_{c,\,Nb} > T > T_{c,\,Al}$ and reveal larger zero-bias conductance than can be explained by a change in superconducting transition temperature with Al thickness alone. We model the data using the Blonder-Tinkham-Klapwijk (BTK) theory and discuss trends in BTK barrier strength, superconducting energy gap, and Dynes broadening as a function of Al film thickness and temperature.

12:00 PM *EQ18.05.07
Reproducible Materials Measurements for Superconducting Qubits and Resonators Corey Rae H. McRae[1,2]; [1]University of Colorado Boulder, United States; [2]National Institute of Standards and Technology, United States

Superconducting quantum circuits are a promising hardware implementation for large-scale quantum computing, but materials losses continue to significantly limit scalability and single-qubit performance. These cryogenic microwave materials losses can thus be characterized by coherence measurements of qubits and resonators. However, experimental factors such as thermalization, packaging, and microwave electronics have significant effects on these coherence measurements as well. In this talk, I outline a roadmap towards reproducible measurements of qubits and resonators and their further application to the investigation and characterization of materials losses.

The Influence of Material Choices on Trapped Ion Performance Todd Barrick, B. K. McFarland, M. C. Revelle and D. L. Stick; Sandia National Laboratories, United States

Surface electrode ion traps permit the individual storage, manipulation, and optical addressing of atomic ions for applications such as highly sensitive sensors, atomic clocks, and quantum computing, to name a few. For these applications to be successful, one must have precise control over the quantum state of the ion, which includes its motional state during entangling operations. Therefore, the ion must be isolated from environmental perturbations like electric field noise which uncontrollably excite the motion of ions. Here, we study the influence of materials used in the fabrication of surface electrode ion traps and how they contribute to electric field noise that resonantly couples to the motional (secular) frequency of a trapped ion. In addition, we will also show experimental data that compares motional heating at different frequencies and with different capacitive grounding methods.

1:30 PM EQ18.06.03
First-Principles Study of sp3-doped (6,5) Single-Walled Carbon Nanotubes as a Potential Optically Interfaced Solid-State Spin Qubit Kasidet Jing Trerayapiwat[1], Xuedan Ma[2,3] and Sahar Sharifzadeh[1,1]; [1]Boston University, United States; [2]Argonne National Laboratory, United States; [3]The University of Chicago, United States

Single-walled carbon nanotubes (SWCNTs) doped with sp3 defects are a promising class of optoelectronic materials with bright tunable photoluminescence and demonstrated single-photon emission capability. Recently, we have shown that doping of (6,5) SWCNT via diazonium reaction results in an isolated electron spin with bright photoemission in the near-infrared range. In order to understand the spin-orbit coupling (SOC) and the spin decoherence mechanism in this material, we apply density functional theory (DFT) simulations, complemented by experiment, on a variety of sp3 defects attached to (6,5) SWCNT. We determine that doping the SWCNT with a heavy atom does not necessarily result in spin-orbit splitting in the near-gap states (a measure of SOC in the excited state) if there is no overlap between the unpaired spin and the metal's atomic orbitals; this overlap can be enforced by choosing a defect with a direct sp3 carbon-metal bond. Furthermore, the strength of spin-orbit splitting increases with reduction of the metal-tube separation or larger intrinsic SOC on the heavy atom. Additionally, we simulate dephasing by considering spin-bath interactions as the source of decoherence. We apply the cluster correlation expansion method with a pure-dephasing spin Hamiltonian to doped SWCNT in presence of water molecules at near 0 K and estimate the magnitude of T2.

1:45 PM EQ18.06.04
Late News: Tailoring Quantum Oscillations of Excitonic Schrodinger's Cats as Qubits Amit Bhunia[1], Mohit Kumar Singh[1], Maryam Al Huwayz[2,3], Mohamed Henini[2] and Shouvik Datta[1]; [1]IISER-Pune, India; [2]The University of Nottingham, United Kingdom; [3]Princess Nourah Bint Abdulrahman University, Saudi Arabia

We report [https://arxiv.org/abs/2107.13518] experimental detection and control of Schrodinger's Cat like macroscopically large, quantum coherent state of a two-component Bose-Einstein condensate of spatially indirect electron-hole pairs or excitons using a resonant tunneling diode of III-V Semiconductors. This provide access to millions of excitons as qubits to allow efficient, fault-tolerant quantum computation. In this work, we measure phase coherent periodic oscillations in photo generated capacitance as a function of applied voltage bias and light intensity over a macroscopically large area. Periodic presence and absence of splitting of excitonic peaks in the optical spectra measured by photocapacitance point towards tunneling induced variations in capacitive coupling between the quantum well and quantum dots. Observation of negative 'quantum capacitance' due to screening of charge carriers by the quantum well indicate Coulomb correlations of interacting excitons in the plane of the sample. We also establish that coherent resonant tunneling in this well-dot heterostructure restricts the available momentum space of the charge carriers within this quantum well. Consequently, the electric polarization vector of the associated indirect excitons collective orients along the direction of applied bias and these excitons undergo Bose-Einstein condensation below ~100 K. Generation of interference beats in photocapacitance oscillation even with incoherent white light further confirm the presence of stable, long range spatial correlation among these indirect excitons. We finally demonstrate collective Rabi oscillations of these macroscopically large, 'multipartite', two-level, coupled and uncoupled quantum states of excitonic condensate as qubits. Therefore, our study not only brings the physics and technology of Bose-Einstein condensation within the reaches of semiconductor chips, but also opens up experimental investigations of the fundamentals of quantum physics using similar techniques.
Operational temperatures of such two-component excitonic BEC can be raised further with more densely packed, ordered array of QDs and/or using materials having larger excitonic binding energies. However, fabrications of single crystals of 0D-2D heterostructures using 2D materials (e.g. transition metal di-chalcogenides, oxides, perovskites etc.) having higher excitonic binding energies are still an open challenge for semiconductor optoelectronics. As of now, these 0D-2D heterostructures can already be scaled up for mass production of miniaturized, portable quantum optoelectronics devices using the existing III-V and/or Nitride based semiconductor fabrication technologies.

Quantum Computing with Spins in Germanium Nico Hendrickx; QuTech and Kavli Institute of Nanoscience, Delft University of Technology, Netherlands

The prospect of building quantum circuits using advanced semiconductor manufacturing techniques position quantum dots as an attractive platform for quantum information processing. Initial demonstrations of one and two-qubit logic have been performed in gallium arsenide and later silicon. However, until recently, interconnecting larger spin qubit systems has remained a challenge.

Over the past years, hole states in strained germanium quantum wells have emerged as a host for spin qubits. These states have favourable properties for defining extended spin qubit arrays. The small effective mass relaxes constraints on lithography, the low degree of disorder enables reproducible quantum dots, the lack of a valley degeneracy ensures an well-defined qubit state and the strong spin-orbit coupling allows for local and electrical qubit control.

Within four years time, this platform [1] has rapidly evolved from materials growth to supporting multi-qubit logic [2]. In this talk, I will discuss our group's efforts on the development of this system, starting from material growth and characterization [3] to our recent results on operating a highly-connected two-dimensional qubit array [4]. We implement qubit logic all electrically and the exchange interaction can be pulses independently to freely program one, two, three, or four qubit gates. Furthermore, we show that we can extend the quantum coherence by several orders of magnitude by implementing dynamical decoupling. All these techniques are combined to perform a quantum circuit that generates a four-qubit Greenberger-Horne-Zeilinger state, showcasing coherent operation of all four qubits together. This positions strained germanium as a unique material for quantum applications. I will furthermore discuss strategies, challenges, and opportunities in scaling these systems up as a step towards the realization of scalable qubit tiles for fault-tolerant quantum processors.

Manipulation of Three-Spin States in a Si/SiGe Triple Quantum Dot Kenta Takeda; RIKEN, Japan

Semiconductor quantum dots are one of the most promising platforms for quantum computing due to their nanofabrication capability for scaling-up. Recent technical advances have enabled high-fidelity one- [1,2] and two-qubit [3] gates for spins in quantum dots. The next crucial step toward scaling up is the demonstration of genuinely multipartite entanglement, an essential resource for quantum error correction. This requires at least three qubits with the full capabilities of control and measurement, a lot further than individual qubit manipulation. In this talk, we first show individual initialization, measurement, and universal manipulation of three electron spins in our Si/SiGe triple quantum dot device. Second, we show generation and characterization of a three-qubit Greenberger–Horne–Zeilinger state, a type of maximally entangled state that is usable to implement a bit-flip or phase-flip quantum error correcting code. We obtain a state fidelity of 88.0 % by quantum state tomography, which witnesses a genuine three-qubit entanglement. We anticipate that our results will enable exploration of multi-spin correlations and demonstration of multi-qubit algorithms in scalable silicon-based quantum computing devices.

Can Plasma Oxidized AlO_x SETs Detect Charge Motion on Silicon MOS Quantum Dots? Yanxue Hong[1,2], Kyungjean Min[2], M. D. Stewart, Jr.[2] and Joshua Pomeroy[2]; [1]University of Maryland, United States; [2]National Institute of Standards and Technology, United States

The design and development of charge stable, plasma oxidized $Al/AlO_x/Al$ single-electron transistors (SETs) for use as charge sensors in single metal layer gated silicon MOS quantum dots will be presented, extending an integrated architecture that enables fabricating both devices simultaneously. In previous work, we achieved long-term charge offset stability (best $\Delta Q_0 = 0.13$ e ± 0.01 e over 7.6 days) by using plasma oxidized AlO_x as tunnel barriers in $Al/AlO_x/Al$ SETs [1], and persistent charge sensing (SNR > 5) of controllable quantum dots on single metal gate layer silicon MOS quantum dot devices [2]. By calculation, the required minimum coupling capacitance between these two devices is approximately 2.8 aF for the AlO_x SET to detect the charge motion on the MOS quantum dot. Here we will present the design of streamlined fabrication process of fabricating $Al/AlO_x/Al$ SETs and MOS quantum dots simultaneously, preliminary modeling and calculations for charge sensing feasibility of vertically and laterally aligned configurations. This integrated architecture is expected to be useful as a diagnostic qubit platform for simplifying the process flow, testing gate materials and tunnel barrier materials, and detecting oxide interface defects, etc.

Defect Detection in Silicon-on-Insulator Transistors for Quantum Information Systems Philippe Ferrandis[1,2,3], Thomas Bédécarrats[4,2] and Mikael Cassé[4,2]; [1]Université de Toulon, France; [2]Univ.Grenoble Alpes, France; [3]Institut Néel, France; [4]CEA, France

Among promising materials for the realization of future quantum processors, silicon has several assets. A silicon quantum bit (qubit) device can be performed with an industry-standard fabrication process and allows a co-integration with classical control hardware [1]. However, an excellent control of carrier transfer in the channel of the transistor is required, ruling out any electrical active defects, which could act as recombination centers. Such an optimization of the device necessitates a fine characterization of the channel to evaluate the purity of the material.
In this work, we investigate the presence of defects in the channel of a fully depleted silicon-on-insulator (FDSOI) transistor designed for qubit applications. A buried oxide of 145 nm formed on a silicon substrate is covered by an 11 nm thick unintentionally doped silicon channel. A SiO_2/HfSiON bilayer and a TiN metallic electrode compose the gate. P-doped source and drain contact regions were realized by implantation. A Si_3N_4 layer is used to passivate uncovered silicon areas. To enlarge the capacitance of the gate and allow measurements, 111 cells were connected in parallel.
The ON state of the transistor is achieved by applying a negative voltage to the gate. Source and drain electrodes were connected together and voltage pulses were applied to the gate contact to perform capacitance deep level transient spectroscopy (DLTS) measurements between 77 K and 350 K. A depleted section of the channel extends beneath the gate and towards the source and drain regions when applying a positive voltage to the gate contact. By tuning a positive reverse bias and negative voltage pulses, we were able to probe the channel and localize the electrical active defects responsible for the DLTS signal.
Three hole traps, labelled H1, H2 and H3, were detected by DLTS at respectively 0.54 eV, 0.57 eV and 0.65 eV above the valence band edge. The apparent capture cross sections of these levels are respectively $7.9x10^{-16}$ cm^2, $2.4x10^{-14}$ cm^2 and $3.3x10^{-12}$ cm^2. H1 and H2 are donor-like states whereas H3 is an acceptor-like state.
Electrical simulations using Synopsys demonstrated that the DLTS probed zone is nearby gate edges and extends towards the source and drain contacts when the gate voltage changes from 0 V to 1 V. According to this feature, all traps have been localized very close to the source and drain implanted zones. The origin of these traps is likely related to damages produced during the formation of the p-doped regions and are assigned to bulk [2] and Si/SiO_2 interface defects [3].
In the temperature range 77 K – 350 K, no traps have been detected in the active region, i.e. below the gate contact. Finally, this investigation highlights the good quality of the channel material and the ability of the studied FDSOI transistor to work as a qubit device.

^{28}Si/SiGe heterostructures provide a compelling host material for a scalable quantum computer,due to the long coherence times of electron spin qubits and compatibility with industry. Here we study ^{28}Si/SiGe heterostructures characterized by different roughness of the critical Si/SiGe quantum well interface to understand the energy splitting of the lowest lying conduction valleys (valley splitting). To improve control of valley splitting in ^{28}Si/SiGe, we implement a feedback loop for materials stack engineering which includes several elements. We use atom probe tomography to provide atomic 3D reconstruction of the material stack and statistical understanding of compositional variations at the Si/SiGe interface over nanoscale dimensions relevant for qubits in quantum

dots. We feed the resulting data into a tight binding model to compute the valley splitting in real quantum wells and dots with varying quantum well thickness, Si/SiGe interface width, and interface chemical roughness. We complete the feedback loop by comparing the obtained simulation results with the valley splitting measured in heterostructure field effect transistors and quantum dots, making use of cryomultiplexer technology for achieving statistical significant metrics with high-throughput. We envision that such a feedback cycle - consisting of atomic understanding of the critical material stack interfaces fed into device modelling and high-throughput cryogenic measurements- may help to engineer optimal stacks for large and controlled values of valley splitting in Si/SiGe.

High-Throughput Search for Magnetic Topological Materials Using Spin-Orbit Spillage, Machine Learning and Experiments Kamal Choudhary; National Institute of Standards and Technology, United States

Magnetic topological insulators and semimetals have a variety of properties that make them attractive for applications, including spintronics and quantum computation, but very few high-quality candidate materials are known. In this paper, we use systematic high-throughput density functional theory calculations to identify magnetic topological materials from the 40000 three-dimensional materials in the JARVIS-DFT database. First, we screen materials with net magnetic moment >0.5μB and spin-orbit spillage (SOS) >0.25, resulting in 25 insulating and 564 metallic candidates. The SOS acts as a signature of spin-orbit-induced band-inversion. Then we carry out calculations of Wannier charge centers, Chern numbers, anomalous Hall conductivities, surface band structures, and Fermi surfaces to determine interesting topological characteristics of the screened compounds. We also train machine learning models for predicting the spillages, band gaps, and magnetic moments of new compounds, to further accelerate the screening process. We experimentally synthesize and characterize a few candidate materials to support our theoretical predictions.

Unconventional Magnetism and Spin Dynamics in the Frustrated Triangular Lattice Antiferromagnet Ba_2MnTeO_6 Joydev Khatua[1,2,3], T. Arh[4,5], Shashi B Mishra[1], H. Luetkens[6], A Zorko[4,5], B. Sana[1], M. S. Ramachandra Rao[7,2], B. R. K. Nanda[1,1,3] and P Khuntia[1,2,3]; [1]Indian Institute of Technology Madras, India; [2]Quantum Centre for Diamond and Emergent Materials, Indian Institute of Technology Madras, India; [3]Functional Oxide Research Group, Indian Institute of Technology Madras, India; [4]Jozef Stefan Institute, India; [5]University of Ljubljana, Slovenia; [6]Paul Scherrer Institute, Switzerland; [7]Nano Functional Materials Technology Centre and Materials Science Research Centre, Indian Institute of Technology Madras, India

Frustrated magnets wherein complex interplay between emergent degrees of freedom, macroscopic ground state degeneracy and competing magnetic interactions can lead to correlated quantum phenomena with exotic excitations highly relevant for potential technological applications. We present thermodynamic, and muon spin relaxation (μSR) measurements accompanied by density functional theory (DFT) results on the double-perovskite Ba_2MnTeO_6 in which Mn ions constitute a perfect triangular lattice. Magnetic susceptibility and specific heat data show the presence of a phase transition at T_N = 21 K. The magnetic specific heat result infers the presence of antiferromagnetic magnon excitations with a gap of 1.4 K below T_N. μSR reveals the presence of static internal magnetic field below T_N and short-range spin correlations high above T_N. Furthermore, critical slowing-down of spin dynamics at T_N and the persistence of spin dynamics even in the magnetically ordered state have been detected by μSR. Three-dimensional magnetic ordering in this frustrated magnet is attributed to the presence of a weak ferromagnetic inter-layer interaction.

Quantum Anomalous Hall Insulators for Topological Quantum Computing Igor Altfeder[1], Robert Walko[1], Albert Davydov[2], Seng Huat Lee[3], Zhiqiang Mao[3] and Alexander Balatsky[4]; [1]The Ohio State University, United States; [2]National Institute of Standards and Technology, United States; [3]The Pennsylvania State University, United States; [4]University of Connecticut, United States

Bound states of electric charge and magnetic monopole are anticipated to behave as anyons, i.e. 2D quantum states obeying fractional statistics. Image magnetic monopoles can be induced in topological systems with broken time-reversal symmetry, such as quantum Hall (QH) and quantum anomalous Hall (QAH) insulators, using a point charge located above the surface. In our experiments with the QAH insulator, charge-monopole composite is produced by the electric field of scanning tunneling microscope (STM) tip, which confines the current vortex of monopole inside ~ 1 nm radius quantum dot. Our studies are performed using magnetic topological insulator $MnBi_2Te_4$ whose surface is modified by STM-lithography to prepare room temperature QAH state displaying unusually high Chern number. We found a rich spectrum of many-body effects and nonlinear behavior manifested in the trapping of tunneling electrons by the current vortex and interaction of monopole with the Mn spin subsystem. High-Chern-number charge-monopole composites are anticipated to be non-Abelian anyons with potential applications in fault-tolerant topological quantum computing.

Performing Sensitive Broadband Microwave Spectroscopy on μm-scale Materials Antonio L. Levy, Zachary S. Barcikowski, Joshua Pomeroy, Pradeep Namboodiri, Rick Silver and Neil M. Zimmerman; National Institute of Standards and Technology, United States

We have developed a new simple broadband ormicrowave spectroscopy technique for μm-scale flakes in which, unlike existing techniques, μm-scale flakes effect orders-of-magnitude (>30 dB) changes in the transmissivity without requiring sophisticated sample preparation or measurement techniques. Broadband microwave spectroscopy is a sensitive probe of the physics of material systems which has been used to study novel physics of mm-scale thin film material systems, such as ordered electron phases , superconductors , and metal-insulator transitions . In recent years, interesting materials have emerged which are only available as μm-scale flakes, and whose novel physics might be better understood through broadband microwave spectroscopy; examples include twisted bilayer graphene [4], 2D materials in which many-body phases are observed [5], and artificial lattices for analog quantum simulations [6]. With most current GHz broadband spectroscopy techniques, the signal for smaller (μm-scale) flakes is too weak to be useful [1, 2, 3].

In the new technique, a CPW containing a series gap in the signal line over the flake is fabricated on the chip, and the transmission spectrum is measured. The spectra are then normalized, we can immediately see spectral features, and we can also extract the complex conductivity. We present results from proof-of-principle experiments conducted for μm-scale P^+ monolayer regions encapsulated in Si, whose conductivity spectrum is expected to be constant in frequency for microwave frequencies. These results show a broadband change in the transmissivity of more than 40 dB, indicating the ability to perform

sensitive contact-free conductivity spectroscopy on μm-scale flakes. We then show through theory and simulations that one will be able to qualitatively measure spectral features of interest, and quantitatively deduce the frequency-dependent complex conductivity. These experimental and theoretical results show that this technique could make profound contributions to the characterization of 2D materials in the coming years.

Quantum Simulations with P-Doped Silicon Nanostructures Maicol A. Ochoa[1,2], Keyi Liu[1,2], Emily Townsend[1,2], Michal Gawelczyk[3], Michal Zielinski[3] and Garnett Bryant[1,2]; [1]National Institute of Standards and Technology, United States; [2]University of Maryland, United States; [3]Nicolaus Copernicus University, Poland

Atomically precise phosphorus-doped silicon nanostructures that incorporate few-atom arrays are attractive architectures for the solid-state implementation of quantum computing technologies and quantum simulations. These devices readily integrate with traditional electronic devices and can be fabricated to control critical properties, such as tunnel couplings and on-site charging energies. Furthermore, single-electron transport and quantum control of the electronic state is possible using atomically aligned gates, source, and drain contacts. Significantly, few-atom devices arranged in any number of different geometries are ideal for exploring a variety of many-body physics effects. This talk presents atomistic calculations and a detailed analysis of the many-electron states and transport properties of devices with two and four P atoms. In particular, we investigate mappings of these systems into the extended range Fermi-Hubbard model and study how the model parameters vary with the array's geometry and electron number. Our approach consists of self-consistent solutions to the Schroedinger-Poisson equations and incorporates the effect of the silicon matrix, electron-electron interactions, and corrections due to exchange and correlation. We also carry out transport calculations beyond the mean-field treatment by using the non-equilibrium Green functions based on the extended Fermi-Hubbard many-electron eigenstates to calculate Coulomb blockade diagrams. By comparing the predictions made with the Fermi-Hubbard model with the results of our detailed atomistic calculations for different dopant geometries, we show when exchange and correlation effects and coupling to higher energy orbitals missing in the Fermi-Hubbard model become important in predicting the stability diagrams of these devices.

11:45 AM EQ18.08.06
Disorder Induced Phase Transitions in Magnetic Topological Insulators Swarnava Ghosh and Markus Eisenbach; Oak Ridge National Laboratory, United States

Topological insulators are a class of quantum materials that have gaps in the bulk but metallic edge or surface states, which are protected by time reversal symmetry. Long-range magnetic order in a topological insulator can break the time reversal symmetry, open an exchange gap in the surface states, thereby leading to exotic topological quantum phenomena. Just like ordinary materials, defects are also omnipresent in topological insulators. The concentration of defects are low; few parts per million for vacancies to few percent for dopants. This makes first principles simulations of defects at realistic concentrations extremely challenging due to the large cell sizes required. We use the Locally Self Consistent Multiple Scattering (LSMS) code to solve the Kohn-Sham equations at realistic concentrations of disorder in the intrinsic magnetic topological insulator $MnSb_2Te_4$. We present the role of disorder such as doping and site-mixing on the magnetic ground state of the intrinsic magnetic topological insulator $MnSb_2Te_4$. Our results show magnetism can be tuned by carefully controlling the concentration of defects in $MnSb_2Te_4$.

Synthesis of Narrow SnTe Nanowires Using Alloy Nanoparticles Pengzi Liu[1,2], Hyeuk Jin Han[1,2], Julia Wei[1], David Hynek[1,2], James L. Hart[1,2], Myung Geun Han[3], Christie J. Trimble[4,4], James Williams[4,4,4], Yimei Zhu[3] and Judy Cha[1,2,5]; [1]Yale University, United States; [2]Yale West Campus, United States; [3]Brookhaven National Laboratory, United States; [4]University of Maryland, United States; [5]Canadian Institute for Advanced Research Azrieli Global Scholar, Canada

The last decade has witnessed substantial progress in probing topological states of matter whose wavefuntions possess a distinct topological invariant signature barring adiabatic deformation from a trivial phase to a non-trivial phase [1]. The search for topological materials is of profound scientific significance and will have applications for spintronics, low-dissipation electronics and quantum computing. Particularly, one dimensional (1D) topological superconductor systems, which are predicted to host localized Majorana bound states (MBSs), can be leveraged for fault-tolerant and scalable topological quantum computing. However, realizing 1D topological superconductors is challenging in synthesis of topological nanowires with sufficiently good sample quality, which can reveal and control the topological properties. Careful studies on precise control of the morphology and dimensions of topological nanowires along the axial and radial directions remain sparse.

In this work, we developed a reliable vapor−liquid−solid (VLS) route to synthesize narrow SnTe nanowires with diameters under 100 nm using Au−Sn−Te alloy nanoparticles as growth catalysts with high yield [2]. Experimentally, this was achieved by performing CVD growths twice. In the first growth, gold nanoparticles react with SnTe vapor to form alloy nanoparticles. In the second growth, the alloy nanoparticles catalyze the growth of narrow SnTe nanowires. The average diameter of the SnTe nanowires grown using alloy nanoparticles is 85 nm, in contrast to the 240 nm obtained using gold

nanoparticles. Transport measurements showed a diameter-dependent residual resistance ratio and magnetoresistance.

We also observed that the ferroelectric transition temperature of SnTe nanowires is diameter-dependent, whose trend suggests that the carrier density decreases for narrower nanowires, likely due to the removal of bulk electron carriers. *In situ* cryogenic transmission electron microscopy (cryo-TEM) experiments down to 25 K confirmed the expected structural transition from the room-temperature cubic phase to the low-temperature rhombohedral phase for these SnTe nanowires. Electron diffraction data and TEM images at 25 K show there are two crystallographic orientations for the low-temperature rhombohedra domains in these SnTe nanowires. Simulation results suggest that both 109 and 71° domain walls are possible to explain our observations. The narrow SnTe nanowires are important to study the nature of the superconductivity induced in these nanowires, which was recently suggested to have a pairing symmetry of $s \pm is$ via Josephson junction measurements [3]. They also serve as a model system for the investigation of possible multiband superconductivity, Majorana bound states, and the interplay between ferroelectricity and topological orders.

Coexistence of Superconductivity, Fluctuations and Spin-Orbit Splitting in $Sn_{1-x}In_xTe$ Thin Film Jiashu Wang, William Powers, Seul-Ki Bac, Logan Riney, Maksym Zhukovskyi, Tatyana Orlova, Xinyu Liu and Badih Assaf; University of Notre Dame, United States

SnTe is identified to be a topological crystalline insulator, whose surface states are protected by crystal mirror symmetry. It has been recently found that by In doping, $Sn_{1-x}In_xTe$ (SIT) can be superconducting and also maintains its topological surface states. However, the non-trivial character of superconductivity in SIT remains debated. Most previous research of SIT was focused on single crystals. The growth and analysis of SIT thin films are necessary to search for boundary Majorana states. Here, we investigated the MBE growth of $Sn_{1-x}In_xTe$(x=0.05-0.3) thin films(~100nm) on BaF_2 (111), and characterized them by X-ray diffraction , Transmission electron microscopy and magneto-transport measurement. A superconducting transition is consistently observed in films, and the critical temperature T_c increases as we increase the In concentration up to 3.5K. Hall measurements show that In is more likely to act as an electron donor instead of an acceptor as reported in earlier works on single crystal. The normal state is shown to host coexisting weak localization (WL) and weak antilocalization (WAL), analyzed using a 2D Hikami Larkin Nagaoka model. The WL only occurs in superconducting samples, indicating that electrons from trivial spin-orbit split states may play a dominant role in the superconducting state. Close to but above T_c, a signature of Maki-Thompson superconducting fluctuations is also observed. Overall, our findings motivate further experiments to find the origin of a possible spin-orbit splitting and study its impact on the pairing symmetry of $Sn_{1-x}In_xTe$. Work supported by NSF-DMR-1905277.

Mobility and Spin Orbit in InAs Heterostructures Maja Cassidy; Microsoft Quantum, Australia

Semiconductor heterostructures based on III-V materials such as InAs are candidate systems for realizing a topological quantum computer based on Majorana zero modes due to their high mobility, strong spin-orbit interaction, and ability to be proximitized by a nearby superconductor. While each of these components can be realized alone, combining them into a single device exhibiting all effects simultaneously and reproducibly remains a significant engineering challenge. In this talk, I will discuss materials processing that limits mobility in InAs 2DEG quantum wells during device fabrication, and discuss strategies for increasing this mobility by repairing the semiconductor-dielectric interface. I will also discuss the effect that these fabrication processes have on the spin orbit coupling within these heterostructures, and pathways to maximizing both mobility and spin orbit in a device.

Heteroepitaxy of Dirac Semimetal Cd_3As_2 by Metal-Organic Chemical-Vapor Deposition Anthony Rice, Christopher R. Tait, Steven Lee, Julia Deitz, Mark Rodriguez, Wei Pan, Taisuke Ohta, Darrell Alliman, Gregory Peake, Annette Sandoval, Nichole Valdez and Paul Sharps; Sandia National Laboratories, United States

We present progress on the synthesis of semimetal Cd_3As_2 by metal-organic chemical-vapor deposition (MOCVD). Specifically, we have optimized the growth conditions needed to obtain technologically useful growth rates and acceptable thin-film microstructures, with our studies evaluating the effects of varying the temperature, pressure, carrier-gas type, and group-V:II molar flow ratio for MOCVD of Cd_3As_2 when performed using dimethylcadmium and tertiarybutylarsine precursors. In the course of the optimization studies, exploratory Cd_3As_2 growths have been carried out on GaSb substrates, InAs substrates, strain-relaxed InAs buffer layers grown on GaSb substrates, and near-lattice-matched AlGaAsSb-alloy buffer layers grown on GaSb substrates. Notably, the InAs-terminated substrate surfaces yield desirable, nearly epitaxial results, while the pure GaSb surfaces instead yield laterally nonuniform, poor-quality, polycrystalline results. For the films presenting epitaxially on InAs, two different growth regimes are seen that depend strongly on the V:II ratio. For Cd_3As_2 thin films grown at a lower V:II ratio near 1.7, extensive microstructural studies have been performed by using multiple advanced imaging microscopies and x-ray diffraction (XRD) modalities. The as-grown films are 5-75 nm in thickness and consist of highly oriented, coalesced polycrystals with lateral domain widths of 30-80 nm. The most optimized films are smooth and specular, exhibiting a surface roughness as low as 1.0 nm rms. Under cross-sectional imaging, the Cd_3As_2-InAs heterointerface appears smooth and abrupt at a lower film thickness, ~30 nm, but becomes quite irregular as the average thickness increases to ~55 nm. The films are strain-relaxed with a residual biaxial tensile strain (e_{xx} = +0.0010) that opposes the initially compressive lattice-mismatch strain of Cd_3As_2 coherent on InAs (e_{xx} = -0.042). For more recent Cd_3As_2 thin-film growths done at a higher V:II ratio near 8.0, there appears to be a substantially improved thin-film microstructure, with thickness fringes emerging in both XRD 2theta-omega scans and x-ray reflectivity scans, which are absent for the growths at lower V:II ratio. Further microstructural characterization of the higher-V:II-ratio films remains as work in progress. Importantly, phase-identification studies find a thin-film crystal structure consistent with the $P4_2/nbc$ space group for growth at the lower V:II ratio; in contrast, the space group appears to change to either $I4_1cd$ or $I4_1/acd$ for growth at the higher V:II ratio. These observed space groups place MOCVD-grown Cd_3As_2 among the Dirac semimetals of substantial interest for topological quantum materials studies. Our presentation will highlight selected results from the above-described research to grow Cd_3As_2 thin films by MOCVD, with a focus on growth-parameter trends, microstructural characterization, and electronic properties.

Supported by the Laboratory Directed Research and Development program at Sandia National Laboratories, a multimission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC., a wholly owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA-0003525.

Collective Mode Spectroscopy of Unconventional Superconductors Nicholas Poniatowski, Jonathan Curtis, Amir Yacoby and Prineha Narang; Harvard University, United States

The study of unconventional superconducting states remains at the forefront of condensed matter physics research, driven in large part by the desire to understand the superconducting ground states of novel quantum materials. One of the defining features of any superconducting state is its collective mode spectrum, which encodes the dynamics of the order parameter. We will discuss how one can leverage the collective mode spectrum of unconventional superconducting states to gain new insights into their order parameter symmetry, making use of existing experimental probes [1,2]. In particular, we will discuss the existence and possible detection of a unique class of collective modes which can be used to identify and characterize time-reversal symmetry breaking superconductors [3].

At the interface of InAs/GaSb, the broken gap alignment leads to an anti-crossing between the InAs s-like conduction levels and the GaSb p-like valence levels. The hybridization of these levels cause a topological gap to open. The observation of the quantum anomalous Hall effect (QAHE) is expected to occur if the s-p ordering is inverted (non-trivial) for one spin species and trivial for the other, which can be achieved through the introduction of magnetism into system. In this work, we characterize a series of Mn doped InAs/GaSb type-II quantum wells. We show the successful growth of 15nm InAs/ 10nm GaSb quantum wells using transition electron microscopy (TEM). Using SQUID magnetometry, we find the samples host a paramagnetic order. Robust SdH oscillations and Hall quantization between 1.5K and 50K are observed in magneto-transport. We perform magneto-optics up to 15T to measure the cyclotron mass. We report a discrepancy between the carrier mass calculated from SdH oscillations and cyclotron resonance. The manifestation of paramagnetism in this system makes it an ideal platform for measuring the magnetic exchange interaction.

Diamond Interfaces by TEM Castro P. Villar[1], Beatriz Soto[1], Gonzalo Alba[1], Jesus Canas[2], José C. Piñero[1], Javier Navas[1], Marina Guitiérrez[1], Josep Montserrat[3], Philippe Godignon[3] and Daniel Araujo[1]; [1]Universidad de Cádiz, Spain; [2]Institute Néel-CNRS, France; [3]Centro Nacional de Microelectrónica - CSIC, Spain

Despite the superior Baliga's figure of merit of diamond with respect to other wide band gap materials [1], it is still not extensively used for electronic devices, in general, or power electronic devices, in particular. Aspects such as size of diamond substrates, extreme mechanical hardness, capability of getting high quality n-type doped layers or reproducibility of high quality growings are some of the reasons that make difficult to implement diamond in power electronics market and constitute a set of challenges to overcome in the manufacture of devices. But not only this, manufacture also involves deposition of other materials on diamond grown layers, as oxides gates for MOS transistors, metals for ohmic or Schottky contacts, which not always are well controlled. In addition, diamond surface termination is also determinant in how all these materials are finally bounded to diamond. Indeed, electrical characteristics depend directly on the latter. Therefore, electrical performances directly result from the structural way in which other materials, as metals or

oxides, are bound to diamond.
Transmission electron microscopy (TEM) is one of the most powerful tools to directly analyze interfaces. Information about roughness of the interface, atomic arrangement, chemical environment, crystalline nature of the oxide onto diamond, orientation relations between diamond and crystals forming the deposited layer, energy gap of the oxide, chemical composition variations or formation of interface specimens can be obtained through TEM related techniques as HREM, HR-STEM, EDX and (V)EELS. XPS or DFT-periodic calculations are complementary to understand the TEM related results and can give relationships to electrical characteristics.
This contribution will present an overview about diamond interfaces characterization carried out at the University of Cádiz on different electronic devices studied by TEM related techniques. In particular, several interfaces as metal/diamond, oxides/diamond and carbides/diamond by means of their atomic interface configuration, i.e., atomic bondings and grain configuration, are investigated and related to their electrical characteristics. In addition, TEM spectroscopies complemented by XPS measurements are shown to be of first importance to understand band setting at such interfaces. Role of interface states and their relation with crystallinity of oxide in MOS stacks will be discussed for Al_2O_3 and ZrO_2 MOSCAPs and MOSFETs. Al_2O_3 is the most common oxide for these purposes and it is well characterized [2], although ZrO_2 is also a promising candidate due to its high dielectric constant [3], large band gap and high breakdown field. Performance of diamond based-Schottky diodes is also greatly dependent on diamond surface terminations [4] and, in the case of tungsten carbide contacts, some results on the WC/O-diamond are presented identifying crystallinity and stoichiometry of WC phases. Oxygen termination has also an important role in Zr/diamond Schottky interfaces.

Interface States and Charges Induced by ZrO_2 Deposited by Different Methods on O-Terminated Diamond Capacitors Beatriz Soto[1], Castro P. Villar[1], Daniel Araujo[1] and Julien Pernot[2]; [1]University of Cádiz, Spain; [2]University of Grenoble Alpes, France

One of the bottlenecks in the fabrication of diamond-based electronic devices is related to the diamond interface state passivation. The surface termination quality and the fact of not having a native oxide hinders high performance and reliability of the device. The improvement of the oxide/diamond interface quality leads to a minimization of the interface states density in the diamond gap which strongly modify the electrical response. The starting point of this study is the interesting characteristics of the ZrO_2 such as the high dielectric constant (of the order of 19.7), the high band gap (6eV characterized by Electron energy loss spectroscopy), its band setting providing a barrier for holes (of the order of 2eV) or the high breakdown field (of the order of $2MVcm^{-1}$). In the present contribution, different zirconia layers have been deposited by two methods: Atomic layer deposition and radio frequency Sputtering. The crystallinity of the layers has been studied by High resolution electron microscopy and its related Fast Fourier transform and by X-ray diffraction. The band alignment will be established by X-ray photoelectron spectroscopy. Also, by Energy dispersive X-ray spectroscopy is possible to analyse the stoichiometry throughout the dielectric comparing the oxygen content, and thus the possibility of finding electron-trapping mechanisms, from the two methods of deposition. Finally, the analysis of the electrical characteristics (I-V, C-V, C-f) for zirconia deposited under several conditions allows an understanding of how microstructure influences electrical performance.

11:15 AM EQ19.01.04
Mapping Boron Distribution by Cathodoluminescence in P-Type Monocrystalline Diamond Nicolas Tappy[1], Christian Monachon[2] and Anna Fontcuberta i Morral[1]; [1]Ecole Polytechnique Fédérale de Lausanne, Switzerland; [2]Attolight SA, Switzerland

The spatially resolved and non-destructive measurement of impurities and defects in diamond is key for the deployment of diamond in electronics. Techniques used so far such as the X-ray Topography using synchrotron radiation for monitoring defects in substrates exhibits a low scalability. In the large-scale production picture, the lack of high throughput characterization technique could rapidly become a bottleneck. We propose that Cathodoluminescence Spectroscopy (CL) is a useful alternative, because of its sensitivity to defects. In addition to this, the excitonic spectrum of diamond has been useful to measure dopant concentrations in diamond for many years, but relies on prior knowledge of the setup performances, i.e. a diamond standard of known doping level for the calibration of the setup.
Going beyond this state-of-the-art, we study dopants in diamond using Time-Resolved CL (TR-CL) with a picosecond time resolution, and CL spectral imaging. TR-CL evidences that the excitation dynamics of a CL experiment are significantly different from their PL counterparts, because many excitons are generated in a very small interaction volume even if few electrons impact the sample. This novelty provides direct, quantitative access to the electrically active Boron concentration in a sample, regardless of compensation or non-incorporated impurities, with sub-micron spatial resolution and attractive measurement throughput. We demonstrate how this can be applied to map doping variations in a Boron-doped High-Pressure-High-Temperature diamond substrate across growth sectors, which shows doping concentration varying over 1 order of magnitude, in the 1.5e16 – 4.0e17 [cm-3] range. The measurements are performed at a spatial scale sufficient to resolve crystalline defects, and study their impact on the spectral signal and Boron incorporation.

11:30 AM EQ19.01.05
Investigating Novel Electrochemiluminescence Reactions Utilising Boron Doped Diamond Electrodes in Aqueous Solutions Samuel Stewart, Emmanuel Scorsone and Matthieu Hamel; CEA-LIST, France

Electrochemiluminescence (ECL) is a technique where chemical species generated at the surface of an electrode interact; producing an excited state, which then emits photons. The intensity of the emitted light is proportional to the concentration of the target molecule and so is quantifiable. Exploiting features of both electrochemical analysis and chemiluminescence, the use of ECL has become very popular in many areas due to the wide range of advantages it displays over more conventional fluorescence techniques: the ability to control the exact time and position of the photon emission, the absence of background optical signal (high signal/noise ratio) and good selectivity.
ECL generally occurs where the oxidized and reduced forms of the target analyte are produced by sweeping from cathodic to anodic potential, or vice versa. The recombination of these two species is what produces the excited state. However, in aqueous solutions this becomes difficult as the relatively high and low potentials needed can cause the electrolysis of water, disrupting the ECL process. This is usually overcome with the use of a co-reacting species, where the luminescent species are oxidized at the electrode together with the co-reactant, giving a strong reducing agent. However, these additional compounds can often be expensive and significantly reduce the selectivity of the technique.
Boron Doped Diamond electrodes have several advantages over other electrode materials. The most important for ECL assays is that it possesses a wide potential window in water, meaning we have the ability to mitigate the splitting of water without the need for the addition of co-reacting species. Another is BDD ability to withstand very high and low potentials (over 1.5V and under -1.5V), this has already been implemented for the in-situ electrochemical cleaning of the electrode for both electrochemical and ECL analysis. It also means that we have the ability to apply these very high potentials for the rapid production radicals (hydroxyl and super oxide) at the surface of the electrode. Many ECL assays depend on the interaction of the target analytes with these

radicals, like in the case of indolic compounds, to produce the exited state that give the ECL signal – but are often performed in organic solvents or with co-reactants. The robustness of diamond gives the opportunity to create ECL reactions and analyses of these compounds in aqueous solution. Here, we investigate the potential of using the unique properties of diamond electrodes to produce novel ECL assays.

SESSION EQ19.02: Devices
Session Chair: Bohuslav Rezek
Tuesday Afternoon, November 30, 2021

Non Volatile Photo-Switch Using a Diamond pn Junction Julien Pernot[1,2], Cédric Masante[1], Martin KAH[1], Gwénolé Jacopin[2], Clément Hébert[3] and Nicolas Rouger[2]; [1]Univ. Grenoble Alpes, France; [2]Centre National de la Recherche Scientifique, France; [3]Institut national de la Santé et de la Recherche Médical, France

Ultrawide bandgap semiconductor technologies offer potentially revolutionary advances in the rapidly developing areas of quantum communication, short wavelength optics, smart energy conversion and biomedical interfaces. These strongly demanding technologies can be partly constructed using conventional devices but new hybrid architectures are needed to overpass current performances and add functionalities. Here, we propose a new concept based on the specific properties of a diamond pn junction combined with both an electric and optical control of the depletion region. Using this junction as a gate in a junction field effect transistor, we report a proof of concept of a non volatile diamond photo-switch. A diamond pn junction made with nitrogen deep donors in the n−side is demonstrated to be optically activated thanks to visible light. The n-type diamond gate is almost devoid of free carriers in the dark and thus insulating. Illuminating the device renders the standard electrical gate control of the transistor efficient. Without illumination, the device is frozen, keeping a permanent memory of the current state. This new way of operating the device opens numerous possibilities to store and transfer information or energy with applications in the field of electrical aircraft or aerospace electronics, power electronics, bio-electronics and quantum communication.

2:00 PM EQ19.02.02
High Voltage (-580 V) Vertical- Diamond MOSFET by 2DHG Channel and Implementing p^--Drift Layer Kosuke Ota[1], Jun Nishimura[1], Naoya Niikura[1], Aoi Morishita[1], Atsushi Hiraiwa[1] and Hiroshi Kawarada[1,2]; [1]Waseda Univ., Japan; [2]Kagami Memorial Research Institute for Materials Science and Technology, Japan

Diamond has excellent physical properties as a semiconductor material, such as a high breakdown electric field (~10 MV/cm), the highest thermal conductivity among solid materials (~22 $Wcm^{-1}K^{-1}$), and a low dielectric constant (~5.7), and is expected to be applied to high-power, high-frequency p-FETs. To realize high-power and high-speed switching complementary inverters, there is an urgent need to develop vertical p-channel power FETs comparable with n-type FETs and suitable for integration. We have reported vertical-type diamond MOSFET using two-dimensional hole gas (2DHG) which is induced at any C-H diamond surface independent from crystal orientation covered by high temperature ALD-Al_2O_3[1][2][3]. However, the drift layer by lightly B doped layer (p^- layer) has not been implemented because the controllability of lightly doping of boron into diamond is very difficult. In this work, we fabricated (001) vertical-type 2DHG diamond MOSFET with a p^--drift layer and achieved a breakdown voltage of V_B: -580 V, which is the highest among the vertical diamond MOSFETs currently reported.
Fabrication process was as follows. First, a p^--drift layer ([N]: 1.0×10^{16} cm^{-3}, [B]: 8.0×10^{17} cm^{-3}) of 4 μm was deposited on a p^+-type diamond substrate using the microwave plasma chemical vapor deposition (MPCVD) method and nitrogen-doped layer of 2 μm were deposited as a vertical current blocking layer on a p^--drift layer by the MPCVD method. Second, trench with a depth (D_T) of 3 μm, a width (W_T) of 6 μm are formed by inductively coupled plasma reactive ion etching using O_2 plasma. After trench formation, a 300 nm regrown undoped layer was deposited by the MPCVD method to induce the 2DHG and secure the drift layer on the trench sidewall. Third, source electrodes (Ti/Pt/Au) were formed and the 200-nm-thick Al_2O_3 was deposited as the gate insulator through the high-temperature atomic layer deposition (ALD) method. Finally, drain electrodes (Ti/Au) was formed on the back surface of the substrate and gate electrode (Al) was formed to complete the vertical-type device. The source-gate length (L_{SG}), gate-trench (L_{GT}), gate-drain (L_{GD}), source-drain (L_{SD}) and gate length (L_G) for this device are 3 μm, 4 μm, 10 μm, 17 μm, 4 μm, respectively. The area size of an active region for this device ($L_{SS} \times W_G = 7.5 \times 10^{-6}$ cm^2) is defined by multiplying the distance between the trench-side edges of two sources (L_{SS}: 30 μm) and the gate width (W_G: 25 μm).
From the I_D-V_{DS} characteristics, the maximum drain current density ($I_{D,max}$) normalized by the gate width is 210 mA/mm at V_{DS}: -50 V and V_{GS}: -20 V. In the active region, the $I_{D,max}$ is 1400 A/cm^2 and the on-resistance (R_{on}) is 23 mΩcm^2. The drain current density obtained in this study is comparable to that of a vertical device of the same device size without a p^--drift layer [1]. No gate leakage current is observed at room temperature (300 K) and on/off ratio is about 6 orders of magnitude. A high breakdown voltage of -580 V is achieved, this value is more than 60 % (200 V) higher than the breakdown voltage (V_B: -359 V) [1] of a device of the same size without a p^--drift layer, and is the highest value reported for vertical diamond FETs. From the above, it can be confirmed that the p-drift layer does not significantly reduce the current value and increase the breakdown voltage. In the near future, a p-type power trench diamond MOSFET with high voltage and low ON-resistance will be realized by increasing the thickness of the p^--drift layer (currently 4 μm) to about 10 μm, implementing a trench gate structure [3] and a high-density boron-doped layer [4] under the source electrode in this device structure.

Late News: 1kV Normally-off Lateral Diamond Reverse Blocking MESFET Jesus Canas[1,2], Alex Pakpour-Tabrizi[3], Richard Jackman[3] and Etienne Gheeraert[1]; [1]Institute NEEL-CNRS, France; [2]universidad de cadiz, Spain; [3]University College London, United Kingdom

Diamond transistors are promising for high temperature, power and frequency applications in harsh environments, including those with high radiation levels. This is due to the unique properties of diamond as a wide band-gap (5.5eV) semiconductor. The majority of Diamond field-effect transistors (FETs) fabricated to-date use a 2D hole gas that emerges when an H-terminated diamond surface comes into contact with a range of adsorbates and/or selected metal oxides. However, this unconventional manner of creating a p-type region in a semiconductor suffers from instability and reproducibility problems and low operational mobility issues.
Several lateral O-terminated diamond FET concepts and architectures have been recently fabricated while for vertical FETs, traditionally favored for high

power devices, fabrication is still challenging despite the recent efforts of the diamond device community. The reported lateral devices display 'normally-on' characteristics, which are not ideal for high power applications. Further, reported breakdown voltages are typically poor in comparison to diamond's full potential mainly due to limitations in substrate and epilayer quality alongside existing processing capabilities. In this work, these problems are addressed. A novel and a *normally-off* lateral Schottky-drain reverse blocking (RB) MESFET based on molybdenum Schottky contacts on O-terminated boron doped diamond has been fabricated. The device display a current level of 70μA/mm and a transconductance of 147μS mm^{-1} at 425 K. Importantly, the blocking voltage capabilities of the devices at this temperature are >1 kV with no leakage current and reproducible characteristics after the high voltage stress test.

2:30 PM EQ19.02.04
C-Si Bonded 2DHG Diamond MOSFETs—Improvement of Interface Characteristics by Thin Gate Insulating Film Yuta Nameki, Te Bi, Wenxi Fei, Jun Nishimura, Naoya Niikura, Atsushi Hiraiwa and Hiroshi Kawarada; Waseda University, Japan

Diamond is the next generation wide bandgap semiconductor material, which can realize high performance power devices. The H-terminated (C-H) diamond has low activation energy, high carrier mobility[1] and high hole density. We have ever developed C-H diamond MOSFETs reported high drain current density[2] and high breakdown voltage[3]. However, C-H diamond has a weak oxidation resistance, there is a problem that it is difficult to apply it to commercialization. Therefore, we proposed C-Si bonded (C-Si) diamond structure using SiO_2 to achieve further diamond device development. The SiO_2 is advantageous for power devices in terms of chemical stability and wide bandgap, so it can be used as the gate insulator in the diamond power device applications. In previous study, we fabricated C-Si diamond MOSFETs with the boron-doped diamond selective growth by using the SiO_2 as the mask for the formation of source-drain electrode and the gate insulator[4,5]. The C-Si diamond device had C-Si bonds as the p-channel. We consider C-O-Si on the diamond-SiO_2 interface can reduce the interface state and improve the field-effect mobility. In addition, the C-Si diamond MOSFET achieved normally-off operation[4]and wide temperature stability (~673 K)[5]. In this study, we have further improved the characteristics by thinning the SiO2 gate insulating film. The fabrication process is as follows. The 2 mm undoped layer was grown on nitrogen-doped (001) diamond substrate by microwave plasma chemical vapor deposition (MPCVD). The 100 nm SiO_2 layer was formed on the substrate by utilizing tetra ethoxy silane chemical vapor deposition (TEOS-CVD). The source-drain patterns were formed by the inductive coupled plasma reactive ion etching. Then, boron-doped diamond ([B]:~10^{21} cm^{-3}). was selectively grown by MPCVD on the selectively etched undoped diamond layer by 50 nm with the SiO_2 mask patterns with. The growth temperature and microwave output power of MPCVD were 1200 K and 360 W, respectively. The C-Si diamond interface has been formed between the undoped diamond and the SiO_2 mask during selective growth of boron-doped diamond layer. Source-drain electrode were deposited on the surface of the selected boron-doped diamond. Ohmic contacts were formed by annealing (773 K). The SiO_2 film was removed by ICP-RIE, apart from the channel region. The 100 nm Al_2O_3 was deposited as a gate insulating on the diamond substrate using the high temperature ALD method (723 K). Finally, gate electrode (Al) was deposited so as to overlap the source-drain electrode by 2 mm. The gate width, gate length and channel length were 25, 14-22 and 4-12 mm, respectively. The maximum drain current density of the C-Si diamond MOSFET normalized by gate width is 108 mA/mm at V_{DS} of -30 V and V_{GS} -40 V, and the maximum transconductance is 3.1 S/mm at the V_{DS} of -30 V. The field effect mobility (m_{EF}) is 122 $cm^2V^{-1}s^{-1}$. This value is comparable or better than that of C-H diamond MOSFETs. In addition, the C-Si diamond MOSFET have the normally-off operation with threshold voltage V_{th} of -0.2 V. This result exhibits that the C-Si bond contributes to normally-off operation of diamond MOSFET indicating a new *V*th control mechanism. Furthermore, this device has a thin gate insulating film, which results in low subthreshold characteristics and a steep on /off ratio. In addition, the maximum drain current density increases due to the increased capacity of the oxide film. The drain current on/off ratio is about 7 orders of magnitude at 300 K. In future, C-Si diamond MOSFET be expected to vertical-type diamond devices, and it will contribute significantly to the diamond p-FET for CMOS circuits combined with GaN or SiC n-FETs.

Propagation Characteristics for Seawater Wireless Communication up to 25 m of Transmission Distance by Utilizing Diamond Solution Gate FET Hirotaka Sato, Teruaki Takarada, Shuto Kawaguchi, Yu H. Chang and Hiroshi Kawarada; Waseda University, Japan

We have investigated the characteristics of electric signal propagation in seawater by utilizing diamond solution gate FET (SGFET) [1]. The channel surface of a SGFET and a gate electrode are directly immersed in solutions and the drain current (I_{DS}) can be remotely modulated by electric signals (V_{GS}) applied on the gate electrode via solution. Due to these properties, we proposed a new electric seawater communication method utilizing the gate electrode as a transmitter, seawater as propagation medium and SGFET as a receiver [2].
Seawater wireless communication has been required in a wide range of fields such as environmental research, scuba diving, and autonomous underwater vehicle. In seawater, radio waves have short transmission distances, due to the high electric conductivity of seawater. Present seawater wireless communication mainly employs the use of acoustic waves. Recently optical waves are considered or. Optical waves face some drawbacks due to turbidity absorbing scattering centers such as sands, planktons in seawater. While acoustics waves exhibit relatively low absorption, they have low frequency band (~kHz) [3].
To address these issues, we have proposed a new seawater wireless communication method utilizing a diamond SGFET that can operate in electrolyte solutions as the receiver. Diamond SGFET can respond to AC electric signals applied on the electrically independent gate electrode, which indicates successful wireless communications. SGFET output signals were observed as differential pulses responding to the input square potential change. In addition, we have reported that increasing the ion concentration in the electrolyte solution favors signal propagation [2]. The result suggests that the signals are not propagated by radio waves, but that sodium and chloride ions in the solution play an important role in propagation. However, the mechanism for signal propagation has not been clarified yet. In this work, we evaluate the amplitude (V_{peak}) of the differential pulses and investigate the effect of the transmission distance (gate-SGFET channel distance) up to 25 m on the output characteristics in order to consider the mechanism of signal propagation.
This communication system composes of three components: a gate electrode as the transmitter, an SGFET as the receiver, and an electrolyte solution as the propagation medium. 3.5 % NaCl solution was filled into PVC tubes with a length of 1 to 25 m (diameter = 2.5 cm). The transmission distance was changed by inserting the gate electrode and SGFET at both ends of each tube. The gate electrode was applied up to 10 MHz and 1 V amplitude square waves electric signal (v_G). The drain electrode of SGFET was connected to a load resistance (R_L) and was applied with a supply voltage (V_{DD}). Then, drain-source voltage (v_{DS}) and load resistance voltage (v_{RL}) were measured as outputs.
The output characteristics show that SGFET respond to v_G at least 200 kHz frequency at the distance of 25 m. The amplitude (V_{peak}) at 50 kHz drastically decreases from 1 m (V_{peak} > 80 mV) to 10 m (V_{peak} < 10 mV). On the other hand, V_{peak} at 50 kHz gradually decreases from 10 m to 25 m, and we obverse that V_{peak} is about 5 mV at 25 m. However, the response above 500 kHz is not observed at 25 m even though diamond SGFET can respond at 10 MHz input voltage v_G at 1 m. This is because the propagation of differential pulses caused by the derivative of input voltage v_G is delayed and the upper limit of frequency response becomes lower as the distance increases.
We explain these results by introducing two types of propagation models; ion conduction current due to solution resistance R_s, and ion plasma wave model

that is propagation as longitudinal waves of sodium and chloride ions.

Lowest Contact Resistance for High Drain Current Density >1A/mm at Diamond MOSFETs with Heavily Boron-Doped Source and Drain Fuga Asai[1], Ken Kudara[1], Masakazu Arai[1], Atsushi Hiraiwa[1] and Hiroshi Kawarada[1,2]; [1]Waseda Univ, Japan; [2]Kagami Memorial Research Institute, Japan

Diamond has a wide band gap (5.5 eV), high thermal conductivity (22 W/cm K), and high breakdown field. Therefore, Diamond is expected to apply RF amplifier. We fabricated high-voltage Diamond MOSFETs with Al_2O_3 (200 nm) as gate insulator formed by high temperature ALD process. We achieved the highest output power density P_{out} = 3.8 W/mm [1] in p-type FETs. The high output has been obtained by reducing on-resistance, increasing operating voltage $V_{DS, Q}$ and current density $I_{D,Q}$, and increasing actual current by extending the gate width W_G. The device with extended W_G may reduce current density because of self-heating, and influence characteristics of devices caused by increase of gate resistance.
In this work, we fabricated ALD-Al_2O_3 MOSFETs with a boron-doped layer on a pure (111) diamond and evaluated DC and RF performance as well as contact resistance in detail. Devices were fabricated on a pure (111) diamond. We etched selectively by ICP-RIE through the evaporated metal mask to form space for heavily boron-doped epitaxial layer (150 nm of p^{++} layer) for source and drain. Source and Drain electrodes are deposited Ti/Pt/Au (20 nm/30 nm/90 nm). The thickness of Al_2O_3 gate insulator is 200 nm. And we adopted double gate finger structure for the reduction of gate resistance.
From I_{DS}-V_{DS} characteristics, the maximum drain current density I_{Dmax} of 1.03 A/mm, R_{on} of 23 Ω mm was obtained at V_{GS} = -28 V and V_{DS} = -40 V. To obtain even higher current density, it is valid to shorten the distance between the source and drain, for example. It is expected that the drain currency density achieves 1.5 A/mm when L_{SD} is designated 0.5 µm. This small L_{SD} device has been manufactured by using electron beam lithography when we coat resist of metal mask for p^{++} layer. We measured TLM pattern on the substrate which are (a) 2DHG and p^{++} layer and (b) only 2DHG without p^{++} layer. As for (a), contact resistance $R_{contact}$ was 1.77 Ω mm and sheet resistance R_{sheet} was 6.7 kΩ/sq. As for (b), $R_{contact}$ was 27.5 Ω mm and R_{sheet} was 16.8 kΩ/sq. These results suggest that p^{++} layer under the source and drain area reduce both contact resistance and sheet resistance. (c)In order to evaluate the contact resistance between boron-doped layer and 2DHG, we measured contact resistance to p^{++}layer and sheet resistance R_{sheet} of p^{++} layer to be 0.49 Ω and 64 Ω/sq, respectively. From these results, each element of resistance can be calculated. $R_{TiC\text{-}Boron}$ was 0.49 Ω mm, R_{Boron} was 0.32 Ω mm, $R_{Boron\text{-}2DHG}$ was 0.96 Ω mm. This result suggests that the barrier between boron-doped layer and 2DHG is not a serious problem because the contact resistance (=0.96 Ω mm) is very small. And the large signal performance of a device was evaluated by using a load pull system at 1 GHz. As for the power output density measured by the load pull system, 3.6 W/mm was obtained on the device of W_G = 200 µm. This value is almost equal to the maximum value of Diamond MOSFETs (= 3.8 W/mm), which was obtained at W_G = 100 µm; that is, actual power in this new device is almost twice as that of former maximum value.
In summary, we fabricated boron-doped MOSFETs on a pure (111) diamond substrate and evaluated DC and RF performance as well as contact resistance between boron-doped layer and 2DHG. As a result, over 1 A/mm of drain current density was obtained. To obtain even higher current density, it is valid to shorten the L_{SD}. As for the TLM measurement, boron-doped layer reduced both contact resistance and sheet resistance. Then we found that the barrier between the boron-doped layer and 2DHG is not a serious problem. As for the large signal performance, power output density 3.6 W/mm was obtained. This is to be equal to the maximum value of Diamond MOSFETs, but actual output power is twice than that of maximum value.

Nanodiamonds Under Control—Size and Synthesis Dependent Properties, Composites, Interfaces and Application Examples from Health to Sensors, Photocatalysis and Energy Bohuslav Rezek[1] and Stepan Stehlik[2]; [1]Czech Technical University, Czechia; [2]The Czech Academy of Sciences, Czechia

Nanodiamonds science and technology has been extensively explored in the past decade with prospects and examples of applications from biomedicine to quantum technologies. Ample reviews and seminal articles are available [Mochalin, Nature Nanotechn. 7 (2012) 11; Arnault (Ed.), Nanodiamonds, Elsevier, 2017]. Yet many scientific and application related problems remain to be addressed. Driving motivation is to better understand, control, and make use of nanodiamonds unique properties for photocatalysis, energy harvesting, sensing, health and safety. In this contribution, we review our recent progress in technology to better control nanodiamond properties and we analyze interactions (structural, chemical, electronic, optical) of nanodiamonds with molecules and inorganic materials by correlating microscopic, spectroscopic, and computational methods. We focus on two representative types of nanodiamonds (NDs) produced by HPHT or detonation synthesis that in some aspects exhibit distinctively different features.
We present a technology of controllable and high-yield purification and size reduction of both types of NDs down to 2 nm (mode size) by using annealing in air at optimized temperatures of 450-520 °C for 10-50 min. The effect differs on HPHT and detonation NDs. Size and nitrogen inhomogeneity in the primary DND particles is revealed via salt-assisted deaggregation. We characterize the effect of size on multiple methods, from DLS and AFM to SAXS and Raman. We observe distinct size-related effects on surface chemistry and Raman spectral features (incl. breathing modes) in sub-5nm range on HPHT and detonation NDs. We show that even at the molecular size the nanodiamond surfaces can be reversibly modified from oxidized to hydrogenated by thermal processes.
We demonstrate use of such controlled nanodiamonds on various examples. For instance, 2 nm H-DNDs enable formation of extremely dense (10^13 cm^{-2}), thin (2 nm), and smooth (RMS < 0.8 nm) nucleation layers and then highly uniform sub-6 nm CVD diamond films. Photoluminescence of SiV centers in the films < 10 nm is fully switched between on and off states by O/H surface terminations. Nanodiamonds themselves inherently assume electrical charge on substrates (up to 0.4 V) that affects both electron emission and photoluminescence. surface potential of nanodiamonds is affected also by adsorbed water that forms a thicker layer on hydrogenated and binds more tightly on oxidized NDs as shown by TGA and FTIR. Specific interaction with biological solutions leads to formation of different protein corona on 2 nm O/H DNDs and thereby to different interaction with cell membrane and cytotoxicity. On bacteria, the most pronounced long-term inhibition of E. coli growth (45%) is provided by hydrogenated NDs, via oxidative stress predominantly.
We show that composites of nanodiamonds with other materials represent a promising future direction. TiO2/nanodiamond composites exhibit more efficient photocatalytic degradation of soman via enhanced hole transfer. Ag/nanodiamond composites exhibit better stability and photoactive effects than

Ag nanoparticles alone. Based on AFM and FTIR analysis, hydrogenated or oxidized DNDs in composites with Au nanoparticles provide control of drug molecule adhesion and assembly (upright or layered) both on nanodiamond and Au and thereby control also impedance biosensor response. Nanodiamond surface chemistry controls also assembly of polypyrrole-DND complexes and thereby generation of photovoltage. Based on the experiments and theoretical DTF computing, polyfunctional DNDs with both oxygen and hydrogen surface groups may be the best nanodiamonds for PV, serving as effective inorganic electron acceptor. We demonstrate prototype spin-coated DND-PPy solar cell incl. cross-sectional SEM analysis.
We gratefully acknowledged the long-term support from the Czech Science Foundation, Ministry of Education Youth and Sport, and the project CZ.02.1.01/0.0/0.0/15_003/0000464 (CAP).

4:30 PM EQ19.03.02
Valence Band Electron Energy Loss Spectroscopy Study of Boron-Doped Nanodiamonds Souvik Bhattacharya[1], Jonathan Boyd[2], Amir H. Talebi[3], Sven Reichardt[3], Olga A. Shenderova[4], Nicolò Maccaferri[3], Ludger Wirtz[3], Giuseppe Strangi[2] and R. Mohan Sankaran[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]Case Western Reserve University, United States; [3]University of Luxembourg, Luxembourg; [4]Adamas Nanotechnologies, United States

Doped semiconductors exhibit interesting optical and optoelectronic properties such as localized surface plasmon resonances[1,2] and carrier-phonon coupling[3]. Boron-doped diamond is a wide band-gap, p-type semiconductor which has been previously found to produce interesting phenomena such as electron-phonon coupling that leads to Fano resonances[4] and superconductivity[5]. Here, we characterize boron-doped nanodiamond powders by electron-energy loss spectroscopy (EELS) using a scanning transmission electron microscope to reveal potentially new optical transitions. The nanodiamond samples were synthesized commercially by high-pressure-high-temperature methods and obtained from Adamas Nanotechnologies. The particles were imaged using high-resolution transmission electron microscopy to confirm the crystalline structure and measure their size which was on the order of 0.5-1 microns. The boron concentration was estimated to be ca. 800 pm by comparing the Fano line shape of the main peak in the Raman spectrum to results in the literature[4]. For EELS, we focused on the valence-band where a clear shoulder was observed on the zero-loss peak (ZLP). Through data processing, the ZLP was either deconvoluted or subtracted from the inelastic scattering spectra using the reflected-tail method and fitted using Voigt peaks to identify multiple peaks in the range of 0.1-0.2 eV. We note that the feature was completely absent in a control undoped nanodiamond sample synthesized under the same conditions. We present theoretical simulations to explain the origin of this signal, which suggest that the new resonances are driven by low-lying electronic excitations in the valence band. We also investigate the role of resonant electron-phonon coupling, which was previously shown to lead to observable changes in the electronic and vibrational properties in boron-doped diamond[6].

Formation of Water-Soluble Onion-Like Carbon by Laser Irradiation of Colloidal Detonation Nanodiamonds Irena Bydzovska[1,2], Ekaterina Shagieva[1], Ivan Gordeev[1], Oleksandr Romanyuk[1], Zuzana Nemeckova[3], Jiri Henych[3,4], Lukas Ondic[1], Alexander Kromka[1] and Stepan Stehlik[1]; [1]Institute of Physics, AS CR, Czechia; [2]Czech Technical University in Prague, Czechia; [3]Institute of Inorganic Chemistry of the Czech Academy of Sciences, Czechia; [4]J.E. Purkyně University in Ústí nad Labem, Czechia

Industrial-scale production and narrow size distribution make detonation nanodiamonds (DNDs) a convenient precursor for onion-like carbon (OLC) formation. Apart from frequently used high-temperature annealing of DNDs in an inert environment, their laser irradiation in liquid can be effectively used for the OLC formation. Due to processing in chemically reactive environment, the produced OLCs can carry specific surface functional groups that mediate their solubility in various solvents[1]. Moreover, the transformation was shown as a reversible process, i.e. nanodiamonds (NDs) were back-transformed after the OLC laser irradiation[2].
In this work, we focused on this process more in detail by monitoring the surface chemistry, zeta potential, and structure of DNDs as a function of laser irradiation duration. Firstly, we used fully deagregated hydrogenated DNDs (H-DNDs) dispersed in ethanol which were irradiated by a 532 nm NdYAG laser with energy 150 mJ in a pulse (5 J/cm^2) at 10 ns pulse duration and 10 Hz repetition rate. The irradiation lasted for 1, 2, 3, 4, 5, 10, 20, 40, and 60 minutes giving a rise to nine samples. With increasing irradiation time, the brown colloid of the pristine H-DND gradually changed to black and finally turned to a transparent yellow colloid. FTIR measurements revealed a monotonical decrease in the C-H$_x$ bands intensities and an increase of the C-O and C=O features. This was accompanied by a zeta potential decrease from 54 mV for the pristine sample down to 34 mV for the 10 min sample. The 20 and 40 min samples were already colloidally unstable. Gradual photo-oxidation of the H-DNDs was confirmed by XPS which revealed an increase of the oxygen content with increasing laser irradiation time. The formation of OLC-like structure was proven by transmission electron microscopy (TEM). In addition, TEM also showed a gradual loss of nanoparticle character with increasing the irradiation time. The 40 min sample no longer consisted of ~5 nm particles but an interconnected chain-like mesostructure. Two fundamental aspects were investigated by Raman spectroscopy. First, we focused on the time-dependent H-DND transformation into OLC structures. In agreement with XPS and TEM, Raman measurements confirmed the gradual increase of the sp^2 C with increasing laser irradiation time. However, no OLC-to-ND back transformation was detected. Second, we investigated the laser-treated samples after their purification from sp^2 carbon by air annealing treatment. Suprisingly, for all samples irradiated up to 40 min, the typical and unchanged DND Raman spectrum was successfully recovered after the annealing in air at 450°C for 300 min. This finding indicates the inhomogeneous sp^3 to sp^2 transformation during the laser irradiation process as well as the insensitivity of the DND Raman spectra to the surface chemistry, size, and transient structural changes. Our results demonstrate the potential and limits of the laser irradiation technique as an effective tool for the controllable formation of water-soluble OLCs and bring deeper understanding to relations between sp^3 and sp^2 nanocarbons.

Dislocations as Topological Wires and Magnets Sevim Polat Genlik and Maryam Ghazisaeidi; The Ohio State University, United States

Dislocations —one dimensional topological defects—in electronic materials, are considered to have a negative influence on electronic properties; their presence is thought to cause non-radiative recombination of charge carriers which lead to overheating of the crystal and malfunction of the device. Therefore, great effort has been made to produce dislocation-free crystals. However, recent studies show that dislocations can also be turned into useful functional features. For instance, it is reported that magnetic properties of dislocations differ from the lattice due to broken symmetry of the magnetic order and local non-stoichiometry of the dislocation core [1][2]. In another study, it is shown that inherent screw dislocations in certain elemental and compound semiconductors generate coherent spin currents through spin orbit coupling effect [3]. Thus, dislocations, with unique and localized magnetic and electronic properties, as well as their interactions in attracting point defects could be engineered to designing next generation technological devices and there is need for a thorough theoretical understanding of their influence on electronic and magnetic properties by means of atomic scale modelling which provide a predictive way to model strongly distorted dislocation core region.
We present a systematic study of the core structure and electronic and magnetic properties of various dislocations in diamond using density functional theory (DFT). DFT calculations are performed with the Vienna ab initio Simulation Package (VASP), using norm-conserving pseudopotentials. Exchange and correlation contributions are treated within both the generalized gradient approximation and hybrid HSE06 (Heyd-Scuseria-Ernzerhof) functionals. To be able to satisfy periodic boundary conditions and to minimize long range elastic field interactions, supercells with two dislocations having opposite sign Burgers vectors (.i.e. dislocation dipole) are used, which result in an infinite quadrupolar array of dislocations. The analysis of the electronic band structure along the dislocation line together with band decomposed charge density distributions reveal mid-gap energy states induced by broken atomic bonds in the dislocation core. Deep levels associated with dislocations are found to be donor type (n-type) charged dislocations. In addition, we compute the interaction of dislocations with nitrogen-vacancy centers. These results have a strong potential for tailoring the functionality of dislocations in various elemental and compound semiconductors for future electronic devices.

EQ19.04.02
Generation of Anti-Reflective Diamond Surfaces Based on Artificial Moth-Eye Nanostructures Louise Kaeswurm and Joachim Spatz; Max Planck Institute for Medical Research, Germany

Reflectivity has always been a problem for a variety of processes involving interfaces and electromagnetic waves. For most substrates, the reflectivity can be reduced by introducing thin anti-reflective (AR) coatings. However, the conventional coating technology reaches its limit when dealing with diamond: due to the high refractive index of diamond it is nearly impossible to find suitable coating materials.
The bioinspired approach to achieve anti-reflective surfaces leads to so called moth-eye nanostructures, pillar-like structures with sizes in the nano- and micrometer-regime on the surface of the substrate. In nature, the structures have proven to effectively reduce the reflectivity. Copying these structures has shown that artificial moth-eye structures are also capable of reducing the reflectivity to a minimum. Here, the AR effect is not based on destructive interference created by defined layers of an AR coating and therefore does not dependent on the fulfillment of interference conditions. In the case of moth-eye nanostructures, a density effect leads to continuous refractive index matching. Due to this, the AR properties are not limited to certain wavelengths or angles of incidence but are achieved for a broad band of incoming wavelengths and angles of incidence. This already poses a great advantage compared to the limited possibilities of conventional coating methods. Additionally, the size and shape of the pillar like structures have an impact on the enhanced optical properties, making it possible to tailor the structures to achieve the desired optical performance. Furthermore, by changing the optical properties in a surface-based and intrinsic process, the challenge of finding suitable coating materials can be neglected and the unique thermal, mechanical and electronic properties of diamond are not falsified by a comparably fragile coating.
So far, conventional lithographic methods have been used to generate such structures. These methods are comparably laborious, especially for large areas. We propose a new method to produces artificial moth-eye structures in polycrystalline diamond: using the self-assembly based block copolymer micellar lithography (BCML) and reactive ion etching (RIE), we found a possibility to implement moth-eye nanostructures in different materials. Originally developed for glassy silicon dioxide (SiO_2), the process has been refined for a variety of different substrates, ranging from simple glasses like SiO_2 to semiconductors like silicon up to high-performance materials like sapphire and diamond. In comparison to the conventional lithographic methods widely used to produce these moth-eye structures, the self-assembly based BCML method is comparably fast but still as reliable as conventional methods. For diamond, the structuring process has increased the maximum transmission over 15 % compared to the untreated substrate, also reducing the reflectance severely. These advantages show the significance of the presented method, especially for high performance materials with atypical properties such as diamond.

SESSION EQ19.05/EQ03.01: Joint Session: Quantum Applications of Diamond I
Session Chair: Julien Pernot
Wednesday Morning, December 1, 2021
Hynes, Level 1, Room 101

10:30 AM *EQ19.05/EQ03.01.01
Challenges of CVD Single Crystal Diamond Engineering for Quantum Applications Jocelyn Achard[1], Alexandre Tallaire[2,1], Ovidiu Brinza[1], Midrel Ngandeu[1], Chaimaa Mahi[1], Audrey Valentin[1], Riadh Issaoui[1], Vianney Mille[1] and Fabien Benedic[1]; [1]LSPM-CNRS, France; [2]IRCP-CNRS, France

The development of applications in quantum sensing require dedicated solid-state material platforms with unprecedented control over quality, purity and

doping. Indeed, Quantum Technologies (QT) explore our ability to coherently control the peculiar properties of nanoscale quantum systems and harness their potential in a wide range of fields including health, communications, security and environment. In particular, sensors and devices having a disrupting performance as compared to classical systems are foreseen in a relatively short-term [1].
Atomic-scale defects in solid-state materials are among the most promising candidates and several platforms are being considered such as donors in silicon, color centers in semiconductors (NVs in diamond and SiC), rare-earth ions in oxides, quantum dots etc. One of the inherent drawbacks of the extreme sensitivity of such spin systems to the field they are supposed to measure, is the necessity to carefully control their close crystalline environment in order to maximize coherence properties. This pushes the fabrication technologies to their limits and requires that tailored materials are produced on purpose. In this presentation, we will review the main challenges in the synthesis of suitable "quantum-grade" materials with a special emphasis to color centers in diamond and more specifically NV centers. Issues related to controlling their density and maximizing their coherence properties through precise engineering will be discussed. (i) Atomic scale defects need to be selectively doped on demand within the matrix. High amounts are usually preferred in most sensing schemes but limits exist in the ability to control growth at high doping levels as well as to avoid interaction between nearby spins. (ii) Nuclear spins within the matrix itself might cause unwanted decoherence and growth of isotopically enriched materials allows considerably extending T_2 times or investigating specific coupling schemes with nearby spins. This has serious implications on the precursors used for material synthesis. (iii) In the same vein, magnetic sensitivity of a sensor based on NV ensembles can be considerably increased by producing diamond with NV centers having preferential orientation which can be obtained by using diamond substrates with specific crystallographic orientation such as (111) or (113) (iv) Controlling the spatial localization of color centers is crucial to the sensing device since their interaction strongly depends on the distance to the field that is to be sensed. Positioning them close to the surface with ion implantation is an efficient and widely followed approach but which comes along with the generation of residual defects that can seriously impact the spin properties.

11:00 AM *EQ19.05/EQ03.01.02
Engineering New Solid State Quantum Defects for Quantum Networks Nathalie P. de Leon; Princeton University, United States

Engineering coherent systems is a central goal of quantum science and quantum information processing. Point defects in diamond known as color centers are a promising physical platform. As atom-like systems, they can exhibit excellent spin coherence and can be manipulated with light. As solid-state defects, they can be produced at high densities and incorporated into scalable devices. Diamond is a uniquely excellent host: it has a large band gap, can be synthesized with sub-ppb impurity concentrations, and can be isotopically purified to eliminate magnetic noise from nuclear spins. Currently-known color centers in diamond either exhibit long spin coherence times or efficient, coherent optical transitions, but not both. We have developed new methods to control the diamond Fermi level in order to stabilize a new color center, the neutral charge state of the silicon vacancy (SiV) center. This center exhibits both the excellent optical properties of the negatively charged SiV center and the long spin coherence times of the NV center, making it a promising candidate for applications as a single atom quantum memory for long distance quantum communication. We have recently discovered bound exciton transitions associated with SiV0, which enable efficient optical spin polarization and optically detected magnetic resonance. Finally, I will describe our efforts to integrate SiV0 centers in nanophotonic devices, specifically in heterogeneously integrated III-V/diamond nanophotonic platforms designed to enhance the atom-photon interaction and achieve quantum frequency conversion to the telecom band.

11:30 AM *EQ19.05/EQ03.01.03
Enhanced Quantum Sensitivity for Diamond Spins via Real-Time Control Lee Bassett; University of Pennsylvania, United States

Despite the technological maturity of nitrogen-vacancy (NV) centers in diamond as a platform for quantum technology, their performance in most applications is hindered by imperfect state initialization and readout [1]. This is especially true for quantum sensing, where the NV center's charge and spin stability are typically degraded by proximity to surfaces and impurities. This talk will present a framework for optimizing the performance of NV-center quantum sensors using all-optical techniques that improve the signal-to-noise ratio through spin-to-charge conversion [2] and deterministic charge initialization [3]. I will also discuss recent efforts to create nanodiamond assemblies and to characterize their material and quantum properties, towards the realization of new sensing modalities.

Inversion Symmetric Color Centers in Diamond for Quantum Technology Gergo Thiering[1], Anton Pershin[1] and Adam Gali[1,2]; [1]Wigner Research Centre for Physics, Hungary; [2]Budapest University of Technology and Economics, Hungary

Inversion symmetry makes the color centers insensitive to stray electric fields in diamond which enables to create indistinguishable solid state single photon sources. The most studied and employed representative is the negatively charged silicon-vacancy defect [SiV(-)] in diamond. However, the fine electronic structure of SiV(-) limits the coherence times of the electron spin, thus it is not practical. One possible route is to use isovalent tin or lead which are predicted to possess longer coherence times [1]. Alternatively, SiV(0) and their akin isovalent variants [2] may be used where the ground state spin has a long coherence time [3]. We show that the excited state of SiV(0) is highly complex in which the Rydberg excited states can be used to optically readout the spin state which is a crucial step towards coherent manipulation of single SiV(0) centers. We identify further inversion symmetric color centers in diamond such as the negatively charged magnesium-vacancy [MgV(-)] defect. We find that the electronic structure of MgV(-) permits the coexistence of two loosely separated spin-states, where both can emerge as a ground state and be interconverted depending on the temperature and external strain. These results demonstrate a route to control the magneto-optical response of a qubit by modulating the operational conditions [4]. We also identified the negatively charged nickel-vacancy center in diamond which has favorable spin coherence time at cryogenic temperature which can be coherently controlled

by all-optical means. Multi-Frequency Spin Dependent Transient Spectroscopy Kenneth Myers and Patrick Lenahan; The Pennsylvania State University, United States

Long ago, Chen and Lang[1] demonstrated spin dependent deep level transient spectroscopy in metal-oxide-semiconductor (MOS) capacitors, combining the advantages of both electron paramagnetic resonance (EPR) and deep level transient spectroscopy (DLTS). EPR and the closely related electrically detected magnetic resonance (EDMR)[2] techniques are able to identify the chemical and physical nature of paramagnetic point defects while DLTS has the capability to determine point defect energy levels. We report on a simplification of the Chen and Lang method which we term spin dependent transient spectroscopy (SDTS) and demonstrate the magnetic field and frequency independence of this technique. Additionally, we show that it can be extended to utilize near zero field magnetoresistance (NZFMR)[3] spectroscopy. Our SDTS measurements were performed on negative-bias-temperature-stressed[4] Ti-Al/SiO_2/p-Si capacitors.

In our SDTS measurements we somewhat modified the spin dependent DLTS technique of Chen and Lang, utilizing a single boxcar averager for time-resolved data acquisition. In addition, we show that this modified technique has essentially the same sensitivity at X-band (≈9.4GHz) and quite low RF (≈500MHz) frequencies. The physics of this method is quite simple. Applying a voltage pulse to the metal gate brings the interface Fermi level from near the valence band to near the conduction band. This creates a current transient due in part to charge carriers filling defect levels at the insulator-semiconductor interface. Since the capture process can be spin dependent, the recombination component of the transient can be affected by magnetic resonance. These observed spin dependent events allow for the identification of the involved interface states.

We have made these measurements as functions of the pulse voltage (V_{min}), sustained base voltage (V_{max}), pulse time, and acquisition window. Each of these parameters has an effect on the amplitude of the spin dependent response. We focus on the pulse and base voltages of our waveform in order to determine energy levels in the bandgap. Additionally, we show that we can perform SDTS at high and low fields/frequencies as well as in the NZFMR regime. In conclusion, we show that SDTS is a potentially powerful new tool with comparable sensitivity to other EDMR techniques with the advantage of observing interface states in simple metal-insulator-semiconductor structures.

Sensing Nuclear Spins of Adsorbed Molecules on a Diamond Surface with Shallow NV Centers Konstantin Herb, John Abendroth, Tianqi Zhu, Erika Janitz and Christian Degen; ETH Zurich, Switzerland

The structure elucidation of macromolecules and molecular complexes is an important topic in molecular biology and biochemistry. The nitrogen vacancy center (NV center)is seen as a promising platform for scaling nuclear magnetic resonance down to the single-molecule level. However, the sensing capability of near-surface NVs – a necessary prerequisite for single-molecule NMR - is severely limited by charge state instabilities and decoherence due to surface traps and electronic and magnetic surface noise, respectively. Here, we report on strategies to improve the stability of NV centers and their coherence properties by controlled termination of the diamond surface, and to functionalize the diamond surface to bind molecules of interest.
In this talk, we discuss the creation of 3 to 7 nm deep NVs in nano-structured diamond surfaces that show T_2 coherence times of 50 to 300 us The creation of photonic structures boosts the collection efficiency and allow us to follow single NV centers as the diamond undergoes surface termination and functionalization steps . We investigate the effects of oxygen- and nitrogen-termination, and find that the former improves the electron spin coherence properties if annealing is performed below the graphitization-threshold. Further, we chemically functionalize the diamond surface with fluorinated silanes and show that, after silanization, a ^{19}F NMR signal can be detected. The successful functionalization is further confirmed by complementary X-ray Photoelectron Spectroscopy (XPS) and fluorescence measurements. We give an outlook on the steps needed to perform nuclear magnetic resonance (NMR) measurements on the single-molecule level.

Diamond CVD Deposition on CF for Aerospace Applications Josué Millán Barba[1,2], Hicham Bakkali[1], Marina Guitiérrez[1], Fernando Lloret[1], Roberto Guzmán de Villoria[3], Manuel Dominguez[1], Ken Haenen[4] and Daniel Araujo[1]; [1]University of Cádiz, Spain; [2]Foundation for the research development and application of composite materials (FIDAMC), Spain; [3]University of Salamanca, Spain; [4]University of Hasselt, Belgium

Carbon fibers reinforce polymers (CFRP) is the principal structural material used in the aerospace industry due to its high strength-low weight ratio as well as its high stiffness. In contrast, CFRP is a bad electrical and heat conductor. This limits heat dissipation which causes high damages when lightning impacts occur. In addition, the aircraft structure should act as a Faraday cage to protect electronic devices which is not possible with standard CFRP. In this work it is evidenced that the use carbon fiber coating made of highly doped boron polycrystalline diamond (HDBPD), increases the electrical conductivity

of carbon fiber (CF) for the manufacture of aeronautical structures.

HDBPD was deposited by microwave plasma enhanced chemical vapor deposition (MW PE CVD) on one commercial carbon fiber used in the aerospace industry, specifically HexTow AS7 from Hexcel, using a clamshell ASTeX 6500 series reactor. The growth conditions chosen to avoid fiber damage due to plasma were: low temperature (700 °C) and pressure (35 Torr), 1% methane and 40 Sccm of trimethylborane (TMB). Once the polycrystalline diamond was deposited on a commercial tow, different individual fibers were taken to prepare samples for transmission electron microscopy (TEM) and atomic force microscopy (AFM). Both the traditional polishing as Focus Ion Beam (FIB) methods were used to check to check the suitability of both methods in this type of CF/diamond material to avid sample preparation artifacts.

Electron beam techniques such as high-resolution electron microscopy (HREM), electron energy loss spectroscopy (EELS) and scanning electron microscopy (SEM), were used to determine their CF/interface/diamond nanostructure. HREM showed that an intermediate layer grows on the fiber surface first, on which the polycrystalline diamond is subsequently formed. The analysis of this layer by EELS revealed its strong sp^2 character which is in accordance with the bibliography where this layer is described as Carbon nanowalls. The subsequent polycrystalline diamond layer was ~1 micrometer thick and contained spherical grains averaging 70 nanometers.

The electrical properties of the HDBPD-carbon fiber were measured using conductive and scanning microwave impedance microscopy atomic force microscopy (C-AFM and sMIM-AFM) and Kelvin method. The improvement of the electrical conductivity of the CF is evidenced after HDBPD deposition.

TCAD Simulation of High Power β-Ga_2O_3/Diamond Heterojunction PIN Diodes Cristian J. Herrera-Rodriguez[1] and Timothy Grotjohn[1,2]; [1]Michigan State University, United States; [2]Fraunhofer USA, United States

CVD Diamond is one of the most promising semiconductor materials for high power applications, because of its exceptional mechanical, electronic and thermal properties, such as wide band-gap, high breakdown electric field, high mobility and high thermal conductivity. Diamond bipolar devices are promising for ultra-high voltage applications (>10kV), but diamond PN junctions provides limitations due to (1) a high turn-on voltage (~5V) giving a significant on-state voltage drop and (2) n-type diamond having higher resistivity and poor ohmic contacts. In order to address this problem, the implementation of an alternative n-type UWBG semiconductors with shallow donor dopants should be considered. Beta-Gallium Oxide (β-Ga_2O_3) is a semiconductor that has gained significant attention due to its attractive properties like its wide bandgap (4.85eV) and high breakdown field in the range of 8 MV/cm. Also, commercially available larger area high quality β-Ga_2O_3 wafers will lead to potentially more affordable high performance power devices. Diamond's outstanding thermal properties can serve as a heat dissipater at high power operations, compensating the poor thermal conductivity of β-Ga_2O_3. As an experimental demonstration of a diamond/ Ga_2O_3 pn junction device structure a photodiode [1] has been demonstrated in the literature using a nanomembrane of Ga_2O_3 on diamond.
In this study we report the device modeling using TCAD Sentaurus and analysis of n-type β-Ga_2O_3/p-type diamond heterojunction PIN diodes for future applications in power electronic devices. Material parameters input entered into the TCAD model will be presented. The heterojunction modeled had a band discontinuity of ΔEc=2.7eV at the conduction band and ΔEv=2.1eV at the valence band. It was observed that at voltages >5V, the on-state shows conductivity modulation in the drift region in the forward regime. The current density, carrier concentration and carrier recombination spatial distribution for the diamond intrinsic region with a thickness of 1um as a function of temperature and carrier lifetime will be examined.

4:30 PM EQ19.07.03
A Scanning Nonlinear Dielectric Microscopic Investigation of Al_2O_3/Diamond MOS Interfaces Yu Ogata[1], Kohei Yamasue[1], Xufang Zhang[2], Tsubasa Matsumoto[2], Norio Tokuda[2] and Yasuo Cho[1]; [1]Tohoku University, Japan; [2]Kanazawa University, Japan

Recently, inversion type p-channel diamond MOSFETs with normally off characteristics have been demonstrated for the first time [1]. However, the improvement of the channel mobility is one of the major issues towards the practical application of the diamond based power devices [2]. The previous studies have suggested that high interface defect density (D_{it}) at the Al_2O_3/diamond interface significantly reduce the channel mobility [2].

Although such macroscopic evaluation method employed in the previous studies is capable of quantitatively evaluating D_{it} with good energy depth resolution, the lateral resolution is quite limited. On the other hand, recently there have been reports suggesting that interface traps have an inhomogeneous spatial distribution, which makes characterizing interface traps with high lateral resolution quite interesting and important [3].

In the present study, in order to give microscopic insights on the physical origin of the high D_{it}, we investigate the Al_2O_3/diamond interfaces using scanning nonlinear dielectric microscopy (SNDM) [4, 5].

SNDM permits nanoscale evaluation of local MOS capacitance [5] which can perform local differential capacitance (dC/dV) imaging, local CV profiling [6], and local deep level transient spectroscopy (DLTS) using a time-resolved SNDM (tr-SNDM) setup [7].

The samples were fabricated from highly B-doped p^+- diamond layer grown on the back side of a high-pressure and high-temperature p-type (111) substrate for ohmic contact formation and had a 50 nm thickness atomic layer deposited Al_2O_3 top layer[1, 2]. We measured three different samples, whose diamond surfaces were terminated by H, O, and OH-groups, respectively.

At first, local CV profiles were here obtained. The H-terminated sample exhibited strongly negative shift reflecting the formation of surface accumulation layer, while the O- and OH-terminated samples showed depletion at 0 V. The three profiles also showed different behaviors in the transition from depletion to accumulation, suggesting D_{it} is highest in the O-terminated samples followed in order by the OH- and H-terminated samples. We could find that these local CV profiles also showed microscopic spatial fluctuations, which might be correlated with D_{it} [8].

Second, we measured dC/dV images of two different areas with atomic flatness and high roughness in the OH-terminated sample. In both images, there are non-uniformly distributed dark, or low dC/dV, spots indicating the low slope of local CV profiles. Since dC/dV becomes lower due to higher D_{it} broadening the local CV profile, the observed images possibly visualize the high D_{it} spots non-uniform distributing at the Al_2O_3/OH-terminated diamond interface and the difference of the interface by the flatness of the diamond surfaces.

Finally, we also performed local DLTS on the same sample. We found the non-uniform D_{it} distribution, again. In addition, the line-shaped features

of D_{it} distribution could be observed especially in the atomic flat area. The line-shaped features might be related to the variation of D_{it} at the atomic steps in the buried interface. In fact, the previous study by conductive atomic force microscopy and Kelvin probe force microscopy also showed the steps seem to generate D_{it} [8].

Diamond Quantum Sensors—From Growth to Applications Mutsuko Hatano; Tokyo Institute of Technology, Japan

Diamond is an excellent host for spin-based qubits, and the spin in diamond has excellent properties. Nitrogen-vacancy (NV) center in diamond is one of the most promising candidates for quantum sensing. The energy levels of NV centers are sensitive to magnetic fields, electric fields, strain, and temperature, enabling scalable applications from the atomic to the macroscopic range [1].
Core technologies on material, sensor systems, and applications for energy electronics and life science are introduced.
Materials
Selectively aligned NV ensemble formed by distinctive CVD-growth for scalable applications.
The heteroepitaxial growth of NV-contained diamond on Si substrate for large area and on-chip integration.
Multi-scale and multi-modal sensor systems
- Direct sensing of nano-scale internal electric-field in the power device [2]
- EV battery monitoring [3]
- Magnetocardiography (MCG) of mammalian animals [4]

Plasma CVD Synthesis of Nitrogen-Vacancy Centers in (111)-Oriented Diamond Hiromitsu Kato, Moriyoshi Haruyama, Yukako Kato, Masahiko Ogura and Toshiharu Makino; AIST, Japan

Nitrogen vacancy (NV) center in diamond has much attention as a quantum material that can realize spin-based sensing due to its excellent characteristics such as long coherence time, fast manipulation rates, optical initialization and readout, etc. Precise control of material-related parameters including NV concentrations, axis alignment, volume, charge-state, are essential for higher sensitivity and are important to bring the NV centers closer to quantum application in practical use. Plasma-enhanced chemical vapor deposition (CVD) with microwave is one of the major approaches to introduce well-defined NV centers in diamond, as well as electron beam irradiation and ion implantation techniques. So far, we have already proposed following ideas based on semiconductor engineering; the charge-state stabilization by n-type Fermi control [1,2], longer coherent time by phosphorus and carbon isotopic control [3], perfect alignment of NV axis [4], device applications with PIN junction [5-7]. All these achievements are based on our comprehensive progresses of CVD diamond growth, impurity doping, junction management, and device fabrication processes. Details will be discussed focusing on technical aspects peculiar to plasma CVD engineering of diamond NV centers.

Fabrication of High-Density NV Ensemble Using Vacancies Created by Transmission Electron Microscope Kyosuke Hayasaka[1], Kyotaro Kanehisa[1], Tetsuya Tatsuishi[1], Yuta Saito[1], Yuki Ueda[1], Kazuki Otani[1], Takashi Tanii[1], Shinobu Onoda[2], Junichi Isoya[3], Shinpei Enomoto[4], Shozo Kono[4] and Hiroshi Kawarada[1,4]; [1]Waseda University, Japan; [2]QST, Japan; [3]University of Tsukuba, Japan; [4]ZAIKEN, Japan

Negatively charged nitrogen vacancy (NV) center is expected to be a platform for magnetic sensors and quantum communications because of its optically detectable spin properties and long coherence time [1]. One of the most leading application of NV center is magnetic sensor with high sensitivity even at room temperature. Especially, the sensitivity of a magnetic sensing scales with the square root of its quantum coherence time and the total number of NV centers [1]. Thus, enhanced NV concentration while maintaining long coherence times is desired to improve magnetic sensitivity.
Ion implantation is frequently used to increase NV concentration [2]. However, this method results in unwanted paramagnetic defects or charge traps due to knock-on-atoms [3]. Delta-doping with CVD diamond growth is also used to create high density NV ensemble [4]. Yet, this technology has the problem of low N-to-NV conversion efficiency. Therefore, it is an effective approach to maximize N-to-NV conversion efficiency while suppressing damage to the substrate by electron irradiation.
Single-ended accelerator [5] or TEM [6] is used to create vacancies on the substrate with electron irradiation. TEM can adjust the electron irradiation amount per unit time by narrowing the beam diameter. As a result, it is possible to irradiate a high dose of electrons that cannot be achieved by the accelerator. TEM also has the advantage of being easily accessible compared to the accelerator. In fact, several groups have reported using a 200-keV TEM for (100) diamonds, while none have reported for (111) diamonds. Since (111) diamond can incorporate more dense nitrogen atoms than (100) diamond [7], electron irradiation of (111) diamond is promising for the realization of high density NV ensemble. Hence, by irradiating (111) diamond with electrons, we investigated the change in NV density and spin properties in the irradiated region and estimated the magnetic sensitivity.
We irradiated nitrogen-rich ([N]=4×10^{19} [cm^{-3}]) HPHT (111) diamond with electrons using 300-keV TEM (JEOL JEM-3010) because the minimum energy of electrons required to form a defect in (111) diamond is 220-keV [8]. Next, a custom-built laser scanning confocal fluorescence microscope (CFM) was used to estimate the concentration of NV center. We also measured the coherence time of the NV ensemble. We then implemented photoluminescence measurements (RENISHAW inVia Basis) to confirm the presence of vacancy as GR1 center in PL spectrum.
As a result, the PL spectra in the electron-irradiated region showed that the peak intensity at 638 nm, which is the ZPL of , intensified with increasing electron dose. The volume density of the NV center in the NV ensemble increased with increasing electron fluence from 10^{16} to 10^{22} [cm^{-2}], The NV volume density was calculated by comparing the luminescence intensity of the CFM image in the NV ensemble with that of the Single NV center. At a dose of 1.0×10^{22} [cm^{-2}], the NV volume density reached to 8×10^{18} [cm^{-3}], which is one of the highest NV density. The coherence time remained on the order of even when the electron fluence was increased, which is expected to improve the magnetic sensitivity.

Study of Electronic and Optical Properties of NV Centers in Diamond for Sensing Applications—First Principles Density Functional Theory and Experimental Approach Hari P. Paudel[1], Scott Crawford[2], Benjamin Chorpening[2] and Yuhua Duan[2]; [1]Leidos Inc/NETL DOE, United States; [2]U.S. Department of Energy National Energy Technology Laboratory, United States

The nitrogen-vacancy (NV) center in a nanodiamond (ND) crystal is one of the best candidate materials for quantum sensing and metrology at elevated environmental conditions. The NV center can be used to achieve an unprecedented level of sensitivity for sensing applications at high temperatures and pressures. In addition, the NV center is proven to be useful for magnetic field sensing. This opens avenues for applications in the sensing of valuable minerals such as rare earth elements (REEs) in crude and waste subsurface materials which carry free electronic spins locally. In this work, we present our computational and experimental studies on electronic and optical properties of bulk diamond with N impurity and N with a carbon (C) vacancy defect. Experimentally, we encapsulate NDs in MOF/polymer materials. We measure the transverse spin relaxation time of NV center in bare and encapsulated NDs. In order to study the surfaces with shallow NV center that are useful for the quantum sensing applications, we will introduce different doping elements on the surfaces and present surface electronic properties.

9:30 AM *EQ03.03.01
Nanoscale Probing of 2D Magnetic Order Joerg Wrachtrup; University of Stuttgart, Germany

The investigation of magnetic order in 2D materials requires dedicated probes. While conventional probes of magnetism with nanoscale resolution, like Lorenz microscopy or MFM fail for few layer- or monolayer samples, STM requires dedicated sample preparation. NV-based magnetic probes on the other hand are very well suited to provide quantitative data with a few ten nm spatial resolution and sufficient sensitivity, even for monolayer samples. In the talk I will describe experiments on $CrBr_3$ which show the domain structure of the material [1]. Upon imaging material with different number of layers we gained insight into interlayer coupling and it impact on magnetic order. We also measure magnetic order over a wide range of temperatures and derive information on the physics of the phase transition of $CrBr_3$. We also measured CrI_3 samples of different thickness and relative order and find signatures of periodic magnetic order in twisted multilayers. Single Crystal Diamond Growth by Chemical Vapor Deposition for High-End Applications—Recent Trends and State of the Art Matthias Schreck and Theodor Grünwald; University of Augsburg, Germany

In order to profit from diamond's unique material properties for demanding device applications, high quality single crystals are needed. For their synthesis by chemical vapor deposition (CVD) two alternative strategies are currently being explored with great effort. The first is based on homoepitaxy using low-dislocation-density crystals from the high pressure high temperature (HPHT) method as growth seeds. While the obtained crystals excel in terms of highest structural quality, the concept still suffers from limitations in size. In the alternative heteroepitaxy concept, diamond is nucleated and grown on a single crystal surface of a foreign material. Among all potential crystalline materials, iridium has been identified as unique. A major advantage of heteroepitaxy consists in its better scalability which has been demonstrated in 2017 by the realization of a diamond/Ir/YSZ/Si(001) wafer with a diameter of of 92 mm [1]. However, the minimum values in dislocation density ($7\times10^6 cm^{-2}$) and mosaic spread (FWHM: polar 0.03° and azimuthal 0.05°) [2], are still significantly higher than for homoepitaxially grown crystals.
After reviewing the current state of the art, recent and new attempts to reduce the dislocation densities are described. These comprise different variants of epitaxial lateral overgrowth (ELO) and metal assisted termination (MAT).
Next, the properties of threading dislocations in heteroepitaxial diamond as traps for holes and electrons have been investigated. The experimentally derived lifetime values facilitate estimations of the corresponding capture cross sections and extrapolations on critical defect densities for potential applications [2].
Progress in dislocation density reduction and increase in lateral dimensions call for efficient techniques to duplicate the wafers so that the excellent structural properties once achieved on large area substrates can be transferred to new samples. In this context, a new smart-cut process with easy scalability has been developed [3].
In the final part, gain formation as an old and fundamental problem in the application of diamond as solid state ionization chamber for dosimetry of high energy radiation is discussed. A model is presented that can quantitatively explain the formation of gain and its huge variation ranging from less than 1 to more than 10^6 [4].

Development and Optimization of CVD Diamond Growth Processes for Magnetic-Field Sensing Applications Andrew M. Edmonds, Matthew Markham, Pierre-Olivier Colard and Daniel Twitchen; Element Six, United Kingdom

Quantum technologies is attracting significant investment due to the range of potential applications, but behind any new technology are enabling materials. Diamond is one such material and ensembles of negatively-charged nitrogen-vacancy (NV^-) centers constitutes a promising platform for sensing applications utilizing the quantum properties of this defect. However, the sensitivity of present NV^- ensemble devices and the need for diamond material with reproducible properties has the potential to hinder progress toward many envisioned commercial-scale applications.

The work covered in this presentation will address the material-related aspects of these challenges by discussing the progress towards the development of chemical vapor deposition (CVD) growth processes incorporating high substitutional-nitrogen (N_S) concentrations (> 8 parts-per-million carbon atoms), specifically targeted for magnetic-field sensing. Through this optimisation process the effects of N-doping during CVD growth have also been investigated by characterization of the as-grown sample properties, including concentrations of [N_S^0] and [N_S^+], as well as color.

Through detailed study of varying CVD processes for high-[N_S] diamond it is shown that increased nitrogen incorporation does not necessarily result in increased densities of unwanted vacancy-related defects which act as a source of broadband absorption in as-grown CVD diamond (commonly resulting in a brown coloration). Previously suggested correlations between [N_S^+] and the level of broadband absorption, as well as the bands at 360 nm and 520 nm are also investigated and strong links have been established in this study. Measurements of the NV concentration, charge ratio and contrast suggest that these grown-in defects have a detrimental impact on the NV-ensemble properties observed after irradiation and annealing.

This work also investigated the potential to produce material with reproducible as-grown [N_S] at a level of ~16 ppm, to demonstrate increased scale production of plates with improved NV-ensemble properties. NV concentration, NV charge ratio, strain homogeneity, and T_2* after irradiation and annealing were investigated in such material by characterizing a batch of samples treated to create 3.8 ppm of NV centres. The measured NV^- and NV^0 concentrations in these samples varied by less than 7% (1 standard deviation) and exhibited well-controlled strain inhomogeneity, as characterized by NV-strain mapping and (as a proxy) birefringence. The resulting T_2* = 1 µs in material enriched with >99.99% ^{12}C was as expected for the concentration of N, establishing that other sources of decoherence have been controlled. The resulting samples also have a high measured fraction of [NV^-]/[NV] in UV-Vis, which ensures a high optically-detected-magnetic-resonance (ODMR) contrast (>10%), which results in enhanced device sensitivity.

The material reported in this work enables immediate sensitivity improvements for present quantum-sensing devices utilizing bulk samples. Additionally, the progress towards µm-scale thickness layers of equivalent material grown on high-purity substrates for magnetic-field imaging applications will be presented.

11:30 AM EQ19.09/EQ03.06.03
Investigation of Germanium-Vacancy Colour Centre Formation in Nanocrystalline CVD Diamond Rani Mary Joy[1], Paulius Pobedinskas[1], Celine Noel[2], Daen Jannis[3], Nicolas Gauquelin[3], Johan Verbeeck[3], Laurent Houssiau[2] and Ken Haenen[1]; [1]UHasselt / IMO-IMOMEC / IMEC, Belgium; [2]University of Namur, Belgium; [3]University of Antwerp, Belgium

Nitrogen-vacancy (NV) centres in single crystal diamond (SCD) have been extensively investigated as promising platforms for photonics, sensing, imaging, and other applications[1]. However, the constraints with such systems include inferior optical properties of NV centres and limitations in the SCD upscaling process. A promising alternative to the NV centre are the Group IV element (Si, Ge, Sn, Pb) defects in diamond[2]. As nanocrystalline diamond (NCD) has wafer scalability, it is interesting to investigate the colour centre formation in NCD layers. In addition, recent studies have demonstrated GeV as a potential temperature sensor[3].

This study reports *in-situ* germanium-vacancy (GeV) fabrication in NCD on Ge substrates using the microwave plasma-enhanced chemical vapour deposition technique. Detonation nanodiamond seeded Ge substrates are exposed to 1% CH_4 in H_2 plasma at 3000 W and 45 Torr process conditions. We discuss the challenges in such an approach, such as the proximity of deposition temperature to Ge's melting point (937°C) and the absence of a carbide phase at the NCD / substrate interface, potentially limiting adhesion. Nevertheless, the gas-phase plasma etching of the substrate, followed by Ge-vacancy formation in diamond, ensures that the Ge substrate can act as a solid dopant source.
Electron energy loss spectroscopy analysis confirms that carbide phases are absent; instead, an amorphous carbon layer of 2 nm forms at the diamond/substrate interface. Hence, growing thicker NCD films (~ 9 µm) self-separating freestanding GeV incorporated diamond films with dimensions up to 1 × 1 cm^2 can be fabricated. Room temperature photoluminescence (PL) measurements reveal a ~ 602 nm peak characteristic of GeV formation in diamond[4,5]. We also present time-of-flight secondary ion mass spectroscopy (ToF-SIMS) results that confirm Ge incorporation in NCD and discuss the non-uniformities in Ge incorporation in the film with PL mapping supported by the high-resolution ToF-SIMS elemental imaging technique. In addition, we also present studies to achieve uniformly distributed GeV in nanodiamonds via spontaneous nucleation as well as overgrowth GeV formation studies in polycrystalline diamond substrates.

p-Type Diamond/n-Type β-Ga_2O_3 Heterojunctions Fabricated Using Direct-Bonding Technique Phongsaphak Sittimart[1,2], Shinya Ohmagari[1,1], Takashi Matsumae[1], Hitoshi Umezawa[1] and Tsuyoshi Yoshitake[2]; [1]National Institute of Advanced Industrial Science and Technology (AIST), Japan; [2]Kyushu University, Japan

Heterojunctions comprising of p-type diamond substrates and thin exfoliated n-type β-Ga_2O_3 layer were fabricated using direct-bonding technique at a low temperature. Due to using low temperature for the fabrication, formation of p-type diamond/n-type β-Ga_2O_3 heterostructure was, therefore, possible. In this work, p^+-diamond/n-Ga_2O_3 and p^--diamond/n-Ga_2O_3 heterostructures were fabricated using direct- bonding technique. From electrical investigations, p^+-diamond/n-Ga_2O_3 heterostructure exhibited ohmic behavior, resulting from p^+-diamond substrate behaving as a metallic layer. In the case of p^--diamond/n-Ga_2O_3 heterostructure, it showed a rectifying action as a conventional *pn* heterojunctions with turn-on voltage ~ 4.5 V, rectifying ratio $>10^9$ at ±10 V and leakage current < 10^{-12} A. Ideality factor and barrier height of p^--diamond/n-Ga_2O_3 heterojunctions were 2.7 and 1.51 eV, respectively. Electrical comparison between p^--diamond/n-Ga_2O_3 heterojunctions and β- Ga_2O_3 Schottky junctions confirmed that p-type diamond/n-type β-Ga_2O_3 heterojunctions were truly formed using direct-bonding technique. This confirmation is suggesting that lightly doped diamond and β-Ga_2O_3 are preferable to realize the formation of diamond/β-Ga_2O_3 heterojunctions. Energy band diagram of the fabricated *pn* heterojunctions was provided. This work can serve as an important reference for fabrication of diamond/β-Ga_2O_3 heterojunctions for application in future electronic devices operating under extreme conditions such as high-power, high temperature and strong radiation.

Controllable Crystal Plane Curvature of CVD Single Crystal Diamond and Its Boundary Between Single-Crystalline and the Polycrystalline within Adjusted Constrained System Shengyuan Bai, Ramón D. Díaz, Aj Bensman and Elias Garratt; Michigan State University, United States

Great details remain unclear to overcome the challenges in diamond growth using Microwave Plasma Assisted Chemical Vapor Deposition (MPACVD). This research will report the single crystal diamond (SCD) grown in several angled holders designed to achieve better epitaxial lateral outgrowth (ELO) and to maintain an optimized lateral growth rate. Multiple depositions are carried out using angled holders from larger angled pockets to smaller angled pockets. These results in larger size ELO with possible PCD growth, intermediate smooth ELO growth, and inward lateral growth.

All as-grown samples are measured with the X-ray rocking curve (XRC) mapping technique to reveal the crystallographic structural properties, and compared to that of the original substrates. Diamond 400 crystal plane curvature/flatness and morphology, XRC FWHM of 400/113/111 diamond peaks are plotted using self-made analytical software to compare the quality revolution before and after the growth. Quantitative birefringence maps are also taken to present the internal crystal structural defects within the CVD diamond. Other than these, the growth behavior within such kinds of adjusted constrained systems will be analyzed to reveal the preference of atomic level diamond growth.

Mapping results show that CVD SCD grown using wider angled pocket, though with PCD rims, has better flatness (small curvature) and higher average structural quality (small FWHM); Diamond grown with intermediate pocket, with pure SCD growth, also has not only a good lateral growth behavior, but also intermediate crystal morphology and intermediate structural quality; Those are using smaller pocket results area shrink, but with larger crystal plane curvature, indicating the CVD SCD is compressed due to the smaller size of the pocket.

Cross polarized birefringence and quantitative birefringence images of all samples care taken to understand the internal structure of the CVD SCDs.

Thus, an intermediate choice would be the best way for iterative SCD growth to maintain the lateral growth rate and the crystal quality at the same time.

1:10 PM EQ19.10.03
Introducing a Unique Technique for Measuring Electrical Conductivity of Heteroepitaxial Diamond at High Temperatures and Determining the

Activation Energy Maddy Behravan; Converse College, United States

Diamond is an attractive material for high power electronic devices because of its unique properties such as wide band-gap and high thermal conductivity. Heteroepitaxial growth of diamond offers the possibility of making devices over a large surface area. In order to characterize electrical properties of heteroepitaxial diamond and address its suitability for electronic application, a diamond device is fabricated from a nominally undoped heteroepitaxial diamond film. The diamond film was grown using plasma enhanced chemical vapor deposition (PECVD). Here the temperature-dependent DC electrical conductivity s (T) of heteroepitaxial diamond is reported. Owing to its extremely low conductivity at room temperature, measurements of current-voltage characteristics were made between 300 °C and 550 °C.
A particular technique was used to measure electrical conductivity of heteroepitaxial diamond at high temperature, which provided for a precise measurement circuits enabling thermal control with sufficient stability for electrical measurements of very small currents ($<10^{-13}$ A). Ohmic contacts with diamond and procedures for preparing diamond surface will be addressed. In this study, a single activation energy of 1.40 eV is found for the diamond device. The heteroepitaxial diamond conductivity profile closely matches that of previously studied natural Type IIa diamond. A thermally activated electrical conductivity s (T), with single activation energy 1.40 eV, does not match natural diamond, but does match previously studied homoepitaxial diamond, suggesting the presence of electronic states comparable with synthetic diamond.

1:15 PM EQ19.10.05
Porous Boron-Doped Ultrananocrystalline Diamond Grown on Anodized 3D Titanium Grid Laís G. Vernasqui[1], Neidenêi G. Vernasqui[1] and Manuel Rodrigo[2]; [1]National Institute for Space Research (inpe.br), Brazil; [2]Universidad de Castilla-La Mancha, Spain

Porous DDB morphology for the electrochemical oxidation process has been a focus of researches in recent years due to the unique DDB properties as well as the possibility to allow contact between the electrolyte and the material, raising the electrochemical area and enhancing the electrode efficiency. In this context, the film porosity may be controlled from nano to macroporous according to the substrate porosity or using some specific diamond surface post-growth treatment. Regardless of the material porous size or its applicability, it is normal to use a seeding pre-treatment with diamond powder to enhance the diamond growth by chemical vapor deposition (CVD) process. Nonetheless, we are presenting diamond films got without substrate seeding. This approach was obtained with success using titanium dioxide nanotube substrate (DTNT) produced on a titanium grid. This process allowed greater surface control and homogeneity. DTNT is a singular substrate because the formed hydrocarbon radicals originated from the methane/hydrogen mixture are used to grow diamond. From this system, the TiO_2-TiC conversion enables and enhances diamond nucleation, which is also increased by the substrate porosity. Besides, carbide formation avoids the usual hydrogen attack observed on titanium substrate also preventing the titanium hydride evolutions. In this context, this work aiming at the ultranocrystalline boron-doped diamond film growth without seeding on DTNT electrochemically anodized on 3D Ti grid (B-$UNCD_{WS}$/DTNT/Ti_{GRID}). The samples were analyzed physically and morphologically by scanning electron microscopy (SEM), micro-Raman scattering spectroscopy, and X-ray diffraction. Electrochemical characterizations were performed regarding the B acceptor concentration evaluations from Mott-Shottky curves while from cyclic voltammetry the reversibility study in redox pair was performed. The Ti grid (25x25x1 mm) was cleaned in acetone and polished in acid solution. Subsequently, the sample was anodized in a 40oC glycerol solution containing fluoride for 3h under 60 V. The counter electrode was a Pt network as an open cylinder that was able to evolve the Ti grid for both sides assuring their simultaneous anodization. After anodization, the sample was put in a hot filament CVD reactor to grow B-UNCD without the diamond powder seeding process. Diamond growth was also provided on the sample backside following a similar procedure. SEM images confirmed a continuous and uniform 3D film following the substrate morphology for both sample sides. The pore bottoms and walls were covered by ultrananocrystalline diamond in addition to the CVD ballas diamond clusters with their density increase with increasing the film growth time. Also, Raman spectra, as well as XRD diffractograms, confirmed the B-$UNCD_{WS}$/DTNT/Ti_{GRID} quality and crystallinity. Their good electrochemical response with doping level from 10^{18} to 10^{20} $B.cm^{-3}$ and satisfactory reversibility in a redox pair confirmed them as promising new electrode material, mainly for anodes in the electrooxidation process.

Synthesis of Nanodiamond Film by UV Laser Annealing of PTFE Pratik Joshi, Siddharth Gupta, Roger Narayan and Jagdish Narayan; North Carolina State University, United States

Nanodiamond (ND) synthesis by nanosecond laser irradiation has sparked a tremendous scientific and technological interest. Herein we have demonstrated the conversion of PTFE (low thermal conductivity polymer) into NDs by the melting route. Notably, UV laser irradiation of PTFE at low energy densities (0.6-0.8 Jcm^{-2}) was effective for amorphization and subsequent melting of amorphous PTFE to obtain NDs. High energy densities (>1 Jcm^{-2}) generated ablation with minimal control over amorphization and melting. COMSOL simulations yielded a melt regrowth velocity of 5.6 m/s. We also noted that the graphitic content in these NDs may be controlled by altering the number of shots. Finally, this ND film was utilized as a seed layer to selectively generate adherent and dense CVD microdiamond film.

1:25 PM EQ19.10.11
Late News: Scalable Fabrication of Clean Nanodiamonds via Salt-Assisted Air Oxidation—Implications for Sensing and Imaging Tongtong Zhang and Zhiqin Chu; The University of Hong Kong, Hong Kong

Nanoscale diamond particles, generally known as nanodiamonds (NDs), have several outstanding material qualities, offering a wide range of potential for basic science and industrial applications. In particular, a number of optically addressable impurity defects, such as nitrogen-vacancy (NV) centers residing in the diamond lattice, have been deployed for next-generation quantum technologies due to their unique spin properties. Currently, there are mainly two methods for the large-scale fabrication of NDs: “bottom-up” detonation NDs and “top-down” milling of bulk high-pressure high-temperature (HPHT) diamond. It is well known that the raw ND powders (i.e., detonation or HPHT) contain a considerable amount of unwanted impurities [e.g., ultra-small (<10 nm) sized NDs, disordered carbons, metal, and metal oxides], which are naturally introduced during synthesis and processing. And previous reports demonstrated that the non-diamond phases present at the surface of NDs are detrimental to the properties of embedded quantum defects (e.g., NV centers). Therefore, the removal of those impurities becomes a critical step before the ultimate applications of the NDs. Several purification methods, like the air oxidation (at 400 - 600 °C) and wet chemical (e.g., $HNO_3/H_2SO_4/HClO_4$, molten KNO_3) treatments, have been adopted to remove the adsorbed impurities on NDs. Despite the considerable effort devoted to overcoming these challenges, it is still difficult to obtain NDs with a well-defined surface, especially when examined at the individual particle level.
Here, we developed a simple, reliable and reproducible purification method, namely the salt-assisted air oxidation (SAAO) treatment, requiring only one additional pre-step, i.e., mixing NDs with a proper amount of salt crystals (e.g., sodium chloride) prior to conventional air oxidation method. Our inspiration for this method came from the cooking procedure used in the preparation of a well-loved Chinese snack, fried chestnuts with stones. The role of the salt crystals added in NDs powder is closely analogous to that of the stones added in the Chinese snack, and ensures that the NDs (the “chestnuts”) are evenly and thoroughly etched by SSAO. This method rounds the original shard-like shape of the NDs with clean surface, and can be scaled up to permit their manufacture in large quantities. We also investigated the underlying mechanism of the SSAO process, i.e., the “salt-assisted etching atmosphere” would easily etch away non-diamond impurities and significantly accelerate the oxidation of NDs as well. These findings will significantly enhance the scope of these little gemstones in diverse scientific and industrial fields, particularly in demanding areas such as biomedical and quantum sensing requiring

stable and sound surface functionalities.

Diamond Quantum Sensing of Cell Mechanics Quan Li; Chinese Univ of Hong Kong, Hong Kong

The long spin coherence time of NV center electrons make it particularly attractive for bio-sensing applications. The NV centers are particularly sensitive to the magnetic field projected along the NV axis, so that orientation change of a diamond sample (containing NVs) would cause detectable modulation in its optically detected magnetic resonance spectrum, a method known as the vector magnetometry. This method has excellent spatial resolution and measurement sensitivity on the orientation change of NVs in the diamond sample. In the present work, we will discuss a newly developed scheme to investigate the mechanical properties of soft materials using diamond nanoparticles as the quantum sensors. The feasibility of the method is firstly demonstrated using polydimethylsiloxane (PDMS) film and gelatin microparticle. The excellent sensitivity and spatial resolution associated with such a technique enable the disclosure of heterostructured nature of the former, and effect of surface tension in the latter. We then study the mechanical properties of fixed Hela cells using the nanodiamond-sensing-enabled non-local deformation measurement, enabling observation of the competition between elasticity and capillarity upon indentations on cells. The works are carried out in collaboration with Renbao Liu, Yue Cui, Wenghang Leong, Kangwei Xia, and Chufeng Liu. We acknowledge funding from GRF of RGC (Project No. 14300720), CRF of RGC (Project No. C4007-19G); and ANR/RGC (project No. A-CUHK404/18).

Towards Next Generation Diamond-Based Sensor Devices Oliver Roman Opaluch, Lahcene Mehmel, Nimba Oshnik and Elke Neu-Ruffing; Technische Universität Kaiserslautern, Germany

Individual, luminescent point defects in diamond termed color centers are stable, atomically small quantum systems. Such individual quantum systems are extremely sensitive sensors, e.g., for magnetic fields. Their strength is to harness quantum mechanics for ultimate sensitivity and versatility while simultaneously boosting spatial resolution in imaging.
To fully exploit the potential of this novel class of sensors, dedicated diamond materials as well as nanostructures are needed. We here present our work on using large area, heteroepitaxial diamond for sensing applications. We also discuss recent results on integrating diamond with two-dimensional, luminescent transition metal dichalcogenides to establish a hybrid sensor material. The talk will furthermore summarize recent advances in fabricating diamond nanostructures for sensing. In addition to material and process optimization, we employ optimal control algorithms to shape the laser pulses as well as microwave pulses that adress the color center spins.

9:00 AM *EQ19.11.03
Diamond Sensing of Magnetic Transitions and Fluctuations of Nanoparticles Renbao Liu[1,2,2]; [1]The Chinese University of Hong Kong, Hong Kong; [2]THE CHINESE UNIVERSITY OF HONG KONG, Hong Kong

Nitrogen-vacancy (NV) center spins in diamond are good quantum sensors for their long quantum coherence times. In particular, quantum coherence of NV centers can be manipulated even at high temperature. Therefore, we can use NV centers to detect magnetic transitions and fluctuations of nanoparticles for a broad range of materials. Here we will present examples of controlling quantum coherence of NV centers at high temperature, detection of magnetic transitions of single nanoparticles, measurement of magnetic fluctuations near Curier temperatures of magnetic nanoparticles, and methods for improving magnetometry sensitivity near zero magnetic fields (which is important for non-invasive study of magnetic properties of materials).

This work was supported by Hong Kong RGC Collaborative Research Fund Project C4006-17G and was done in collaboration with Q. Li, G.-Q. Liu, C. F. Liu, N. Wang, K. Xia, W.-H. Leong, T. Zhang, X. SESSION EQ19.12: Growth, Doping, Processing and Characterization
Session Chair: Ken Haenen
Tuesday Morning, December 7, 2021
EQ19-Virtual

10:30 AM *EQ19.12.01
Diamond Etching Based on Carbon Solid Solution into Nickel for Wafer and Device Fabrication Processes Norio Tokuda[1], Xufang Zhang[1], Tsubasa Matsumoto[1], Takao Inokuma[1], Christoph E. Nebel[2,1] and Satoshi Yamasaki[1]; [1]Kanazawa Univ, Japan; [2]Diamond and Carbon Applications, Germany

Diamond is expected to be the semiconductor material of the next-generation high-power and high-frequency devices as well as quantum technologies because of its superior physical and electronic properties. Etching is one of the most important techniques for semiconductor wafer and device fabrication processes. The etching techniques for SiC and GaN as next generation power semiconductor materials have been already established. However, the

diamond etching technique has not yet reached the required quality for semiconductor wafer and device processing because of the inherent difficulties arising by its extremely high physical hardness and chemical stability.
Recently, we have reported a novel diamond etching process based on the carbon (C) solid solution into Ni [1-5]. The etching is a solid-solid reaction, which occurs at Ni/diamond interfaces. Therefore, the process can selectively etch diamond surfaces in contact with Ni. We also demonstrated diamond imprint lithography with Ni mold [2] and surface planarization with flat Ni plates [3] based on this novel diamond etching process. Additionally, the diamond etching shows a high etching rate (~10 μm/min) and strong anisotropy [4,5], which is similar to the anisotropic Si etching using KOH solution for device fabrication. This novel diamond etching processes will be introduced in detail.

11:00 AM EQ19.12.02
On the Observation of Mott-Gurney Behavior in Diamond Schottky and PIN Diodes Kelly Woo[1], Mohamadali Malakoutian[1], Manpuneet Benipal[2], Franz A. Koeck[3], Robert Nemanich[3] and Srabanti Chowdhury[1]; [1]Stanford University, United States; [2]Advent Diamond Inc., United States; [3]Arizona State University, United States

Diamond is perhaps the most attractive candidate for ultra-high voltage (multi-kV) power electronics due to its large bandgap (5.47 eV), high breakdown electric field (10 MV/cm), high carrier mobility, high thermal conductivity (10-20 W/cm.K), and low coefficient of thermal expansion (~1.1um/mK) [1]. Thus, the development of diamond Schottky barrier diodes and PIN diodes may lead to much more efficient power electronics. The diamond diodes fabricated in this work have shown superlinear current-voltage curves in the forward bias region following the Mott-Gurney law, allowing for higher on-current densities at lower voltages.
In this work, intrinsic layers of varying thicknesses (~0.5-7um) and n-type top layers of 100nm with up to 5e19 /cm^3 phosphorous doping were grown on (111) and (100)-oriented diamond p+ (type IIb diamond) substrates by Microwave Plasma Enhanced Chemical Vapor Deposition. To fabricate the diode, Ti/Pt/Au was evaporated on the backside of the p+ diamond plate to form an ohmic contact, and depending on the crystal orientation, the circular contacts made to the n-layer on top were either ohmic or Schottky. Because phosphorous incorporation is significantly improved on (111) oriented surfaces as opposed to (100) substrates, the diodes on the (111) substrate have shown PIN diode behavior, whereas the diodes based on the (100) substrates exhibit Schottky diode behavior [3].
In our Schottky devices, we have observed that the turn on characteristics can be analyzed through the thermionic emission equation $J_F=A^*T^2\exp(-q\Phi_B/(kT))[\exp(-qV_F/(nkT)-1)]$, where A^* is the Richardson constant, Φ_B is the Schottky barrier height, and n is the ideality factor [2][3]. However, at higher voltages after turn-on, the current exhibits Mott-Gurney behavior or space charge limited current. Because of the low doping densities in the intrinsic layers of the devices, the total on current at higher bias regions are instead dominated by charge carriers injected from the highly doped adjacent regions as opposed to the intrinsic carriers present in the drift region. As a result, the current can be described by the equation $J_{MG}=(9/8)\varepsilon_0\varepsilon_r\mu V^2/d^3$, where ε_r is the relative permittivity of diamond, μ is the carrier mobility, V is the bias voltage, and d is the drift region thickness [2]. This behavior, a characteristic notable in vacuum diodes, allows for greater current densities at lower forward biases in comparison to traditional diode behavior which typically exhibits linear behavior based in Ohm's law. Diode current increasing as the square of the voltage applied across it should be viewed favorably in power electronics as it may allow for lower voltage operation at equivalent current output, thus leading to lower power consumption and reduction of thermal runaway effects. This observation of Mott-Gurney's law is an indication of highly developed diamond growth techniques producing high quality material, as well as optimized diode fabrication. Additionally, it was observed that as the intrinsic layer thicknesses were increased, the turn on voltage and onset of Mott-Gurney effect was shifted to higher voltages. Also, by elevating the temperature (up to 400ºC) the current was increased due to increased ionized carriers and a lower turn-on voltage was observed. As a result, the onset of Mott-Gurney effect was shifted to lower voltages as well.

Phosphorus Doping Considerations for Controlled Diamond Interfaces Franz A. Koeck and Robert Nemanich; Arizona State University, United States

Diamond based electronics could exploit the unique materials properties (carrier mobilities, breakdown voltage, thermal characteristics) that would enable superior devices in particular for high-power, high frequency applications. Practical solid state devices necessitate n-type and p-type material with controlled properties specifically the doping concentration and its profile, both, in the bulk and at interfaces. Interface or near surface doping properties will also be important for heterostructures. While abrupt doping profiles should provide preferred performance, these abrupt interfaces are not always observed and cannot always be reliably prepared. As a result, graded junctions would then define device characteristics like current flow, switching speed and breakdown voltage. We present results for phosphorus doped homoepitaxial diamond on (111) substrates. The epitaxial layers were prepared by microwave-plasma assisted chemical vapor deposition utilizing a 200ppm trimethylphosphine (TMP) in hydrogen mixture as dopant source in addition to hydrogen and methane to achieve a phosphorus concentration > 1x10^{19} cm^{-3}. With a dual-wavelength pyrometer and optical emission spectroscopy, the in-situ growth characterization was related to results from secondary ion-mass spectroscopy (SIMS), which was utilized to determine the doping profile of the epitaxial diamond layer. Phosphorus doped homoepitaxial diamond layers were grown on intrinsic CVD substrates in various plasma focusing geometries and a relation to the doping profile was established. With enhanced plasma focusing a shift toward a more abrupt doping profile was observed. Optical emission spectroscopy of the phosphorus related signal (930nm) during growth indicated a relation to the doping profile. With dual-wavelength pyrometer temperature measurements a small change (5°C orabout 0.5%) in the growth temperature resulted in a change of about 7% in the doping concentration. These observations indicated the sensitivity of the phosphorus incorporation on the growth temperature and availability of donor species in the reactor. We will further elaborate on the effects of the substrate surface (miscut angle, polishing) on the phosphorus incorporation.

Energy Sciences under award DE-SC0021230.

11:30 AM EQ19.12.06
Analytical Expression of the Fermi Level for Doped and Compensated Diamond—A Tool for the Diamond Electronics Analysis Gonzalo Alba[1], Beatriz Soto[1], Jesus Canas[1,2], Castro P. Villar[1], Rodrigo Alcántara[1] and Daniel Araujo[1]; [1]University of Cádiz, Spain; [2]Institut Néel, France

Diamond outstanding properties make it a promising candidate for its application on high-power rectifying electronic devices. The intrinsic nature of diamond is related to the diamond electronic devices strong dependence on doping, and surface/interface phenomena. The understanding and control of such phenomena is key for the development of reliable electronic devices that can compete with current silicon-based solutions.
The position of the Fermi level is a fundamental parameter that has served for the prediction of the ideal band diagram of electronic devices and is also required for the extraction of some of its fundamental operational parameters. Among others, the Schottky barrier height of metal-diamond junctions can be estimated based on Capacitance-Voltage (C-V) measurements by which the resulting built-in potential is added to the Fermi level to diamond valence band energy distance. For Metal-oxide-diamond structures the ideal flat band voltage is obtained as the metal-diamond Fermi level distance, which allows to identify and estimate the oxide charge net density by comparison to the experimental C-V value. Other techniques such as Kelvin Probe Atomic Force Microscopy or X-ray photoelectron spectroscopy also allows the determination of the Fermi level position and requires theoretical values for the characterization of the diamond electronic phenomena.
Besides its wide application, the calculation for the diamond Fermi level position is commonly made based on numerical calculations. In the present contribution, an analytical expression for the Fermi level on diamond is deduced in order to simplify diamond-based electronic device design and analysis procedures. The limits of this expression, i.e. the validity of the Boltzmann approximation, are discussed and its application to some real cases shown.

Diamond Field-Effect Transistors with Modulation Doping Makoto Kasu[1], Niloy Chandra Saha[1], Seong-Woo Kim[2] and Toshiyuki Oishi[1]; [1]Saga University, Japan; [2]Adamant Namiki Precision Jewel, Japan

Diamond semiconductor can be used to develop high-power devices owing to its wide bandgap of 5.47 eV and superior properties compared to SiC and GaN. Till date, we have demonstrated field-effect transistors (FETs) with NO_2 p-type doping on hydrogen-terminated diamond (H-diamond) with an output power density of 345 MW/cm^2 [1]. However, conventionally doped diamond FET structures have several problems, such as lower hole mobility (μ) (~100 cm^2/V s) in the channel than in the bulk (>1200 cm^2/V s) and degradation of hole channel during lengthy operations. To overcome these limitations, we propose modulation or selective doping in diamond. We separated the NO_2 acceptor impurities from the hole channel on H-diamond using an Al_2O_3 gate insulator layer in the FET structure.
First, we investigated the modulation-doping effect by employing Hall effect measurements of a modulation-doped sample with the structure $Al_2O_3/NO_2/Al_2O_3$ spacer layer/H-diamond by changing the thickness of Al_2O_3 spacer layer. Kenzan Diamonds®, high-quality (001) heteroepitaxial diamonds [2]. The results revealed that the sample with an Al_2O_3 spacer layer thickness of 8 nm exhibited maximum mobility by maintaining high hole sheet concentration. Thus, we observed the effects of modulation doping unambiguously.
Second, we performed temperature-variable Hall effect measurements of the modulation-doped sample and observed that the high mobility and hole sheet concentration were retained until at least 500 K. Thus, the thermal stability was improved. The low temperature dependence of mobility exhibited the characteristics of modulation doping.
Next, we fabricated modulation-doped diamond FETs. The NO_2 p-type doping was performed on the H-diamond surface to form the access channels and on the 8-nm-thick first Al_2O_3 gate insulator layer. The diamond FETs exhibited a maximum drain current density of −627 mA/mm and maximum transconductance of 131 mS/mm. The effective mobility increased to 2465 cm^2/V s near the gate threshold voltage, which was a factor of 3.7 greater than that of the conventionally doped FETs, and was near the highest reported value (3800 cm^2/V s) in the purest form of diamond. The off-drain voltage was –703 V and the on-state resistance was 37.55 Ω mm. Consequently, Baliga's figure-of-merit, an available output power density of the modulation-doped FET, was obtained experimentally as 179 MW/cm^2.

Homoepitaxial Growth Mechanism of Heavily Nitrogen Doped Diamond (111) Films Yuta Nakano[1], Shu Inagaki[1], Kazuki Kobayashi[1], Xufang Zhang[1,2], Tsubasa Matsumoto[1,2], Takao Inokuma[1], Satoshi Yamasaki[2], Christoph E. Nebel[2,3] and Norio Tokuda[1,2]; [1]Graduate School of Natural Science and Technology, Kanazawa Univ., Japan; [2]Nanomaterials Research Institute, Kanazawa Univ., Japan; [3]Diamond and Carbon Applications, Germany

High-quality nitrogen-doped diamond is expected to be applied for power devices and high-sensitive quantum sensors at room temperature [1,2]. For example, for n-channel MOSFETs, to reduce the contact resistance, it is important to use diamond films with high nitrogen concentration ([N]). In addition, for high-sensitive quantum sensors, to improve the sensor sensitivity, it is important to increase [N] involving high [NV^-] with high film quality. However, previous studies have reported that high [N] doping causes nucleation and deterioration of film quality, but the details about nucleation mechanism are not yet known [3,4]. Thus, in this study, we investigated the effect of N-doped growth on nucleation and used lateral growth modes to eliminate nucleation factors other than N-doping [5,6]. Furthermore, we analyzed the nucleation mechanism using first-principles calculations. As a result, it was found that the carbon atoms in the plasma are more easily adsorbed by the nitrogen atoms than the carbon atoms on the substrate. Moreover, by optimizing the N-doped lateral growth conditions, we succeeded in developing a growth technique that suppresses 2D nucleation as much as possible.
Atomically flat diamond surfaces were grown by homoepitaxial lateral growth on HPHT Ib type diamond (111) mesas in order to prevent 2D nucleation and hillocks due to dislocations in the diamond substrate; then homoepitaxial N-doped growth was carried out under N_2/CH_4 = 0 ~ 2000 % for 10 min. The surface morphology was evaluated with a laser microscope and an atomic force microscope. The nucleation mechanism was examined by the potential energy surface (PES) calculation using Octopus as a simulator.

Inverse Design of Multi-Functional Diamond Nanoparticles Using Machine Learning Amanda Barnard and Sichao Li; Australian National University, Australia

Inverse design, which predicts the required structure based on a desired property, is a necessary part of industrial design. Property/structure relationships of materials are far more difficult that the forward structure/property relationships, however, since there could be numerous combinations of materials characteristics that present the same properties and conventional predictions do not distinguish between them. They are even more challenge in nanomaterial design, where the design space is even greater, and materials are prized for their multi-functionality. Optimization based on hypothetical databases predicted using machine learning has shown promise in recent years, but suffers from a high computational cost, lack of specificity, and no guarantees that the optimal nanomaterial has been found. There are simply too many unknown variables (structural characteristics) and not enough known variables (properties) for optimization to be reliable. In this presentation we will describe an alternative approach to inverse design that overcomes each of these limitations. By drawing on the multi-functionality of nanomaterials and using multi-target machine learning methods, we develop a workflow that is fast, easy to use, and predicts the characteristics of a single nanoparticle that simultaneously meets a set of performance criteria, with a fault tolerance. The method focusses the outcome on the most important characteristics in an entirely data-driven way, and with comparable accuracy and generalizability as traditional forward structure/property machine learning predictions. We have demonstrated the new inverse design workflow on diamond nanoparticles, an important platform with significant potential for a range of industrial applications.

1:30 PM EQ19.13.02
Density Functional Theory Study of the Adsorption of Nitric Oxide and Nitrous Oxide on Hydrogen-Terminated Diamond (100) Surfaces Jenille Cruz[1], Michael Groves[1] and Mahesh Neupane[2]; [1]California State University, Fullerton, United States; [2]CCDC US Army Research Laboratory, United States

Diamond's unique geometric and electronic properties have gathered interest, for it can undergo a surface transfer doping mechanism which can then be used to build high-field, high-frequency device applications [1]. Recent experimental evidence suggests that adsorbing NxOy functional groups on hydrogen-terminated diamond surfaces could play an important role in improving device parameters such as current density and threshold voltage [2, 3]. In this research, we performed a computational study on the adsorption of the NxOy functional groups on diamond (100) surfaces using Density Functional Theory (DFT). The adsorption energies were calculated to predict the most favorable structure. Band structures and density of states will be reported to explain the electronic properties of the most favorable system for device design. Nudged Elastic Band calculations will also be reported for the adsorption pathways to form these most stable adsorbate configurations. This research will present several models of NxOy functional groups on diamond (100) surfaces and will provide critical insight into surface electronic properties of the diamond surfaces for surface doped diamond devices.

1:45 PM *EQ19.13.03
Development of Electrochemical Application on Boron-Doped Diamond Electrodes Yasuaki Einaga; Keio University, Japan

Boron-doped diamond (BDD) electrodes are very attractive material, because of their wide potential window, low background current, chemical inertness, and mechanical durability.[1] In these years, we have reported several examples for electrochemical sensor applications.[2] Here, novel microsensing systems for in vivo real time detection of local drug kinetics are reported. Furthermore, applications for electrochemical organic synthesis[3] including CO_2 reduction[4], and electrochemiluminescence (ECL) systems[5] are also reported.

Microsensing system for *in vivo* real time detection of local drug kinetics[2b]

We have developed a microsensing system for *in vivo* real time detection of local drug kinetics and its physiological relevance. The system consists of two different sensors of both a micro-sensor composed of BDD microelectrodes with tip diameter ~40 μm and a glass microelectrode. By using the system, we have first tested bumetanide, a diuretic that is ototoxic but applicable to epilepsy treatment.

CO_2 reduction[4]

We investigated the electrochemical reduction of CO_2 to HCOOH in a flow cell using BDD electrodes. The faradaic efficiency (FE) for the production of HCOOH was as high as 94.7%. The selectivity for the production of HCOOH was more than 99%. Furthermore, recently, by optimizing certain parameters and conditions used in the electrochemical process with BDD electrodes, such as the electrolyte, the boron concentration of the BDD electrode, and the applied potential, we were able to control the selectivity and efficiency with which carbon monoxide is produced.[4c] Recently, an intermittent flow cell system was presented. A stop-start motion of the flow conditions in the intermittent cell was created using a piston pump, and this considerably increases the rate of electrochemical conversion of CO_2 to HCOOH compared to a continuous flow system.[4d]

Electrochemiluminescence (ECL)[5]

A novel coreactant-free electrogenerated chemiluminescence (ECL) system is developed where $Ru(bpy)_3^{2+}$ emission was obtained on BDD electrodes. The method exploits the unique ability of BDD to operate at very high oxidation potential in aqueous solutions and to promote the conversion of inert SO_4^{2-} into the reactive coreactant $S_2O_8^{2-}$. This novel procedure was rather straightforward, not requiring any particular electrode geometry, and, since the coreactant was only generated in situ the interference with biological samples was minimized. The underlying mechanism was similar to that of the $Ru(bpy)_3^{2+}/S_2O_8^{2-}$ system. Furthermore, recently, another ECL system was presented. The system took advantage of the unique properties of BDD to promote oxidation of carbonate (CO_3^{2-}) into peroxydicarbonate ($C_2O_6^{2-}$), which further reacted with water to form hydrogen peroxide (H_2O_2), which acted as a coreactant for $Ru(bpy)_3^{2+}$ ECL.

Fabrication and Characterization of the Boron Nitride/Boron Doped Diamond Heterostructure Avani Patel, Jesse Brown, Kari Slotten, David Smith and Robert Nemanich; Arizona State University, United States

Boron Nitride is an ultra-wide bandgap material with significant potential as an active or dielectric layer in high-power switches, high-frequency transistors, diodes, detectors, and other applications. The cubic phase (c-BN) is a semiconductor with a 6.4 eV bandgap and a near lattice match to diamond. The layered hexagonal phase (h-BN) may perform as a dielectric in hydrogen terminated-diamond field effect transistors. High-quality BN / diamond heterostructures (whether as heteroepitaxial semiconductor or as a gate dielectric) requires a smooth interface. At Arizona State University, we have grown BN thin films on B-doped, p-type diamond substrates using electron cyclotron resonance microwave plasma chemical vapor deposition (ECR MPCVD). By varying the growth conditions, the BN layer can have predominant c-BN or h-BN structure. Results show that a smooth, flat interface can be achieved for layers that are predominantly h-BN, while some c-BN layers show island growth and relatively rough interface structures. The morphology of the interface and growth surface is characterized with optical phase contrast microscopy and cross section TEM. The electrical properties of the mixed phase c/h-BN are electrically characterized using lithographically patterned contacts. Results correlate the growth parameters with the morphology and electrical properties of the c/h-BN – diamond heterostructure.

2:30 PM EQ19.01.03
Phosphorus Incorporation and Its Effects on Residual Stress in Linear Antenna CVD Nanocrystalline Diamond Films Rani Mary Joy[1,2], Paulius Pobedinskas[1,2], Daen Jannis[3,3], Nicolas Gauquelin[3,3], Kamatchi J. Sankaran[4], Fernando Lloret[5], Derese Desta[1], Hans-Gerd Boyen[1,2], Jan D'Haen[1,2], Johan Verbeeck[3,3] and Ken Haenen[1,2]; [1]Hasselt University, Belgium; [2]IMEC vzw, Belgium; [3]University of Antwerp, Belgium; [4]CSIR, India; [5]Universidad de Cádiz, Spain

Owing to its superior mechanical and tribological properties, diamond is an attractive candidate used in various applications, including micro / nanoelectromechanical systems (MEMS / NEMS) [1]. Although single crystal diamond (SCD) has been successfully integrated and used for such MEMS / NEMS based devices, high fabrication costs and limited upscaling hinders its wide industrial usage. Such bottlenecks can be mitigated using nanocrystalline diamond (NCD) and (U)NCD as an alternative. Furthermore, with the availability of large-area diamond deposition systems, such as the linear antenna microwave CVD (LA MW CVD), such (U)NCD based devices can potentially be fabricated on an industrial scale [2]. However, very few studies have reported stress studies, an essential parameter for device integration, in NCD films grown in such systems [3].

In this work, we present residual stress studies in NCD films (~ 250 nm thick) deposited on silicon substrates in the LA MW CVD system. We compare intrinsic and doped films grown in a $H_2/CH_4/CO_2$ plasma and with varying phosphine (PH_3) gas concentrations up to a maximum [P]/[C] ratio of 8090 ppm and substrate temperatures between 400°C and 900°C while maintaining working pressure at 0.23 mbar and MW power at 2800 W process conditions.

Scanning electron microscopy results reveal that under increasing [P]/[C] ratios, the film morphology transitions from NCD with randomly facetted grains to ultra-NCD-like with dendrite features. Similar morphology changes also occur at higher substrate temperatures above 800°C. Raman analysis verifies diamond formation, and the corresponding sp^3/sp^2 bonded carbon ratios correlate well with the associated changes in film morphology. Substrate curvature measurements reveal compressive stress in all the samples in this study, with residual stress decreasing under increasing [P]/[C] concentrations in the plasma and higher substate temperatures. The lowest value of -0.25 GPa is observed for the NCD films grown with a [P]/[C] ratio of 8090 ppm and 900°C substrate temperature. Furthermore, transmission electron microscopy results indicate that additional impurities, such as silicon and oxygen, are present in the deposited films.

Based on the above results, a qualitative relationship between the sp^3 content and projected mean grain size is proposed and the origin and the role of impurities in residual stress evolution in LA MW CVD diamond films is discussed. Finally, X-ray photoelectron spectroscopy results that indicate successful phosphorus incorporation into the carbon matrix for the layers deposited at 900°C are presented.

SESSION EQ19.14: Nanodiamond II
Session Chair: Emmanuel Scorsone
Tuesday Afternoon, December 7, 2021
EQ19-Virtual

4:00 PM *EQ19.14.01
Multicolor Fluorescent Diamond Particles for Multiplexed Imaging and Sensing Olga A. Shenderova[1], Nicholas Nunn[2], Marco Torelli[1], Alexander Zaitsev[3], Alexander I. Shames[4], Alexander Smirnov[2], Carlos Meriles[5] and Ashok Ajoy[6]; [1]Adamas Nanotechnologies, United States; [2]North Carolina State University, United States; [3]College of Staten Island, CUNY, United States; [4]Ben-Gurion University of the Negev, Israel; [5]City University of New York-City College of New York, United States; [6]University of California, Berkeley, United States

Nitrogen is the most common impurity in diamond and forms different types of color centers, particularly via combination of one or more N atoms with vacancies. Traditional production of fluorescent diamond particles focuses primarily on the introduction vacancies via irradiation with high energy electrons and subsequent thermal annealing to promote vacancy diffusion and formation of stable optical centers with N. The N content and state are inherited from diamond synthesis and N rearrangement via diffusion is typically not considered for modifications during traditional post-synthesis processing. As a result, the fluorescent color palette is typically restricted to particles emitting only in red or green, either from NV centers produced in type Ib synthetic diamond containing single N atoms, or NVN centers produced in type Ia natural diamond containing N pairs, respectively. Recently, we

demonstrated that ultra-high temperature annealing (>1500 °C) facilitating N diffusion in the lattice, generates conditions for the controlled formation of one-, two- and three-atom nitrogen complexes with vacancies in electron irradiated type Ib synthetic diamond, providing vibrant luminescence in the red (NV), green (NVN) and blue (N3 centers) spectral ranges [1]. Remarkably, this treatment also enhanced the optically induced ^{13}C hyperpolarization [2], which promotes a new paradigm in dual-mode fluorescence/magnetic resonance imaging enabled by multicolor fluorescent nanodiamonds [3]. Ultra-high temperature annealing also significantly impacts the quantum properties of NV centers, leading to increased spin-lattice (T1) and spin-spin (T2, T2*) coherence times, increased ODMR contrast, and magnetically induced fluorescence contrast. This opens routes for multiplexed labeling in combination with sensing when NV centers coexist with NVN or N3 centers within individual particles. We discuss opportunities for nano- and microparticulate diamond in a number of imaging and sensing applications in biological and industrial fields based on controlled and reproducible formation of specific color centers previously not possible in type Ib synthetic diamond.

4:30 PM EQ19.14.02
Surface Functionalized Nanodiamond with Protein Repulsion and Targeting Capabilities Viktor Merz and Anke Krueger; Julius-Maximilians-Universität Würzburg, Germany

The chemical, physical and biological properties of a material are strongly related to its surface. For nanodiamond (ND), this holds true as well. And its surface can be modified easily using its broad variety of surface groups.[1] Thus, ND is attractive for applications in biological environments as it also possesss high biocompatibility and low toxicity. Further, it is available in large quantities and additional characteristics, such as luminescence from lattice defects make them candidates for applications such as imaging, drug delivery etc.

However, when nanoparticles are dispersed in typicyl cell culture media or body fluids, proteins from these media are adsorbed and a so-called “protein corona” forms around the particles. This corona can mask the actual functional moieties of the surface and is rather strongly attached by non-covalent interactions. Both, the colloidal stability and the physiological properties are not controllable anymore.[2]
Here, we report nanodiamond functionalized with a multifunctional surface termination,[3] consisting of zwitterionic moieties as headgroups in combination with oligoethylene glycol chains attached to hydrophobic chains to improve the colloidal dispersion in buffered cell culture media and the prevention of protein corona formation. Further, the attachment and effect of other charged surface groups such as small peptides will be discussed.
This project has received funding from the Volkswagenstiftung under Grant Agreement no. 88393

Direct and Quantitative Characterization of Detonation Nanodiamond Dispersion in Biomedical Relevant Media Using Cryo-TEM Shery L. Chang, Inga Kuschnerus and Haotian Wen; University of New South Wales, Australia

Detonation nanodiamonds (DNDs) are diamond nanoparticles synthesized through detonation process with a size-range of 3-5nm. Their small size, non-toxicity and biocompatibility has drawn huge interests, particularly in the biomedical field. To capitalize the large total surface area and flexible surface chemistry afforded by the unique particle size and surface structure, understanding the DND dispersion behaviour has been one of the endeavours to improve their application potential in the biomedical field.
We have recently shown that purified DNDs dispersed in water, without any additional surface modification, exhibit a striking lacey network-like morphology, formed dynamically by self-assembled chain-like structures. This discovery was carried out using direct cryo-TEM imaging of the DND dispersions. Moreover, using cryo-TEM electron tomography, we found that there is a preferential orientation of the DND aggregates that results in a 2-D planar superstructure. These new findings have significant impact on the performance of DNDs, particularly for biomedical applications. For example, in drug delivery applications, the monodispersed DNDs offer higher surface area that can promote drug loading whereas the formation of aggregate can slow down the release.
In light of the importance of the DND dispersion and their aggregate morphology distributions to the biomedical applications, we have conducted a systematic study of purified and surface functionalized DNDs dispersed in biomedically relevant media with varying pH and saline content. The large datasets generated in our studies using cryo-TEM was analyzed using our recently developed machine learning (ML) based approach. The ML analysis from cryo-TEM datasets on DND assembly will offer direct and quantitative information regarding the aggregation behavior as well as its size and morphology distribution in biomedical relevant media which is a crucial step towards a better design of DNDs for biomedical and further applications.

5:15 PM EQ19.14.04
Enhancement of Thermal and Structural Properties of Diamond Nucleation on GaN HEMTs Mohamadali Malakoutian[1], Kelly Woo[1], Shubhra Pasayat[2] and Srabanti Chowdhury[1]; [1]Stanford University, United States; [2]University of California, Santa Barbara, United States

The significantly high thermal conductivity of diamond up to 2200 W/m.K makes it an ideal choice for heat spreading applications by integration to high-frequency high-power devices such as GaN high-electron-mobility-transistors (HEMTs). One of the approaches for diamond integration to GaN HEMTs is chemical vapor deposition (CVD) of polycrystalline (PC) diamond on top of the device [1]. PC diamond has a lower thermal conductivity (100-1000 W/m.K) compared with single crystal diamond depending on its average grain size [2]. However, this lower thermal conductivity is still higher than any other competing materials such as Si_3N_4, GaN, AlGaN, and SiC. Besides thermal conductivity, the thermal boundary resistance (TBR) between the diamond heat spreading layer and GaN device is a key property which determines diamond cooling capabilities, as it can change the whole GaN channel thermal resistance. The smoothness/abruptness of the interface between diamond and GaN along with the nature of diamond nucleation during the CVD growth defines the TBR value.
Due to the presence of high temperature H_2-plasma in the CVD chamber during diamond growth, it is challenging to grow diamond without any protection layer on top of the GaN. This protection layer (MOCVD-grown Si_3N_4) not only protects the GaN channel from exposure to H_2-plasma and decomposition but also enhances diamond adhesion to the substrate by promoting covalent bonding. Carbon diffusion inside the Si_3N_4 replaces some of the nitrogen atoms ($2N + 3H_2 \leftrightarrow 2NH_3$) and transforms a portion of this layer to SiC which forms covalent bonds with diamond [3]. However, it is essential to identify which carbon state is nucleating on SiC in the first 1-2 nm of the diamond nucleation layer. It can be amorphous carbon (sp^2 a-C) or sp^3 diamond depending on the nucleation recipe before the main growth. The ideal case is to nucleate sp^3 carbon states on SiC as it yields a lower thermal resistance at the interface. In this work, we identify the local carbon state by using scanning tunneling electron microscopy (STEM) to perform electron energy loss spectroscopy

(EELS), a technique which studies the excitations from the 1s orbital of carbon to the states above the Fermi level (K-edge) [4]. This study showed that by using a low-density CH_4/H_2-plasma and high temperature (> 700 ºC) for diamond nucleation, a monolayer of sp^2 a-C is first formed on the surface and then the carbon state gradually transforms to sp^3 diamond. With this nucleation method, carbon only diffused ~1 nm inside the Si_3N_4 protection layer. On the other hand, when using a high density CH_4/H_2-plasma at lower temperatures (~ 600 ºC) no a-C peak was observed on the K-edge intensity mapping spectra and sp^3 carbon immediately nucleated on SiC layer. In this sample carbon diffused into the Si_3N_4 layer ~ 5 nm due to the highly energized CH_3^+ radicals in the chamber. According to the Si_3N_4 thickness before the diamond growth and the target use of the remaining portion of the Si_3N_4 we can select accurate plasma parameters (microwave power, chamber pressure, CH_4concentration, and sample surface temperature) for the nucleation stage of the diamond growth. Our nucleation recipe achieved both strong adhesion of the diamond to the substrate and low thermal resistance interface formation enabling high efficiency channel cooling capabilities at higher power levels.

Synthesis and Processing of Chemically Stable V_2CT_x MXene with Improved Properties Kyle Matthews, Teng Zhang, Christopher E. Shuck, Armin VahidMohammadi and Yury Gogotsi; Drexel University, United States

Two-dimensional (2D) transition metal carbide and nitrides, MXenes, exhibit promising properties in different applications such as energy storage, sensing, and optoelectronics, to name a few.(*1*) These materials have a general formula of $M_{n+1}X_nT_x$ where M is a transition metal, X is carbon and/or nitrogen, and T_x represents surface functional groups on the outer layers. Since the discovery of MXenes in 2011, research has mainly focused on $Ti_3C_2T_x$ because of its established synthesis protocols and high chemical stability, while investigation of other experimentally made, stoichiometric MXenes has been trailing behind. Among other MXenes, M_2XT_x MXenes such as Vanadium carbide (V_2CT_x) promise exceptional theoretical properties due to the increased active surface area in M_2XT_x MXenes and the multiple available oxidation states in Vanadium systems. Despite its attractive properties, however, research related to V_2CT_x has mostly been limited to its multilayered state due to rapid oxidation after delamination. Herein, we have developed improved etching and delamination protocols through formulating new etchants and intercalants to increase the yield of synthesis and prepare high-quality and less defective V_2CT_x flakes. Furthermore, we show that through post-processing protocols the shelf life of delaminated V_2CT_x dispersions can be extended from only a few hours to multiple months with almost no degradation. Various characterization techniques such as X-ray diffraction (XRD), scanning electron microscopy (SEM), UV-Vis, and thermogravimetric analysis were used to investigate the synthesized materials. The combined synthesis and post-processing protocols presented here result in high quality and chemically stable V_2CT_x that shows improved electronic properties.

Selective-Area van der Waals Epitaxy of h-BN/Graphene Heterostructures via Defect-Engineering Using Focused He Ion Beam Joao Marcelo Lopes[1], Martin Heilmann[1,2], Victor Deinhardt[3,4], Abbes Tahraoui[1] and Katja Höflich[3,4]; [1]Paul-Drude-institut für Festkörperelektronik, Leibniz-Institut im Forschungsverbund Berlin e.V., Germany; [2]IMEC, Belgium; [3]Ferdinand-Braun Institut gGmbH, Leibniz-Institut für Höchstfrequenztechnik, Germany; [4]Helmholtz-Zentrum Berlin für Materialien und Energie GmbH, Germany

Van der Waals (vdW) heterostructures combining dissimilar 2D materials offer a great prospect for the realization of atomically thin devices with tailored properties [1]. To achieve a high density, bottom-up integration, the synthesis of such heterostructures via vdW epitaxy is a promising alternative to mechanical transfer, which is problematic in terms of scaling and reproducibility. Nevertheless, due to the weak bonding between 2D crystals, vdW epitaxy is sensitive to various surface defects, usually leading to uncontrolled nucleation and thus non-uniform growth of polycrystalline material [2]. Hence, the control over nucleation location is considered to be one of the key challenges to achieve scalable and high-quality fabrication of 2D heterostructures [3]. In this contribution, we report on the use of focused ion beam (FIB) within a He ion microscope [4] as a novel tool to deliberately create atomic scale defects in graphene on SiC(0001), which act as nucleation sites for atomically h-BN grown via molecular beam epitaxy. Thereby, we demonstrate a mask-less, selective-area growth of h-BN/graphene heterostacks, in which nucleation yield and crystal quality of h-BN is controlled by the ion beam parameters used for the defect formation. The epitaxially grown h-BN exhibits electron tunneling characteristics comparable to those of h-BN flakes exfoliated from high-quality bulk crystals [5]. Our results open a new pathway for the scalable fabrication of not only h-BN/graphene systems, but also of other vdW heterostructures composed of 2D materials that can be synthesized via vdW epitaxy, such as layered semiconductors [3] and ferromagnets [6].

Design and Fabrication of Boron-Rich 2D MXene Flakes for High Efficiency Neutron Absorption Shi-Hyun Seok, Ju-Hyoung Han, Young Ho Jin, Jaewon Wang, Jaeeun Park and Soon-Yong Kwon; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Neutron radiation is extremely hazardous because it can induce radioactivity in most irradiated substances, including body tissues. Therefore, construction of effective nuclear reactors and repositories with appropriate neutron shielding or absorption measures to prevent exceeding nuclear criticality is necessary. B_4C is widely used as a neutron-shielding material for reactor systems because of its high neutron-absorption efficiency (i.e., neutron-absorbing cross section for ^{10}B). Several composites such as borated stainless steel, B_4C-reinforced Al, and B_4C-reinforced polymers have been developed. However, the practical application of these composites in the fabrication of containers or casks is limited because of their low B content and insufficient workability. In addition, their relatively thick thickness (> 1 cm) required for sufficient neutron shielding severely hinder the light-weight application. Two-dimensional (2D) transition metal carbides, namely MXenes, have recently attracted considerable attention for several applications because of their large surface area, good mechanical properties, and the presence of numerous chemically active sites. The layered structure and surface functional groups of MXenes facilitate the formation of large interlayer spaces and confer high interfacial strength, respectively. In our work, 2D $Ti_3C_2T_x$ (T refers to surface termination group) MXene flakes were chosen to cooperate with B_4C neutron absorbing powder to fabricate hierarchically layered composite films by vacuum filtration. Through the control of particle sizes and resultant electrostatic repulsion, a homogeneous dispersion of MXene flakes and B_4C powder, both with negative surface charges, was obtained. By the self-intercalation of the submicron B_4C powder between the vacuum-filtrated 2D MXene flakes with sufficiently large lateral sizes up to several micrometers, a hybrid film was successfully developed. Notably, the film showed a wide range of boron capacity (20–60 wt%) and the B_4C reinforcements were uniformly dispersed in the MXene flakes, forming multi-interfacial layers: this was facilitated by the van der Waals interactions and the hydrogen bonds formed upon the addition of a small amount of an organic binder. The free-standing hybrid film exhibited excellent neutron absorption ability (with an absorption capacity of ≈39.8 %) at an ultralow thickness (< 40 μm), leading to a macroscopic cross-section of ≈127.6 cm^{-1}, which is the highest value among the previous reports on boron-based neutron shielding materials to date (typically, 1-34 cm^{-1}). Moreover, the mechanical flexibility of 2D films and simple processing showed the possibility for shielding surfaces of any shape with reduced net weight and volume. Thus, the as-prepared film can be used as an efficient neutron-absorbing coating material not only in nuclear repositories, but also in other fields requiring accurate shielding such as spacesuit, radiation medical, and neutron transmutation doping.

Engineering High-Mobility 2D In_2O_3 Semiconductors Printed From Liquid Metals Andrew B. Hamlin, Youxiong Ye, Julia Huddy, Md Saifur Rahman and William J. Scheideler; Dartmouth College, United States

2D conducting metal oxides offer outstanding optoelectronic properties for applications in sensing, microelectronics, and flexible electronics. Here, we unlock the ultra-high electron mobility of 2D oxides formed by a rapid, liquid-metal (LM) printing process that transfers ultrathin (~ 2 nm), crystalline monolayers and bilayers of In_2O_3 at low temperatures just above the melting point of indium (156 °C). We demonstrate the use of quantum confinement and low-temperature post-annealing to control the electronic density of states (DOS) of the 2D In_2O_3, fabricating thin-film transistors with ultrahigh mobility (μ_0 > 65 cm^2/Vs) at linear printing speeds from 0.6 to 36 meters/min.

LM-printed monolayer and bilayer InO_x were characterized by XRD and TEM to understand their thickness-dependent crystallinity. The films exhibit a mixture of large crystalline domains (20-40 nm, laterally) of cubic In_2O_3 and amorphous regions as deposited. Post-annealing at temperatures from 150 to 250 °C further enhances the crystallinity and grain size, as observed via the (222) cubic peak as well as through TEM imaging and diffraction patterns. UV-Vis measurements indicate that this post-annealing regulates the Burstein-Moss shift in the optical bandgap, lowering the free carrier concentration and leading to positive threshold voltages in high-performance 2D transistors. To our knowledge, this is the first report of such scalable (30 cm^2) device integration of these atomic-scale 2D oxides at deposition temperatures broadly suitable for high-performance flexible electronics.

2:30 PM EQ20.01.05
Preparation and Patterning of 2D MoS_2 from Solution-Processed Precursors Using EHD Jet Printer Thi Thu Thuy Can and Woon-Seop Choi; Hoseo University, Korea (the Republic of)

Recently, transition-metal dichalcogenides (TMDs) have attracted much attention as new materials for electronics devices, electrocatalysts, photocatalysts, sensors, batteries, and bio-applications. Most TMDs are two-dimensional (2D) materials with a single layer. Bonds between each layer are made up of Van der Waals bonds, while intra-layer atoms bind together as covalent bonds.

Chemical vapor deposition (CVD) with sulfur gas is the most popular method for synthesizing large- scale 2D materials with high quality. Various MoS_2 can be obtained from this meth[od using various precursors with different properties, process temperatures, and substrate materials. Solution process methods show advantages for preparing films with large size, high throughput, low cost, thickness control, and an environmentally friendly process. Even though there is sulfur in the precursors of the solution-process synthesis methods, supplementing the sulfur that is lost in the high-temperature CVD process is unavoidable.
We developed a unique solution process to obtain large-size and uniform MoS_2 atomic layers without CVD (CVD-free). MoS_2 atomic layers could be fabricated using the S-rich precursor solution and one-step annealing. The sulfurization process is omitted to simplify the entire process, and wafer-scale and larger-scale synthesis of MoS_2 can be achieved by simple thermal treatment. The atomic layers of the synthesized MoS_2 were identified as 2 layers for 0.0070 M, 3 layers for 0.0125 M, and 5 layers for 0.0250 M of MoS_2 solution by STEM-FIB. MoS_2 patterns were made at a resolution of around 150 µm with highly uniform coverage using electrohydrodynamic (EHD)-jet printing for the first time. The EHD jet-printed MoS_2 TFTs show good electrical properties of 19.4 $cm^2\ V^{-1}\ s^{-1}$.

Going Where Silicon Cannot Reach—Print-in-Place and Recyclable Electronics from Low-Dimensional Nanomaterials Aaron D. Franklin; Duke University, United States

For decades we've been hearing about the promise of printing electronics directly onto any surface. However, despite significant progress in the development of inks and printing processes, reports on fully, direct-write printed electronics continue to rely on excessive thermal treatments and/or fabrication processes that are external from the printer. In this talk, recent progress towards print-in-place electronics will be discussed; print-in-place involves loading a substrate into a printer, printing all needed layers, then removing the substrate with electronic devices immediately ready to test. A key component of these print-in-place transistors is the use of inks from various nanomaterials, including: 2D graphene and hexagonal boron nitride, 1D carbon nanotubes, and quasi-1D silver nanowires. Using an aerosol jet printer, these mixed-dimensional inks are printed into functional 1D-2D thin-film transistors (TFTs) without ever removing the substrate from the printer and using a maximum process temperature of 80 °C with most processing occurring at room temperature. To achieve this, significant advancements were made to minimize the intermixing of printed layers, drive down sintering temperature, and achieve sufficient thin-film electrical properties. Devices are demonstrated on various substrates, including paper, and evidence of the potential for printing directly onto biological surfaces will be shown. What's more, recent progress towards a completely recyclable printed transistor will be discussed, fabricated entirely using nanoscale carbon-based inks. These demonstrations give evidence for an electronic future involving devices with fabrication and/or function that goes beyond what is possible with silicon-based technologies.

SESSION EQ20.02: Physical Properties in 2D Materials I—Ferroelectricity, Magnetism and Beyond

Study of Novel Mixed Metallic Chalcophosphates van der Waals System—$Fe_{2-x}Co_xP_2S_6$ Matthew Cheng[1], Yea-Shine Lee[1], Daniel Chica[1], Eric Qian[1], Abishek Iyer[1], M. Arslan Shehzad[1,2], Roberto dos Reis[1,2], Mercouri G. Kanatzidis[1] and Vinayak Dravid[1,2,3]; [1]Northwestern University, United States; [2]Northwestern University Atomic and Nanoscale Characterization Experimental (NUANCE) Center, Northwestern University, United States; [3]International Institute for Nanotechnology (IIN), Northwestern University, United States

The metal chalcophosphates (MPX3) are layered van der Waals materials that have recently gained attention due to their intrinsic magnetic properties. These systems are composed of [P2X6]4- bipyramid anion units, where each P is tetrahedrally bonded to three chalcogen atoms. These anion units are surrounded in a honeycomb arrangement by metal cations, where each metal cation site is octahedrally coordinated to chalcogen atoms. By incorporating different metal cation species into the available octahedral sites different magnetic phases can be induced. Among the metal chalcophosphates, Fe2P2S6 and Co2P2S6 are known for their interesting magnetic properties. Fe2P2S6 is unique as it exhibits out-of-plane orientation magnetic moments when cooled under its Neels temperature. In contrast, Co2P2S6 exhibits in-plane alignment of magnetic moments. However, mixing these metallic cations Fe2-xCoxP2S6 has not been studied yet. This mixed metallic system can be used as a platform to study new form of magnetic states through magnetic frustration.
Here, we present a thorough investigation of the mixed Fe2-xCoxP2S6 system and study the structure, chemical states, and magnetic behavior as the Fe:Co is varied. A novel flux method is used which enables us to synthesize a series of Fe2-xCoxP2S6 with different Fe:Co (1:0, 7:1, 1:1, 1:7, and 0:1). Elemental studies have confirmed the single crystals stoichiometry of these mixed cation systems. This was further supported by structural analysis which confirms a linear expansion of the lattice from Co to Fe.All of the mixed metal cation systems exhibits a transition from a paramagnetic to antiferromagnetic state when cooled beneath each system's Neels temperature. Interestingly, we found a dependence of the transition temperature to the ratio of Fe:Co. Furthermore, this dependence is confirmed by the electronic structural behavior which showed two distinct work functions in the Fe2-xCoxP2S6 system. This strong correlation is likely linked to a distinct ordering that is apparent from high resolution electron energy loss spectroscopy. This work provides an in-depth road map for the investigation of mixed metallic cation chalcophosphates and can be utilized as a resource for future studies on low dimensional materials in next generation electronic devices.

Computational Discovery and Investigation of Two Dimensional Ferroelectric Materials Mo Li, Olamide Omisakin, Hao Mei and Joshua Young; New Jersey Institute of Technology, United States

Two dimensional materials with ferroelectricity (i.e., having a switchable spontaneous electric polarization) have recently been proposed as components for ultrathin electronic devices. However, such materials with large out-of-plane polarizations, ideal for such applications, are challenging to find. Recently, Chandrasekaran et al. proposed that the functionalized MXene Sc_2CO_2 has a metastable state with an out-of-plane electric polarization larger than other common 2D ferroelectrics. [1] In this work, we used density functional theory (DFT) calculations to investigate additional M_2CX_2 materials (M = Sc, Y, La

and X = O, F). We found that (1) chemical substitution of Sc with Y and/or O with F can preferentially stabilize the ferroelectric phase as the ground state (with the dynamic stability verified with phonon calculations); (2) such substitution can also be used to systematically tune the polarization and band gap; and (3) these monolayers display large piezoelectric coefficients. We then demonstrate how these properties can be continuously tuned by the application of external strain or by alloying to create $Sc_2Y_{2(1-x)}CO_2$ monolayers. These findings demonstrate that, as with traditional bulk ferroelectrics, chemical substitution and external stimuli are powerful ways to stabilize and control the properties of low dimensional ferroelectric materials. Finally, we extend this to new families by using a high throughput DFT approach to scan through a database of 2D materials and compute their polarization to find and verify new 2D ferroelectric materials with out-of-plane polarizations.

Intrinsic Stacking Disorder in Exfoliated $MoTe_2$ Due to Dimensional Confinement James L. Hart[1,1], Myung Geun Han[2], David Hynek[1,1], Elisabeth Bianco[3], John A. Schneeloch[4], Yu Tao[4], Despina Louca[4], Lena Kourkoutis[3], Yimei Zhu[2] and Judy Cha[1,1]; [1]Yale University, United States; [2]Brookhaven National Laboratory, United States; [3]Cornell University, United States; [4]University of Virginia, United States

T-type $MoTe_2$ has drawn increasing attention due to properties such as extreme magnetoresistance, exotic superconductivity, and non-trivial band topology. In bulk, $MoTe_2$ undergoes a layer stacking transition from the 1T' to the T_d phase at T_c ~ 250 K, which alters the topology (higher-order topological insulator to Weyl semimetal) and induces ferroelectricity. Determining the layer stacking in thin film $MoTe_2$ is essential for device applications, but to date, the stacking remains poorly understood in nanoscale $MoTe_2$ samples. Here, we present *in situ* cryogenic transmission electron microscopy (cryo-TEM) measurements of exfoliated $MoTe_2$ flakes from 17 to 700 K, complemented by quantitative multi-slice simulations, electrical transport measurements, and Raman spectroscopy. Across the studied temperature range of 17 – 700 K, we find that the layer stacking in exfoliated $MoTe_2$ flakes is highly disordered, with nanoscale 1T' and T_d domains, as well as regions with seemingly random stacking. With cooling to 17 K (230 K below the bulk T_c), there is a modest increase in T_d-type stacking, but the stacking remains mainly disordered. Through comparison with measurements of exfoliated WTe_2 flakes – which retain the same T_d stacking found in bulk WTe_2 – we argue that the observed disorder in $MoTe_2$ is not due to mechanical exfoliation. Instead, we argue that the observed disorder is an intrinsic effect of dimensional confinement. The observation of highly disordered stacking in exfoliated $MoTe_2$ has significant implications for the interpretation of superconductivity, giant nonlinear hall effect, and other exotic properties measured in thin $MoTe_2$ flakes.

4:45 PM EQ20.02.05

Electrically Detected Phase Transition of Two-Dimensional Ferromagnetic Insulator by Proximity Effect with Graphene Tuan K. Chau[1], Sung J. Hong[2] and Dongseok Suh[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Kangwon National University, Korea (the Republic of)

Since monolayer graphene was discovered and its electrical transport properties were well studied [1-3]. The graphene field effect transistor (FET) was used for probing the oxygen vacancies of $SrTiO_3$ substrate, studying the interface with a ferroelectric substrate, or detecting the hidden localized states at the interface with h-BN [4-6]. Recently, various 2D magnetic materials ($Cr_2Ge_2Te_6$, CrI_3, Fe_3GeTe_2, etc.) were reported [7-9]. With van der Waals type of the material, its heterostructures have been extensively investigated, demonstrating their fundamental properties and prototypical devices [10,11]. In this study, we have investigated proximity-coupling between 2D magnet ($Cr_2Ge_2Te_6$, CGT) and graphene. The transport parameters such as hysteresis in back-gate voltage sweep, carrier density, and mobility were abruptly changed at a temperature around ~60 K corresponding to Curie temperature (T_C) where CGT transfer from paramagnetic to ferromagnetic phase. In addition, the quantum Hall state of graphene with filling factor n = 6 similarly shows critical occurrence near T_c, which can be attributed to the additional contribution of magnetization. These results imply that graphene can be utilized to monitor the magnetic phase transition of the adjacent CGT layer. Therefore, graphene-based vdW heterostructures is expected to become a novel electrical platform for exploring various phases in 2D magnetic insulators.

Atomistic Spin Textures On-Demand in the van der Waals Layered Magnet CrSBr Julian Klein[1], Thang Pham[1], Joachim D. Thomsen[1], Jonathan Curtis[2], Michael Lorke[3], Matthias Florian[3], Alexander Steinhoff[3], Ren Wiscons[4], Jan Luxa[5], Zdenek Sofer[5], Frank Jahnke[3], Prineha Narang[2] and Frances M. Ross[1]; [1]Massachusetts Institute of Technology, United States; [2]Harvard University, United States; [3]Institut für Theoretische Physik, Germany; [4]Columbia University, United States; [5]University of Chemistry and Technology Prague, Czechia

The observation of long-range magnetic order in van der Waals layered materials down to the monolayer limit has sparked great interest for the study of low-dimensional magnetism. [1] However, the air-sensitivity of conventional magnetic layered materials like CrI_3has hindered further nanoscale investigation. Recently, CrSBr [2] has been rediscovered: it is a layered magnet that shows air stability and therefore presents exciting opportunities for atomistic measurements and manipulation. CrSBr is a semiconductor with a bandgap of approximately 1.6 eV. It has a high Néel temperature of 145 K and shows strong light-matter interaction, which makes this material interesting for the study of magneto-transport and magneto-optical excitations. [3, 4] Here, we establish CrSBr as a material platform that allows unprecedented nanoscale control over structural and therefore magnetic properties. Layered materials in general offer a myriad of degrees of freedom to tailor the crystal structure down to the single atom scale. In the case of CrSBr, we find that controlled irradiation with electrons in a scanning transmission electron microscope induces a local phase transformation. [5] The transformed material is also a 2D layered structure, but its layers are perpendicular to those in the original material. We investigate the mechanism of the phase transformation by tracking individual atom column intensities as well as local strain, column by column. We find that the phase transformation occurs through Cr atom migration into the van der Waals gap and we show examples of twin boundaries and grain boundaries, controlled knock-out of rows of Cr atoms, and moiré twisted CrSBr. Ab-initio and spin-wave theory suggest that the individual layers in the new phase are magnetic, and the material has an energy gap and a fully spin-polarized band structure. We therefore anticipate that directing this phase transformation at the atomic scale can create spin textures with specific properties that could be tailored towards applications. Overall, we propose that CrSBr and other air-stable magnets with similar crystal structure will become unique platforms for the design, measurement, and application of nanoscale magnetic textures.

Ferromagnetic Quasi-One Dimensional van der Waals Lattices—A New Platform Towards Freestanding Magnetic Nanowires Yi Qu[1], Maxx Arguilla[1], Qiang Zhang[2] and Mircea Dinca[1]; [1]Massachusetts Institute of Technology, United States; [2]Oak Ridge National Laboratory, United States

The demand towards accessing one-dimensional (1D) magnetic nanostructures has grown tremendously—as driven by numerous discoveries of novel physical properties in these systems as well as their integration into next-generation data storage devices and bioengineered artificial organelles. However, with current bottom-up synthetic pathways, achieving precise control over crystallinity, long-range morphology, and surface termination in magnetic nanowires, especially as they approach the Angstrom size regime, remains challenging. In this talk, we will describe our recent efforts in developing a new material platform to access freestanding ferromagnetic nanowires from top-down routes. We realize this by exfoliating a unique class of bulk magnetic crystals comprised of quasi-1D inorganic chains that are predominantly held together by van der Waals (vdW) forces. Based on these quasi-1D vdW crystals, we establish the intrinsic magnetic anisotropy in the bulk structure *via* powder neutron diffraction and demonstrate that these bulk 1D vdW crystals can be readily exfoliated into 10 ± 2.8 nm thick nanowires using solution-phase exfoliation. As expected from exfoliating a vdW lattice, the resulting nanowires possess cylindrical cross-sections with negligible anisotropy and surfaces that are resistant towards oxidation in ambient conditions. We find that the reduction in size of the bulk crystal, upon exfoliation into long and thin nanowires, directly decreases the magnetic ordering temperature of these phases and results to a significant increase in both the coercive field and remanence, both of which are the hallmarks of a hard ferromagnet. Overall, these findings collectively demonstrate the adaptability of well-established exfoliation methods into new classes of functional vdW lattices, which we envision would enable unique opportunities in the creation of 1D magnetic nanostructures and the realization of new magnetic properties and applications at or near the limit of 1D confinement.

5:30 PM EQ20.02.08
Cavity-Enhanced Linear Dichroism in a van der Waals Antiferromagnet Huiqin Zhang[1], Zhuoliang Ni[1], Aofeng Bai[2], Jason Lynch[1], Deep M. Jariwala[1], Frank Peiris[2] and Liang Wu[1]; [1]University of Pennsylvania, United States; [2]Kenyon College, United States

The coupling of electronic states with crystal lattice underlies a wealth of condensed matter phenomena. Coupling of electronic charge with lattice vibrations or distortions underlies superconductivity, charge density wave and metal-insulator transitions. In contrast, coupling between electronic charge and spins has been scarcely investigated, particularly in the optical domain. The recent discovery of anti-ferromagnetic (AFM) insulators of the form MPX3 (M = Fe, Mn, Ni; X= S, Se) has opened new avenues in studying spin-charge correlations via optical means. Here we report such an interaction in AFM FePS3 crystals which induces strong in-plane anisotropy, resulting in linear dichroism (LD). We identify that this LD is characteristic of the AFM spin ordering in the crystal coincident with the Neel transition temperature (~118 K). Further, we show that the LD is tunable both spectrally and in magnitude up to near-unity (~98.4%) levels when coupled to an optical cavity. Finally, through transfer-matrix simulations, we also demonstrate the dispersion of the LD in the visible-near infrared range as a function of the cavity length and the FePS3 thickness. We observe a close agreement between experiments and simulations and prove that the LD can be enhanced from 5% (in bulk) to 98.4% (in ~200nm thick samples) by virtue of cavity coupling and engineering the dielectric stack. Our findings open a new route to probing spin-charge coupling in magnetic materials and have implications in the design of novel birefringent nanophotonic elements.

5:45 PM EQ20.02.09
Monolayer Half van der Waals Heavy Metals via Confinement Heteroepitaxy Alexander Vera, Wilson Yanev, Cequn Li, Kaije Yang, Boyang Zheng, Timothy Bowen, Siavash Rajabpour, Yuanxi Wang, Vincent Crespi, Chaoxing Liu, Jun Zhu, Nitin Samarth and Joshua A. Robinson; The Pennsylvania State University, United States

Atomically thin heavy metals (Pb, Bi) are expected to exhibit strong spin orbit coupling and broken spin degeneracy, making them viable candidates for next-generation quantum applications in both spin-dependent devices (i.e. spintronics) and spin-dependent phenomena (ex. quantum spin Hall effects). However, most ultrathin, mono-elemental metals are extremely sensitive to oxidation and degradation in ambient conditions. To answer this, our group has developed a synthesis route known as confinement heteroepitaxy (CHet), through which we have created large-area, atomically thin 2D-Pb, 2D-Bi, and 2D-PbGa capped by a quasi-freestanding epitaxial graphene which provides air-stability. Through our *ex-situ* characterization work, we have demonstrated strong spin splitting (~500meV) and a unique out-of-plane spin polarization for 2D-Pb, superconductivity up to 3K in 2D-PbGa, and strong photoluminescence in 2D-Bi, implying their potential as precursors for next-generation, quantum spin technologies.

Epitaxy of TMDs on Sapphire—Progress Toward Wafer-Scale Single Crystal Monolayers Haoyue Zhu, Tanushree H. Choudhury, Nicholas Trainor, Benjamin Huet, Thomas McKnight, Anushka Bansal and Joan M. Redwing; The Pennsylvania State University, United States

Wafer-scale synthesis of semiconducting transition metal dichalcogenide (TMDs) monolayers such as MoS_2, WS_2 and WSe_2 is of significant interest for device applications to circumvent size limitations associated with the use of exfoliated flakes. Epitaxy is required to achieve single crystal monolayers over large areas via coalescence of TMD domains with the same crystallographic direction. Sapphire has emerged as a promising substrate for wafer-scale epitaxy due to its commensurability with the hexagonal lattice of TMDs and its good thermal and chemical stability. However, the three-fold symmetry of TMDs typically results in inversion domains, also referred to as 60^o twins, on substrates such as c-plane sapphire forming twin boundaries upon coalescence that are generally undesired.

In this study, we demonstrate the epitaxial growth of TMD monolayers on 2" diameter c-plane sapphire substrates with a significantly reduced density of inversion domains. Steps on the sapphire are shown to break the surface symmetry giving rise to a preferred domain orientation. Metalorganic chemical vapor deposition (MOCVD) was used for the epitaxial growth of WSe_2 and WS_2 monolayers on c-plane sapphire in a cold-wall horizontal quartz-tube reactor. A three-step nucleation-ripening-lateral growth process, carried out at temperatures ranging from 850°C to 1000°C, was used to achieve epitaxial films using $W(CO)_6$, H_2Se and H_2S as precursors in a H_2 carrier gas. Nucleation was observed to occur at the terrace edge and the growing domains align epitaxially with the underlying (0001) sapphire lattice. As a result of the nucleation process, the domains grow with a zig-zag edge facing the terrace edge which imparts a preferential direction to the domains. The percentage of domains with a preferred direction ranges from 75%-86% depending on MOCVD growth conditions. Continued lateral growth for times ranging from 10-30 minutes results in fully coalesced TMD monolayers that are epitaxially oriented on the sapphire, as assessed by in-plane x-ray diffraction, with a reduced density of inversion domain boundaries and good circular helicity. The results demonstrate the important role of surface structure in nucleation and epitaxial growth of TMD monolayers.

CMOS Compatible Substitutionally Doped N- and P-type 2D WSe_2 Azimkhan Kozhakhmetov[1], Samuel Stolz[2], Anne Marie Tan[3,4], Rahul Pendurthi[1], Saiphaneendra Bachu[1], Furkan Turker[1], Nasim Alem[1,5,6], Jessica Kachian[7], Saptarshi Das[1,1,5], Richard Hennig[4], Oliver Gröning[2], Bruno Schuler[2] and Joshua A. Robinson[1,6]; [1]The Pennsylvania State University, United States; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [3]Nanyang Technological University, Singapore; [4]University of Florida, United States; [5]Materials Research Institute, The Pennsylvania State University, United States; [6]Two-Dimensional Crystal Consortium, The Pennsylvania State University, United States; [7]Intel Corporation, United States

Doping is the cornerstone of modern semiconductor technology where extrinsic semiconductors are the fundamental building blocks of everyday electronic devices. Recently emerged two-dimensional (2D) transition metal dichalcogenides (TMDs) are actively considered as one of the potential materials system for next-generation electronics, where significant progress has been made in the wafer-scale synthesis of pristine TMDs as large as 300 mm. Even though electronic-grade, industrial-scale intrinsic materials exist, to date, similar success does not hold for scalable doping of TMDs, which remains at the proof-of-concept stage.

In this study, we present scalable rhenium (n-type) and vanadium doping (p-type) of 2D WSe_2 films at front-end-of-line (FEOL) and back-end-of-line (BEOL) compatible temperatures via gas source chemical vapor deposition (CVD). Detailed experimental and theoretical studies demonstrate that Re and V substitutionally replace W atoms in the WSe_2 lattice and introduce discrete energy states that lie close to the conduction band and valance band, respectively. The concentration of the dopants can be precisely controlled down to <0.0001 at % and confirmed with a combination of x-ray photoelectron spectroscopy (XPS) and time-of-flight secondary ion mass spectroscopy (ToF-SIMS). Incorporated Re and V atoms break the translational symmetry of the host lattice resulting in increased density of defect-activated Raman modes. Moreover, the density of positive and negative trions is increased as a function of V and Re atom concentration leading to the complete quench of the photoluminescence spectra due to the non-radiative recombination nature of the trions. Transport measurements verify the n- and p-type nature of the rhenium and vanadium dopants, respectively. Moreover, we demonstrate that the dopants are not efficiently ionized in monolayer WSe_2 due to ineffective Coulomb screening and a strong dependence of dopant ionization energy on the thickness of the 2D films. Our findings are the first demonstration of extrinsic 2D semiconductors that are fully compatible with state-of-the-art Si processing which will be indispensable in constructing a heterogeneous platform for "Beyond Moore" technology.

11:15 AM EQ20.03.03

BEOL Compatible MOCVD-Grown Re-Doped MoS_2 for Next Generation Cu/TMD Hybrid Interconnects Riccardo Torsi, Yu-Chuan Lin and Joshua A. Robinson; The Pennsylvania State University, United States

The International Roadmap for Semiconductors expressed the urgent need for ultrathin (~1nm) diffusion barrier materials for copper interconnects. Recently, 2D transition metal dichalcogenides (TMD) such as MoS_2 have been proposed as a possible solution to this technological need as they can offer excellent diffusion blocking capabilities even at low thickness unlike conventional barrier materials. The challenge with 2D TMD integration as barrier materials is that synthesis of high-quality layers is typically achieved via vapor-phase techniques like chemical vapor deposition (CVD) at temperatures much higher than the back-end-of line (BEOL) limit (<500C). In this study we demonstrate the growth of nanometer think Re-doped MoS_2 *via* metal organic chemical vapor deposition (MOCVD) at BEOL-compatible temperatures with excellent Cu diffusion barrier performance. Employing $Re_2(CO)_{10}$ as a gas-source dopant precursor within the MOCVD process, we exhibit unprecedented control over Mo-substitutional doping concentration even up to degenerate levels confirmed by a combination of X-ray photoelectron spectroscopy (XPS) and Time-of-Flight Secondary Ion Mass Spectrometry (ToF-SIMS) measurements. With this precise regulation of dopant source flux and resulting Re concentration, we show how both diffusion blocking capabilities and carrier mobility of the grown MoS_2 films change as a function of dopant concentration. Time dependent dielectric breakdown (TDDB) tests are employed to measure the breakdown time and benchmark the Re-doped MoS_2 films against industry standard barrier materials (Ta/TaN) as well as other 2D nanosheet-based diffusion barriers. Carrier mobility on the other hand is extracted by fabricating back-gated and electrolyte double layer gated field-effect transistors (FETs). These results show that degenerately doped MoS_2 films are a promising candidate for ultrathin next-generation Cu/TMD hybrid interconnects.

11:30 AM EQ20.03.04

Polycrystalline MoS_2 Thin Films at 100 °C by Plasma-Enhanced Atomic Layer Deposition Miika Mattinen[1], Farzan Gity[2], Emma Coleman[2], Ray Duffy[2], Erwin Kessels[1] and Ageeth A. Bol[1]; [1]Eindhoven University of Technology, Netherlands; [2]Tyndall National Institute, Ireland

Semiconducting transition metal dichalcogenides (TMDCs), such as MoS_2, exhibit vast potential in a variety of applications due to their unique and favorable electronic, optical, and mechanical properties. However, the commonly used gas-phase TMDC deposition methods require high temperatures that are incompatible with many applications and substrates, in particular the emerging field of flexible electronics.[1]

In this contribution, we demonstrate wafer-scale deposition of polycrystalline MoS_2 thin films at very low temperatures down to 100 °C using plasma-enhanced (PE) atomic layer deposition (ALD). ALD is a scalable, semiconductor industry compatible gas-phase method producing uniform, high-quality thin films with accurately controlled thickness. These attributes have led to rapidly growing interest in ALD for preparing TMDCs.[2,3]

Our PEALD process is based on self-limiting, alternating surface reactions of a metalorganic molybdenum precursor $Mo(N^tBu)_2(NMe_2)_2$ and mixed $H_2S/H_2/Ar$ plasma.[4] We have identified the critical role of hydrogen during the plasma step in controlling the composition and properties of molybdenum sulfide films. By increasing the H_2/H_2S ratio, we are able to deposit polycrystalline MoS_2 films at temperatures as low as 100 °C. To the best of our knowledge, this represents the lowest temperature for crystalline MoS_2 films prepared by any chemical gas-phase method.

Based on thorough film characterization, we find that adding hydrogen in the plasma helps avoid excess sulfur incorporation at low temperatures. The correct stoichiometry, in turn, enables crystallization of MoS_2. Furthermore, the H_2/H_2S ratio is found to control growth rate, film morphology, and electrical properties. For example, electrical conductivity can be increased by at least four orders of magnitude by increasing the H_2/H_2S ratio. Thus, the PEALD process enables tailoring molybdenum sulfide films to meet the requirements of different applications. We are currently investigating the

electronic transport properties of our MoS_2 films prepared at conditions that are compatible with flexible electronics as well as other applications and substrates with a low thermal budget.

11:45 AM EQ20.03.05
Highly Controlled Alloying of 2D MoS_2, WS_2 and NbS_2 by Atomic Layer Deposition Jeff J. Schulpen[1], Cindy Lam[1], Marcel A. Verheijen[1,2], Erwin Kessels[1], Vincent Vandalon[1] and Ageeth A. Bol[1]; [1]Technische Universiteit Eindhoven, Netherlands; [2]Eurofins, Netherlands

Semiconducting 2D transition metal dichalcogenides (TMDs) such as MoS_2 and WS_2 have many unique properties such as stable excitons at room temperature and direct-gap luminescence at monolayer thickness, making them promising materials for various applications such as photovoltaics, optical sensing and catalysis. In particular, alloys of 2D TMDs hold great potential due to their composition-controlled properties, making them more versatile than pure TMDs. Hence, there is a clear need for a synthesis method of 2D TMD alloys that can exert excellent control over the alloy composition. While TMD alloys have been synthesized by chemical vapor deposition (CVD), the control of this method is limited, which is exemplified by the lack of control over *atomic ordering* (i.e. mixing or clustering of the alloy's constituents).

In this work we employ plasma-enhanced atomic layer deposition (ALD) to synthesize the 2D TMD alloys $Mo_xW_{1-x}S_2$ and $Nb_xW_{1-x}S_2$. As MoS_2 and WS_2 are both semiconductors, $Mo_xW_{1-x}S_2$ is a good case study for a tunable-bandgap semiconductor. The growth of the nanocrystalline $Mo_xW_{1-x}S_2$ alloys is shown to be exceptionally well-behaved, as their composition follows the ideal rule of mixtures. Beyond resulting in excellent control over fundamental properties such as the bandgap (evidenced by optical absorption spectroscopy), this ideal alloying behavior enables us to control the *atomic ordering* (i.e. mixing or clustering) of the alloys in the deposition process. Specifically, it is shown by atomic resolution HAADF-STEM that the atomic ordering can be tuned from a randomly mixed $Mo_xW_{1-x}S_2$ alloy to an alloy that exhibits clusters of MoS_2 and WS_2. When a sub-monolayer film with clustered atomic ordering is grown, the resulting film effectively consists of 2D core-shell nanoparticles (MoS_2 islands epitaxially bordered by WS_2) which are expected to have fascinating novel properties.

On the other hand, Nb is a group-VB transition metal whereas W is a group-VIB transition metal, making $Nb_xW_{1-x}S_2$ a relevant case study for electronic applications where well-controlled doping is desired. For the $NbS_2 - WS_2$ alloy system, we observe similarly well-behaved rule-of-mixtures growth. The electronic properties of the $Nb_xW_{1-x}S_2$ alloy are studied based on Hall measurements and their suitability for transistors is evaluated. Furthermore, the atomic arrangement of the alloy is studied using HAADF-STEM to gain fundamental insight into the alloying behavior of the $NbS_2 - WS_2$ system.

Our results demonstrate excellent control over the composition and *atomic ordering* of 2D TMD alloys by ALD, thus enabling fine tuning of the material properties as well as the emergence of novel properties, thereby opening up many possibilities for next-generation devices based on 2D materials.

SESSION EQ20.04: Advances in Memory and Logic Enabled by 2D Materials

1:30 PM *EQ20.04.01
2D Atomic Memory and Computing/Communication Applications Deji Akinwande; The University of Texas at Austin, United States

This talk will present our latest research adventures on 2D atomic nanomaterials towards greater scientific understanding and applications. In particular, the talk will highlight our work on non-volatile memory (atomristors) that can be employed in various applications including information storage, brain-inspired computing, and zero-power RF/THz switches. Non-volatile memory device based on atomically-thin materials is an application of defects, and is a rapidly advancing field with rich physics that can be attributed to metal ion binding to native defects. The promising 2D materials for neuromorphic computing include a library of TMDs (e.g. MoS2), and hBN. In particular, hBN memory devices feature very low switching energy, a relatively wide range of stable programmable resistance states, and good endurance and retention. Recent progress has also demonstrated wafer-scale integration of 2D memory devices with a prospect to leverage silicon electronics for fully integrated systems.

2:00 PM *EQ20.04.02
2D/3D Heterostructures for Advanced Logic and Memory Devices Deep M. Jariwala; University of Pennsylvania, United States

The isolation of a growing number of two-dimensional (2D) materials has inspired worldwide efforts to integrate distinct 2D materials into van der Waals (vdW) heterostructures. While a tremendous amount of research activity has occurred in assembling disparate 2D materials into "all-2D" van der Waals heterostructures and making outstanding progress on fundamental studies, practical applications of 2D materials will require a broader integration strategy. I will present our ongoing and recent work on integration of 2D materials with 3D electronic materials to realize logic switches and memory devices with novel functionality that can potentially augment the performance and functionality of Silicon technology. First, I will present our recent work on gate-tunable diode[1] as well as tunnel junction devices based on integration of 2D chalcogenides with Si and GaN. I will show that combining 2D semiconductors with 3D semiconductors allows highly-tunable diode devices with applications in logic. Following this I will present our recent work on non-volatile memories based on Ferroelectric Field Effect Transistors (FE-FETs) made using a heterostructure of MoS_2/AlScN[2] and I also will present our work on Ferroelectric Diode devices based on thin AlScN and ultrafast switching in them.[3, 4] Finally, I will also present our recent and ongoing work on probing buried 2D semiconductor/3D metal interfaces[5] and their impact on contact polarity and resistance engineering in electronic and opto-electronic devices.
I will end by giving a broad perspective on future opportunities of 2D semiconductors in basic science and applied microelectronics technology.

Field-Effect Conductivity Scaling for Two-Dimensional Materials with Tunable Impurity Potentials Chulin Wang, Lintao Peng, Spencer Wells, Jeffrey Cain, Yi-Kai Huang, Vinayak Dravid, Mark C. Hersam and Matthew Grayson; Northwestern University, United States

In this work, a scaling law is demonstrated in the conductivity of gated two-dimensional (2D) materials with tunable concentration of impurity scatterers, such as from shallow capacitively charged traps or adsorbed gas molecules. For the same device at different concentration of scatterers, a single scaled conductivity curve is observed upon rescaling the non-linear gate-dependent conductivity by a mobility scaling factor r to represent different strength of impurity-induced scattering potential while simultaneously shifting the gate voltage by an amount ΔV_g to represent different concentrations of impurity-induced doping. The scaling effect is demonstrated first by cooling an encapsulated black phosphorus (BP) 2D multilayer at T_L = 100 K with charge trap scatterers that are populated by cooling down from room temperature under a gate bias. A second case of mobility scaling is observed in a Bi_2Se_3 2D monolayer at room temperature exposed to gas adsorbate scatterers. The 2D nature of these samples weakly screens the charge of the adjustable density of point-like scatterers. The observed scaling in the conductance curve can be explained with a simple mobility model whereby the screened potential of individual scatterers determines the scaled conductivity versus density curve.
In the case of BP multilayers, the sample is tested under a series of bias cooling process which appears to remotely charge a trap layer with a tunable concentration of impurity scatterers. A gate bias is first applied on the back gate at room temperature. Then, the sample is cooled down to T_L = 100 K under the same gate voltage, namely the bias cooling voltage V_{BC}. Once the sample reaches T_L, the gate bias is then swept. For each V_{BC}, a distinct field-effect conductivity curve is obtained at T_L. The lineshapes of these curves have little in common. Remarkably, however, these curves can be empirically aligned onto a single curve if one artificially scales the conductivity by a factor r and shifts the gate voltage by ΔV_g, where a distinct pair of parameters r and ΔV_g is associated with each V_{BC}. The model is validated by taking Hall measurements for each bias cooling voltage V_{BC}, whereby the carrier densities are also observed to collapse onto a single curve upon shifting the gate voltage by ΔV_g.
These observations are interpreted with a charge-trap model. It is commonly known that the BP is susceptible to surface oxidization. The oxidization sites host charge traps that can be capacitively loaded. During the bias cooling process, the charge traps that have deep energy barriers are effectively frozen out, thereby determining the strength of the scattering potential and the concentration of doping in the device at T_L. Further, our analysis suggests that the mobility-limiting factors are charged impurity scattering and surface roughness scattering in the positive and negative limits of gate bias, respectively. The shallow charge trap model described here shows how naively estimated field-effect mobilities may be commonly over-estimated in 2D FET devices.
The Bi_2Se_3 monolayer device is studied under a gaseous environment from vacuum to forming gas to air. Various field-effect conductivity curves are obtained in each environment. Following the conductivity scaling analysis, the parameters indicate that the impurities are positively charged and scattering strength increases irrespective to the type of gas molecules present.
The scaled 2D conductivity analysis introduced in this work can serve as a fingerprint for a given material over an extended gate voltage range, allowing one to determine the characteristic field-effect conductivity with any impurity density and gate voltage for a given type of impurity. From the slope of the mobility scaling factor r plotted versus gate shift ΔV_g, one can further determine whether the impurities are acceptor-like or donor-like.

4:00 PM *EQ20.05/SB06.03.01
Novel van der Waals Materials and Their Potential for Biosensing Shengxi Huang; The Pennsylvania State University, United States

Emerging 2D and topological quantum materials have gained increasing attention due to their unique electronic and optical properties, and have shown promise in sensing applications. The realization of sensing devices using these materials still faces several challenges. For example, it is critical to gain clear understandings of (1) the fundamental light-matter interactions and their relations to the atomic structures, which govern many key material properties and device performances; and (2) the coupling with other nanostructures and molecules, which is a required structure for sensing devices and systems. This talk introduces new discoveries and pioneering works on these critical challenges, and novel applications of these materials in biochemical sensing. The first part of this talk presents light-matter interactions and techniques to augment material performance, including 3D Weyl semimetals, 2D Janus transition metal dichalcogenides, and 1D nanoscrolls. The characterization techniques employed, including low-frequency Raman spectroscopy, polarization- and time-resolved spectroscopy, and ultrafast electron diffraction, can be widely used in other material systems. The second part of this talk focuses on the interaction of 2D materials with organic molecules and related sensing applications. In particular, a novel enhancement effect of molecular Raman signals on 2D surface was discovered, which offers a new paradigm of biochemical sensing with high specificity, high multiplexity, and low noise. The selection rule for the 2D material substrates has been revealed, which is critical for device design. Two sensing applications for Alzheimer's disease and respiratory viruses will also be discussed. Overall, the works presented in this talk are significant in fundamental quantum science, and offer important guidelines for practical applications in sensing and quantum technologies. The methodologies used here also provide a framework for the future study of many emerging materials and sensing scenarios.

4:30 PM *EQ20.05/SB06.03.02
Novel 2D Material Based Devices for Biosensing Deblina Sarkar; Massachusetts Institute of Technology, United States

Sensors are ubiquitous in today's world starting from healthcare to security and forensic industries. Especially, 2D materials are highly promising for sensing applications because of their large surface to volume ratio, possibility to obtain pristine interfaces and opprtunites for unique device design leveraging the ability form Van der Waal's heterostructures. Here, we will discuss the advantages of 2D material based Field effect Transistors (FETs) for highly sensitive and label-free electrical detection of biomolecules. Going beyond conventional FETs, we will discuss how novel quantum mechanical transistors can overcome the fundamental limitations in sensitivity of conventional electrical biosensors. We will also present how 2D materials can particularly enable the develpment of such novel quantum mechanical devices, which can open up new avenues in point-of-care applications.

5:00 PM *EQ20.05/SB06.03.03
Realizing Biomimetic Neuromorphic Functionality with 2D Material Electronic Devices Mark C. Hersam; Northwestern University, United States

The exponentially improving performance of conventional digital computers has slowed in recent years due to the speed and power consumption issues that are largely attributable to the von Neumann bottleneck (i.e., the need to transfer data between spatially separate processor and memory blocks). In contrast, neuromorphic (i.e., brain-like) computing aims to circumvent the limitations of von Neumann architectures by spatially co-locating processor and memory blocks or even combining logic and data storage functions within the same device. In addition to reducing power consumption in conventional computing, neuromorphic devices also provide efficient architectures for emerging applications such as image recognition, machine learning, and artificial intelligence [1]. With this motivation in mind, this talk will explore how the reduced dielectric screening in 2D nanoelectronic materials enables opportunities for novel gate-tunable neuromorphic devices [2]. For example, by utilizing self-aligned, atomically thin p-n heterojunctions, dual-gated Gaussian heterojunction transistors have been realized, which show fully tunable anti-ambipolar transfer characteristics that are suitable for artificial neurons, competitive learning, and spiking circuits [3]. In addition, by exploiting field-driven defect motion in monolayer transition metal dichalcogenides, gate-tunable memristive phenomena have been achieved, which serve as the basis of hybrid memristor/transistor devices (i.e., 'memtransistors') that concurrently provide logic and data storage functions [4]. The planar geometry of memtransistors further allows multiple contacts to the channel region and dual gating that mimic the behavior of biological systems such as heterosynaptic responses [5]. Overall, this work introduces new foundational circuit elements for neuromorphic computing in addition to providing alternative pathways for studying and utilizing the unique quantum characteristics of 2D nanoelectronic materials [6].

EQ20.06.01
Structure and Properties of a Novel Heptacoordinated Complex Based on Sr^{2+} and 1,2,4,5-tetrakis(4-carboxyphenyl)benzene Muhammad Usman[1,2], Lydia Ogebule[1], Evgenii Oskolkov[3,1], Raúl Castañeda[1] and Tatiana Timofeeva[1]; [1]New Mexico Highlands University, United States; [2]Academia Sinica, Taiwan; [3]University at Buffalo, The State University of New York, United States

Metal-organic frameworks (MOFs) have emerged as a class of structurally diverse materials with immense potential for many applications. Their often fascinating properties, apart from composition, depend strongly on the structure. An important subclass – MOFs based on naturally abundant and generally non-toxic alkaline metals – have recently offered a sustainable alternative to conventional rare-earth and transition metal complexes. Among the elements of the alkaline metals group, strontium (Sr) currently remains the most exotic and least studied in context of metal-organic complexes. However, few recent reports have suggested Sr-based complexes' suitability as semiconducting materials, which is rare for the class of MOFs. In this work two structurally different Sr^{2+} MOFs of the same composition were prepared by introducing slight changes into the synthesis conditions. Single crystal diffraction data was obtained and used to determine the structures of both complexes. The discovered structural differences have shown that control of crystalline structure and topology by small changes in preparation method is possible for similar alkaline metal complexes. High stability to temperatures up to 250 C^o was confirmed by thermogravimetric analysis. Optical properties were studied and bandgap values determined. With facile synthesis method, synthetic tunability and remarkable properties both complexes exhibit high promise in semiconducting technology.

EQ20.06.02
Pseudo-Polymorphism in Layered Tetragonal FeS Intercalates Kirill Kovnir[1,2]; [1]Iowa State University, United States; [2]US DOE Ames Laboratory, United States

Tetragonal iron sulfide and selenide, Fe*Q* (*Q* = S, Se), adopt the simplest crystal structures of the iron-based superconductors. Their layered structures are suitable for development of the hybrid magnetic and superconducting materials by the intercalation of the host species in the interlayer space. Low-temperature solution-assisted intercalations provides an access to rich phase space of intercalates based on C,N,O,H-containing molecular species. A complete description of the Fe-*Q* layer as well as the intercalate is required to accurately link these structural aspects to a material's bulk properties. While interplanar van der Waals stacking is ideal for diverse intercalation it can limit crystal quality and in turn complicate the structure-properties analysis. To determine exact composition and challenging complex crystal structures of two pseudo-polymorphic Fe-S-en (*en* = ethylenediamine) layered hybrid phases we applied a synergistic combination of elemental composition, decomposition behavior, high-resolution synchrotron X-ray diffraction and total scattering, ^{57}Fe Mössbauer spectroscopy, and electron diffraction methods. The intricate interplay between Fe vacancies, puckering of the Fe-s layers, number and charge of the intercalated species, structural distortion, and magnetic properties will be discussed. Our work shows an importance of detailed characterization of the crystal structure of intercalated compounds to understand the origin of the observed properties and develop proper structure-properties relationships.

EQ20.06.03
Quasi-One-Dimensional Transition-Metal Trichalcogenide for Low-Dimensional Electronic Device Applications Archit Dhingra, Alexey Lipatov, Alexander Sinitskii and Peter Dowben; University of Nebraska-Lincoln, United States

Transition metal trichalcogenides (TMTs) are quasi-one-dimensional semiconductors with modest band gaps that offer an opportunity to fabricate transistors with widths less than 10 nm, as they lack undesirable edge effects that plague other well-studied two-dimensional materials (namely: graphene-based materials and transition metal dichalcogenides). Among the family of TMTs, TiS_3, ZrS_3, and In_4Se_3 are n-type semiconductors, while HfS_3 is a p-type semiconducting trichalcogenide with high spin-orbit coupling. Besides, in addition to their electronic properties and adequate band gaps, their opto-

electronic properties project them as promising candidates for photodetector applications. That is to say, potential of TiS_3, ZrS_3 and In_4Se_3 for photodetector applications is now known owing to successful experimental demonstrations of working light polarization-dependent phototransistors made from these TMTs; and this is consistent with appreciable photo-response of HfS_3 reported elsewhere.[1] Furthermore, temperature-dependent X-ray photoemission spectroscopy (XPS) and Raman spectroscopy have been employed to investigate and quantify the extent of electron-phonon scattering in these transition metal trichalcogenides. The Debye–Waller factor plots (based on the temperature-dependent XPS) for S 2p and Hf 4f core-levels of HfS_3 suggest that there exists a phase transition between 225 K and 240 K; however, no such phenomenon is seen for TiS_3, ZrS_3, and In_4Se_3. Thus, HfS_3 exhibits higher electron-phonon scattering at temperatures above 240 K than at temperatures below 225 K. Generally, it is clear that phonon scattering affects carrier mobilities of transition metal trichalcogenides. Nonetheless, the interaction between the Au metal contacts and the various transition metal trichalcogenides, which differs substantially, also affects the measured carrier mobilities. The Au thickness-dependent XPS measurements confirm Schottky-barrier formation at the Au/HfS_3 and Au/In_4Se_3 interfaces, which is different from what is seen at the Au/TiS_3 and Au/ZrS_3 interfaces. This, in turn, implies that the work function of Au is less than that of HfS_3 because the formation of a Schottky-barrier at the metal/p-type semiconductor interface is only possible if the work function of the p-type semiconductor is higher than that of the metal. Nevertheless, noteworthy in this regard is that for other Au/TMT interfaces, some complex interfacial chemistry also plays a big role. Yet, there are good reasons to believe that the fabrication of transition metal trichalcogenides-based Schottky transistors, Schottky diodes, and phototransistors are all possible. These results are important as they open new pathways for efficient integration of logic and sensing, which is key to robotics applications.

EQ20.06.04

Graphene Growth on Non-Metallic Substrates by Chemical Vapor Deposition Sandra Rodriguez Villanueva[1,2], Frank Mendoza[3], Alvaro Instan[1], Brad Weiner[4,2], Ram Katiyar[1] and Gerardo Morell[1,2]; [1]University of Puerto-Rio Piedras, United States; [2]Molecular Sciences Research Center, United States; [3]University of Puerto Rico at Mayagüez, United States; [4]University of Puerto Rico at Río Piedras, United States

For optoelectronic applications, graphene is usually growth on metallic substrates then transferred into a dielectric. This process leaves large amounts of residual chemicals and a high risk of wrinkling or breakage of the film. A solution is to growth graphene directly on the dielectric, but this still is very challenging.

In this work, we show the direct synthesis of graphene on SiO_2/Si and SiC by hot-filament chemical vapor deposition. The graphene deposition was conducted at low pressures (35 Torr) with a mixture methane in hydrogen and a substrate temperature ~ 900°C followed by abrupt cooling to room temperature. A thin strip of copper layer was sputtered in the middle of the SiO_2/Si substrates as a catalytic material. The structural properties of the graphene films were analyzed using Raman Spectroscopy, Atomic Force Microscopy (AFM), and X-ray photoelectron spectroscopy (XPS). Raman mapping and AFM measurements indicate the growth of few-layer graphene films in all cases. X-ray photoelectron spectroscopy confirmed the presence of graphene deposition on SiO_2/Si and SiC substrates. The results show that the effect of the surface catalytic of copper allows the graphene growth beyond the copper strip and all over the SiO_2/Si substrates.

Polarity Switch of WS_2 Transistors Through *In Situ* Ion Beam-Modified Contacts Alexander T. Mangus, Hattan Abuzaid and Aaron D. Franklin; Duke University, United States

As modern transistor technologies reach their physical limits, new materials are being actively explored for device scaling strategies, novel device structures, or integration strategies. Two-dimensional (2D) transition metal dichalcogenides (TMDs) show promise because their atomic thickness enables aggressive channel length scaling and they are compatible with low thermal budget fabrication into transistors. For TMDs to be practical for logic transistors, complementary (both n- and p-type) devices need to be realized. Typically, semiconductors tend to show either p- or n-type behavior in transistors, depending on how their energy bands align with the Fermi level of the source/drain contact metals. Theoretically, metals can be carefully chosen by considering their work functions to give n- or p-type devices based on preferential carrier injection to the conduction or valence band, respectively. However, in real devices, Fermi-level pinning and related effects limit the effectiveness of this approach. In previous works, modification of the metal-TMD interface with an Ar^+ ion beam has been shown to enhance device performance in MoS_2 transistors, with increased on-current and on/off-current ratio [1-2]. In this study, we demonstrate the effect of this *in-situ* Ar^+ ion beam modification of the metal-TMD contact interface for Pd-contacted WS_2 transistors. The ion beam was used to modify the inert surface of the TMD (selectively in the contact regions) to generate dangling bonds for promoting improving carrier injection with the Pd. Having the ion beam in the same high vacuum chamber as the electron beam evaporator for metal deposition enabled a fully *in-situ* process, which reduced contaminantion from ambient exposure before contact deposition. To eliminate flake-to-flake variation, multiple modified and unmodified devices were fabricated on each flake of the mechanically exfoliated WS_2. Raman spectroscopy was used to study the impact of the ion beam modification on the WS_2 surface. An unanticipated polarity switch in these WS_2 transistors was driven by the ion beam modification, which enhanced the p-branch current, causing a polarity switch compared to the devices with unmodified Pd-WS_2 contacts. The p-branch on-current in the modified devices showed an enhancement of two to three times, on average, over the n-branch on-current of the unmodified devices. This discovery presents a unique path towards complementary WS_2 devices to be easily fabricated with the addition of an ion beam modification step to the fabrication process. Based on these findings, ion beam effects should be studied more extensively on other TMDs using a multitude of different metals to thoroughly characterize the enhancement and polarity switching effects that may occur.

2D Nanocoating for High-Voltage Discharge Resistant Dielectrics Antigoni Konstantinou, Hiep Nguyen, Yifei Wang and Yang Cao; University of Connecticut, United States

There are serious safety concerns with materials that are used in high-voltage applications because electric arc represents one of the most sever thermal plasma energy discharges involving extremely high temperature (>25kK)[1]. Therefore, the need for electrical discharge resistant dielectrics is imperative for safe high voltage design. A milestone of the 2D materials that are still using in this kind of applications is mica, of which the best properties are retained in the form as tape insulation. On the other hand, modern applications require conformal coating or injection molded insulation with superior discharge resistance and mica does not fulfill this requirement. Also, high layer thickness of mica insulation system behaves as a barrier for heat conduction dissipation. Therefore, the development of a novel polymer-based coating with self-assembling, inorganic 2D nanofiller montmorillonite (MMT) appears to be a promising way to overcome these problems. In this study, spray coating is applied to Kapton substrates to significantly increase discharge resistance. The electric performance of 2D nanoclay coated dielectrics is extensively characterized via voltage endurance and breakdown strength testing. The samples are further characterized using microscopy, x-ray diffraction, and broadband dielectric spectroscopy.

Preparation of Ge(111) Substrates for Bismuthene and Stanene Jessica Dong, Kaylyn Holmes, Ruizhe Kang, Jennifer Hoffman, Charles Brooks and Julia Mundy; Harvard, United States

Monolayers of bismuth and tin arranged in a honeycomb lattice hold great promise for next-generation electronics. These materials, so-called “bismuthene” and “stanene”, could host a quantum spin Hall effect near room-temperature. Unlike graphene, however, these materials cannot be readily exfoliated from a bulk crystal and must be stabilized in the thin film form. Here we use molecular-beam epitaxy to construct these metastable structures. We discuss the preparation of the Ge(111) surface as a platform for our epitaxial deposition.

Interface Chemistry, Band Alignment and Thermal Stability of Metal Contacts on MoS_2 Xinglu Wang, Seong Yeoul Kim, Yi Shen and Robert Wallace; The University of Texas at Dallas, United States

The high contact resistance of transition-metal dichalcogenide (TMD)-based devices is one of the bottlenecks that limit the application of TMDs in various domains. The contact resistance of TMD-based devices is strongly related to the interface chemistry and band alignment at the contact metal/TMD interfaces. To understand the metal/MoS_2 interface chemistry and band alignment, Ni and Ag metal contacts are deposited on MoS_2 bulk and chemical vapor deposition bilayer MoS_2 (2L-MoS_2) film samples under ultrahigh vacuum (UHV, ~3×10^{-11} mbar) and high vacuum (~3×10^{-6} mbar) conditions. X-ray photoelectron spectroscopy (XPS) is used to characterize the interface chemistry and band alignment of the metal/MoS_2 stacks. Ni forms covalent contact on MoS_2 bulk and 2L- MoS_2 film by reducing MoS_2 to form interfacial metal sulfides. In contrast, van der Waals gaps form at the Ag/MoS_2 bulk and Ag/2L-MoS_2 film interfaces, proved by the absence of an additional metal sulfide chemical state and the detection of Ag islands on the surface. Different from other metal/MoS_2 systems studied in this work, Ag shows potential to form an Ohmic contact on MoS_2 bulk regardless of the deposition ambient. Fermi levels (E_F's) are pinned near the intrinsic E_F of the 2L-MoS_2 film with high defect density regardless of the work function of the metal, which highlights the impact of substrate defect density on the E_F pinning effect and contact resistance.
To achieve reliable MoS_2 based devices with a higher thermal budget, it is imperative in understanding the impact of thermal treatment on the interface chemistry of the Ni/MoS_2 interface. 1 nm Ni films were deposited on CVD 1L-MoS_2/SiO_2/Si and 2L-MoS_2/SiO_2/Si wafers, and exfoliated MoS_2 bulk crystal in UHV. *In-situ* XPS was employed to study the interface chemistry and band alignment after Ni deposition and subsequent stepwise UHV annealing up to 400 °C. Ni in-diffusion is detected for all the Ni/MoS_2 systems after annealing at 300 °C in UHV. The defects generated by Ni reduction of MoS_2 and Ni in-diffusion cause the interfacial reaction at the MoS_2/SiO_2 interface after annealing at 400 °C for the CVD MoS_2 film systems. This work highlights the influence of the processing condition on the interface chemistry and band alignment of metal contacts/TMD/oxide stacks and their implications on the device performance. The interface reaction between CVD few-layer MoS_2 film and SiO_2/Si wafer necessitates the careful processing of the transferred or deposited TMD thin films on oxide substrates.

How Surface Tension Matters in Polymer-Free Graphene Transfer Aisha A. Okmi[1,2], Ninxin Li[1], Guanhui Gao[3], Yelyzaveta Rublova[4], Tara Jabegu[1], Diren Maraba[1], Rui He[5], Yue Zhang[6], Xuemei Xiao[6], Pei Dong[5], Boxing Xu[6] and Sidong Lei[1,7]; [1]Georgia State University, United States; [2]Jazan University, Saudi Arabia; [3]Rice University, United States; [4]Institute of Chemical Physics, University of Latvia, Latvia; [5]George Mason University, United States; [6]University of Virginia, United States; [7]Center of Nano-Optics, Georgia State University, Atlanta, United States

Although chemical vapor deposition (CVD) enables large graphene sheets, the polymer-free transfer techniques of this type of graphene are still challenging. The main reason that complicates graphene's current direct transfer techniques is the non-understood effect of high surface tension (ST) of water on graphene during this type of transfer. For instance, it is widely accepted that ST of water (72 dyne/cm) would break graphene sheets during metal etching or solution replacement. In this work, we have achieved several experiments and calculations to unveil the actual effect of high ST on graphene and to provide a simple, effective, and clean method to achieve graphene transfer. We designed a specific way that allows tuning surface tension of liquids underneath graphene. We successfully transferred graphene at ST lower than the initial ST (ST of the water) and provided a wide range of liquids that can be used to replace water underneath graphene. Leveraging the high ST of water, a graphene water membrane (GWM) would be formed, providing a new understanding of the graphene-water molecules dynamics. GWM was functioned successfully to deliver graphene to varied substrates. Our work removes the long believed idea that high ST has a damaging effect on graphene. Additionally, it expands the graphene applications in several fields, such as sensors and actuators.

EQ20.06.14
Dominating Interlayer Resonant Energy Transfer in Type-II 2D Heterostructures Arka Karmakar[1], Abdullah Al-Mahboob[1], Christopher E. Petoukhoff[1], Oksana Kravchyna[1], Nicholas S. Chan[1], Takashi Taniguchi[2], Kenji Watanabe[2] and Keshav M. Dani[1]; [1]Okinawa Institute of Science and Technology Graduate University, Japan; [2]National Institute for Materials Science, Japan

Type-II heterostructures (HSs) are building blocks of next generation electronic and optoelectronic devices. Till date, studies have shown that the interlayer charge transfer (CT) mechanism is the dominating carrier relaxation pathway in type-II transition metal dichalcogenide (TMD) HSs. This work shows in a type-II HS formed between monolayers of group-6 and group-7 TMD materials, nonradiative energy transfer (ET) dominates over the traditional CT process even *without* a charge-blocking interlayer. Without charge-blocking interlayer, the measured ET efficiency is 70%, which leads to 3.6 times photoluminescence (PL) enhancement from the acceptor material in HS area. By completely blocking the interlayer CT process we achieved more than one order magnitude higher PL emission from the acceptor material in the HS area. The PL enhancement factor (I/I_0) shows a distance (d) dependency of $1/d^2$, revealing the interaction between the TMD layers via 2D-to-2D dipole coupling. This study not only provides significant insight into the competing interlayer processes, but also shows an innovative way to increase the PL quantum yield of the desired TMD material using ET process.

Late News: Degradation of 2D Materials Formed by Crosslinking of Hydrophilic Macromolecules Rainhard Machatschek[1,2], Shivam Saretia[1,2] and Andreas Lendlein[1,2]; [1]Helmholtz Zentrum Hereon, Germany; [2]University of Potsdam, Germany

In 2D materials, each constituent is permanently in contact with the environment. While this is beneficial for applications such as catalysis or sensors, such exposure to its surrounding makes 2D materials susceptible to mechanical stress, chemical modification and degradation. Clearly, the prospective application of 2D materials determines whether degradation or long-term stability is required. Yet, the degradation behavior of 2D materials under different environmental conditions remains largely unexplored.
Here, we use the Langmuir monolayer technique to study the preparation and degradation of 2D materials, formed in situ by the reaction of monolayers of

hydrophilic polymers with suitable cross-linkers. In particular, we are interested in the influence of acidic, alkaline and oxidative environments on the mass loss and the mechanical properties of the 2D sheets. We show how functional groups that are particularly susceptible to distinct environmental factors enable a rapid loss of mass and mechanical strength. The experimental results are compared to existing theoretical models for the degradation of 2D polymer networks, as a first step towards a prediction of the environmental fate of these fascinating materials.

Origins of Fermi Level Pinning for Ni and Ag Contacts on Transition Metal (Mo and W) Dichalcogenides—Interface Chemistry and Band Alignment Xinglu Wang, Seong Yeoul Kim, Yi Shen and Robert Wallace; The University of Texas at Dallas, United States

Transition metal dichalcogenides (TMDs) are intriguing due to their unique properties and potentials for applications in next-generation electronic devices. However, strong Fermi level (E_F) pinning manifests at the metal/TMD interfaces, which could tremendously restrain the carrier injection into the channel. In this work, we illustrate the interface chemistry and band alignment of Ni and Ag on the Molybdenum and Tungsten based (Mo, W-based) TMDs. Ni reduction of all the TMD substrates and the formation of intermetallic products are detected by X-ray photoelectron spectroscopy (XPS) after *in-situ* ultra-high vacuum (UHV, ~ 3×10^{-11} mbar) and *ex-situ* high vacuum (HV, ~ 3×10^{-6} mbar) metal depositions. E_F's are pinned close to the middle of the bandgap for Ni contacts with $MoSe_2$ and $MoTe_2$. In contrast, Ni tends to form n-type and p-type Schottky contacts with WS_2 and WSe_2, respectively. Van der Waals interfaces form between Ag and TMDs with E_F's pinned close to the intrinsic E_F's of the TMDs, indicating the impact of the natural defects of the TMD substrates. The oxidation of metal contacts and the metal/TMD interfaces are observed for most of the *ex-situ* HV samples. The metal deposition mechanism is characterized by atomic force microscopy and the surface morphology is correlated to the interface chemistry. The implications of interface chemistry on the *true* band alignment of Ni and Ag contacts on Mo and W-based TMDs will be discussed. This work improves the understanding of the possible E_F pinning origins at the metal/TMD interfaces.

Metal Particle-Enabled Width-Controlled Growth of Atomically-Thin Molybdenum Disulfide Nanoribbons with Width-Dependent Quantum Transport Behavior Xufan Li[1], Baichang Li[2], Jincheng Lei[3], Ksenia V. Bets[3], Xiahan Sang[4], Yang Liu[2], Raymond R. Unocic[4], Boris I. Yakobson[3], James Hone[2] and Avetik R. Harutyunyan[1]; [1]Honda Research Institute USA Inc., United States; [2]Columbia University, United States; [3]Rice University, United States; [4]Oak Ridge National Laboratory, United States

Transition metal dichalcogenides (TMDs) exhibit a variety of electronic behaviors depending on the number of layers and width. Therefore, developing facile methods for their controllable synthesis is of central importance. We present a way to control the width by employing metal nanoparticles and the number of layers by substrates. We found that on some types of substrates metal nanoparticle promotes both heterogenous nucleation of the first layer of TMDs (e.g., MoS_2) and simultaneously homoepitaxial tip growth of a second layer via vapor-liquid-solid (VLS) mechanism, resulting in bilayer nanoribbons with the width down to sub-10 nm as controlled by the nanoparticle diameter; while on some other types of substrates single layer of MoS_2 nanoribbons are directly grown via the VLS mechanism through the metal nanoparticle. Simulations further confirm the VLS growth mechanism towards nanoribbons and its orders of magnitude faster growth speed compared to the conventional non-catalytic growth of flakes. Width-dependent photoluminescence and Coulomb-blockade oscillation observed in the transfer characteristics of the nanoribbons at temperatures up to 60 K demonstrate the width evinces the value of this proposed synthesis strategy for future nanoelectronics.

Phonon-Mediated Hydrodynamic Transport in Layered Quantum Materials Yaxian Wang, George Varnavides and Prineha Narang; Harvard University, United States

Hydrodynamic electron flow in condensed matters has been one of the most active research areas recently. While progress from both theory and experimental techniques are made, open questions regarding the underlying mechanisms in layered quantum materials still remain. We utilize ab initio techniques to treat the electron scattering events explicitly, and show in combination with the Boltzmann transport equation a generic metric of hydrodynamic transport taking into account temperature, channel width, and impurity length, which can be directly verified by various experimental techniques.
We start by investigating different electron scattering mean free paths in WTe2, and show that that phonon mediated electron-electron interaction could lead to much shorter momentum conserving mean free path (lmc) than momentum relaxing lmr, facilitating hydrodynamic behavior in systems where the direct Coulomb interaction is largely screened [Vool 2021].
We then present the transport regime limits in PdCoO2, and identify the finite size effects in both the quasi-hydrodynamic and quasi-ballistic transport regimes, which leads to the the in-plane conductivity anisotropy observed recently [Maja 2019, Maja 2021]. We further discuss the dynamics of phonons through the lifetime hierarchy from interactions with electrons and the lattice, and confirm that phonons do play an important role in the electronic transport phenomena [Varnavides, Wang 2021].
Finally, we predict prominent hydrodynamic effects in other layered semimetals ZrSiS and TaAs2, and propose a few key ingredients including high carrier mobility, large electron-phonon matrix elements, and slow phonon-phonon scattering. The plethora of low symmetry crystals whose Fermi surfaces are composed of d orbitals from the transition metal and p orbitals from the metalloids provides a much larger pool for further study. This work provides ab initio signatures of material-specifics to explore hydrodynamic electron flow in a much larger family of condensed matter systems, and thus offers insights into further study of electron interactions through transport phenomena.

Light Matter Interaction and Quantum Confinement in 2D Polar Metals Margaux Lassaunière[1], Jakob Henz[1], Wen He[2], Siavash Rajabpour[3], Alexander Vera[3], Katharina Nisi[1], Shruti Subramanian[3], Su Ying Quek[2], Joshua A. Robinson[3] and Ursula Wurstbauer[1]; [1]University of Münster, Germany; [2]National University of Singapore, Singapore; [3]The Pennsylvania State University, United States

Important for all (quantum) optical technologies is the manipulation of the light-matter interaction to achieve a high level of control, particularly in technologically relevant solid-state nanomaterials. Atomically thin two-dimensional layered materials receive great interest because of their unique properties. A novel class of atomically thin materials such as 2D polar metals such as 2D gallium or 2D indium and their ternary alloys that exhibit fascinating properties like superconductivity [1,2] strong nonlinear optical properties emerging by giant second harmonic generation [3] and epsilon near zero behavior in the visible and NIR range [4]. The layer dependence of the energies of localized plasmons due to interband transition strongly suggest quantum confined 2D metal films. In contrast, monolayers and hetero-bilayers of semiconducting transition metal dichalcogenides (SC-TMDCs) excel due to their strong exciton dominated light matter interaction with the possibility to study and manipulate dense and correlated exciton ensemble [5-7] and to realize quantum light sources [8].
In this talk, we will introduce the rather new class of 2D materials, 2D polar metals and focus on their linear optical response measured by imaging spectroscopic ellipsometry in dependence of the temperature covering room temperature to 800mK. At low temperatures emergent behavior such as superconductivity occurs such that we are able to monitor the dielectric functions across the phase transitions.

We acknowledge funding by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under Germany's Excellence Strategy – EXC 2089/1 – 390776260 and projects Wu 637/4- 1, 4 – 2, 7-1 and SPP 2244.

Intercalation-Induced Phase Transition in T_d-WTe_2 Mengjing Wang, Aakash Kumar, Hao Dong, John Woods, Joshua Pondick, Alyssa Shiyu Xu, Peijun Guo, Diana Qiu and Judy Cha; Yale University, United States

Intercalation of lithium into van der Waals gaps of two-dimensional (2D) materials has been exploited to induce useful electronic and structural phase transitions enabled by its high electron doping power on the order of 10^{14} e/cm^2. For example, semiconducting 2H-MoS_2 can be transformed into metallic 1T'-MoS_2 with lithium intercalation. Despite the extensive studies of lithium intercalation in MoS_2 and WS_2, the effects of lithium intercalation in other 2D transition metal dichalcogenides have rarely been explored. Herein, we report a reversible structural phase transition in 2D semi-metallic Td-WTe_2 by electrochemical lithium intercalation. The phase transition dynamics were systematically investigated with a combination of *in situ* characterization tools to monitor the changes in the optical, structural, and electrical properties of WTe_2 as a function of intercalation driving voltage in real-time. The intercalation-induced new phase was probed structurally by *in situ* polarization angle-dependent Raman spectroscopy, which revealed new Raman peaks as well as a distinct symmetry for the high-frequency intralayer and low-frequency interlayer vibration modes at the phase transition point. Surprisingly, the new phase shows an increase of longitudinal resistance by two orders of magnitude and a significant reduction of carrier density at the phase transition point, probed by *in situ* Hall measurements as a function of intercalation. The *in situ* transport data suggests that the new phase has a distinct electronic band structure from the T_d phase. Based on our observations and *ab initio* calculations, we suggest possible crystal structures and corresponding electronic band structures for the intercalation-induced phase in WTe_2.

12:00 PM EQ20.08.05
Two-Dimensional Charge Order Stabilized in Clean Polytype Heterostructures Suk Hyun Sung[1], Noah Schnitzer[2], Steve Novakov[1], Ismail El Baggari[3], Xiangpeng Luo[1], Jiseok Gim[1], Nguyen Vu[1], Zidong Li[1], Todd Brintlinger[4], Yu Liu[5], Wenjian Lu[5], Yuping Sun[5], Parag Deotare[1], Kai Sun[1], Liuyan Zhao[1], Lena Kourkoutis[2], John T. Heron[1] and Robert Hovden[1]; [1]University of Michigan, United States; [2]Cornell University, United States; [3]The Rowland Institute at Harvard, United States; [4]U.S. Naval Research Laboratory, United States; [5]Institute of Solid State Physics, Chinese Academy of Sciences, China

Strong evidence suggests that transformative correlated electron behavior may exist only in unrealized clean 2D materials such as 1T-TaS_2 [1]. Unfortunately, experiment [2, 3] and theory [4] suggest that extrinsic disorder in free standing 2D layers impedes correlation-driven quantum behavior. Here we demonstrate a new route to realizing fragile 2D quantum states through epitaxial polytype engineering of van der Waals materials [5]. The isolation of truly 2D charge density waves (CDWs) between metallic layers stabilizes commensurate long-range order and lifts the coupling between neighboring CDW layers to restore mirror symmetries via interlayer CDW twinning. The twinned-commensurate (tC-) CDW reported herein has a single metal–insulator phase transition at ~350 K as measured structurally and electronically. Fast in-situ transmission electron microscopy and scanned nanobeam diffraction map the formation of tC-CDWs. This work introduces epitaxial polytype engineering of van der Waals materials to access latent 2D ground states distinct from conventional 2D fabrication.

CDWs are an emergent periodic modulation of the electron density that permeates a crystal with strong electron-lattice coupling [6, 7]. TaS_2 and TaS_xSe_{2-x} host several CDWs that spontaneously break crystal symmetries, mediate metal–insulator transitions [6, 8], and compete with superconductivity [9–11]. These quantum states are promising candidates for novel devices [12–15], efficient ultrafast non-volatile switching [16, 17], and suggest elusive chiral superconductivity [18, 19]. Unfortunately, extrinsic and thermal disorder in free standing 2D layers degrades correlation-driven quantum behavior and clean 2D CDWs or superconductivity are near absent. Room temperature access to spatially coherent CDWs and clean 2D confinement could enable a paradigm shift toward device logic and quantum computing.

Here we show the critical temperature for spatially-coherent, commensurate (C-) CDW in 1T-TaS_2 can be raised to well above room temperature (~150 K above the expected transition) by synthesizing clean interleaved 2D polytypic heterostructures [5]. This stabilizes a collective insulating ground state (i.e. C-CDW) not expected to exist at room temperature. We show the formation of these spatially coherent states occurs when 2D CDWs are confined between metallic prismatic polytypes. Metallic layers screen impurity potentials to suppress the disordered nearly-commensurate (NC-CDW) phase. At the same time, interleaving disables interlayer coupling between CDWs . This raises the critical temperature of the C-CDW and forms out-of-plane twinned commensurate (tC) CDWs as revealed by scanned nanobeam electron diffraction. These results demonstrate polytype engineering as a route to isolating 2D

collective quantum states in a well-defined extrinsic environment with identical chemistry but distinct band structure.

Stages in the Structural and Chemical Modification of Zeolitic Imidazole Frameworks (ZIFs) Under Electron–Beam Irradiation Supriya Ghosh and Andre Mkhoyan; University of Minnesota, Twin Cities, United States

Zeolitic imidazole frameworks (ZIFs) are a type of metal organic framework (MOF), where Zn metal atoms are tetrahedrally coordinated to imidazole linkers.[1] ZIFs are widely studied as potential materials of interest in electronic devices and sensor applications due to their low-dielectric constants. For device applications, high precision patterning of the ZIFs is essential, which has been demonstrated by using an electron and X-ray beam. To optimize these patterning techniques, it is necessary to understand the structural and chemical changes happening in the MOF framework upon electron-beam irradiation. This has been widely studied in other inorganic crystalline materials like zeolites, but is limited for MOFs.[2] Here, we study the transition of a ZIF-L MOF from an ordered crystalline state to a disordered amorphous state using dose-controlled transmission electron microscopy (TEM) coupled with electron energy-loss spectroscopy (EELS) to simultaneously monitor chemical changes during the transition.
First, structural changes in ZIF-L were monitored using dose-dependent electron diffraction. It was observed that at an accumulated dose of ~ 100 e/Å^2, there is a complete loss in diffraction intensity along with the appearance of broad amorphous like peaks indicating the formation of an amorphous ZIF-L phase. Further, shifts in diffraction peaks with dose indicates a decrease in the lattice parameters, which is also observed as particle shrinkage in the high-angle annular dark-field scanning TEM (HAADF-STEM) images. Thus, in the initial stages of beam exposure, it can be concluded that there is a collapse of the porous framework resulting in the formation of a “disordered” amorphous ZIF-L phase, retaining the short-range order of the parent framework.
To study the chemical changes in ZIF-L during this transformation, core-level EELS spectra were obtained from C, N and Zn as a function of dose to monitor changes in the fine-structure which are sensitive to the local chemical environment. At doses < 100 e/Å^2, changes in the fine-structure were minor indicating no changes in the local bonding of the amorphous ZIF-L. At higher doses > 500 e/Å^2, considerable changes were observed in the core-level EELS fine-structure, resulting from the radiolytic modification of the imidazole linkers by the loss of methyl groups and ring opening reactions, degrading the linker in the second stage of the structural modification. These results point to a completely radiolytic behavior of the electron-beam-ZIF interaction. Further, these structural modifications impact the dielectric properties of the material by shifting the energy for the optical transitions, which are important for device applications.[3]

Designer Quantum States in van der Waals Heterostructures and Metal-Organic Frameworks Orlando J. Silveira[1], Peter Liljeroth[1], Teemu Ojanen[2] and Adam Foster[1]; [1]Aalto University, Finland; [2]Tampere University, Finland

In general, the progress in the field of condensed matter comes from the discovery of new materials with novel properties. For instance, the discovery of two dimensional (2D) materials such as graphene in 2004 and transition metal dichalcogenides (TMDs) in 2005 had great impact on the scientific community, giving rise to tremendous and ongoing activity in both theoretical and experimental fields. Following that, van der Waals (vdW) heterostructures have gained attention, where two or more atomically thin layers interact with each other through weak vdW forces, and induced effects due to the proximity of the layers lead to intriguing properties that can be engineered for several practical applications. Recently, with the advance on experimental techniques to fabricate and isolate new materials, as well as to probe their features, other novel properties have also been reported intrinsically in 2D materials: spontaneous magnetization, quantum Hall effect and superconductivity. Nonetheless, the rational design of new heterostructures combining these materials, and thus their properties, allows the development of new quantum phases of matter that have not been observed in stand-alone materials, such as the topological superconductivity, which has aroused great interest in recent years due to the potential applications in topological quantum computers. Here we present results obtained for the 2D magnetic $CrBr_3$ monolayer deposited on top of the layered superconductor $NbSe_2$, as well as the metal-organic framework M-DCA (with M=Cu, Co and Ni) deposited either on graphene or $NbSe_2$, focusing mainly on their electronic and structural

properties obtained through density functional theory (DFT) and tight-binding (TB) calculations. We compare these directly to state-of-the-art Scanning Tunnelling Microscopy experiments and develop a framework for the systematic design of quantum materials.

1D van der Waals Molecular Wires—Exfoliation Energies, Electronic Properties and How to Find Them in the Lab Yanbing Zhu[1], Daniel Rehn[2], Evan Antoniuk[1], Gowoon Cheon[1], Rodrigo Freitas[3], Aditi Krishnapriyan[4] and Evan Reed[1]; [1]Stanford University, United States; [2]Los Alamos National Laboratory, United States; [3]Massachusetts Institute of Technology, United States; [4]Lawrence Berkeley National Laboratory, United States

Two-dimensional (2D) materials derived from van der Waals (vdW)-bonded layered crystals have been the subject of considerable research focus, but analogous one-dimensional (1D) materials have received less attention while potentially also exfoliable and useful for optical or electronic applications. These bulk crystals consist of covalently bonded multi-atom atomic chains with weak van der Waals bonds between adjacent chains. Using density-functional-theory-based methods, we find the binding energies of several 1D families of materials to be within typical exfoliation ranges possible for 2D materials. In addition, we compute the electronic properties of a variety of insulating, semiconducting, and metallic individual wires and find differences that could enable the identification of and distinction between 1D, 2D, and 3D forms during mechanical exfoliation onto a substrate. We find 1D wires from chemical families of the forms $PdBr_2$, SbSeI, and $GePdS_3$ are likely to be distinguishable from bulk materials via photoluminescence. Like 2D vdW materials, we find some of these 1D vdW materials have the potential to retain their bulk properties down to nearly atomic film thicknesses, including the structural families of HfI_3 and PNF_2, a useful property for some applications including electronic interconnects.

Machine learning methods are also used to predict previously undiscovered low-dimensional van der Waals materials, targeting compositions with conductive and potentially magnetic properties. We find different models trained on different subsets of the data recover similar predicted unsynthesized 1D materials, illustrating model robustness. A particular composition, MoI_3,which is predicted by the model to be 1D, is indeed confirmed to exist with wire-like subcomponents. We train on classes of materials tailored for potential experimental synthesizability, specifically for chalcogen, halogen, and pnictogen-containing compounds due to their ease of synthesis using chemical vapour deposition (CVD) and chemical vapour transport (CVT).

Inhomogeneity in Large Area Exfoliated Transition Metal Dichalcogenide Monolayers Mohammad A. Hossain, Yue Zhang and Arend van der Zande; University of Illinois at Urbana-Champaign, United States

In nanomaterial synthesis, there is a tradeoff between scalability, material quality and uniformity. The tradeoff is especially evident in the case of two dimensional (2D) materials, which are layered materials with single or few atoms thick layers that are held together by weak van der Waals forces. Semiconducting transition metal dichalcogenides (TMDC) from the family of 2D materials offer opportunities including exploring strongly bound excitons and engineering highly deformable, high mobility electronics. However, progress in translating these materials from scientific curiosities to applications is largely limited by the availability of synthesis techniques that are both scalable and yet lead to high quality materials. A new approach gaining momentum is to use large area exfoliation through selective adhesion of bulk 2D materials to metal adlayers to get monolayers with the quality and lateral sizes similar to the starting bulk crystal. These techniques rely on the stronger adhesion of gold to the TMDC layers compared to the interlayer van der Waals adhesion in the bulk crystal[1-6].

In this work, we demonstrate a modified gold mediated technique for large area exfoliation of high quality TMDC monolayers over millimeter scales which leads to much higher yield and uniformity compared with previous approaches. With the higher uniformity from the exfoliation, we discover a surprising inhomogeneity in the quality of the starting bulk crystal at ~ 100 um length scales which was not evident through traditional exfoliation techniques.

Our technique adds an additional step by relaxing the gold adhesion layer when laminating onto the 2D bulk surface, leading to better conformation at the Au-TMDC interface. As a result, we were able exfoliate monolayers with lateral sizes up to 5 mm, limited only by the size of the starting bulk crystal. To make direct quantitative comparison, we exfoliated large monolayers of WSe_2 from the same bulk crystal using multiple large area exfoliation techniques. On average, the yield was 75% using our approach compared with 45% for other similar approaches. In addition, our approach leads to fewer cracks, higher reproducibility, and higher optical uniformity from other approaches.

Intriguingly, by comparing optical maps of sequential transfers from the same bulk crystal, we observe inhomogeneities in the optical response on the scale of 100 μm that are in the same relative positions on each monolayer. By comparing the photoluminescence peak positions and intensities, we relate these variations to discrete changes in the defect density or material doping present in the bulk crystals.

These results show that the uniformity of exfoliation is now limited not by the uniformity of transfer, but the quality of the starting material. The variations even within bulk crystals show that care must be taken when comparing properties based on defect density – highly pertinent to many device applications relevant to properties including doping, contact engineering, excitonic states, and mobility.

Finite-Size Effects of Electron Transport in Anisotropic Quasi-Two Dimensional Metals George Varnavides[1,2], Yaxian Wang[1], Philip J. Moll[3], Polina Anikeeva[2] and Prineha Narang[1]; [1]Harvard University, United States; [2]Massachusetts Institute of Technology, United States; [3]École Polytechnique Fédérale de Lausanne, Switzerland

Non-magnetic delafossite metals, such as $PdCoO_2$ and $PtCoO_2$, exhibit single-band, quasi-two dimensional Fermi surfaces (FS) which can host extremely long carrier mean free paths, despite their high carrier-density[1,2]. This provides opportunities to investigate unconventional carrier transport where the intrinsic scattering mechanisms additionally compete with the micro-scale device's length-scale, resulting in finite-size effects such as the recently observed crystal symmetry-forbidden directional ``quasi-ballistic" transport[3,4]. Interestingly, the hexagonal FS of these delafossite metals deviates strongly from a circular FS - with pronounced facets, leading to an anisotropic Fermi velocity distribution[3,4].

Here, we parametrize the electronic 2D Boltzmann transport equation (BTE) to account for the in-plane FS anisotropy and include both momentum-relaxing and momentum-conserving interactions[5]. This allows us to investigate unconventional electronic transport in these systems by numerically solving the anisotropic BTE, across a range of momentum-relaxing and momentum-conserving interaction lengthscales, to create transport regime plots for each FS orientation. Using first principles calculations of the (momentum-relaxing) electron-phonon and (momentum-conserving) phonon-mediated electron-electron interactions, we populate the resulting transport regime plots and classify electronic transport in $PdCoO_2$ between the "quasi-diffusive", "quasi-ballistic", and "quasi-hydrodynamic" transport limits as a function of temperature.

Consistent with experimental observations we find the directional dependence of electron flow, which gives rise to crystal symmetry-forbidden in-plane resistivity anisotropy, is strongest at low temperature in the "quasi-ballistic" regime, i.e. in the absence of momentum-conserving interactions[5]. As momentum-conserving interactions increase, leading to collective flow which acts to homogenize the current distribution, the effect gets weaker in the "quasi-hydrodynamic" regime identified between 10-25 K, albeit still expected to be measurable[5]. This work provides insights into understanding electron transport from microscopic scattering mechanisms and Fermi surface geometries, paving the way for designing finite-size devices from high carrier-density quasi two-dimensional metals.

EQ20.10.11
Mechanical Properties and Thermal Stability of a Free-Standing Monolayer Amorphous Carbon Levi C. Felix[1], Raphael M. Tromer[1], Pedro Autreto[2], Luiz A. Ribeiro[3] and Douglas S. Galvao[1]; [1]State University of Campinas, Brazil; [2]Universidade Federal do ABC, Brazil; [3]Universidade de Brasil, Brazil

Recently, the first synthesis of a free-standing monolayer amorphous carbon (MAC) was reported [1]. MAC is a pure carbon structure composed of randomly distributed five, six, seven, and eight atom rings and has many structural differences from a random network. Its electronic properties are similar to boron nitride. Also, several nanostructures, such as nanotubes and nanoscrolls, build from MACs were found to be stable [2]. In this work, we have investigated, through fully atomistic reactive molecular dynamics simulations the structural and thermal MAC properties. Our results [3] show that MAC and graphene (G) sheets of similar dimensions have quite distinct mechanical behavior. In general, G exhibits one stage of the elastic regime, followed by abrupt fracture (brittle), while MAC exhibits several structural stages where the stress values drop, but with no abrupt fractures (ductile). These stages present structural reconstructions followed by the appearance of linear atomic chains (LAC) in the final fracture stages. LAC are commonly observed in fractured carbon-based nanostructures [4]. These extensive MAC reconstructions are possible due to the large distribution of bond lengths and bond angle values, and the presence of different types of rings, which creates multiple stress release channels. The G and MAC fracture dynamics are also different, while PG presents abrupt fractures and fast crack propagation, MAC exhibits more localized fractures that prevent fast crack propagation and works as efficient stress release mechanisms. MAC is softer than G, their corresponding Young's modulus values are 881 and 587 GPa, respectively. MAC also exhibits remarkable thermal stability with a melting point (5368K) very close to that of G (5643K).

Layered $CuIn_7Se_{11}$ for Near-Infrared and Polarization-Sensitive Photodetector Ningxin Li; Georgia State University, United States

Ternary copper indium selenide (CIS), as a novel two-dimensional (2D) material, has a high external quantum efficiency and a sufficiently narrow bandgap (1.1 eV), making it a promising candidate for the development of ultra-thin and flexible current photodetectors. Since CIS can exhibit a variety of structures depending on the ratio between Cu and In, here, we investigate the optoelectronic response characteristics of the new 2D atomically layered ternary compound that was synthesized with the ratio between Cu and In was 1:7 ($CuIn_7Se_{11}$), consistent with the range where the layered phase forms. We discovered that, unlike conventional 2D materials which have the blue-shifted phenomena in photoconductivity spectra as the thickness decreases, the $CuIn_7Se_{11}$ shows an opposite trend of red-shift. This unique feature makes it an ideal candidate for a red light or near-infrared photodetector material. Additionally, we unveil a strong linear polarization dependence in its photoconductivity response, which also exhibits an intriguing relationship with the sample thickness and working temperature. This may indicate a phase transition occurs at low temperature and induced the variation in dipolar transition law. Our study will provide an alternative material system for the fabrication of highly-effective polarization-sensitive visible and near-infrared photodetector.

EQ20.10.16
Late News: Chemical Design of Molecular Frameworks as Stimuli Responsive Phase Change Materials Dara E. Weiss; Johns Hopkins University, United States

While the permanent porosity and crystalline structure of metal-organic frameworks (MOFs) has been exploited for gas sequestration and catalysis, recent attention has focused on the potential for MOFs to enable a new generation of sensors, actuators, and low-power consumption electronics. To do so,

chemical design of MOFs and other molecular frameworks that exhibit stimuli-responsive properties is necessary. Previous work from the Kempa group demonstrated the gas-phase assembly of 2D MOFs comprised of redox-active, stimuli-responsive Mo_2(isonicotinate)$_4$ paddlewheels. Here we present and investigate the tunable properties of MOFs assembled from derivatives of this di-Mo paddlewheel. A notable example is comprised of Mo_2(isonicotinamide)$_4$ clusters, which we show can be assembled using solution- and gas-phase methods into MOFs with 2D and quasi-1D topologies. X-Ray diffraction (XRD) data collected on Mo_2(isonicotinate)$_4$ and on Mo_2(isonicotinamide)$_4$ MOFs at various partial pressures of CO_2 reveal the structural origins of interlayer gas uptake anomalies. These data suggest that the commensurately stacked 2D monolayers can dynamically and reversibly re-order to assume new phases in response to external stimuli. Device transport measurements can reveal not only the significant modulation of framework conductivity corresponding to the induced phase changes, but also the role of the metal-ligand coordination environment. These efforts lay the groundwork for implementation of these designer molecular frameworks as switches and dynamically tunable membranes.

EQ20.10.17
Late News: Photo-Transistor Based on 2D Materials Heterojunction with Periodically Arrayed Nanopore Structures for Enhancing Performance Min-Hye Jeong, Sang-Hyun Lee, Hyun-Soo Ra and Jong-Soo Lee; Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

Two dimensional materials are promising building blocks for various optoelectronic application such as ultra-high-mobility transistors, tunable p-n junction diodes, solar cells, light-emitting diodes and their unique properties have attracted attention. However, in the case of monolayer materials, strongly bound excitons generated by Coulomb interaction inhibit the formation of free carriers due to the absence of internal potential. Here, we demonstrate p-n junction phototransistor, which has a novel hybrid photonic crystal structure for improve the optical properties of the photo transistor in active area. To understand enhanced optical properties and optoelectronic interaction with our novel hybrid structure, we have performed density functional theory calculations as well as Raman spectroscopy, Photoluminescence (PL), Time-Resolved Photoluminescence (TR-PL) and measurement of electrical and optical transport properties for device characteristics. The characteristics of the heterojunction devices with PANS reveal enhanced photodetector figures-of-merit compared with pristine heterojunction devices. The phototransistor with novel hybrid photonic crystal structure shows dramatically enhanced photo current (A), responsivity (A/W) and detectivity (Jones). Therefore, it is important advantage in using our novel hybrid nanopores structure in optoelectronic application.

EQ20.10.18
Late News: Reversible and Controllable Threshold Voltage Modulation for n-channel MoS2 and p-channel MoTe2 Field-Effect Transistors via Multiple Counter Doping with ODTS/Poly-L-lysine Charge Enhancers Seung G. Seo and Sung Hun Jin; Incheon University, Korea (the Republic of)

Confronted by the inherent physical limitations in scaling down Si technology, transition metal dichalcogenides (TMDCs) as alternatives are being tremendously researched and paid attention to. However, mature counter doping technology for TMDCs is still elusive, and thus, a controllable and reversible charge enhancer is adopted for acceptor (or donor)-like doping via octadecyltrichlorosilane (ODTS) (or poly-L-lysine (PLL)) treatment. Furthermore, multiple counter doping for TMDC field-effect transistors (FETs), combined with a threshold voltage (V_{th}) freezing scheme, renders the V_{th} modulation controllable, with negligible degradation and decent sustainability of FETs even after each treatment of a representative charge enhancer. In parallel, the counter doping mechanism is systematically investigated via photoluminescence spectroscopy, X-ray photoelectron spectroscopy, atomic force microscopy (AFM), surface energy characterization, and measurement of optoelectronic properties under illumination with light of various wavelength. More impressively, complementary inverters, composed of type-converted molybdenum ditelluride ($MoTe_2$) FETs and hetero-TMDC FETs in enhancement mode, are demonstrated via respective ODTS/PLL treatment. Herein, driving backplane application for micro-light-emitting diode (μ-LED) displays and physical validation of a corresponding counter doping scheme even for flexible polyethylene terephthalate (PET) substrates could be leveraged to relieve daunting challenges in the application of nanoscale Si-based 3D stacked systems, with potential adoption of ultralow power and monolithic optical interconnection technology.

EQ20.10.19
Late News: Type-Controllable MoTe2 Thin-Film Transistors Driven Quantum Dot Light-Emitting Diodes with Ligand Modification Geunwoo Baek[1], Seung G. Seo[2], Donghyo Hahm[3], Wan Ki Bae[3], Jeonghun Kwak[1] and Sung Hun Jin[2]; [1]Seoul National University, Korea (the Republic of); [2]Incheon National University, Korea (the Republic of); [3]Sungkyunkwan University, Korea (the Republic of)

Recently, transition metal dichalcogenide (TMDC) has gained tremendous interests in electronic/optoelectronic applications because it has prominent optical/electrical properties, a controllable bandgap, superior electrostatic gate coupling, and immunity to a short channel effect. Despite these outstanding merits, the study of emerging devices incorporated with TMDC thin film transistors (TFTs) and quantum dot light-emitting diodes (QLEDs) has been rarely reported. In this sense, TMDCs have one of the excellent candidates to realize the switching device for QLED displays in lieu of conventional Si technology. So, we adopted a molybdenum ditelluride ($MoTe_2$) as a switching component exhibiting a negligible Fermi-level pinning phenomenon, light insensitive properties, and the availability of type conversion. In this study, molecular doping by Poly-L-lysine (PLL) is adopted for a type conversion of $MoTe_2$ TFTs and surface ligand modification is utilized for the improvement of QLED performance. Based on these methodologies, we firstly demonstrate active-matrixed light-emitting devices, composed of ultra-thin $MoTe_2$ TFTs and highly efficient QLEDs. As a result, the driving capability of $MoTe_2$ TFTs for the operation of QLEDs display provides the successful and advanced applications as next generation display backplane transistors of QLEDs.

EQ20.10.22
Low-Temperature and Magnetoresistance Behavior of Ti_3C_2-MXene for Sensing Applications Krzysztof Grabowski, Kamil Goc, Tomasz Straczek, Shreyas Srivatsa, Tadeusz Uhl and Czeslaw Kapusta; AGH University of Science and Technology, Poland

MXenes are a family of two-dimensional (2D) nanomaterial. Titanium Carbide MXene (Ti_3C_2-MXene) is the first inorganic compound discovered among the MXene family in 2011. Ti_3C_2-MXenes have been studied extensively for their physical properties and chemical stability. There have also been many applications of these MXenes for sensing applications. In this present work, we discuss the response of Ti_3C_2-MXene nanomaterials to low-temperature. The Ti_3C_2-MXene samples are tested for their change in electrical resistivity for a wide range of temperatures (3K – 300 K). The unique behaviors observed in Ti_3C_2-MXene as well as their precursor MAX (Ti_3AlC_2-MAX) phase material are presented. Then the magnetoresistance behavior of Ti_3C_2-MXene and Ti_3C_2-MAX phase materials are studied at various temperatures leading to their analysis and reporting. These unique behaviors of Ti_3C_2-MXenes have the capability for sensor development and thus extensive repeatability tests are conducted. The sensing applications of Ti_3C_2-MXene at low temperatures with their magnetoresistance behavior opens avenues for the application of these sensors for space technology and explorations. Finally, the possibilities of various sensors using the magnetoresistance behavior are envisaged.

EQ20.20.21
Graphene Confined in Layered Silicate Barbara Pacakova[1], Marian Matejdes[2], Paulo H. Michels Brito[1], Leander Michels[1], Josef Breu[2] and Jon O. Fossum[1]; [1]Norwegian University of Science and Technology, Norway; [2]Bayerisches Polymer Institut und Lehrstuhl für Anorganische Chemie 1, Universität Bayreuth, Germany

The real use of graphene in electronic devices, such as field-effect transistors (FET), meets several principal complications. Opening of graphene band gap usually leads to significant drop of electron mobility; limitation of Klein tunneling paradox can prevent graphene-based devices from switching into the OFF state. Some of the complications can be overcome by combining graphene with insulating layers in two-dimensional heterostructures that allow for fabrication of a graphene-based FET with a high ON and OFF switching ratio [1], and precise control over graphene doping. However, fabrication of such heterostructures is not trivial. The best performing heterostructures are made by manual assembly, which is not very efficient method for their mass production.

We have prepared two-dimensional heterostructures more efficiently, by growing graphene from a nitrogen-carbon precursor inside the confined space of a layered silicate. This approach promises simultaneous band-gap opening in graphene and formation of final heterostructures in one step. The resulting structure has the form of a multi-layered sandwich composed of nitrogen-doped (N-doped) graphene-like layers and the single layer sheets of synthetic layered silicate, sodium fluorohectorite.

Can such a large-scale production method generate well-defined and homogeneous clean system useable for FET or other electronic applications of graphene? To answer this question, we need to examine the layered heterostructure itself, to reveal the nature of the N-doped graphene-like layers. As the initial point, it is of high benefit to know how are the nitrogen atoms distributed within the graphene lattice. Electronic transport properties of sandwich multi-layers, which are important parameters for device performance, can be then explained in the context of geometry of individual layers.

Nitrogen doping of graphene is the efficient way of band-gap modification, as it allows band-gap opening and its transformation to an *n* or a *p*-type semiconductor [2]. Nitrogen can be incorporated into the graphene lattice in three different configurations [2,3], with planar sp^2 (pyridinic and pyrrolic) and tetrahedral sp^3 (quaternary N) hybridizations. Depending on the level of the sp^2-N doping and the geometry of the N-doped graphene lattice, band gap can vary from 0.14 eV up to 0.7 eV[4]. Characteristic C-C, N-C and N-N bond lengths depend on the lattice configuration and differ from the un-doped graphene[2,4].

Growth of the N-doped graphene in confined space [3] is a promising method superior to the other preparation strategies, as it provides selective formation of pyridinic and pyrrolic groups in the graphene lattice and suppress formation of quaternary N. Carbon lattice doped with planar N-sites can serve as useful building block for use in the supercapacitors, batteries, transistors, fuel cells and other semiconductor applications[2] , and also possess high activity in the oxidation reduction reactions [3] in contrast to the lattice containing quaternary N. In all cases, types of nitrogen doping, lattice geometry and defects together with the lattice distortions significantly alter both properties, performance and the suitable application potential of the N-doped graphene[2]. Its combination with layered silicate is a promising step towards the real applications.

Atomically Thin Canvas for Quantum Optoelectronics Hongkun Park; Harvard Univ, United States

Transition metal dichalcogenide monolayers are atomically thin semiconductors that can host tightly bound excitons. Recent advances in materials growth and fabrication have enabled the preparation of high-quality van der Waals heterostructures incorporating these two-dimensional materials. In this presentation, I will describe our efforts to use these heterostructures as a “canvas” to realize new quantum optoelectronic devices for excitons and electrons. I will discuss how we improve the spectral/spatial uniformity and coherence of excitons and realize atomically thin mirrors and active metasurfaces. I will also describe our recent observation of long-sought electron Wigner crystal phases in these heterostructures without a magnetic field or moiré potential. Our studies illustrate that the heterostructures made of atomically thin semiconductors are an attractive solid-state platform for exploring novel excitonic and correlate-electron phenomena.

Rydberg Exciton Emission Dynamics in Monolayer $MoTe_2$ Souvik Biswas[1], Joeson Wong[1], Eoin Caffrey[1], Sergiy Krylyuk[2], Hamidreza Akbari[1], Kenji Watanabe[3], Takashi Taniguchi[3], Albert Davydov[2], Zakaria Al Balushi[1,4] and Harry A. Atwater[1]; [1]California Institute of Technology, United States; [2]National Institute of Standards and Technology, United States; [3]National Institute for Materials Science, Japan; [4]University of California, Berkeley, United States

Low dimensional systems, such as monolayer TMDCs, host strong non-hydrogenic Rydberg-series excitonic resonances that dominate the optical spectrum. Here, we investigated the dynamical radiative properties of the excitonic Rydberg series-driven photoluminescence in monolayer $MoTe_2$. High quality hBN-encapsulated $MoTe_2$ monolayer heterostructures with electrical contacts and back gate, which enabled modulation of the doping density in $MoTe_2$, were fabricated to perform low temperature (~4.5K) photoluminescence measurements. We observed bright, narrow emission from the first three states of the excitonic Rydberg series, namely A1s, 2s and 3s with record linewidths of ~3, 6 and 10 meV, respectively. All these states exhibit linear scaling with incident excitation pump fluence. Upon injecting excess free charges on either electron or hole side in $MoTe_2$, dipole oscillator strengths were rapidly transferred from the excitonic to the corresponding trionic (charged exciton/attractive polaron) states. Energy shifts between the neutral and dressed excitonic states were observed as a function of gate voltage, which strongly depend on the Rydberg state of the exciton – indicating strong excitonic wavefunction dependent screening properties and electron-exciton interaction. Our findings provide a route to realize exotic excitonic phases in monolayer or twisted bilayer $MoTe_2$.

Temperature and Gate Dependent Refractive Index Modulation and Epsilon-Near-Zero Response in Monolayer Molybdenum Diselenide Melissa Li, Souvik Biswas, Claudio U. Hail and Harry A. Atwater; California Institute of Technology, United States

Dynamic control of the optical scattering properties in resonant nanostructures is central to the realization of active nanophotonics, but concepts thus far

have primarily used dielectric or plasmonic Mie resonances which have limited electrical tunability. Here, we report over 200% modulation in both the real and imaginary part of the complex refractive index in hBN-encapsulated monolayer molybdenum diselenide ($MoSe_2$) by tuning the exciton resonances. Gate modulated control of the Fermi level allows us to explore the doping dependence of the A and B exciton resonances for temperatures between 4 K to 150 K. We observe both a temperature and carrier density dependent variation in the permittivity and transition from metallic to dielectric response in the epsilon-near-zero wavelength range. We attribute the change in the refractive index to the interplay between radiative and nonradiative channels that are dependent on carrier density and temperature. Our findings of large electrical tunability of the complex refractive index is accompanied by large changes in reflectance amplitude and phase, suggesting the potential of monolayer $MoSe_2$ as an active material for emerging photonics applications.

11:30 AM EQ20.11.04
Deeply Subwavelength Light Confinement and Guiding with Bulk Transition Metal Dichalcogenides Haonan Ling and Artur Davoyan; University of California, Los Angeles, United States

In this work we investigate theoretically and experimentally light guiding in nanometer-scale waveguides made of transition metal dichalcogenides (TMDCs). We explore the limits of light guiding and show that in certain configurations owing to unique material properties light can be squeezed and guided in nanometer thick channels. In our experimental effort we discuss the fabrication approach and the preliminary measurements examining performance of such waveguides.
TMDCs are an emerging type of layered van der Waals semiconductors possessing unique electronic and optical properties [1,2], which make them promising candidates for photonic applications. Specifically, bulk TMDCs are of great interest for a range of optical applications, including metasurfaces [3], gratings [4], and nano-resonators [5,]. Recently promise of bulk TMDCS for integrated nanophotonics [6] was also explored. Here we show that owing to their unique optical properties, including high refractive index, room temperature excitonic resonance and strong anisotropy, bulk TMDCs are capable of guiding light in a deeply subwavelength regime.
We begin our analysis with a study of dispersion relations and influence of materials anisotropy on optical field confinements in slab waveguides. We show that owing to high refractive index light can be efficiently guided in 120 nm thick TMDC flakes. We then examine the limits of light guidance in structures made of bulk TMDCs, especially in nanometer-size void waveguides, which are formed within a bulk of MoS_2 material. In such systems we find that the light can be efficiently confined in very narrow air channels, down to even sub-nanometer scale. We show that by selecting appropriate waveguide dimensions over 75% of the power can be squeezed into a waveguide with less than 35 nm air gap across a broad spectral range (visible to near infrared). We then study how material anisotropy influences the light confinement and guidance and show that interlayer voids provide a simpler approach to device fabrication and experimental study of the phenomenon. Finally we discuss the influence of losses and show that such waveguides can be low loss in the sub-band gap regime. Our theoretical findings are of direct interest to highly confined optical interconnects and to light materials coupling in atomic size channels of 2D materials.
Lastly, we discuss pathways for experimental demonstration of light guiding in such nanometer scale devices. We discuss our approach to fabricating such nanoscale waveguides, in which we have optimized processes to obtaining structures made of ~100 nm MoS_2. Next we discuss design and fabrication of grating coupler excitation of bulk MoS_2 waveguides. We then perform far-field measurements in 800 nm-1100 nm band that indicate that light can be efficiently guided in such subwavelength structures.
In conclusion, our work paves the way to a new type of highly confined low loss optical waveguides, which will find use in a broad range of applications including among others integrated photonics, quantum optics and sensing.

High Quality Factor Polariton Nanoresonators and Planar Programmable Optics with van der Waals Materials Michele Tamagnone[1], Xinghui Yin[2], Antonio Ambrosio[1] and Federico Capasso[2]; [1]Istituto Italiano di Tecnologia, Italy; [2]Harvard University, United States

Nanophotonics is expected to play a key role in the next decades. The miniaturization and integration of these components has, however, an additional challenge with respect to nanoelectronics devices, namely the diffraction limit. If dielectric materials are used, light cannot be confined and guided if the size of the waveguides and components is below a critical size which is determined by the wavelength and the refractive index of the used dielectric material.
However, this limit can be circumvented if materials supporting polaritons are used instead of dielectrics. Polaritons consist in a strong interaction between light and a dipole-carrying excitation (e.g. plasmons, phonons and excitons).
Phonon polaritons in van der Waals (vdW) materials such as hexagonal boron nitride (h-BN) and molybdenum trioxide (MoO3) have been extensively studied with techniques including near-field scanning optical microscopy (NSOM) and are considered as particularly good candidates for miniaturized photonics in the mid-infrared [1-6].
In this contribution we will first present some recent results from our group. We first demonstrate high quality factor phonon polaritons resonators (with Q reaching almost 500) based on isotopically pure h-BN and MoO3 [6]. Compared to previous devices based on non-isotopically-pure hBN [3], these resonators can achieve a Q factor up to 3 time larger due to the intrinsic higher quality of the phonon in the material [4]. The resonators (arrays of disks with thickness of tens of nanometers and diameters of hundreds of nanometers) have been fabricated with electron beam lithography followed by reactive ion etching of the vdW materials. Using FTIR spectroscopy and NSOM we observed and studied the resonance in both the restrahlen bands for hBN and in all 3 restrahlen bands in MoO3, finding high quality factors in all hBN bands and in the third band of MoO3. Strikingly, the resonance is maintained even if the volume of the resonator is 10^6 times smaller than the cube of the wavelength in free space, and thanks to the hyperbolic properties of hBN and MoO3 it can be pushed further down.
We then determined a theoretical upper bound on the quality factor of the resonators working for polaritonic resonators in the sub-wavelength limit. Through rigorous manipulation of Maxwell's equations, we found that the linewidth of the resonator can never be smaller than the intrinsic linewidth of the polaritonic resonance.
Second, we will show flat reconfigurable photonic devices based on a heterostructure of isotopically pure hBN deposited on a thin layer of the phase-change material GeSbTe[5]. With a laser diode we can induce crystallization of GST ("write" process) and we can restore the amorphous state ("erase"

process). Because the crystalline form has much larger refractive index, we can induce waveguides for hBN phonon polaritons via substrate effects. We demonstrated fully programmable and reprogrammable lenses, metalenses and prisms for bidimensional polaritons. We also created guided wave resonators with periodic substrate patterning, which are akin to photonic crystals but with phonon polaritons.
Finally, we will discuss applications of these devices for bio-chemical sensing and photodetectors.

Microscopic Carrier Distribution Imaging of Atomically-Thin van der Waals Semiconductors by Scanning Nonlinear Dielectric Microscopy Kohei Yamasue and Yasuo Cho; Tohoku University, Japan

Atomically-thin van der Waals semiconductor materials have attracted much attention because of their superior and unique material properties. However, the precise control of carrier doping levels is still a challenge due to their intrinsic high surface-to-volume ratio [1]. In fact, MoS_2 can be p-doped in bulk by Nb doping but show p- to n-type transition as the number of layers decreases [2]. In addition, the performance of the devices using these materials is often affected by a semiconductor-substrate interface and the doping levels may also be changed through various treatments in device process.
Imaging microscopic carrier distributions will help the understanding the mechanism of the doping level changes. As a key imaging technology, here we demonstrate that scanning nonlinear dielectric microscopy (SNDM) permits the imaging of dominant carrier distribution of atomically-thin layers [3]. SNDM normally measures the voltage derivative of local capacitance (dC/dV) below the tip. SNDM imaging is useful because dC/dV images reflect the dominant carrier distributions. The polarity of dC/dV is inverted depending on the polarity of dominant carriers and its magnitude varies with dominant carrier concentration. It is also notable that, because of capacitance sensing using near-field microwave electric fields, this microscopy can image atomically-thin materials on a substrate without preparing contact electrodes to the sample or fabricating test device structures.
Here we report the details of dominant carrier distributions in Nb-doped MoS_2 layers mechanically exfoliated on a SiO_2/Si substrate [4]. The sample had a bulk p-doping level of 5×10^{19} /cm^3. By dC/dV imaging of a sample with various thickness, we visualized p- to n-type transition of Nb-doped MoS_2. As expected, thick layers were actually p-doped but we found that, as the layer number (L) decreased, hole concentration became lower. In more detail, for layers with $L > 6$, dC/dV signals did not depend on L significantly, while for $L \leq 6$, they significantly varied with the decrease of L. The signals became zero at $L = 3$ once, the polarity was finally inverted for $L = 2$, 1. This implies that a counter n-doping effect called surface electron accumulation [5] manifested for $L \leq 6$ and dominated the doping levels for $L = 1$ and 2. We could estimate surface level to be 1×10^{13} /cm^2. In addition, from our analysis, we suggest that a large part of p-type carriers supplied from Nb accepters were trapped at the interface states. The density of trapped carriers were estimated to be on the order of 10^{12} /cm^2. These results are actually consistent with the previous literatures [1, 2]. Furthermore, we also examined the impact of ultraviolet-ozone (UV/O_3) treatment on p-doping level. UV/O_3 treatment can be used prior to the growth of gate dielectric films to make a nucleation layer on the dangling bond-free materials [5]. We performed UV/O_3 treatment of the sample in air (~10 mW/cm^2, 185 nm and 254 nm). We found that the signal polarity was inverted even on the thicker layers after the treatment. This shows that UV/O_3 treatment has n-type doping effect, which is strong enough to cause p- to n-type transition even on the thicker layers. The results here demonstrate that SNDM provides microscopic key information for understanding and controlling the doping levels in atomically-thin van der Waals semiconductors.

Strategies for Local Control of the Structure and Properties of the 2D Layered Magnet CrSBr Frances M. Ross; Massachusetts Institute of Technology, United States

Two dimensional (2D) materials with magnetic properties open exciting new design opportunities for nanoscale magneto-electric devices. The layered magnet CrSBr is particularly interesting because of its stability in air, giving this material a key advantage for device integration compared to other 2D magnets such as CrI_3. Since practical devices based on 2D materials often involve contacting, patterning or modifying the layers, it is important to develop methods for controlling the structure and properties of CrSBr at the local, nanoscale level. Here we discuss strategies for achieving this goal, making use of approaches that have proved promising for other 2D materials. We first discuss local control of structure. We find that electron beam irradiation in a scanning transmission electron microscope induces a surprising structural change, where certain atoms migrate into the van der Waals gap to create a new phase with layer direction (and, in theory, magnetization) perpendicular to the initial layers. The ability to modulate the magnetization direction deterministically is of great interest for device applications. We also study local chemical modulation in solid-solution alloys such as $CrSCl_xBr_{1-x}$. In these materials we investigate the distribution of the alloying elements, aiming to understand magnetism and phase transformations in such tailored 2D magnets. We finally discuss strategies for contacts, focusing on the opportunities for epitaxial growth of metals and other 3D crystals onto the CrSBr surface. We have developed an approach to grow single crystal or heterostructured metals on graphene, hBN and transition metal dichalcogenides; the 2D/3D contact resistance is known to improve for larger crystals with fewer grain boundaries. We will explore how nucleation and epitaxy phenomena play out for

pristine and patterned CrSBr with its distinctive crystal symmetry. We believe that atomistic level structural and chemical modification and control are crucial for understanding properties and designing novel low-dimensional magnetic devices that use these fascinating materials.

2:30 PM EQ20.12.04
The Structural and Vibrational Properties of Intrinsic and Extrinsically-Induced Defects in the 2D Layered van der Waals Magnet CrSBr Kierstin P. Torres[1], Julian Klein[1], Thang Pham[1], Joachim D. Thomsen[1], Kate Reidy[1], Agnieszka Kuc[2,3], Michael Lorke[4], Jan Luxa[5], Zdenek Sofer[5] and Frances M. Ross[1]; [1]Massachusetts Institute of Technology, United States; [2]Helmholtz-Zentrum Dresden-Rossendorf, Institut Forschungsstelle Leipzig, Germany; [3]Jacobs University Bremen, Germany; [4]Universität Bremen, Germany; [5]University of Chemistry and Technology Prague, Czechia

Layered two-dimensional (2D) magnetic materials have intriguing low-dimensional magnetic physics and promising applications in spintronic and magneto-electronic devices. CrI_3 has emerged as a well-studied 2D magnet. [1] However, its poor stability in ambient conditions has been a significant hindrance towards its integration in devices, heterostructures, and further experiments. In contrast, the layered van der Waals antiferromagnet CrSBr [2] is suggested to be air-stable in the mono- and few-layer limit, making it a promising alternative for magneto-transport and magneto-optical studies and device applications. [3, 4] In addition, CrSBr is a semiconductor with a bandgap of ~1.6 eV, a Néel temperature of 145 K, and a strong light-matter interaction. In this work, we investigate the crystal stability and impact of defects on mono-, bi- and few-layer CrSBr using a combination of Raman spectroscopy, scanning transmission electron microscopy (STEM) and helium ion irradiation in a helium ion microscope (HIM). We study two types of samples: (i) CrSBr exfoliated via the scotch tape method and stored at ambient conditions over intervals up to months, and (ii) CrSBr exfoliated and irradiated with helium ions. We find that in pristine, mono-, and few-layer CrSBr, Raman peak shifts are a direct fingerprint of the layer number. By varying the excitation laser energy, we additionally observe resonant Raman modes due to enhanced electron-phonon coupling. Studying Raman line shapes of mono-, bi-, and few-layer CrSBr over long time periods, we find that this material is stable under ambient conditions, with only slight changes in peak shape over time. We also compare CrSBr flakes before and after annealing. At the monolayer level, changes between the annealed and unannealed spectra are most pronounced. This agrees with STEM images of annealed monolayers that display significant degradation and defect formation, whereas bilayers appear to be stable. To better understand the influence of defects on the vibrational properties, we intentionally introduce defects through controlled helium ion irradiation. With increasing helium ion dose, Raman peaks shift and broaden significantly, suggesting increased defect concentration and phonon confinement, as further manifested by our STEM studies. We further corroborate our results by ab-initio calculations of the phonon dispersion. Overall, we demonstrate how Raman spectroscopy is useful towards assessing the stability of CrSBr and its suitability in device applications.

Physical and Chemical Impacts of Atomic Reconstruction in Twistronic 2D Layers Daniel K. Bediako; University of California, Berkeley, United States

Atomically thin or two-dimensional (2D) materials can be assembled into bespoke heterostructures to produce some extraordinary physical phenomena. Likewise, these highly manipulatable materials are useful platforms for exploring fundamental questions of interfacial chemical/electrochemical reactivity. In this talk, I will discuss how spontaneous mechanical deformations (atomic reconstruction) and resultant intralayer strain fields at twisted bilayer graphene have been quantitatively imaged using Bragg interferometry, based on four-dimensional scanning transmission electron microscopy, and the impact of these mechanical deformations to the electronic band structure of these moiré superlattices. The talk will then explore how various degrees of freedom that are unique to 2D materials may be used to tailor interfacial charge transfer at well defined mesoscopic electrodes and the outlook for new paradigms of functional materials for energy conversion and low-power electronic devices.

SESSION EQ20.25: On-Demand
Sunday Morning, December 5, 2021
On-Demand

8:00 AM EQ20.10.23
Load-Dependent Friction Hysteresis on Graphitic Surfaces in *n*-alkanes Behnoosh Sattari Baboukani[1], Zhijiang Ye[2] and Prathima Nalam[3]; [1]University at Buffalo, United States; [2]Miami University, United States; [3]University at Buffalo, The State University of New York, United States

Recent advances in two-dimensional (2D) materials such as graphene, molybdenum disulfide (MoS_2), boron nitride (BN), *etc*., have opened a new path in utilizing the atomically thin layers as oil-based additives due to their ultra-low shear strength, weak interlayer interactions, and the surface chemical stability. It is crucial to develop a fundamental understanding of the dissipation mechanisms for 2D materials in the presence of hydrocarbons to control friction using 2D materials as additives in oil-based lubrication. This work presents the load-dependent atomic force microscope (AFM) friction measurements in *n*-hexadecane solutions on two graphitic surfaces, i.e., highly oriented pyrolytic graphite (HOPG) and exfoliated few-layer graphene (FLG). A sublinear increase in the friction forces with load was measured on both graphitic surfaces, with FLG measuring 30% higher friction force than HOPG (at 60 nN). Further, the nanoscale friction forces exhibit hysteresis between the loading (increasing) and unloading (decreasing) normal forces. Below a specific transition load, higher friction forces were measured during unloading than the loading for a given load, while above the transition load, the friction hysteresis becomes insignificant. The origins for friction force and load-dependent friction hysteresis were explored by measuring the adhesion and roughness of the graphitic surfaces and the solvation layering behavior. Similar RMS roughness values and insignificant adhesion forces were obtained among the graphitic surface; however, higher forces were required to squeeze the solvation layers out of contact for FLG compared to HOPG surfaces. Molecular dynamics (MD) simulations assisted in understanding the impact of solvation layers of *n*-hexadecane on the load-bearing capacity and the friction forces of the graphitic interfaces. The load-dependent friction hysteresis originates from the irreversible reorganization of *n*-hexadecane solvation layers on the graphitic surfaces during the loading and unloading phenomena.

8:05 AM EQ20.08.04
Complex Hysteresis and Memory Effects Observed in the Charge-Density-Wave Phases of the Transition Metal Dichalcogenide $TaS_{1.2}Se_{0.8}$ Benjamin Smith[1], Aimee Nevill[1], Liam Farrar[2], Charles Sayers[3], Sara Dale[1], Simon Bending[1], Daniel Wolverson[1] and Enrico da Como[1]; [1]University of Bath, United Kingdom; [2]University of St Andrews, United Kingdom; [3]Politecnico di Milano, Italy

The tantalum dichalcogenides (TaS_2, $TaSe_2$ and their intermediate alloys) are members of the layered transition metal dichalcogenide (TMD) family of materials. The tantalum dichalcogenides present a variety of different phases at different temperatures and pressures including metallic [1], Mott insulating [2], charge density wave (CDW) [3] and superconducting [4]. Of particular interest are the low-temperature CDW phases, which display further phase transitions between different CDWs (e.g., commensurate CDW, incommensurate CDW and quasi-commensurate CDW). An understanding of the interplay

of these different phases would provide a valuable insight into the nature of the electron-electron and electron-phonon interactions in these materials. Further, such properties of the tantalum dichalcogenides support their use in a variety of applications where different resistive states can be easily switched using temperature or pressure - for example, for data storage or other memory applications [5] [6].
Here, we shall present our studies on the intermediate alloy $TaS_{1.2}Se_{0.8}$. Large-area crystals have been grown in-house, using a chemical vapour transport method. We have characterised the material using a variety of experimental techniques, including temperature-dependent electrical transport, Raman spectroscopy and X-ray diffraction. These measurements have revealed the hysteretic properties of this alloy over a single cooling-heating cycle (320 – 4 K for the transport measurements). Furthermore, we have observed a fascinating 'memory effect' in this material, in which a second cooling-heating cycle yields a completely different hysteresis loop. This 'memory effect' has been observed in multiple crystals from several different growth batches and has been observed in both our transport and Raman measurements. The effect appears to be closely linked to the doping concentration we have used (S = 1.2, Se = 0.8), as we have not observed any such memory effect in crystals grown with slightly different stoichiometries (e.g., S = 1.3, Se = 0.7). We have further examined this effect by using a range of cooling/heating rates. These measurements have displayed a clear dependence on cooling/heating rate, which provide us with crucial insights into the mechanisms of the CDW phase transitions, in particular the nearly-commensurate to commensurate transition, in which domains of commensurability increase in size and eventually merge to form a fully-commensurate system. Meanwhile, our Raman measurements are vital in helping us to understand the CDW mechanism in this material, and the contributions of electron-electron and electron-phonon interactions in the formation and transitions of the CDWs.

Correlative and Cryogenic Imaging of TMDs Thomas Dieing[1], Ute Schmidt[1], Patrick Altmann[2], Mirko Bacani[2] and Olaf Hollricher[1]; [1]WITec GmbH, Germany; [2]attocube systems AG, Germany

WSe_2 and MoS_2, as transition metal dichalcogenides (TMDs), belong to a new class of nanomaterials with great potential for optoelectronic device applications. Thickness, changes in crystal symmetry, and growth defects are a few fundamental parameters that define the electronic, optical and thermal properties of two-dimensional (2D) crystals and for which different characterization techniques are required. In addition, the dependency of material characteristics on temperature and/or external magnetic fields is receiving increasing attention. Here we present the correlative analysis of these TMDs using Atomic Force Microscopy (AFM), Photoluminescence (PL) Imaging, Second Harmonic Generation (SHG) imaging and confocal Raman imaging under ambient and cryogenic conditions. The combination of the insights obtained by AFM, PL, SHG and Raman on WSe_2 measured under ambient conditions allow an interpretation of the cause of PL wavelength emission shifts, strain states and contaminations during the growth process. The strongly localized peak shift variations around the rim of the WSe_2 flake and their possible explanations based on the correlative results are particularly interesting. The addition of temperature-dependent PL imaging using a cryostat capable of cooling the sample down to 2K also allows the determination of the peak shift, both on the rim as well as in the center of such a flake, as a function of temperature. The newly established CryoRaman system, a combination of a WITec confocal Raman microscope and an attocube attoDry2100 closed-cycle cryostat, uses a high NA low temperature objective that allows for optical resolution close to that which is available under ambient conditions. Using this system, it was possible to discern low frequency Raman bands of WSe_2 for layering identification and observe them under varying polarization directions of the incoming laser light at cryogenic temperatures. The ability to apply high magnetic fields (up to 12T) additionally enables observation of the effect of the magnetic field on the recorded Raman spectra and reveals further properties of the TMDs.

SESSION EQ20.14: Large Scale Electronic Grade Synthesis of 2D Materials II

8:00 AM EQ20.14.01
A New Computational Framework for Structural Characterization and Edge-Growth Kinetics of Transition Metal Dichalcogenides—Reaxff Reactive Force Field Nadire Nayir[1,1,2], Yuanxi Wang[1,1], Danielle Hickey[1,1], Yanzhou Ji[1], Tanushree H. Choudhury[1], Long-Qing Chen[1,1], Nasim Alem[1,1], Joan M. Redwing[1,1], Vincent Crespi[1,2] and Adri van Duin[1,1]; [1]The Pennsylvania State University, United States; [2]Karamanoglu Mehmetbey University, Turkey

Presented by Nadire Nayir
Mechanical Engineering, The Pennsylvania State University, State College, PA, United States.
2D Crystal Consortium, The Pennsylvania State University, State college, PA, United States.
Physics, Karamanoglu Mehmetbey University, Karaman, Turkey.

We introduce new reactive potentials (ReaxFF)[1,2,3,4] for large-scale molecular dynamics simulations of the synthesis, processing, and characterization of two-dimensional transition metal dichalcogenides (MoS_2, WSe_2, $MoSe_2$, and WS_2), guided by an extensive quantum mechanical dataset on both periodic and non-periodic systems and validated against HAADF/STEM experiments. These new potentials are designed to capture the most essential features of TMD thin films and elucidate the structural transition from metallic to semiconducting phases, the energetics of various defects, and the Se-vacancy migration barrier. The new ReaxFF descriptions provide valuable insights into nucleation of the 1T-phase on the 2H basal plane or edges, rotational and translational grain boundaries, and the coupled effect of chemical potential and edge stability on the formation of S- and W-oriented grain boundaries. Since controllable edge-mediated growth kinetics of 2D-$MoSe_2$ are of great interest to the 2D community, these potentials are trained further against the edge formation energies of $MoSe_2$ nanoribbons with different Se coverages, we believe they will be a powerful complementary tool to experimental studies by simulating the edge-growth kinetics of 2D-$MoSe_2$ at high speed and low cost.

Effects of Growth Substrate on the Nucleation of Monolayer $MoTe_2$
David Hynek[1], Raivat Singhania[2], James L. Hart[1], Benjamin Davis[2], Mengjing Wang[1], Nick Strandwitz[2] and Judy Cha[1]; [1]Yale University, United States; [2]Lehigh University, United States

$MoTe_2$ is a 2D transition metal dichalcogenide with small energy differences between its polymorphs, allowing access to a wide range of electronic states including the room-temperature semiconducting 2H state and semimetallic 1T′ state, and low-temperature topological T_d state. Due to this, $MoTe_2$ is a model material for studying phase transformations and structure-property relationships and has potential applications in low-power, non-volatile phase change memory.
These phase changes can be induced through application of strain and charge doping, and are affected greatly by the choice of substrate. Thus, understanding the interfacial effects between $MoTe_2$ films and substrate is important for selective synthesis and control over different crystalline phases of $MoTe_2$. Further, while there are many growth studies to investigate the effects of substrate for 2D sulfides and selenides, there is a lack of fundamental understanding of the growth mechanisms for the tellurides.
Here, we examined the effect of the substrate on the morphology and crystalline phase of $MoTe_2$ by tracking the nucleation and growth of $MoTe_2$ on different substrates (*CrystEngComm* **2021**, doi:10.1039/d1ce00275a). We grew monolayer $MoTe_2$ by converting MoO_x thin films deposited on three different substrates: sapphire Al_2O_3 (0001), amorphous SiO_2, and amorphous AlO_x, following the synthesis method we developed for large-area $MoTe_2$ thin films (*ACS Nano* **2021**, 15, 1, 410–418). We systematically examined the early stages of the conversion reaction occurring on the three substrates to elucidate the substrate effects on the nucleation of $MoTe_2$. We observe that the chemical composition of the substrate is more important than the surface topography and crystallinity of the substrate, with high quality monolayer 2H $MoTe_2$ formed on both Al_2O_3 (0001) and AlO_x in contrast to mixed phase 2H/1T′ $MoTe_2$ formed on SiO_2, as determined by Raman spectroscopy, x-ray photoelectron spectroscopy, cross-sectional transmission electron microscopy, and atomic force microscopy. We attribute these results to increased wetting between Te or Mo atoms on AlO_x vs. SiO_2, which allows for improved lateral mobility and reconfiguration. Our work highlights the role of chemistry regarding substrate interactions during the synthesis of 2D materials and particularly the diffusion of metal species on different oxide films.

Jariwala[4], Saptarshi Das[1] and Joan M. Redwing[1]; [1]The Pennsylvania State University, United States; [2]Indian Institute of Technology Bombay, India; [3]The University of Alabama, United States; [4]University of Pennsylvania, United States

Monolayers of transition metal dichalcogenides (TMDs) are promising materials for electronic, optoelectronic, spintronic and valleytronic devices. Furthermore, wafer-scale epitaxial growth of TMD monolayers has been demonstrated[1,2]; however, fundamental understanding of these processes is limited. In this work, we demonstrate and compare the epitaxial growth of MoS_2, WS_2 and WSe_2 on 2” c-plane sapphire wafers using metal-organic chemical vapor deposition (MOCVD). Heat and mass transport within the reactor was modelled with computational fluid dynamics (CFD) to help predict and understand the effect of process parameters such as substrate rotation on the growth rate and uniformity of the TMD films. The films displayed uniform thickness and topography across the wafer, as measured via atomic force microscopy. X-ray diffraction measurements confirmed the films were epitaxial with respect to the sapphire substrate, while dark field transmission electron microscopy was used to image microstructural features such as translational and anti-phase grain boundaries in the coalesced monolayers. Different excitonic species such as trions and defect-bound excitons were observed with variable-temperature photoluminescence (PL) spectroscopy, while optical properties measured by spectroscopic ellipsometry closely matched predictions from theoretical models. The electronic properties of the films were measured using FETs, with the sulfide and selenide films having carrier mobilities of ~20 cm^2/Vs and ~2.5 cm^2/Vs, respectively. The lower carrier mobility in the WSe_2 films correlates with defect-related exciton emission which was observed in the PL spectrum.

We also systematically studied how the transition metal and chalcogen species affected the growth of the monolayers. For example, under similar growth conditions, WSe_2 exhibited larger domains and lower nucleation densities compared to WS_2 films, which suggests that surface diffusivity is higher on sapphire under a selenium ambient compared to sulfur. For W-containing TMDs, a three-step nucleation-ripening-lateral growth process was more effective in achieving uniform domain size compared to a single-step growth process. In contrast, no such difference was observed for MoS_2; several possible causes are currently under investigation. Understanding these trends will prove useful in the rational selection of growth parameters for TMD films.

Synthesis and Phase Tuning of $MoTe_2$ Nanosheets by Chemical Vapor Deposition
Pinaka Pani Tummala[1,2,3], Christian Martella[1], Sara Ghomi[4], Samarsadat Mirenayat[5], Alessio Quadrelli[6], Mario Alia[1], Matteo Cocuzza[4], Cristina Lenardi[6], Luca Nobili[5], Roberto Mantovan[1], Alessio Lamperti[1] and Alessandro Molle[1]; [1]CNR-IMM, Italy; [2]KU Leuven, Belgium; [3]Università Cattolica del Sacro Cuore, Italy; [4]Politecnico di Torino, Italy; [5]Politecnico di Milano, Italy; [6]Università degli Studi di Milano, Italy

Among transition metal dichalcogenides (TMDs), molybdenum ditelluride ($MoTe_2$) shows significant attention due to its polymorphic nature from semiconductor to topological insulator and Weyl-semimetal. To date, considerable efforts have been devoted for synthesizing large area $MoTe_2$ suitable for the fabrication of devices to be integrated in different applications. As compared to other synthesis methods, chemical vapor deposition (CVD) is a facile and promising way for synthesizing large scale $MoTe_2$ nanosheets.
Here we report the CVD growth and controlled phase tuning strategies for obtaining 1T’(metallic) and 2H(semiconducting) molybdenum ditelluride ($MoTe_2$) nanosheets via two ways: 1) co-deposition of tellurium and MoO_3 powder precursors and 2) tellurization of pre-deposited Mo thin film. In first

case, we employed CVD through powder precursors targeting large area growth of thin $MoTe_2$ nanosheets with controlled allotropic 1T' and 2H phases. We investigated how the local tellurium vapor concentrations determines the $MoTe_2$ phase (2H and 1T') depending on the flow rate of the Ar carrier gas and with the insertion of a physical barrier in the reaction chamber. The effect of the physical barrier is also reflected in the shape of the crystallite population and in their log-normal areal distribution pointing out to a homogeneous nucleation mode of the $MoTe_2$ crystals [1]. On the other hand, in tellurization we show a detailed study of the heterogeneous vapor-solid reaction between an e-beam pre-deposited molybdenum film and tellurium vapor, thus yielding a large area growth of $MoTe_2$ onto SiO_2/Si substrate [2]. $MoTe_2$ growth is mainly influenced by involved kinetics, tellurium concentration and geometry configurations inside the CVD furnace. As grown $MoTe_2$ nanosheets were characterized by several techniques such as Raman spectroscopy, scanning electron microscopy (SEM), atomic force microscopy (AFM) and X-ray photoelectron spectroscopy (XPS). This study is a crucial step for enabling 1T' and 2H-$MoTe_2$ integration in numerous potential applications in novel micro- and nano-electronics, quantum technologies, integrated photonics, and thermoelectric devices.

Oxide Scale Sublimation Chemical Vapor Deposition: Controllable Growth of Monolayer MoS_2 Crystals on Catalytic Glass Xu Yang, Shisheng Li, Naoki Ikeda and Yoshiki Sakuma; National Institute for Materials Science, Japan

Abstract
In this study, a newly-proposed oxide scale sublimation chemical vapor deposition (OSSCVD) technique is demonstrated for the controlled growth of two-dimensional (2D) monolayer MoS_2 crystals. With the new reactor configuration, MoO_3, which is generated in situ by flowing O_2 over Mo metal surface, can be sublimated by heating and supplied separately from the H_2S source in a controlled manner through mass flow controllers and pneumatic switching valves. A series of proof-of-concept growth experiments with varied gas flow rate and growth time was carried out using high-temperature resistant alkali-aluminosilicate glass, Dragontrail (DT-glass), as catalytic substrate. We confirmed that OSSCVD enables the growth of MoS_2 with significantly improved flexibility, controllability, and reproducibility that are absent in the conventional powder-source CVD. As a result, single-crystalline MoS_2 triangular domains as large as 25 μm was observed reproducibly, followed by the fully-covered continuous MoS_2 layer within 25 minutes. Photoluminescence and Raman spectroscopies revealed that both the achieved domains and the continuous film possess monolayer MoS_2 features and good optical quality. Meanwhile, the characteristics of fabricated field effect transistors showed maximum electron mobility of 13 cm^2/Vs, indicating a good electrical property as well. Utilizing DT-glass as substrate, the MoS_2 growth process is strongly affected by suppressed nucleation density and enhanced lateral growth, probably due to the catalytic effect of sodium and/or potassium in the glass. Particularly, we found that before growth in situ DT-glass substrate treatment by H_2S enables a remarkably enlarged domain size with reduced domain density. Intriguingly, these growth improvements might be primarily related to the alkali metal elements extracted from DT-glass to the reactor inner walls rather than the modification on the glass surface during the H_2S pretreatment process. The results achieved in this work open new avenues for growing high-quality MoS_2 and other 2D transition metal dichalcogenides using the simple OSSCVD and the cost-effective catalytic glass substrate. More details will be presented at the conference.

Tuning Electronic Structure in Wafer-Scale Continuous Monolayer MoS_2 by Chemical Vapor Deposition Shu-Ju Tsai[1], Yi-Cheng Lin[1], Sumayah Shakil Wani[2], Yu-Lun Chueh[2] and H. Hoe Tan[3]; [1]Taiwan Instrument Research Institute, National Applied Research Laboratories, Taiwan; [2]National Tsing Hua University, Taiwan; [3]The Australian National University, Australia

Monolayer molybdenum disulfide (ML-MoS_2) with excellent exotic electronic and optical properties has shown great potential for applications in transistors, sensors, energy harvesting, light-emitting diodes, catalysis, flexible devices, etc. However, it is a great challenge to achieve wafer-scale growth of continuous monolayer for MoS_2 and to control the doping because of its intrinsic *n*-type conductivity. Substitution doping (such as Nb, Mn, N atoms) has been proved to be an effective approach to tune their native properties toward *p*-type and enhance device performance. Herein, we report the growth of sulfur-rich large-area monolayer MoS_2 by a one-step chemical vapor deposition method. Much attention will be paid to the electric properties and the atomic structures of the sulfur-rich MoS_2 using Kelvin Probe Force Microscopy (KPFM, Bruker ICON) and X-ray photoelectron spectroscopy (XPS), respectively. Further studies of electrical measurements indicate that the *p*-type transport behavior can be observed in sulfur-rich MoS_2 field-effect transistor (FET) devices. The results of these studies will have a considerable impact on the tuning the electronic structure of two-dimensional TMDs, and create new direction for fundamental study and their novel device applications.

Wafer-Scale Epitaxial $MoSe_2$ on Epitaxial hBN—A Combination of MBE and MOVPE Katarzyna Ludwiczak, Aleksandra K. Dabrowska, Johannes Binder, Mateusz Tokarczyk, Jakub Iwanski, Grzegorz Kowalski, Rafal Bozek, Roman Stepniewski, Wojciech Pacuski and Andrzej Wysmolek; University of Warsaw, Poland

Ultrathin transition metal dichalcogenides (TMD) are two-dimensional semiconductors exhibiting exceptional optical, mechanical and chemical properties. Hence, they can complement other layered materials like graphene in various next-generation nanodevices.
High-quality TMD monolayers can be obtained by mechanical exfoliation - a process that is extremely time-consuming, non-deterministic and provides flakes of only a few-micrometers in size. Here, we present a heteroepitaxial method to grow single layer $MoSe_2$ directly on hBN, allowing to overcome the before mentioned problems.
In our approach, we use Metalorganic Vapour Phase Epitaxy (MOVPE) to grow few-nanometres thick layers of hexagonal boron nitride (h-BN) on two-inch sapphire substrates [1,2]. We present thorough optical and structural studies, demonstrating a high structural quality of the samples. h-BN possesses a wide bandgap (~6 eV) that makes it a perfect insulating barrier in heterostructures and is also known to improve optical properties of other layered materials due to the lack of dangling bonds on its surface [3]. Therefore, we use the epitaxial h-BN as a substrate for a subsequent growth of a monolayer of molybdenum diselenide ($MoSe_2$) using Molecular Beam Epitaxy (MBE) [4].
We studied the optical quality of the obtained TMD layers as a function of h-BN substrate thickness by performing Raman scattering and photoluminescence measurements. For the samples from well-optimized processes, we observe excitonic lines that can be resolved into two peaks corresponding to the neutral exciton A and trion at low temperatures (4 K), indicating that the material is of excellent optical quality.

Further characterization includes optical mapping of the whole two-inch samples, which proves a high homogeneity of the material. Such measurements additionally demonstrate the formation of a single atomic layer of $MoSe_2$.
Our results constitute a large step towards the wafer-scale growth of van der Waals heterostructures, which is of crucial importance for future applications. Our work also demonstrates for the first time, that using epitaxial h-BN, $MoSe_2$ of excellent optical quality can be scaled up to the size of 2 inch wafers. Moreover, the presented method can be easily applied to grow other TMD which can be used to construct optoelectronic devices such as photodetectors, LEDs and phototransistors.

9:25 AM EQ20.14.11
MBE Growth of VS_2 Layer and Its Electronic Structure Hyuk Jin Kim[1], Byoung Ki Choi[1], In Hak Lee[2], Min Jay Kim[1], Tae Gyu Rhee[1] and Young Jun Chang[1]; [1]University of Seoul, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

Vanadium disulfide (VS_2) has recently attracted much attention due to their intriguing properties, such as charge density wave (CDW), ferromagnetism, and surface catalytic behavior. However, VS_2 has received relatively little experimental research compared to other vanadium chalcogenides (VSe_2, VTe_2), so physical properties of VS_2 such as an origin of CDW, and ferromagnetism are experimentally unsettled. Here, we report MBE growth of VS_2 with different thicknesses. We investigated temperature dependent electronic structure studies by using angle-resolved photoemission spectroscopy (ARPES) measurements and show the signature of CDW transition above 300 K. Furthermore, we investigated enhanced water-dissociation properties of few layer VS2 layers by using ambient pressure X-ray photoemission spectroscopy (APXPS) measurements. These results suggest promising properties of VS_2 and related metallic sulfides.

9:30 AM EQ20.14.12
Growth of InSe on Si(111) 7x7 Surface By Molecular Beam Epitaxy Derrick Shao Heng Liu, Maria Hilse and Roman Engel-Herbert; The Pennsylvania State University, United States

InSe was recently reported as another candidate in the family of layered semiconductor material with tremendous application potential because of its high charge carrier mobility of above 1000 cm^2/Vs at room temperature, a high photoresponsivity and sizeable principal optical bandgap of 1.2 eV in the bulk that can be tuned by the number of InSe layers up to 1.9 eV in a bilayer structure, a natural ultra-thin body form factor suitable to ensure excellent electrostatic control over the channel and synthesis parameters compatible with the stringent back-end-of-line requirements.
In this talk the results of InSe thin films grown by molecular beam epitaxy (MBE) on Si(111) will be presented. By taking advantage of excellent in-situ control and monitoring capability of MBE, specifically a precise temperature control using IR cameras as well as employing the approach of controlled flux gradients across the wafer, we have identified suitable growth conditions to synthesize single phase InSe, thus demonstrating the capability of large scale high-quality InSe film on 3 inch Si(111) wafers despite the very narrow growth parameter window. We will discuss how different growth parameters affect the phase formation and surface morphology of the films. We have mapped out the growth parameter space for which single phase InSe can be grown in the temperature range between 350°C to 500°C. The single phased InSe films are confirmed by reflection high energy electron diffraction (RHEED) and X-ray diffraction. The films surface morphology is found to be affected by the chemistry composition of the growth front and growth temperature. In-rich growth fronts at lower temperatures promote the formation of pyramid-like triangles, while lower growth rates and higher temperature suppressed the pyramid formation, giving rise to smooth film surfaces with atomic terraces. Raman and photoluminescence (PL) measurements as well as X-ray photoelectron spectroscopy results will be correlated with the growth conditions and transport measurements to provide a comprehensive understanding towards wafer scale high quality growth of this promising semiconductor.

Exciton-Polaritons in van der Waals Materials Explored by Electron Beams Nahid Talebi; Christian Albrechts Universtät zu Kiel, Germany

Semiconducting van der Waals materials, including transition metal dichalcogenides (TMDCs) and tetradymites are fascinating platforms for strong light-matter interactions. Thanks to their weak anisotropic dielectric screening, their excitonic landscape include bright and dark-exciton with large binding energies. Therefore, excitons can be excited, for example by optical means, at the room temperature. Normally, exciton-photon interactions are in the form of weak interactions, as revealed from luminescence spectroscopy. Strong exciton-photon couplings though could lead to the emergence of exciton polaritons allowing for coherent transfer of the electromagnetic energy with applications in optoelectronic devices.
Strategies for enhancing the coupling between excitons and photons include the exploitation of photonic resonators or plasmonic effects. Such strong-coupling effects thus normally incorporate optical means for excitations and detections. Here, we use cathodoluminescence spectroscopy technique that is based on the spontaneous interaction of electron beams with the optical modes, hence could be a signature of the spontaneous coherence caused by collective polaritonic polarizations in the material [1, 2]. Our talk thus constitute three explorations: First, we investigate exciton-photon couplings in thin Wse_2 films [3]. Thanks to the Fabry-Perot-like resonances in thin films, the guided photonic modes pursue a longer interaction time with exciton A in the material and hence undergo a strong interaction with exciton A. We will show that the strong-coupling effect could be traced out by observing the splitting in the eigen energies and be detected spectroscopically, whereas the near-field interference effects demonstrate the excitation of exciton polaritons with their dispersions perfectly matching our theoretical results. Second, the interaction between exciton polaritons and the optical modes of a plasmonic lattice

is investigated. We will show that depending on the thickness of the WSe_2 film, the excitons luminescence response is either quenched or enhanced, signifying the interplay between the strong-coupling and screening effects. Third, we investigate exciton polaritons in Bi_2Se_3 thin films [4]. Thanks to the hyperbolic response of the material, hyperbolic exciton polaritons are excited that in contrast with the excitons polaritons in WSe_2 – that are bulk polaritons – are bound to the surfaces and edges of the materials. We particularly show that hyperbolic edge exciton-polariton sustain a long propagation length with promising applications in optics-electronics interconnects.

Probing Excitons in 2D Semiconductors and Heterostructures in Momentum Space Tony F. Heinz[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

One of the characteristic features of 2D semiconductors is the strong role of many-body electronic effects that result from the reduced dimensionality and reduced dielectric screening in these systems. In particular, the optically excited states of 2D materials and heterostructures are dominated by exciton transitions, giving rise to many distinctive properties, such as sharp, strong features and the ability to tune transition energies by external dielectric screening.

Despite our deepening understanding of excitons in 2D semiconductors and their heterostructures through advances in optical spectroscopy, some fundamental aspects of the properties of excitons in 2D semiconductors have been difficult to address directly by experiment. These include a determination of the location in momentum space of the electron and hole forming an exciton and a determination of the actual excitonic wavefunction. In this talk, we will describe recent advances in the application of time-resolved ARPES (angularly resolved photoemission spectroscopy) based on femtosecond laser sources [1,2]. This technique allows one to investigate the nature of excited states of 2D materials directly in momentum space.

We will present results demonstrating how the method allows us to identify the valley characteristics of both the electron and hole forming excitons in both 2D semiconductors and 2D heterostructures in the transition metal dichalcogenide family. The dynamics of exciton relaxation and scattering can also be captured in ultrafast pump-probe measurements. Further, the measured dispersion characteristics of the electrons photoemitted from an exciton, as opposed to a photoemission of excited free carriers, show a distinctive dispersion relation reflecting the characteristics of the remaining hole. A particularly important possibility of this approach is the direct imaging of the excitonic wavefunction through its mapping into the momentum distribution of the photoemitted electrons. We will demonstrate how this can be applied not only to isolated monolayers, but also to interlayer excitons in semiconductor heterostructures.

This work was performed in collaboration with the group of Keshav Dani at OIST, Japan, with theoretical contributions for Ting Cao at the University of Washington and Felipe da Jornada at Stanford University.

Interlayer Exciton Mediated Second Harmonic Generation Control in Transition Metal Dichalcogenides Shivangi Shree[1,2], Delphine Lagarde[2], Laurent Lombez[2], Cedric Robert[2], Andrea Balocchi[2], Kenji Watanabe[3], Takaaki Taniguchi[3], Xavier Marie[2], Iann C. Gerber[2], Mikhail Glazov[4], Leonid Golub[4], Ioannis Paradisanos[2] and Bernhard Urbaszek[2]; [1]University of Washington, United States; [2]Institut National des Sciences Appliquées de Toulouse, France; [3]National Institute for Materials Science, Japan; [4]Ioffe Institute, Russian Federation

Non-linear optical spectroscopy of atomically thin crystals gives crucial insights into their physical properties and investigates potential applications. Second harmonic generation (SHG) is a non-linear optical process, where two photons coherently combine into one photon of twice their energy. SHG is vital both as a spectroscopic tool and also for applications of a large class of materials such as II-VI and III-V semiconductors, nanotubes, magnetic- and non-magnetic layered materials, perovskites and antiferromagnetic oxides.

Efficient SHG occurs for crystals with broken inversion symmetry, such as transition metal dichalcogenide monolayers. Here we show tuning of non-linear optical processes in an inversion symmetric crystal. This tunability is based on the unique properties of bilayer MoS2, that shows strong optical oscillator strength for the intra- but also interlayer exciton resonances. As we tune the SHG signal onto these resonances by varying the laser energy, the SHG amplitude is enhanced by several orders of magnitude. In the resonant case the bilayer SHG signal reaches amplitudes comparable to the off-resonant signal from a monolayer. In applied electric fields the interlayer exciton energies can be tuned due to their in-built electric dipole via the Stark effect. As a result the interlayer exciton degeneracy is lifted and the bilayer SHG response is further enhanced by an additional two orders of magnitude, well reproduced by our model calculations [1]. Since interlayer exciton transitions are highly tunable also by choosing twist angle and material combination in heterostructures our results open up new approaches for designing the SHG response of layered materials.

Improving Exciton Valley Polarization by Scattering Jun Yan[1], Yueh-Chun Wu[1], Takashi Taniguchi[2] and Kenji Watanabe[2]; [1]University of Massachusetts Amherst, United States; [2]National Institute for Materials Science, Japan

Scattering in a device often causes performance degradation. Here we experimentally demonstrate a counter-intuitive enhancement of device performance induced by scattering. In monolayer MoS2, we show that scattering can markedly improve its excitonic valley polarization. We report seven- and twelve-

folds of valley polarization enhancement due to thermally activated and charge doping induced scattering respectively. This interesting effect is attributed to the disruption of valley pseudospin precession arising from rapid modulation of exciton momentum and concomitant exchange interaction field, which is analogous to motional narrowing in nuclear magnetic resonance spectroscopy. Our work advances understanding of valley depolarization mechanisms in transition metal dichalcogenide atomic layers and illustrates a novel approach for controlling and improving valleytronic devices.

Factors Influencing Valley Splitting in 2D Heterointerfaces Steven T. Hartman and Ghanshyam Pilania; Los Alamos National Laboratory, United States

With the recent advances in synthesis and characterization of two-dimensional materials, there is great interest in exploiting their favorable electronic properties to create compact devices. In particular, materials which lack inversion symmetry can break degeneracy between otherwise equivalent crystal momentum valleys if the time-reversal symmetry is also removed. This allows the generation of valley-polarized carrier populations, because each valley preferentially absorbs a certain polarization of light and the lack of degeneracy changes the absorption frequency for each valley. Traditionally, the symmetry has been broken with an external magnetic field, but the proximity effect of a magnetic substrate layer can potentially induce stronger Zeeman splitting of the valleys without the need for a bulky magnet. A number of computational studies have identified valleytronic/substrate material pairs which break the degeneracy between valleys, and a few have been experimentally verified. However, a systematic understanding is absent because most studies only test one or two interfaces, and differing methods make it hard to compare results.
For this reason, we have done a larger computational search of eight different materials pairs in three possible stackings, with the goal of identifying the design principles which generate much greater valley splitting in certain interfaces than in others. The valleytronic layers are transition metal dichalcogenides $(Mo,W)(S,Se)_2$, while we use two antiferromagnetic (Mn, Ni)PSe_3 substrates or the ferromagnets $CrBr_3$ and $CrGeTe_3$ to generate the proximity effect; we choose the specific pairs according to their predicted strain and band alignment, as well as their experimental relevance. While there are several common definitions of valley splitting, we select the difference between same-spin excitation energies at K vs. K'. Our first-principles calculations find a wide range of valley splittings from -26.7 to 9.8 meV, with strong dependence on both chemistry and stacking pattern. The largest valley splitting is obtained in a ferromagnetic interface which has unusually strong band hybridization between the two layers, and we analyze the possible effects of this hybridization. We identify several factors which can influence the sign and magnitude of the valley splitting.
"Strong Zeeman Splitting in Orbital-Hybridized Valleytronic Interfaces," Steven T. Hartman and Ghanshyam Pilania (in preparation).

Organic-Polymer Coated Superacid-Treated Tungsten Disulfide with Air-Stable Strong Photoluminescence Intensity Takahiro Nakahara, Takeshi Yoshimura, Norifumi Fujimura and Daisuke Kiriya; Osaka Prefecture University, Japan

Monolayer transition metal dichalcogenides (TMDCs) have attracted attention as direct band-gap semiconductor materials consisting of three atomic thin-layer (0.7 nm thick). A near-unity photoluminescence (PL) quantum yield of a monolayer MoS_2 was demonstrated via treatment with a superacid molecular (bis(trifuloromethane)sulfonimide (TFSI)) under excitation laser intensity of 10^{-4}~10^{-2} W cm^{-2} [1]. Recently, the superacid treatment followed by UV irradiation leads to strong photoluminescence with high yield [2]. In this study, we examined the same treatment on tungsten disulfide (WS_2), which has sulfur in its structure similar to MoS_2 and investigated the relationship between the superacid molecular treatment and UV light irradiation, as well as the dependence on the solvent to prepare the superacid solution. Furthermore, we achieved the air-stability of the superacid-treated WS_2 by coating with an organic polymer for more than 30 days.
A mechanically exfoliated monolayer WS_2 was immersed in 1 mg/mL superacid solution followed by UV light irradiation. PL measurements were performed for the samples as-exfoliated, TFSI-treated, and UV light irradiated after the TFSI-treatment. The as-exfoliated WS_2 shows strong PL intensity compared to MoS_2 cases, and the magnitude of the intensity is more than 300 times. The PL intensities of a monolayer WS_2 after the TFSI-treatment and the following UV light-irradiation were 7 times and 11 times enhancement, respectively, from the as-exfoliated sample. The magnitude of the enhancement was not as large compared to the previous MoS_2 cases [2], however, the PL intensity of the monolayer WS_2 of the treatment showed about 10 times stronger than that of MoS_2.
To further investigate the modulation of PL intensity of the monolayer WS_2, the solvent dependency of TFSI solution was investigated by comparing the hydrophobic 1,2-dichloroethane (DCE) and the hydrophilic acetonitrile. As a result, it was confirmed that the PL intensity of the hydrophilic acetonitrile was almost twice that of the hydrophobic DCE on average. This behavior would be due to the wettability of the acetonitrile solution of TFSI on WS_2.
We further achieved the stabilization of the strong photoluminescence of the superacid-treated WS_2 for more than 30 days in the air by coating with organic polymers. This behavior would be due to the physical separation of the TFSI molecules from the adsorption of H_2O molecules.
According to the above results, the combination of TFSI treatment and UV light irradiation results in strong photoluminescence enhancement in WS_2. In addition, the TFSI solution was prepared using hydrophilic acetonitrile as a solvent, which enabled us to investigate the optimal method for increasing the PL intensity in this system. We developed the stabilization of the strong photoluminescence of the superacid-treated WS_2 by coating with an organic polymer for more than 30 days in the air. In the presentation, we will discuss the detailed mechanism of air stability as well.

4:00 PM *EQ20.16.01
The Magic of Moiré Materials Allan H. MacDonald; The University of Texas at Austin, United States

Two-dimensional crystals that are overlaid with a difference in lattice constant or a relative twist form a moiré pattern. In semiconductors and semimetals, the low-energy electronic properties of these systems are described by Hamiltonians with the periodicity of the moiré pattern, opening up a strategy to make artificial two-dimensional crystals with lattice constants on the ten nm scale. I refer to these artificial crystals as moiré materials. Because of their large lattice constants, the band filling factors of moiré materials can be electrically tuned over large ranges without introducing chemical dopants. Moiré materials, can be used to flexibly simulate the physics of real atomic scale crystals, and to create new states of matter. I will overview progress that has been made in understanding the low-temperature properties of twisted graphene and transition-metal dichalcogenide multilayers, the first moiré materials,

and provide a perspective on prospects for future room-temperature applications. My talk will emphasize the physics of broken spin/valley flavor symmetries including the frequent emergence of Chern insulator states, and moire material ferromagnetism and superconductivity.

Direct Imaging of Wigner Crystal States in a WSe_2/WS_2 Moiré Superlattice Michael Crommie[1,2,3], Hongyuan Li[1], Shaowei Li[1,3,4], Mit H. Naik[1], Takashi Taniguchi[5], Kenji Watanabe[5], Sefaattin Tongay[6], Alex Zettl[1,2,3], Steven Louie[1,2] and Feng Wang[1,2,3]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Kavli Energy NanoScience Institute, United States; [4]University of California, San Diego, United States; [5]International Center for Materials Nanoarchitectonics, Japan; [6]Arizona State University, United States

Moiré superlattices in transition metal dichalcogenide (TMD) heterostructures host novel correlated quantum phenomena due to the interplay of narrow moiré flat bands and strong, long-range Coulomb interactions. One such phenomenon is the Wigner crystal, a 2D crystallization of electrons. Recent optical spectroscopy has provided evidence of generalized Wigner crystal states in TMD moiré superlattices (a generalized Wigner crystal is one in which the electrons can fractionally fill a lattice). Direct observation of 2D Wigner crystals in real space, however, has remained an outstanding challenge. Scanning tunneling microscopy (STM) in principle has sufficient spatial resolution to image a Wigner crystal, but conventional STM measurements perturb fragile Wigner crystal states in the process of measurement. Here I will discuss recent work where we have performed real-space imaging of 2D Wigner crystals in a WSe_2/WS_2 moiré heterostructure using a new non-invasive STM spectroscopy technique. This involves the use of a graphene sensing layer placed in close proximity to an occupied WSe_2/WS_2 moiré superlattice. The STM tunnel current into the graphene sensing layer is modified by the underlying electron lattice of the Wigner crystal in the WSe_2/WS_2 heterostructure. Our measurement directly visualizes different lattice configurations associated with Wigner crystal states at fractional electron fillings of n = 1/3, 1/2, and 2/3, where n is the electron number per site (n is controlled by voltages that can be separately applied to both a top and a bottom gate). The n=1/3 and n=2/3 Wigner crystal states are observed to exhibit triangular and a honeycomb lattices, respectively, in order to minimize nearest-neighbor Coulomb interactions. The n = 1/2 state, on the other hand, spontaneously breaks the original C3 symmetry and forms a stripe structure in real space.

5:00 PM EQ20.16.03
Quantum Anomalous Hall Effect in Magic-Angle van der Waals Materials—Enabler of Cryogenic Memory Systems Shamiul Alam[1], Md Shafayat Hossain[2] and Ahmedullah Aziz[1]; [1]University of Tennessee, Knoxville, United States; [2]Princeton University, United States

The quantum anomalous Hall effect (QAHE) stems from the interplay between magnetism and the energy band structure of topological materials. The hallmark of QAHE is the precise quantization of Hall resistance at $\pm h/e^2$ (h = Planck's constant, e = charge of an electron) without an external magnetic field. Notably, QAHE features topologically protected, dissipation-less current channels along the edge of the sample, and thus can be of great interest for emerging electronic devices. However, there is no clear pathway to utilize QAHE at the device/circuit/system level. Recently, intrinsic QAHE has been observed in twisted bilayer graphene (tBLG) moiré heterostructure [1] and tri-layer graphene [2], where the well-defined QAH states can be tuned by applying a bias current. Leveraging this aspect, we propose and construct a cryogenic non-volatile memory system using tBLG moiré heterostructure [3]. We define the memory states ('1' and '0') with the two Hall resistance states ($\pm h/e^2$). We utilize the hysteretic dependence of Hall resistance on the bias current to write into the accessed cell. During a read operation, the Hall voltage of the accessed cell shows different polarities depending on the stored memory state. Finally, the polarity of the Hall voltage is sensed using a voltage comparator to decide the memory state stored in the accessed cell. The designed memory system can operate with ultra-low power because of the nano-ampere level of bias current requirement for switching between two Hall resistance states. To scale up, we design a memory array (similar to a 3D Cross-point array) with novel peripherals (accessing and sensing mechanism) to ensure the highest scalability, minimum leakage power, and to avoid accidental data manipulation. Thanks to its small cell size and simple peripherals, the designed QAHE based memory array promises to solve the scalability issue faced by the state-of-the-art superconducting memories. We believe, this work will provide a framework for realizing memory systems based on the emerging magic-angle Van der Waals materials for cryogenic applications.

Orientation-Dependent Linear and Nonlinear Optical Properties in Layered 2D Materials Manpreet Boora, Geeta Sachdeva, Jae Yong Suh and Ravindra Pandey; Michigan Technological University, United States

Transition metal dichalcogenides (TMDs) of semiconductor band structures have recently emerged as a new family of two-dimensional (2D) materials. TMDs can have a tunable bandgap in the range of 1 − 3 eV, which enables their application in ultrathin field-effect transistors, sensors, and optoelectronic devices. Tungsten-based TMDCs such as WS2 and WSe2 have electronic states that support a strong interlayer coupling, and they exhibit an indirect-to-direct band gap transition when the number of layers decreases. After the discovery of magic angles in twisted graphene, it was found that electronic flat bands appeared for relatively small angles close to 0° and 60° in twisted bilayers of TMDs. We propose to explore the linear and nonlinear optical properties at these relatively small twist angles so that we could understand the optical physics behind the singularities appearing at these twist angles. At small relative twist angles, the stacking can generate the so-called Moiré excitons with Moiré patterns. The transitions of the Moiré excitons can be measured by photoluminescence spectroscopy, which enables the study of interlayer coupling effects.The electrical and optical properties of these stacks are significantly influenced by the twist angle, reflecting the modulated electronic band structure due to angle-dependent interlayer coupling. In our work, we use density functional theory (DFT) calculations on the electronic and optical properties of multilayer WS2 and WSe2. Calculations of the band structures, frequency-dependent dielectric function, and optical absorbance for mono, bi, and trilayers of WS2 and WSe2 shows that the optical properties strongly depend on the twist angles between two or more stacked layers. Also, many possible combinations of the crystal axes in bilayer TMDs, which cause a change in the symmetry, enable us to control the nonlinear properties. Based on DFT calculations, we propose to study the nonlinear optical properties of TMDs, such as second and third harmonic generations as a function of the number of layers and stacking orientation.

Tuning Interlayer Coupling in Twisted Janus MoSSe/MoS_2 Heterostructures Kunyan Zhang[1], Yunfan Guo[2], Daniel Larson[3], Ziyan Zhu[3], Shiang Fang[4], Efthimios Kaxiras[3], Jing Kong[2] and Shengxi Huang[1]; [1]The Pennsylvania State University, United States; [2]Massachusetts Institute of Technology, United States; [3]Harvard University, United States; [4]Rutgers, The State University of New Jersey, United States

Interlayer coupling in van der Waals heterostacks governs a variety of optical and electronic properties. Janus transition metal dichalcogenides (TMDs), a newly emerged TMD with out-of-plane asymmetry, offers a simple and versatile approach to tune the interlayer coupling. Our previous work has

demonstrated that Janus MoSSe can enhance the interlayer coupling with MoS_2 by up to 13% compared to the corresponding TMD bilayers. Here, we employed Janus MoSSe to tune the interlayer phononic and intralayer excitonic properties of Janus MoSSe/MoS_2 by forming heterostructures with S/S and Se/S interfaces, in which the sulfur or selenium side of MoSSe is in contact with bottom MoS_2, and with twist angles between the in-plane crystalline axes. The S/S heterobilayer exhibited a stronger interlayer coupling than the Se/S heterobilayer as shown by low-frequency Raman modes. The stronger interlayer coupling was in agreement with the density-functional theory calculations and was explained by a smaller interlayer distance in S/S heterostructures. Besides, the intrinsic dipole at S/S and Se/S interfaces led to enhanced and reduced charge transfer and thus different intralayer exciton relaxation, respectively. Our work opens the avenue to manipulate the asymmetry of Janus TMD to tailor the van der Waals interfacial interactions.

Late News: First-Principles Calculations of Minimally Twisted MoSe2/WSe2 Bilayers Madeleine Phillips and C. S. Hellberg; Naval Research Laboratory, United States

We present density functional theory (DFT) calculations of $MoSe_2$/WSe_2 bilayers twisted a small angle (~ 3º-5º) away from the commensurate 2H stacking. As the twist angle decreases, our calculations show the emergence of flat bands in both conduction and valence bands. The degeneracies of the flat bands suggest their origins in features of the 2H band structure. We also analyze the atomic relaxation of the twisted $MoSe_2$/WSe_2 bilayer away from the rigid moiré structure. While full reconstruction is not achieved at the angles we study, we begin to see the increase in area of regions of low energy stacking. We show that the states associated with the conduction and valence band flat bands are localized in different regions of local stacking. The localization of states is pronounced even though reconstruction is incomplete.

SESSION EQ20.17: Phase Modulation in Synthetic 2D Materials II

Monday Afternoon, December 6, 2021
EQ20-Virtual

6:30 PM EQ20.17.01
Gallium Sulfide as a Novel 2D Phase Change Semiconductor Stefano Dicorato[1,2]; [1]Institute of Nanotechnology, CNR-NANOTEC, Italy; [2]University of Bari "Aldo Moro", Italy

In recent years, phase-change materials (PCMs) have received increasing attention because of their unique properties, exploited in data storage/processing applications. PCMs require pronounced contrast in optical and/or electrical properties between two different structural state. Alternative PCMs to conventional chalcogenide alloys, containing Ge, Sb, and Te, (GST) are being extensively studied.
In the rising family of two-dimensional, 2D, materials, group (III) chalcogenides such as, GaS, Ga2S3, GaSe, GaTe, gallium sulfide, GaS is interesting as phase-change material in the optical range due to its wide bandgap of approximately 2.4 eV in the bulk form. GaS is a layered van der Waals semiconductor consisting in the stacking of covalently bond S-Ga-Ga-S atomic planes, where the successive tetralayers are held together via van der Waals forces. Few layers of GaS have successfully been produced by mechanical exfoliation, liquid exfoliation[4], chemical vapor deposition (CVD), Atomic Layer Deposition (ALD), and used in field effect transistors (FET), near-blue light emitting devices, photodetectors[2], energy storage, gas sensing[3], and in hydrogen evolution catalysis.
Here we present characteristics of few layers GaS grown by CVD. We establish the interplay between number of layers, from monolayers up to 10 layers, of GaS and its structural, optical and electrical properties. Those characteristics have been determined through an extensive characterization by Raman spectroscopy, run as a function of laser wavelength and number of GaS layers, scanning electron microscopy (SEM) used to image the morphology of the layers and count the number of layers, X-ray photoelectron spectroscopy to determine the chemical Ga:S ratio and hence, stoichiometry of the layers, spectroscopic ellipsometry used to determine the dielectric function and optical gap as a function of number of layers, as well as photoconductivity measurements also depending on number of layers.
The effect of thermal processing on those structural, compositional, opto-electronic properties is also thoroughly discussed for the first time to the best of our knowledge.
We also present results on 2D heterojunctions of GaS/graphene for blue-light photodetector, exploring different configurations of GaS/Graphene coupling. We dalso iscuss the role of graphene electron transfer on the phase change dynamics of GaS. This study represents a step forward 2D phase change heterostructures.

Tailoring the Optical and Electrical Properties of $MoTe_2$ via Electrochemical Intercalation of Lithium Alyssa Shiyu Xu, Joshua Pondick, Mengjing Wang and Judy Cha; Yale University, United States

Intercalation of lithium ions is one of the most effective methods to realize structural transformation and to tune the optical and electrical properties of two-dimensional transition metal dichalcogenides (2D TMDs). Numerous studies have focused on the phase transition from semiconducting 2H phase to metallic 1T (or 1T') phase in MoS_2 and WS_2 induced by the intercalation of lithium ions. However, few reports explore the effects of lithium intercalation in other TMDs, such as Mo- or W- ditellurides. In particular, novel electronic and energy devices can be achieved using the lithium-intercalated $MoTe_2$ with its intriguing electrical, topological and catalytic properties. Density-functional theory (DFT) calculations suggest that lithium-adsorbed T'-$MoTe_2$ is thermodynamically more stable than H-$MoTe_2$ at the same electron-doped level and the energy barrier to trigger the H to T' phase transition for monolayer $MoTe_2$ should be less than that for monolayer MoS_2 or $MoSe_2$ by lithium intercalation. [1]
Here, we report electrochemical lithium intercalation into 2H- and 1T'- $MoTe_2$ flakes. We observe that intercalated lithium dopes electrons to 2H-$MoTe_2$, as evidenced by the downshift of the peak position and broadening of the full-width at half maximum (FWHM) of A_{1g} peak in Raman spectroscopy. Further, the n-type doping of intercalated lithium to 2H-$MoTe_2$ is confirmed by the increase in conductivity of 2H-$MoTe_2$ with lithium intercalation. However, *in situ* Raman spectroscopy shows that 2H-$MoTe_2$ does not covert to 1T' phase by the intercalation of lithium ions, but directly breaks down to Mo metal clusters and lithium tellurides at an applied electrochemical voltage of 0.7 – 0.8 V. For 1T'-$MoTe_2$, the 1T' phase is stable down to 1.2 V of the applied electrochemical voltage, and a new phase is observed with no prominent Raman peaks between 0.8 – 1.1 V before becoming amorphous at 0.7 V. Our study thus suggests that, while calculations indicate that lithium-intercalated 1T'-$MoTe_2$ might be thermodynamically more stable than 2H phase, experimentally this is not realized. We hypothesize that this discrepancy is due to a high nucleation barrier of the 1T' phase, where the nucleation barrier

cannot be overcome by the applied electrochemical voltage at room temperature. Our results thus highlight the importance of phase transition pathways, in addition to the final phases at thermodynamic equilibrium, in intercalation-induced phase transitions in 2D TMDs.

Li-Intercalation-Induced Phase Transition in As_2P_3 Dinushika C. Vithanage, Manthila Rajapakse, Bhupendra Karki, Kazi Jannatul Tasnim, Ali Ibrahim Alzahrani, Usman Abu, Gamini Sumanasekera, Jacek Jasinski and Ming Yu; University of Louisville, United States

Layered As_2P_3 compounds were synthesized from red phosphorus and gray arsenic by chemical vapor transport growth method. A systematic study on electrochemical intercalation in As_2P_3 was carried out by both *in-situ* Raman scattering and *ex-situ* X-ray diffraction (XRD). A dedicated electrochemical cell under Galvanostatic discharge for *in-situ* Raman spectroscopy studies was used to study time evolution of vibrational modes under lithiation. During Lithium intercalation in As_2P_3, an abrupt shift in characteristic Raman peak positions of As_2P_3 after **x = 0.06** (in $Li_x(As_2P_3)_{1-x}$) was observed. At this degree of lithiation (x), an emergence of new peaks ~ 200 cm^{-1} and ~ 406 cm^{-1} were also observed. It is believed that an intercalation induced phase transition taking place at this specific intercalation level. *Ex-situ* XRD spectra also show evidence for different structural phases in the pristine alloy (before intercalation) and after intercalation beyond **x=0.06**. Raman shifts indicate competing effects of strain and charge transfer at the initial intercalation levels followed by structural reorganization before the phase transition. In the final stages of the intercalation, the entire process is governed by charge transfer.

7:15 PM EQ20.17.04
Heterointerface Control over Lithium-Induced Phase Transitions in MoS_2 Heterostructures Joshua Pondick, Aakash Kumar, Mengjing Wang, Sajad Yazdani, John Woods, Diana Qiu and Judy Cha; Yale University, United States

Phase transitions of two-dimensional (2D) materials and their heterostructures enable many applications including electrochemical energy storage, catalysis, and memory. These phase transitions are initiated by nucleation, and the transition pathways between phases are complex and heavily influenced by factors such as nanoscale confinement and interfaces. To effectively exploit these phase transitions for device applications, understanding the thermodynamics and kinetics of the nucleation pathways is essential; however, nucleation pathways remain virtually unexplored for many 2D transition metal dichalcogenides (TMDs) that have been demonstrated to undergo phase transitions.

Here we demonstrate that the lithium intercalation-induced 2H-1T' phase transition in the TMD MoS_2 proceeds via nucleation of the 1T' phase at a heterointerface by monitoring the phase transition of MoS_2/graphene and MoS_2/hexagonal boron nitride (*h*BN) heterostructures during intercalation with Raman spectroscopy *in situ*. We observe that graphene-MoS_2 heterointerfaces require an increase of 0.8 V in applied electrochemical potential to nucleate the 1T' phase in MoS_2, while *h*BN-MoS_2 heterointerfaces do not. The increased nucleation barrier at graphene-MoS_2 heterointerfaces is due to the reduced doping power of lithium to MoS_2 at the heterointerface as lithium also dopes graphene based on *ab initio* calculations. Further, we show that the growth of the 1T' domain propagates along the heterointerface, rather than through the interior of MoS_2. Our results provide the first experimental observations of the heterogeneous nucleation and growth of intercalation-induced phase transitions in two-dimensional materials and heterointerface effects on the phase transition.

7:30 PM EQ20.17.05
Energetics of Black As_xP_{1-x} Alloy and the Effect of Li Intercalation Kazi Jannatul Tasnim, Md Rajib Khan Musa, Manthila Rajapakse, Dinushika C. Vithanage, Gamini Sumanasekera, Jacek Jasinski and Ming Yu; University of Louisville, United States

A methodical density functional theory calculation has been performed to understand the effect of alloying in stabilizing black As_xP_{1-x} system and the role of Li intercalation on black As_xP_{1-x} alloy. The structures of black As_xP_{1-x} alloy were constructed by randomly substituting phosphorus (P) atoms with arsenic (As) atoms in the framework of the black phosphorus. Various distributions of As atoms for a given As concentration were considered and the constructed alloy systems were optimized within a full relaxation process which allows all the atoms fully relaxed with no restriction on the lattice symmetry and volume. It was found that in the energetically most stable black As_xP_{1-x} alloys, both As and P atoms prefer to forming armchair As-As and P-P bonds, aligning along zigzag direction. Due to the larger atomic size of As, a local distortion was found after the release of the local strain. The in-plane lattice constants (*a* and *c*) and the volume approximately follow the Vegard's law, but the vertical lattice constant (*b*) shows a fluctuation as the function of As concentration. The Li interaction has been performed on $Li_x(As_{0.375}P_{0.625})$ system. Our results show that a structural transformation occurs under the Li intercalation. With increasing Li concentration, the AB stacking of black $As_{0.375}P_{0.625}$ flipped from symmetric to antisymmetric ordering, then the lattice transferred from orthorhombic to rhombohedral, and a bond-breaking happened with an assembly of buckled rhombohedral nanoribbons and zigzag chains. This study pointed out that Li atoms intercalated in black $As_{0.375}P_{0.625}$ could act as 'catalyst' in a local structural transformation, indicating a possible pass way for structural phase transition and even a discovery of novel materials.

Competing Forces Behind Charge Density Wave in Transition Metal Dichalcogenides Mohammad Saeed Bahramy; University of Manchester, United Kingdom

Charge density wave (CDW) is one of the most common, yet least understood, quantum phenomena in condensed matter physics. Occurring in metallic systems, it forms a new ordered state with a distorted lattice structure and modulated charge density distribution. Astonishingly, these modulations emerge in various patterns with disparate dimensional charactersitics, even within the same family of materials. In this talk, I propose a general framework [1], that helps us to unify distinct trends of CDW instability. To show this, I focus on an isoelectronic group of transition metal dichalcogenide, 2*H*-*M*X2 (*M*=Nb, Ta and *X*=S, Se) which are best known for their puzzling CDW orderings. For example, while NbSe2 exhibits a strongly enhanced CDW order in two dimensions, TaSe2 and TaS2 behave oppositely, with CDW being absent in NbS2 entirely. Combining Raman scattering spectroscopy with first-principles calculations, I show that such a disparity arises from a competition of ionic charge transfer, electron-phonon coupling, and electron correlation. Despite its simplicity, the approach presented here, in principle, explain dimensional dependence of CDW in any material, thereby shedding new light on this intriguing quantum phenomenon and its underlying mechanisms.

8:00 PM EQ20.17.07
Highly Anisotropic Properties of $(PbSe)_{1+\delta}(VSe_2)_{1,2}$ 2D Layered Rotationally Disordered Charge Density Wave Heterostructures Yu Wang[1], Danielle Hamann[2], Dmitri Cordova[2], Marisa Choffel[2], Zhi Cai[1], Evguenia Karapetrova[3], Li Shi[4], David Johnson[2] and Stephen Cronin[1]; [1]University of Southern California, United States; [2]University of Oregon, United States; [3]Argonne National Laboratory, United States; [4]The University of Texas at Austin, United States

We explore the effect of charge density wave (CDW) phase transition on the in-plane and cross-plane properties of $(PbSe)_{1+\delta}(VSe_2)_1$ and $(PbSe)_{1+\delta}(VSe_2)_2$ heterostructures. For in-plane transport measurements of $(PbSe)_{1+\delta}(VSe_2)_1$, we observe an abrupt 86% increase in the Seebeck coefficient, 245% increase in the power factor, and a slight decrease in resistivity before and after the CDW transition. This phenomenon is not observed in $(PbSe)_{1+\delta}(VSe_2)_2$ and is highly unusual compared to the general trend observed in other materials. The abrupt transition shows a deviation from the Mott relationship through electron-electron and electron-phonon interactions. Raman spectra analysis of the $(PbSe)_{1+\delta}(VSe_2)_1$ material shows the emergence of additional peaks associated with CDW transition in VSe_2 material. Temperature-dependent in-plane X-ray diffraction (XRD) spectra show a change in the in-plane thermal expansion coefficient of VSe_2 layers in $(PbSe)_{1+\delta}(VSe_2)_1$ due to lattice distortion. The increase in the power factor and a slight decrease in the resistivity due to CDW suggest a potential mechanism for enhancing the thermoelectric performance at the low temperature region. Anisotropic transport measurements of $(PbSe)_{1+\delta}(VSe_2)_1$ show 4 orders of magnitude differences between cross-plane and in-plane resistivities over the entire measured temperature range (77 - 300 K). There is a 30% change for cross-plane resistivity of $(PbSe)_{1+\delta}(VSe_2)_1$ during the measured temperature range, while the change of in-plane resistivity is only less than 8%. The designed measurement platform can be generalized to explore anisotropic properties of various 2D layered heterostructures.

Vapor Phase Intercalation of Cesium into Black Phosphorous Usman Abu, Md Rajib Khan Musa, Manthila Rajapakse, Bhupendra Karki, Dinushika Chathurani Vithanage, Yu Ming, Gamini Sumanasekara and Jacek Jasinski; University of Louisville, United States

Among the bulk of post-graphene 2D layered materials, black phosphorous (BP) has attracted much attention since the isolation of its layers in 2014 because of its exotic properties which include: high carrier mobility, in-plane anisotropy, and thickness-dependent bandgap. Intercalation has been used to expand the versatility of BP by tuning its properties and inducing structural phase transitions for diverse applications. This happens by introducing foreign atoms (intercalants) into the van der Waals (vdW) gaps of BP. There have been past attempts to understand the underlying mechanism of intercalation in BP using different intercalants and intercalation strategies. Herein, we carry out an ex-situ study of the structural evolution and an in-situ study of the electrical transport properties of BP as it is intercalated with cesium (Cs) in the vapor phase. The Raman studies of Cs-intercalated and pristine BP indicates a redshift of its characteristic vibrational modes (A^1_g,B_{2g} and A^2_g) relative to the pristine ones where B_{2g} and A^2g modes shifted 1.3 times faster than A^1g mode; reinforcing the established preference of alkali ions to intercalate in the in-plane direction (arm-chair and zig-zag) of BP rather than the out-of-plane direction while the x-ray diffraction (XRD) patterns of Cs-intercalated BP suggest weakening vdW interactions between BP layers. Scanning electron microscopy (SEM) was done to quantify the amount of Cs intercalated into BP while x-ray photoelectron spectroscopy (XPS) was used to analyze the chemistry of these samples. Density functional theory (DFT) calculations were also carried out to help explain experimental findings.

Origins of Charge Density Wave Sliding-Based Switching in Layered 1T-TaS2 Materials from First Principles Vishal Ravi[1], Sophie Weber[2], Jonah B. Haber[2,1], Eran Maniv[2,1], Shannon Haley[2,1], James G. Analytis[2,1] and Jeffrey Neaton[2,1,3]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Kavli Energy NanoScience Institute at Berkeley, United States

Layered van der Waals materials, in particular transition metal dichalcogenides (TMDs) exhibit a wide variety of exotic electronic and photophysical phenomena, such as non-trivial topology and valleytronics [1]. These desirable properties, combined with their quasi-two-dimensional nature, make TMDs particularly attractive as candidate materials for nanoscale non-volatile logic and memory devices. The TMD 1T-TaS2 is particularly promising for device applications due to its rich phase diagram, including multiple distinct charge density wave (CDW) phases, all of which can be manipulated by electromagnetic perturbations. Specifically, 1T-TaS2 exhibits multiple distinct charge density wave (CDW) phases. We focus on the low-temperature, commensurate CDW phase which manifests as an in-plane Star of David-type deformation of the tantalum sublattice. An additional degree of freedom arises from numerous metastable stacking configurations of the adjacent CDW layers. The onset of the Star of David CDW transforms the material's electronic structure at low temperatures [2] in a way that enables a metal-insulator transition upon cooling through a critical temperature. Within this lowtemperature, insulating CDW phase, recent experiments have demonstrated that 1T-TaS2 can be switched between states of high and low resistance by application of orthogonal current pulses. While anisotropic switching has been observed in thin-film flakes in the insulating state at low temperatures [3], this behavior arises even in the 3D limit, although the role played by the interlayer stacking on the nature of the CDW phase and switching is unknown. Motivated by previous calculations demonstrating the dramatic effect of CDW stacking on the electronic structure of 1T-TaS2, we investigate the hypothesis that the resistivity switching may be caused by a current-induced change in the CDW stacking sequence using first-principles density functional theory calculations. For a number of stacking sequences, we examine the computed band structure's anisotropy in connection with the possible dynamics and mechanisms of CDW movement, and we propose a model for the nature of 2D CDW sliding, identifying low-energy pathways for CDW motion. Using this detailed information, we construct a quantitative hypothesis to explain the switching behavior observed experimentally [4]. Our work leads to new understanding of CDWs in layered van der Waals materials and their dynamics, and could reveal novel energy-efficient routes for the electric field control of logic and memory for the next generation of switching devices. Layer Dependent and Air Stable Ferromagnetism in Atomically Thin van der Waals $CrPS_4$ Jieun Lee; Seoul National University, Korea (the Republic of)

Ferromagnetism in two-dimensional materials presents a promising platform for the development of novel ultrathin spintronic devices with new functionalities. Recently discovered ferromagnetic van der Waals crystals such as CrI_3, readily isolated two-dimensional crystals, are highly tunable

through external fields or structural modifications. However, there remains a challenge because of material instability under air exposure. In this talk, we report the observation of a new air stable and layer dependent ferromagnetic (FM) van der Waals crystal, $CrPS_4$, using magneto-optic Kerr effect microscopy. In contrast to the antiferromagnetic (AFM) bulk, the FM out-of-plane spin orientation is found in the monolayer crystal. Furthermore, alternating AFM and FM properties observed in even and odd layers suggest robust antiferromagnetic exchange interactions between layers. The observed ferromagnetism in these crystals remains resilient even after the air exposure of about half a day, opening a door to the practical applications of van der Waals spintronics.

Late News: Thickness and Spin Dependence of Raman Modes in 2D Magnetic Fe3GeTe2—A First-Principles Study Liangbo Liang, Xiangru Kong and Tom Berlijn; Oak Ridge National Lab, United States

Two-dimensional (2D) layered magnetic materials have attracted increasing attention after the 2D ferromagnetic order was first discovered in chromium compounds such as CrI_3 and $Cr_2Ge_2Te_6$. The family of 2D magnets continues to grow larger and larger: in addition to insulating CrI_3 and $Cr_2Ge_2Te_6$, Fe_3GeTe_2 as a 2D magnetic metal has also joined the family. The outstanding physical properties in Fe_3GeTe_2 demonstrate its potential values in fundamental research and future applications. Before any practical applications of 2D magnets, the lattice vibrations (i.e., phonons), the magnetic orders (i.e., spins), and their coupling need to be understood first. Raman spectroscopy is among the most fast and reliable experimental techniques that can probe both phonons and spins in 2D magnetic materials. To explain and guide experimental Raman measurements, first-principles modeling of Raman scattering based on density functional theory (DFT) is often required. Here, I will highlight a recent Raman modeling-driven project on Fe_3GeTe_2 [1]. Its phonon vibrations and Raman intensities were calculated from the bulk to the monolayer. The spin-phonon coupling effect was investigated by considering different interlayer magnetic orders: ferromagnetic and antiferromagnetic. The frequencies of Raman modes in Fe_3GeTe_2 were found to exhibit considerable dependence on both the layer number and spin order. The results not only reveal the notable spin-phonon interactions in Fe_3GeTe_2, but also demonstrate that Raman modes can be utilized for characterizing the sample thickness and interlayer magnetic order in Fe_3GeTe_2.

Origin and Stabilization of Ferrielectricity in Layered Thiophosphates—A First-Principles Case Study of $CuInP_2Se_6$ Nikhil Sivadas, Peter Doak and Panchapakesan Ganesh; Oak Ridge National Laboratory, United States

Recently, ferroelectricity in layered materials "*beyond graphene*" has attracted a lot of attention because of its applications in high-density nonvolatile memory devices. However, very few layered materials demonstrate switchable out-of-plane polarization. Of them, the transition metal thiophosphates are a promising family of *beyond graphene* materials that host out-of-plane ferrielectricity (FiE) with large values of polarization [1-2]. Further, research efforts in these materials have reported a plethora of properties including negative piezoelectricity, negative electrostriction, large dielectric tunability, and unconventional field-induced switching behavior, all of which depend strongly on the polarization [3-5]. Despite the growing interest, a clear understanding of the origin and stabilization of the polar phase is still lacking in transition metal thiophosphate.

Using first-principles calculations and group-theoretical methods, we study the origin and stabilization of FiE in $CuInP_2Se_6$ [6]. We find that the polar distortions of metal atoms create most of the polarization in the FiE phase. Surprisingly, the stabilization of the FiE phase comes from an anharmonic coupling between the polar mode and a fully symmetric Raman-active mode comprising primarily of the Se atoms. This coupling is large, with the degree of anharmonicity is comparable to improper ferroelectrics. Thus, the origin of polarization is different from the factors that stabilizes the FiE phase in $CuInP_2Se_6$, unlike conventional ferroelectrics. Our results open possibilities for dynamical control of the single-step ferroelectric switching barrier by directly tuning the Raman-active mode. These finding has important implications not only for designing next-generation microelectronic devices that can overcome the voltage-time dilemma [7] but also in understanding the emergent responses in these materials.

MnPS3—A Different Twist on 2D Materials Kevin Roccapriore[1], Nan Huang[2], Vinit Sharma[1,2], David G. Mandrus[1,2] and Sergei V. Kalinin[1]; [1]Oak Ridge National Laboratory, United States; [2]The University of Tennessee, Knoxville, United States

Owing to dimensionality constraints, two-dimensional materials are of great interest for a number of different applications ranging from nanophotonics and plasmonics to mechanics and nanoelectronics.[1,2] Much focus has been on the ubiquitous graphene, as well as transition metal dichalcogenides,[3] where several applications and unique physics have been uncovered.[4] Recently, the emergent field of twistronics has enabled tremendous functionality based on twist angle between two single atomic layers.[5,6] Consequently, a great number of alternative materials have been overlooked and is arguably a source of many missed opportunities.
Here we explore the electronic and structural properties of MnPS3 using scanning transmission electron microscopy (STEM) and monochromated electron energy loss spectroscopy (EELS). Previous work on MnPS3 has largely considered it as a candidate for an antiferromagnetic 2D magnet by studying its magnetic ordering.[7,8] Through electron microscopy, we find that compared to other layered materials, MnPS3 is a host for several unique characteristics. We focus on two of these phenomena that we have recently discovered by STEM-EELS in which both great utility and distinct physics reside.
One of the most striking behaviors of MnPS3 is its sensitivity to electron beam irradiation. The effect this has on the crystal structure of MnPS3, however, is remarkable, and to our knowledge, is the first time such an effect has been observed. By electron beam irradiation, we observe the spontaneous formation of Moiré patterns with varying length scales. In effect, the electron beam in the STEM provides a modification tool that selectively induces the formation of Moiré patterns. Moreover, several degrees of freedom are present in this capability and consequently several Moiré wavelengths can be produced by the electron beam. We consider different mechanisms of Moiré pattern formation, explore the electronic property changes of the modified material as measured by STEM-EELS, as well as discuss possible applications this holds.
A second property of MnPS3 of potential great interest to the nanophotonics community lies in its support of localized plasmon resonances. Particularly, we find through hyperspectral STEM-EELS analysis that an edge plasmon near 5 eV is supported in varying number of layers. Crucially, the localization length of the edge plasmon is on the order of two-unit cells – i.e., it is extremely confined, and at the same time is relatively strong. Moreover, due to the

electron beam sensitivity of MnPS3, edges can be engineered at will by controlling the position and dose of the electron beam, paving the way toward quantum nanophotonic and plasmonic applications. We discuss the plasmonic behavior of the system and suggest its candidacy as a nanophotonic waveguide and emitter.

Twistronics with Real Time Control Cory Dean; Columbia University, United States

The ability to isolate atomically thin crystals, such as graphene, boron nitride, and the transition metal dichalcogenides, and then mechanically layer them to form new heterostructures has driven a recent revolution in materials design. These layered structures are held together by weak van der waals forces, rather than chemical bonding making it possible to readily mix and match 2D materials spanning a wide range of properties, virtually at will. More recently it has been demonstrated that the weak interlayer coupling also makes it possible to arbitrarily tune the rotation angle between adjacent layers and that varying this twist angle can lead to dramatic transformations in electronic, optical and magnetic of the combined heterostructure. Exploiting this new degree of freedom, which has been termed twistronics, has already revealed remarkable new opportunities with twisted layered structures demonstrating the ability to tune through metallic, insulating, semiconducting, semimetal, magnetic, superconducting, and topological behaviour by simply varying the twist angle. So far the vast majority of studies have reported static devices, where the twist angle is established during the fabrication process such that each device represents a single twist angle. However the weak interlayer bonding means that it is possible to realize devices where the twist angle can be dynamically varied post-fabrication. Here I will discuss our ongoing efforts to develop improved in-situ control with the goal towards realizing fully tunable devices structures consisting of just two atomic layers. I will discuss recent progress in terms of mechanical rotation of individual monolayers, improved understanding of interfacial dissipation mechanisms, implementation of in-situ feedback of twist angle and new approaches towards developing non-mechanical control of the heterostructure geometry at the nanoscale. Prospects for realizing functional twistronic devices with real-time in-situ control will be discussed.

Pinning-Free Metal Contacts to MoS_2 Monolayers for FET Applications Li Lain-Jong; University of Hong Kong, Hong Kong

Two dimensional materials (2D) have desirable properties such as high mobility at an atomic thickness, superior electrostatic control, and potential for low-power electronics. Forming a low resistance contacts to 2D such as MoS_2 is one key challenge for realizing 2D electronics. The presence of Schottky barrier height (SBH), associated with the metal-induced gap states (MIGS), limits the contact performance. In a top contact geometry, we find that the semimetallic bismuth contacted to MoS2 monolayers lead to a pinning-free Ohmic contact. A record-low contact resistance (RC) of 123 Ω μm is achieved. For the edge contact geometry, Fermi-level pinning-free Ni-MoS_2 edge contact transistor devices are obtained using in-situ etching and metal deposition. We conclude that the edge contact fabrication processes strongly affect the electrical characteristics such as Schottky barrier height where the in-situ process gives the best performance and pinning-free characteristics.

8:30 AM *EQ20.19.02
Drawing Devices on Paper with van der Waals Materials Andres Castellanos-Gomez; Spanish National Research Council, Spain

A big chunk of the price tag of electronic components is due to the cost of silicon wafer substrates. Although silicon is a highly abundant and cheap element, the transformation and processing from the raw material into high quality silicon wafers results very costly. In fact, the cost of silicon substrates constitutes ~1/3rd of the total cost of a memory chip and about ~1/10th of the cost of a high-end state of the art micro-processor. The societal, industrial and technological demands of ultra-low-cost electronic components has spurred the quests towards lower cost substrates. This has motivated a surge of works on paper-based electronics in the last years. In fact, paper substrates cost (~0.1 €/m^2) is orders of magnitude lower than that of polymer substrates (PET ~2 €/m^2 and PI ~30 €/m^2) and crystalline silicon (~1000 €/m^2).

Despite the promises of paper-based electronics, there are several challenges to be solved. One of the major challenges is that the rough, fiber-based structure of paper makes it impossible to fabricate devices using conventional lithographic techniques. In this talk I will discuss our last works to integrate different van der Waals materials onto standard paper substrates [1-4].

Unlocking the Potentials of Emerging Two-Dimensional Materials for Electronic and Optoelectronic Devices Mohammed Amer; University of California, Los Angeles, United States

Devices based on 2-Dimensional materials have been extensively investigated in recent years. Reasons such as superior electrical, optical, thermal, and mechanical properties have made these materials attractive for the next generation of devices. Yet, the realization of these 2D devices is still hindered by many challenges including a comprehensive understanding of the electrical and optical characteristics of 2D materials. In this talk, I will discuss our recent work carried out on different 2-D devices. First, I will discuss our recent development of our new pulsed thermal annealing technique to produce a controlled and tunable light emission from black phosphorus nanosheet. This tunable light emission exhibits a wide bandwidth reaching up to110nm. This wide bandwidth has been found to be caused by the formation of black phosphorus oxide, which exhibit a direct bandgap that can cause radiative processes at room temperature.

Second, I will demonstrate our recent work on Hafnium Diselenide ($HfSe_2$), an emerging 2D material that exhibit a bandgap of ~1.1eV which is analogous to silicon. I will show how $HfSe_2$ can exhibit conductivity switch using deterministic laser induced methods. This conductivity switch has been observed in both phases of $HfSe_2$ (1T and 2H). This conductivity switch has been attributed to an increase in the Schottky barrier height at the contacts, which pushes the Fermi level closer to the valance band, causing the observation of this conductivity switch.

Moreover, I will discuss our recent results obtained on Germanium Sulfide devices. Due to its similar structure to black phosphorus, GeS can be a promising material for device applications. Yet, GeS based devices are facing a major challenge due to the high contact resistance obtained. I will demonstrate our new method of 2D doping of GeS that exhibit an intentional conductivity switch from *p*-type to *n*-type with a conductivity enhancement reaching more than 10 folds. Our technique relies on deterministic deposition of degradable black phosphorus nanosheets which chemically interacts with GeS channel. We also observe a striking Negative Differential Resistance (NDR) accompanied during the transient doping of GeS devices. We characterize these devices and show that this NDR behavior is caused by partial doping in the transient state, which creates resonant tunneling paths causing the observation of this remarkable NDR behavior.

Finally, I will discuss our recent fabrication work on exfoliated Tellurene nanosheets for device applications. This material which exhibits superior thermoelectric and optoelectronic properties, is facing a major exfoliation challenge. Previous work has demonstrated solution processing technique to obtain few layers Te nanosheets . Yet, additive chemicals during liquid exfoliation may impose a potential risk in altering the pristine nature of Tellurene. I will demonstrate Tellurene thinning using specific oxygen annealing technique. Morphology measurements show a favorable thinning direction which is attributed to the anisotropy of the material. This thinning method can be a stepping milestone towards pristine few layers Tellurene devices. Our results demonstrate promising future for 2D materials to be used in device applications.

9:15 AM EQ20.19.04
Unraveling the Effect of Defects, Domain Size and Chemical Doping on Photophysics and Charge Transport in Covalent Organic Frameworks Raja Ghosh; University of California, San Diego, United States

Understanding the underlying physical mechanisms that govern charge transport in two-dimensional (2D) covalent organic frameworks (COFs) will facilitate the development of novel COF-based devices for optoelectronic and thermoelectric applications. In this context, the low energy mid-infrared absorption contains valuable information about the structure-property relationships and the extent of intra- and inter-framework “hole” polaron delocalization in doped and undoped COF structures. A theory describing the spatial coherence length of polarons in disordered COFs is presented, revealing a simple relationship between the oscillator strength of the mid infrared absorption band and the polaron coherence function. Emphasis is placed on the fundamental nature and origin of the components polarized along the intra- and inter-framework directions and their dependence on the spatial distribution of disorder as well as the position of the dopant counter-anion relative to the framework. The Hamiltonian, represented in a multiarticle basis set,[1] has been successful in quantitatively reproducing recently measured spectra recorded in doped COF films and our analysis provides conclusive evidence of why iodine doped COFs have so far shown lower bulk conductivity compared to doped polythiophenes.[2] Finally, we propose new research directions to address existing limitations and improve charge transport in COFs for applications in functional molecular electronic devices.

9:30 AM EQ20.19.05
Effect of Surface Functional Groups on MXene Conductivity Rabi Khanal and Stephan Irle; Oak Ridge National Laboratory, United States

MXenes are a rapidly developing class of two-dimensional materials with suitable properties for use in emerging electrochemical energy storage devices, including batteries and supercapacitors. The chemical synthesis of MXene leads to the surfaces being functionalized with different functional groups (O, OH, and F). Since MXene layers are only atomically thin, such surface functionalities can play an essential role in the electrical conductivity of MXene. Conductivity is a key for both the transport and storage of ions in MXene during their energy applications. While there are some experimental studies on the electrical conductivity of MXene, theoretical conductivity studies are rare. Investigations of charge carrier transport in MXene nanowires necessarily involves calculations with hundreds of atoms at the quantum level, which typically requires extraordinary computational resources. Complications due to the surface structure variability increases with model system size and increasing numbers of functional groups. The density-functional tight-binding (DFTB) approach enables the treatment of complex systems with several hundred to thousands of atoms at the quantum level at reduced computational cost with good accuracy compared to DFT. In this study, we use DFTB calculations with the nonequilibrium Green’s functions (NEGF) technique to calculate in-plane transport in the MXenes (i.e., within the MXene layers) as a function of composition. All MXene compositions were found to show a linear relationship between current and voltage at lower potentials, indicating their metallic character. However, their I-V curves, i.e., conductivity, show different trends among different compositions. MXenes without any surface terminations (Ti_3C_2) show higher conductivity compared to MXenes with surface functionalization ($Ti_3C_2O_2$ and $Ti_3C_2(OH)_2$). Among the MXenes with O and OH termination, MXenes with O surface termination have lower conductivity than OH surface termination. Conductivity changes with the ratio of O and OH on the MXene surface. I-V curves and their conductivities correlate with transmission functions and the electronic density of states (DOS) around the Fermi level. The surface composition-dependent conductivity of the MXenes provides a path to tune their conductivity for enhanced pseudocapacitive performance.

Layer-Number Dependence of Metallic Transport Behavior in MoS_2 by Molecular Charge Transfer Doping Keigo Matsuyama, Takeshi Yoshimura, Norifumi Fujimura and Daisuke Kiriya; Osaka Prefecture University, Japan

Transition metal chalcogenides (TMDCs) are two-dimensional semiconductor materials with a thickness of ~0.7 nm at the monolayer limit. A carrier modulation method of TMDCs is surface charge transfer doping by a junction with other materials such as potassium, Cs_2CO_3, and polyvinyl alcohol, etc. [1] One of the strongest modulating agents is the molecular benzyl viologen (BV) [1,2]. In previous work, BV-molecular treated MoS_2 showed degenerate semiconducting behavior without electrostatic gate-dependence in the metal-oxide-semiconductor field-effect-transistors (MOSFETs). However, the device characteristics of the organic BV-doped TMDC MOSFET have not been characterized sufficiently, and the metallic behavior by the molecular-doped has not been examined yet. The metallic behavior should be analyzed from the temperature-dependent transport behavior. In this study, we demonstrate the temperature and magnetic-field dependence of the monolayer and multilayer MoS_2 MOSFETs and characterize the behavior of the organic BV-treated MoS_2 as the metallic state and discuss the conduction mechanism of the device.
We fabricated back-gated MOSFET using monolayer and multilayer (~10 nm thick) MoS_2 flakes on Si/SiO_2 substrate and carefully measured the transport properties in the temperature range from cryogenic (~2K) to room temperature. The conductance of the device increased with decreasing the temperature in both monolayer and multilayer devices without applying gate-voltage. Therefore, the BV-doped MoS_2 obviously transformed from a semiconductor to a metallic situation.
As expected from the temperature-dependency of the BV-doped MoS_2 MOSFET, the transfer characteristic curves of BV-treated devices showed a gate-independent behavior with an ON/OFF ratio of ~10^1 in both monolayer and multilayer devices at room temperature. We further analyzed the gate- and temperature-dependency of the MOSFETs of monolayer and multilayer MoS_2 MOSFETs. In the case of monolayer MoS_2 MOSFET, the conductance just increases with decreasing the temperature even applying negative gate-voltage. On the other hand, the conductivity in the multilayer sample decreases under the negative gate-voltage with decreasing the temperature, therefore, the transport mechanism would be different in the monolayer and multilayer samples. To discuss further the details of the transport behavior, we focused on the contact resistance of the BV-doped devices. Monolayer MoS_2 MOSFET shows small gate-dependency of the contact resistance, therefore, the direct current path between the electrode and MoS_2 channel would be constructed. On the other hand, the multilayer MoS_2 device showed a large dependence of the gate voltage, this may be attributed to the additional carrier conduction under the multilayer MoS_2. In the presentation, we will discuss the details of the transport behaviors.

Brain-Mimic Optoelectronic Memory Functions of Vertically Aligned Graphene/Diamond Heterojunctions Yuga Ito, Yuki Mizuno and Kenji Ueda; Nagoya University, Japan

Graphene/diamond (carbon sp^2-sp^3) interfaces have attracted much attention because the interfaces become sources of various interesting electronic phenomena. Recently, we found that vertically-aligned graphene (VG)/diamond heterojunctions (C sp^2-sp^3 interfaces) became photo-controllable memristors [1], which are optically controllable memory-resistors with nonvolatile memory and switching functions. One of the most important application of the photo-controllable memristors is thought to be optoelectronic memory, which possess both photo-sensing and data storage function. In this study, we demonstrate that VG/diamond heterojunctions can be used as special types of optoelectronic memory, that is, brain mimic optoelectronic memory, that exhibit some of the basic functions of the human brain, such as an excitatory postsynaptic current (EPSC) and transition from short (STM) to long-term memory (LTM) states.
VG/diamond bilayers were grown *in situ* by using microwave plasma CVD, and VG/diamond junctions with diameters of 80-160 μm were fabricated using the bilayers [1, 2]. The *I-V* characteristics of these junctions in response to photoirradiation were measured using blue light emitting diodes (LEDs) or a fluorescent lamp in air at room temperature.
Raman, SEM and TEM results suggest that VG/diamond heterostructures with sharp interfaces were successfully formed. The VG/diamond junctions exhibited hysteretic I-V characteristics. The resistance of the junctions was changed to low or high resistance states by the light irradiation with bias voltage application and the resistance states was maintained in nonvolatile manner. The resistance difference ratio between the HRS and LRS (= R_{HRS}/R_{LRS}) was approximately 10^2 and was maintained for 2 days.
The VG/diamond junctions also exhibited clear responses to optical pulses and brain-like optoelectronic memory properties were observed. The junctions' current, which depended on the conductivity of the junctions, increased stepwise in response to each optical pulse, and a value of approximately 11 nA was obtained after applying 10 optical pulses. The current was subsequently maintained without significant deterioration. This generation of a current after frequent stimulation (via optical pulses) is analogous to the generation of the EPSC at biological synapses. Thus, the present VG/diamond junctions can be said to have produced an EPSC in response to optical stimulation. The magnitude of the EPSC generated by the junctions could be tuned by varying the intensity, width, frequency and numbers of the optical pulses, suggesting good controllability of the EPSC based on applying optical spikes. The energy consumption per event under these conditions was estimated to be approximately 440 pJ. This energy value is quite low and suggests the possibility of fabricating devices that mimic brain functions with very low energy consumption.
The memory retention time of the junctions was changed from shorter to longer by increasing the irradiated numbers of optical pulses. The behaviors of conductance decay can be described well by using the following decay function, $G(t)/G_0 = \exp[-(t/\tau)^{\beta}]$, which was often used for analysis of forgetting characters of the human brain. The relaxation time τ for above 7 pulses became ~2 orders higher than those for below 4 pulses. The memory character of the junctions was changed by optical pulses, and transition from STM to LTM states was caused by stronger optical stimulation. These kind of STM-LTM transition was also caused by controlling frequency of optical pulses. These results indicate that the VG/diamond junctions can be used as novel brain mimic optoelectronic memory devices, where weakly stimulated information was lost immediately and only strongly stimulated information was kept for a long time.

2D Heterostructures with Fe:MoS2 Toward Magnetic Tunneling Junction Siwei Chen, Zitao Tang, Mengqi Fang, Shichen Fu, Kyungnam Kang and Eui-Hyeok Yang; Stevens Institute of Technology, United States

The emergence of two-dimensional (2D) magnets offers exciting opportunities to discover new physical phenomena. Theoretical studies predicted that substitutional doping of magnetic atoms in transition metal dichalcogenide (TMD) monolayers would enable 2D ferromagnets at room temperature, which is a critical requirement for practical applications [1]. Experiential observations of magnetism have been made in bulk TMDs or transition metal-doped few-layer TMDs, using dopants, including V, Mn, Co, Ni, Cu, Nb and Re [2, 3]. Recently, the RT ferromagnetism was successfully demonstrated in *in-situ* Fe-doped MoS_2 (Fe:MoS_2) and V-doped WSe_2 (V:WSe_2) *via* chemical vapor deposition (CVD) [4, 5]. These 2D magnets can be used as electrodes or

barriers in vdW magnetic tunnel junctions (MTJs). Previous reports include an MTJ using MoS_2, CrI_3, or graphene as a tunneling barrier and using Fe_3GeTe_2 or $Cr_2Ge_2Te_6$ as magnetic electrodes [6–8]. The magnetic switching in the MTJ can be achieved using spin-transfer torque (STT), where the orientation of the Fe layer can be fliped using a spin-polarized current. A fast the current-induced magnetization switching (CIMS) is important for high-speed and low power next-generation spintronics devices [9], which we expect to achieve using 2D magnets. Here, we present the layer-transfer of graphene and Fe-doped MoS_2 (Fe:MoS_2) monolayers on hBN toward fabricating an MTJ consisting of a Fe/hBN/Fe:MoS_2 heterostructure. This Fe:MoS_2 monolayers were synthesized *via* low-pressure chemical vapor deposition to induce magnetic properties at a room temperature. Here, hBN is used as the tunneling barrier, Fe:MoS_2 as the free layer, and Fe thin film as the fixed layer. As a next step, we will characterize the junction magnetoresistance inside an ultra-low vibration cryogen-free cooling closed-cycle cryostat with a temperature range from 4 K to 300 K. We will measure the CIMS by applying short current pulses over the junction. This work is expected to pave the way to developing van der Waals spintronics based on various magnetic transitional metal dichalcogenides.

Laser-Induced Graphene with Controlled Heteroatom-Doping Based on Molecularly Engineered Polyimides Ki-Ho Nam, Moataz Abdulhafez, Golnaz Najaf Tomaraei and Mostafa Bedewy; University of Pittsburgh, United States

Localized graphitization of aromatic polyimides (PIs) can be achieved by laser direct write process owing to the high absorptance in the infrared wavelength range of commercial CO_2 laser cutting/scribing machines. This one-step photothermal process allows the formation of unique hierarchical nano-/micro-structured graphene patterns on the surface of polyimide film. Nevertheless, controlling chemical doping in this laser-induced graphene, has been limited thus far. Herein, we present a facile approach for manufacturing patternable, heteroatom-doped, hierarchically porous graphene from molecularly engineered PI films using a continuous-wave 10.6 μm laser in ambient air. Conventional two-step polymerization of PIs was carried out from 4,4'-oxydianiline and three different commercially available tetracarboxylic dianhydrides with different internal linkages such as phenylene, trifluoromethyl or sulfone groups. We show that the chemical structure of PIs and laser fluence of the incident radiation affect the gas evolution, inducing different structure rearrangements, as interesting heteroatom self-doping (N-doping, F-doping, S-doping) and consequently different electrical and electrochemical properties. Impressively, the electrical resistivity of F-doped laser-induced graphene can be precisely tuned to lower than ~13 Ω sq^{-1} Moreover, these fabricated grapehene electrodes are capable of detecting nanomolar concentrations of neurotransmitter, which is promising for implantable neural probes. Hence, the proposed laser one-step synthesis of graphitic structures can be readily extended for the fabrication of various advanced materials including early diagnosis of neurological disorders.

10:35 AM EQ20.20.02
Synthesis of Two-Dimensional Plasmonic Molybdenum Oxide Nanomaterials by Femtosecond Laser Irradiation Fan Ye[1,1,2], Darren Chang[1,2], Ahsan Ayub[1], Khaled Ibrahim[1,2], Ahmed Shahin[1,2], Reza Karimi[1], Shawn Wettig[1], Joseph Sanderson[1] and Kevin Musselman[1,2]; [1]University of Waterloo, Canada; [2]Waterloo Institute for Nanotechnology, Canada

A novel process to synthesize plasmonic MoO_{3-X} nanosheets is demonstrated, in which MoS_2 powders suspended in ethanol/water are irradiated with pulses from a femtosecond laser, resulting in simultaneous Coulomb explosion, photoexfoliation, and oxidation. The oxidation process is found to start with the formation of hydrogen-bonded molybdenum oxide (H_XMoO_3), followed by the release of -OH_2 groups to create oxygen vacancies, and finally the MoO_{3-X} is oxidized to MoO_3 after extended irradiation. The formation of H_XMoO_3 is the critical step to create enough oxygen vacancies for localized surface plasmon resonance (LSPR), and this step is attributed to H_3^+ dissociated from ethanol under femtosecond laser irradiation. It is found that 80-90% ethanol is the optimal concentration to synthesize plasmonic MoO_{3-X}, where the balance of water facilitates the release of the -OH_2 groups to create the required vacancies. It is shown that different organic solvents like methanol, 1-propanol and isopropyl alcohol that were reported to generate large amounts of H_3^+ under femtosecond laser irradiation can also oxidize MoS_2 into plasmonic MoO_{3-X}. The LSPR properties of the synthesized MoO_{3-X} are evaluated by UV-vis spectroscopy and photothermal conversion measurements.

10:40 AM EQ20.20.03
Low Temperature Direct Growth of Multilayer Graphene on SiN_x/Si Through Ni Catalyzed Solid Phase Reaction for EUV Pellicle Hyeyoung Kim[1,2], Junhyeok Jeon[1,2], Sangmin Lee[1], Seul-Gi Kim[1], Ki-Bum Kim[3], Hyeongkeun Kim[1], Hyun-Mi Kim[1] and Ji-Beom Yoo[2]; [1]Korea Electronics Technology Institute, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of); [3]Seoul National University, Korea (the Republic of)

Graphene has a transmittance higher than 85% for extreme ultraviolet (EUV) light (13.5 nm) and high in-plane Young's modulus. Graphene can satisfy all characteristic indicators as a material of EUV pellicles. Among the many techniques developed for synthesizing high-quality graphene, metal induced crystallization (MIC) of amorphous carbon is a unique technique for fabricating uniform multilayer graphene (MLG) that has an advantage in pellicle application due to no additional transfer process. In this study, we investigated Ni catalyzed crystallization of amorphous carbon on SiN_x/Si substrate, and further on diffusion mechanism between amorphous carbon and Ni. We found the optimal conditions to form a highly uniform MLG as a material for EUV pellicle. We observed the effect of carbon density and thickness ratio of Ni and carbon layer($t_{a\text{-}C}/t_{Ni}$) on the MIC and succeeded in forming uniform graphene on 8 inch wafer with short annealing of 1 h at 500ºC. The density of amorphous carbon was tuned by changing sputtering conditions such as power and gas flow rate. The formation of MLG on SiN_x/Si was confirmed by Raman spectroscopy, atomic force microscopy, cross-section transmission

electron microscopy. The kinetic model between amorphous carbon and nickel was substantiated by experimental findings based on amorphous carbon/Ni stacked structures of various thicknesses and densities with different heat treatment conditions.

10:45 AM EQ20.20.05
Synthesis of Graphene Nanoribbons and Nanosheets Formed in Metals by an Electrocharging Assisted Process, Their Properties and Applications Lourdes G. Salamanca-Riba[1], Oded Rabin[1,1], Manfred Wuttig[1] and Shenjia Zhang[2]; [1]University of Maryland, United States; [2]General Cable, United States

Carbon nanostructures, such as graphene and carbon nanotubes incorporated in metals have recently gained great interest for the possibility of enhancing the electrical and thermal conductivities as well as mechanical strength of the metal. This is possible because of the combination of excellent charge carrier mobility, thermal conductivity and mechanical strength of the carbon nanostructures and the high density of electrons in the metal. The improved properties make these nanocarbon metal composites unique candidates in applications such as high power transmission lines, interconnects, heat exchangers, motors, photovoltaic cells and transparent electrodes, among others. We developed a process to synthesize graphitic nanostructures in metals by the application of a high electrical current to liquid metal containing particles of activated carbon. The process called electrocharging assisted process transforms the activated carbon particles from amorphous to crystalline graphitic nanoribbons in the liquid metal. Upon solidification of the metal the nanoribbons self-assemble with an epitaxial relation with the metal. We have used Al 1350 and activated carbon particles of ~100 nm and obtained samples with global electrical conductivities more than 5% higher than the parent alloy as well as enhanced local stiffness, measured by nanoindentation. The conductivity enhancement is correlated with increasing crystallite size and concentration of the produced graphitic nanostructures. We have investigated different parameters in the process such as applied current, duration of the current, stirring speed of the liquid metal (with and without Argon bubbler) to optimize the process. The approach is scalable to large scale manufacturing.
Supported by DOE EERE Award EE0008313.

10:50 AM EQ20.20.07
Sonication-Based Selective Removal of Mechanically-Exfoliated Bulk MX_2 Flakes on the Substrate Tatsuya Nakamoto, Takeshi Yoshimura, Norifumi Fujimura and Daisuke Kiriya; Osaka Pref. Univ, Japan

Two-dimensional (2D) materials gather attention because of their large carrier mobility, transparency, and high-optoelectronic characters in a thin-confined structure. Transition metal chalcogenides (TMDCs) with the formula of MX_2 (M = transition metals, X = chalcogen atoms) are a family of 2D materials; MoS_2 is a representative material of TMDCs, which shows direct bandgap in a single layer. The single-layer MoS_2 further shows distinctive physical properties such as piezoelectric effect and second harmonic generation due to its symmetry-breaking structure.
It would be important to obtain thin layers selectively on the substrate to study 2D materials effectively. Usually, samples are prepared via a mechanical exfoliation method because the method is simple, and the exfoliated crystals usually show good crystallinity. Although the exfoliation method can transfer monolayers on the substrate, a large number of bulk flakes are simultaneously obtained. The bulk flakes cause trouble to make devices because the electric lines sometimes may disconnect by overwrapping the thick flakes. Once transfer the flakes, it is very hard to remove the bulk flakes selectively. In this study, we show our method of selective removal of bulk flakes from the substrate and maintain thin layers including monolayers by applying sonication in organic solvents.
MoS_2 flakes are transferred on a Si/SiO_2 substrate using a general mechanical exfoliation method with scotch tape. Various thick flakes cover the substrate. Then, the substrate is sonicated under an organic solvent for 5 minutes at most. After the sonication, the bulk flakes are selectively removed, and the thin layers, including monolayers, remain on the substrate.
In the process of flake-removal process, the solvent is critical. In some solvents, the selectivity is very low, and a lot of bulk flakes remained on the surface. This removal process is highly solution-dependent. The relationship between the solvent and residual rate is analyzed in terms of polar dispersion factors of the solvents. In the presentation, we will show the details of the mechanism of the selective removal of the sonication method.

High Performance Self-Powered MoS_2/ReS_2 Broadband Photodetector Riya Wadhwa and Mukesh Kumar; Indian Institute of Technology Ropar, India

Two dimensional (2D) layered materials emerged enormously in the past decade, largely being investigated fundamentally and practically. The unique layered structure and atomic-scale thickness make them attractive to have exclusive electrical and optical properties than their bulk counterparts. 2D layered materials easily integrated and formed heterostructure due to the dangling bond free surfaces. Heterostructure can access more functioning ability beyond its individual constituent. However, for novel electronic/optoelectronic device applications, it is very critical to understand the charge carrier dynamics at the interface of heterostructures. Here, we report a highly sensitive self-powered MoS_2/ReS_2 broadband photodetector, covering visible (400 nm) to NIR (1100 nm) regime with a high value of responsivity 42.61 A/W at 1V under the illumination of 800 nm, which is approximately 16 times of the reference pristine MoS_2 photodetector. The favourable energy band alignment of n-n hetero-junction is responsible for enhanced photo-responsivity and self-driven feature of the detector. Moreover, fast rise/decay transient photoresponse (20/19 ms) strongly advocate the spatial separation of charge carrier across the interface. This work facilitates the understanding of fundamental interfacial study of a new growing van der waals heterostructures for the development of novel device applications.

11:00 AM EQ20.20.09
Harnessing the Bendability of Atomically Thin MoS_2 Layers Grown by Perylene Assisted Chemical Vapour Deposition Christian Martella[1], Erika Kozma[2], Pinaka Pani Tummala[1], Paolo Targa[3], Davide Codegoni[3], Alessio Lamperti[1] and Alessandro Molle[1]; [1]CNR Institute for Microelectronics and Microsystems, Italy; [2]Consiglio Nazionale delle Ricerche, Italy; [3]ST Microelectronics, Italy

Two-dimensional (2D) layered materials exhibit an intrinsic attitude to sustain high curvature angle without rupture. [1]Therefore, shaping 2D layers into complex curved geometries is emerging as an exciting way to access unprecedented physical properties driven by two different responses to the strain-induced morphological modifications. On one hand, deformations of the atomic lattice positions lead to energetic bandstructure modifications with dramatic impacts on the opto-electronic properties of the 2D materials.[2] On the other hand, accommodation of strain through slip-and-shear mechanisms of the layers leads to superlubricity .[3]
Here we show that shape transformations in atomically thin MoS_2 layers can be controlled in the first stage of their formation by means of chemical vapor deposition on pre-patterned substrates by design. Aiming at harnessing the local curvature of mono- and few-layers MoS_2, we functionalize the pre-patterned substrates via aromatic perylene molecules serving as nucleation seeding promoters.[4] Based on the analysis of atomically resolved transmission electron microscope images, we demonstrated that the so-grown MoS_2 layers bend conformally without rupture and detachment from the substrate even at the extreme geometric features (asperities, edges, etc..) only when the seeding promoter is used. Moreover, theoretical energetic arguments allow us to quantitative derive the role of the perylene molecules to increase the interfacial adhesion energy between MoS_2 and SiO_2 substrate by balancing the strain and bending energy contributions.

High-Performance NO_2 Sensor Based on an Atomically Ordered TMD Alloy Mehmet Dogan[1,2], Amin Azizi[1,3], Hu Long[1,2,3], Jeffrey Cain[1,2,3], Kyunghoon Lee[1,2,3], Rahmatollah Eskandari[1], Alessandro Varieschi[1], Emily C. Glazer[1], Alex Zettl[1,2,3] and Marvin L. Cohen[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Kavli Energy NanoScience Institute, United States

Developing sensors that can be operated at room-temperature and ambient conditions has been an important goal for a wide range of applications. Coupled with this goal is the desire to have sensors that are small, low-power, fast and able to detect small concentrations of a molecular species. Here, we demonstrate a room-temperature, highly sensitive, selective, stable, and reversible chemical sensor based on single layer and few layers of the transition-metal dichalcogenide alloy $Re_{0.5}Nb_{0.5}S_2$. This alloy exhibits short-range ordering of atomic species due to the geometric frustration in the triangular sublattice that corresponds to the transition metal atoms. The resulting sensing device exhibits a thickness-dependent carrier type due to the band alignment changing with thickness. Upon exposure to NO_2 molecules, its electrical resistance considerably increases or decreases depending on thickness. The sensor is highly selective to NO_2 with only minimal response to other gases such as NH_3, CH_2O, and CO_2. Surprisingly, in the presence of humidity, the sensor shows complete reversibility with fast recovery at room temperature, in contrast with other similar sensors whose performance is lowered with humidity. In this presentation, we focus on the theoretical analysis of the sensing platform and identify the atomically sensitive transduction mechanism. We also explain the structural properties of the $Re_{0.5}Nb_{0.5}S_2$ and its electronic properties.

11:10 AM EQ20.20.11
Heteroepitaxy and Property of Triple-Layered Ruddlesden-Popper Phase $La_{n+1}Ni_nO_{3n+1}$ with Tetravalent-Dopants Akifumi Matsuda[1], Shohei Hisatomi[1], Yuki Goto[1], Satoru Kaneko[2,1] and Mamoru Yoshimoto[1]; [1]Tokyo Institute of Technology, Japan; [2]Kanagawa Institute of Industrial Science and Technology, Japan

Lanthanum nickelates ($La_{n+1}Ni_nO_{3n+1}$) with two-dimensional perovskite structure, so called Ruddlesden-Popper phases, have attracted interests for their electronic properties derived from their layered structure and mixed valence Ni-ions [1]. These two-dimensional perovskite layers are also expected as precursors to develop infinite-layer nickelate such as Sr-doped $NdNiO_3$ for which superconducting behavior was reported recently[2]. Epitaxy of multilayered $La_{n+1}Ni_nO_{3n+1}$ thin films and characterizing their structure, electronic state, and properties according to interfacial strain and aliovalent doping would contribute to further comprehension of their solid-state physics. There are also reports of $La_{n+1}Ni_nO_{3n+1}$ for its metal-insulator-transition according to oxygen deficiency, and applicability to SOFC cathodes and gas sensors [1,3]. However, aliovalent doping in $La_4Ni_3O_{10}$ epitaxial thin films similar to La_2NiO_4 and $La_3Ni_2O_7$ still requires further researches to understand its effect on structure and properties [5,6]. In this study, epitaxial growth of triple-layered $La_4Ni_3O_{10}$ thin films and the effect of tetravalent dopants substituting La^{3+} on the growth, structure, and electric properties was investigated.
The lanthanum nickelate thin films were grown on single crystal substrates such as $SrTiO_3$, $NdGaO_3$, and $LaAlO_3$ by pulsed laser deposition technique equipped with a KrF excimer laser (λ=248 nm, d~20 ns, and E~1.0 J/cm^2). The films were deposited at substrate temperature range from room-temperature (not heated intentionally) to 750°C in ~10 Pa O_2-flowed ambience (base pressure ~3×10^{-6} Pa) using sintered targets of pure and (Hf^{4+}, Sn^{4+}) co-doped $La_4Ni_3O_{10}$. The thin films were subsequently post-annealed in high-purity O_2 atmosphere (1 atm, 200 sccm) at temperature up to 1100°C to improve crystallinity as well as to modify the crystal phases and the valence of Ni-ions. The epitaxy of $La_4Ni_3O_{10}$ (001) thin films after annealing in O_2 was verified by {001} diffraction and four-fold planar symmetry detected in XRD 2θ/ω and φ scans, while epitaxial growth of La_2NiO_4 (100) was observed for the as-grown films. The Hf and Sn-doped $La_4Ni_3O_{10}$ (001) thin films with thickness of ~100 nm demonstrated low resistivity of ~5×10^{-3} Ωcm at room-temperature. The obtained epitaxial thin films would allow us further formation and analyses of aliovalent doped and multi-layered infinite layer nickalates reduced from the Ruddlesden-Popper phase. Additional detailed structural analyses of the doped $La_4Ni_3O_{10}$ thin films, and the effect of the tetravalent doping on the electronic property would also be discussed.

Late News: Synthetic Control Over Edge Structure in WSe2 Crystals Reynolds Dziobek-Garrett, Shreya Sriramineni, Ona Ambrozaite and Thomas Kempa; Johns Hopkins University, United States

Recent developments have shown that chemical synthesis is a powerful tool for controlling the size, shape, and composition of two-dimensional (2D) crystals with broad implications for their implementation in optoelectronic and quantum devices. However, the gas-phase reactions carried out by most researchers are not conducive to precise manipulation of the 2D crystal edge structure. Here we demonstrate a salt-assisted low-pressure chemical vapor deposition method, which enables growth of 2D WSe_2 monolayers whose edge morphology can be tuned from straight, to sawtooth, to fractal-like by adjusting the ratio of WO_3 to NaCl. We discuss the volatility of the metal precursor and its role in dictating not only the edge structure, but also the defect density within the as-grown crystals. These studies provide important insight into new 2D crystal growth modes and synthetic strategies for producing crystals with unique structures and optoelectronic properties.

11:20 AM EQ20.20.13
Enhancing Low-Frequency Raman Scattering in Exfoliated CVD-Grown 2D Nanosheets of Transition Metal Dichalcogenides Using Metal/Dielectric Substrates Bharathi Rajeswaran, Rajashree Konar, Eti Teblum, Hagit Aviv, Gilbert D. Nessim and Yaakov Tischler; Bar-Ilan University, Israel

Layered 2D sheets of Transition Metal Dichalcogenides (TMDCs) exhibit interesting optical and electronic properties such as indirect to direct bandgap transition and valley-spin coupling when scaling from bulk to a few layers. TMDCs are also flexible and versatile for constructing a wide range of heterostructures with atomic-level control over their layer thickness, devoid of issues pertaining to lattice mismatch. Hence layered TMDCs have the potential for realizing novel high-performance optoelectronic devices over a broad operating spectral range. Therefore, a detailed structural study on these materials is important to develop novel electronic and optoelectronic devices. Low-Frequency Raman (LFR) Spectroscopy is an ideal tool to investigate the signature structural information and the layer-to-layer dependency of TMDCs. LFR is a highly efficient technique for material analysis and layer identification with significant advantages over other vibrational or fluorescence spectroscopy methods. This technique remains to date one of the most popular characterization tools because of its non-invasive nature and ultra-fast detection limits. With LFR measurements, crucial information such as the tilt and number of layers can be determined. For instance, enhancement in optical properties can be understood by monitoring the evolution of the in-plane (shear- E'/E_g) and the out-of-plane ((A'_1/A_{1g})) vibration modes with the number of layers.
In this work, we explore a combination of metal/dielectric substrates to enhance the LFR scattering of different 2H-TMDC layers of WSe_2, WS_2, $MoSe_2$, and thereby to understand the structure of these nanoscale films. Phase-pure 2H-TMDCs were grown via an in-built two furnace ambient pressure CVD and the layers of exfoliated flakes were studied. Layer thickness and number of layers of 2H-$MoSe_2$, WSe_2, and WS_2 were varied. We used different substrates such as coatings of Al_2O_3 with different thickness on top of Al mirror layer, Al coated glass and Raman-grade CaF_2 among other substrates, to study bi-layers and a few layers of the above-mentioned TMDCs. We observe an enhancement of 30 times in LFR signal corresponding to WSe_2 and WS_2 on an Al_2O_3 coated Al substrate with oxide thickness of 80 nm and Al thickness of 200 nm.

Late News: Method for Enrichment with Semiconducting Single-Walled Carbon Nanotubes by Aerosol N2O Etching Alena A. Alekseeva[1], Dmitry Krasnikov[1], Grigory Livshitz[1], Stepan Romanov[1], Pavel Sorokin[2], Andrey Klimovich[3] and Albert Nasibulin[1]; [1]Skolkovo Institute of Science and Technology, Russian Federation; [2]University of Science and Technology MISIS, Russian Federation; [3]A.M. Prokhorov General Physics Institute, Russian Federation

Nowadays, flexible electronics demands new materials for integrated circuits of high flexibility and stretchability [1] . Single-walled carbon nanotubes (SWCNTs) are one of the most promising materials for utilization in the flexible integrated circuits owing to the outstanding electrical and mechanical properties [2]. However, the electronic and optoelectronic applications demand an advanced control of the nanotubes properties such as: length distribution, defectiveness, and most importantly ratio of semiconducting/metallic SWCNTs [3].

Most synthesis methods yield in 1/3 of metallic SWCNTs, thus, obtaining purely semiconducting species is a complex multistep procedure. Common strategies include either precise chirality distribution tuning during SWCNTs synthesis, post-synthesis etching of SWCNTs powders and films by oxidizing agents, or chirality separation. However, despite being well-established, these methods are suffering from multistage treatments, induced damage of SWCNTs [4], and irreversible attachment of surfactants that diminish performance of semiconducting devices [5].

Herein we report a simple one-step method for selective etching of metallic SWCNTs with nitrous oxide in aerosol phase. Our approach bases on faster oxidization rate of metallic SWCNTs compared to semiconducting ones, with advantage of aerosol chemical vapor deposition method, providing flow of individual SWCNTs in gas phase. We show a scalable method for obtaining semiconducting enriched SWCNT films with selectivity of 97% by treatment of pristine SWCNT aerosols for 6 sec at 600°C in the atmosphere of 30% N_2O. We assess structural changes in the nanotubes structure using comprehensive set of methods: UV-vis-NIR and Raman spectroscopies, differential mobility of aerosol particles, X-ray photoelectron spectroscopy, scanning and transmission electron microscopies and investigate the mechanism employing the DFT studies. We verify optimal etching conditions by equivalent sheet resistance, and temperature dependence of resistance dependencies, and the performance of SWCNT thin films as a channel material for thin film field-effect transistors, which showed an average improvement of on/off current ratio from 10^0-$10^1$to 10^3- 10^4 and open state resistance from $10^2$to 10^9 Ω/μm for statistics over 9000 devices.

Drain-Gate Connected Graphene/TMD Diode with Near Unity Ideality Factor Mihyang Park and Woojong Yu; Sungkyunkwan University, Korea (the Republic of)

Two-dimensional materials such as graphene, transition metal dichalcogenide(TMD), h-BN have been studied in various fields and their stacking

heterostructures have also received great attention. However, devices fabricated by stacking two-dimensional materials have an issue about ideality factor that cannot reach unity compared to the PN junction diode.
To solve this problem, we fabricated a two-terminal diode without forming the heterojunction or doping, just simply connecting the gate and drain. We used graphene as a bottom gate and TMD such as MoS_2 and WSe_2 as a conducting channel. Our gate-drain connected diode obtained ideality factor near unity. When drain-gate voltage is negative, which is reverse bias, Schottky barrier height is high so that current flow can be suppressed. In contrast, when drain-gate voltage is positive, which is forward bias, Schottky barrier height is low so that current can flow easily. This is further confirmed by Schottky barrier height modulation with varying drain-gate voltage by low-temperature measurement. The Schottky barrier height difference of 0.2eV was observed between the reverse bias and forward bias. The important role of the drain-connected bottom gate was also confirmed with varying carrier density with different drain-gate voltage, by hall-bar measurement. Due to the drain-gate connected structure, when a reverse bias is applied to the drain, the bottom gate is also negatively charged and a negative field is applied to the channel, thereby lowering the carrier concentration. Similarly, when it is forward bias, the carrier concentration in the channel increases due to the positively charged bottom gate.

Investigations of MoS_2 on Carrier Selective Contacts for Photovoltaic Applications Colleen Lattyak[1], Martin Vehse[1], Marco A. Gonzalez[2] and Carsten Agert[1]; [1]DLR Institute of Networked Energy Systems, Germany; [2]Carl von Ossietzky University of Oldenburg, Germany

Molybdenum disulfide (MoS_2) is a transition metal dichalcogenide known for its exceptional optoelectronic properties in its few- and monolayer form. It has a band gap in the range of 1.2 to 1.9 eV, depending on the layer thickness. This, along with other optoelectronic properties such as high absorptivity, makes MoS_2 a promising absorber layer in photovoltaic (PV) applications, like PV windows. Through optical simulation and Raman and photoluminescence (PL) spectroscopy we investigate the potential of MoS_2 in combination with the transparent carrier selective contacts molybdenum oxide and titanium oxide. The optical simulations show that this combination of layers has the potential to be semi-transparent and color neutral with possible current densities of 1 to 5 mA/cm^2 and average visible transmittance of 42% and 32% for device stacks with monolayer and few layer (< 5nm) MoS_2, respectively. Results from Raman and PL spectroscopy indicate that molybdenum oxide and titanium oxide influence the contribution of excitonic charge carriers in the MoS_2 absorber. This is observed in the form of spectral shifts in both Raman and PL. This can be explained by doping and screening effects induced by the metal-oxide layers. Both metal oxides can induce charge carrier extraction from the MoS_2, observed as quenching of the PL spectra. We compare these effects in exfoliated single crystalline MoS_2 flakes and transferred centimeter scale atomic layer deposition grown MoS_2 films and find that they are the same. This indicates that the knowledge gained from studying single crystalline flakes can be transferred to large area MoS_2 films which are a possible route to realize larger scale applications. The results from our optical simulation and optical spectroscopy, we will show the potential of this layer stack for applications such as transparent photovoltaic windows.

Position-Controlled Fabrication of Vertically-Aligned Mo/MoS_2 Core-Shell Nanopillar Arrays Louis Maduro, Marc Noordam, Maarten Bolhuis, Laurens Kuipers and Sonia Conesa-Boj; Delft University of Technology, Netherlands

The fabrication of two-dimensional (2D) materials, such as transition metal dichalcogenides (TMDs), in geometries beyond the standard platelet-like configuration exhibits significant challenges which severely limit the range of available morphologies. These challenges arise due to the anisotropic character of their bonding, van der Waals out-of-plane while covalent in-plane. Furthermore, industrial applications based on TMDs nanostructures with non-standard morphologies require full control on the size-, morphology- and position in the wafer scale. Such a precise control remains an open problem whose solution would lead to the opening of novel directions in terms of electronic and optoelectronic applications. Here, we report on a novel strategy to fabricate vertical position-controlled Mo/MoS_2 core-shell nanopillars (NPs). Metal-molybdenum (Mo) NPs are first patterned in a silicon wafer using lithography and cryo-etching. These Mo NPs are then used as scaffolds for the synthesis of Mo/MoS_2 core/shell NPs by exposing them in a rich sulfur environment. Cross-sectional transmission electron microscopy (TEM) analysis reveals the well-defined morphologies and the Mo/MoS_2 core/shell nature of the NPs. We demonstrate that individual Mo/MoS_2 core/shell NPs exhibit enhanced second order nonlinear optical processes, with an intensity increase up to a factor 40 as compared with regular MoS_2 flakes. Our results, and specifically the high degree of morphology- and position-control achieved on the core/shell NPs, represent an important step towards realising one-dimensional TMD-based nanostructures as building blocks of a new generation of sensors, nanophotonic devices, and hydrogen evolution reactions.

11:45 AM EQ20.20.18
Centimetre Scale Synthesis of Monolayer WS_2 Using Single Zone APCVD—Study of Growth Mechanism and Photodetector Properties Pallavi Aggarwal, Shuchi Kaushik, Prashant Bisht, Madan Sharma, Aditya Singh, Bodh Raj Mehta and Rajendra Singh; Indian Institute of Technology Delhi, India

Importance of two-dimensional transition metal dichalcogenide (2D TMDC) has been well known due to their novel optical and electrical properties but their growth mechanism has still been unclear. In this study, we have accomplished 1×1 cm^2 monolayer WS_2 film on sapphire substrate using single zone atmospheric pressure chemical vapor deposition (APCVD) method. The work is centered upon the detailed explanation on the growth of large area film by employing the importance of alkali halides and other growth parameters like gas flow rate, growth time, quantity of sulfur powder with respect to WO_3 powder, and substrate temperature. Structural and optical characterization were done using optical microscopy, Raman spectroscopy, Raman mapping, photoluminescence, UV-Visible spectroscopy, atomic force microscopy (AFM), and high-resolution transmission electron microscopy (HRTEM). Herein, optical microscopic images represent different stages of the growth of thin film, UV-Visible absorption spectra show the presence of A, B, and C excitons indicating its broad range absorption capability, Raman and PL spectra show peaks characteristic to the monolayer WS_2, and the thickness is 1 nm as measured from the height profile image which further confirms it to be monolayer. Moreover, single crystal nature of the as-grown film is deduced from the HRTEM images and SAED pattern which depict only single set of diffraction planes. Chemical composition of the film is confirmed from XPS spectra which exhibit peak characteristic to W^{+4} and S^{2-} ions in bulk WS_2 revealing its complete sulfurization.
Following the high quality of the as-grown films as deduced from the afore mentioned characterizations, photodetector was fabricated by using standard e-beam lithography technique to study its photo response over a wide range of wavelengths from 380 nm to 660 nm. Responsivity and detectivity spectra indicate broad range photo-response from UV to visible region with highest value of 847 mA/W and 6.27×10^{12} Jones at 380 nm, respectively.

11:50 AM EQ20.20.19
Water-Soluble Layer Assisted Transfer of Large-Area MoS_2 for Application in Photodetectors Madan Sharma, Aditya Singh and Rajendra Singh; Indian Institute of Technology Delhi, India

Molybdenum disulfide (MoS_2), having excellent optical and electrical properties and tunable bandgap, offers new opportunities for next-generation electronic devices. It is difficult to grow MoS_2 onto most substrates (specially on flexible substrates) due to growth limitations such as temperature, growth promoters, precursors, etc. In the present work, we have first grown large-area (centimeter-scale) trilayer MoS_2/SiO_2 via CVD and then transferred onto various substrates (sapphire, SiO_2, flexible substrates) without degradation of film quality. To transfer the MoS_2, a water-soluble layer (Na_2S/Na_2SO_4) was

grown on the growth substrate during the growth of MoS_2 film, such that the MoS_2 lies on top of the water-soluble layer. Upon treating with DI water, the water-soluble film dissolves, causing the MoS_2 film to lift off and float to the surface. The film is then cleaned and transferred onto the desired substrate. Optical, morphological, and XPS results show that transferred film is highly clean and damage-free. A broadband (NIR-Vis-UV) photodetector was also fabricated onto transferred 3L MoS_2/sapphire to show the compatibility of the transfer process with the nanodevice fabrication. The photocurrent was enhanced 100 times and 10 times to dark current in UV and visible region, respectively. The maximum responsivity was found to be 8.6 mA/W. The proposed work offers enormous potential for the industrial implementation of 2D material technology platforms. Also, this process may be used to transfer other 2D materials like WS_2, $MoSe_2$, etc.

11:55 AM EQ20.20.20
Synthesis of Orientation Controlled WS_2 Thin Films for Enhanced Gas Sensing Performance Prashant Bisht[1], Arvind Kumar[1], Branson Belle[2] and Bodh Raj Mehta[1]; [1]Indian Institute of Technology Delhi, India; [2]SINTEF Industry, Norway

In this study, in-plane, and out-of-plane growth of WS_2 on SiO_2/Si substrate has been achieved using pulsed laser deposition technique. We have systematically studied the effect on the growth of the thin films at different sets of pressure (30 mTorr, 50 mTorr, and 70 mTorr) and temperature (400 °C, 500 °C, and 600 °C). Samples grown at the combination of low temperature and low vacuum showed a vertical flake-like growth, whereas at high temperature and high vacuum horizontal growth was achieved. XRD and Raman spectra show the formation of the 2H-WS_2 phase with (002) dominant plane which reflects the layered growth. FESEM, AFM, and HRTEM depict the growth evolution at different deposition parameters and thickness of the thin film. XPS compares the chemical state and composition of the as-grown films. Deposition pressure and substrate temperature were found crucial for controlling the stoichiometry and texture of WS_2 thin film. Furthermore, the gas sensing performance of the as-grown horizontal and vertical film has been compared. Later showed an enhanced response and selectivity towards NO_2 gas with a LOD of 100ppb at room temperature. The reason might be ascribed to the presence of a comparatively large number of active edge sites which are more reactive as compared to the flat basal planes present in the horizontal film.

12:00 PM EQ20.10.13
Phase Engineering of Group VIB Transition Metal Dichalcogenides via a Thermodynamically Designed Gas-Solid Reaction Geosan Kang[1], Dae-Hyun Nam[2], Gun-Do Lee[1] and Young-Chang Joo[1]; [1]Seoul National University, Korea (the Republic of); [2]Daegu Gyeongbuk Institute of Science & Technology, Korea (the Republic of)

2D transition metal dichalcogenides (TMDs) have been increasingly studied due to their wide range of optical, mechanical, chemical, and electric properties, from metal to insulator. 2D TMDs has graphene-like layered structure but with a controllable wide-bandgap by their atomic arrangement. Structural phase control in TMDs provides a variety of material phenomena that can be applied to tune the intrinsic properties. In general, group VIB TMDs can have thermodynamically stable semiconducting 2H phases and metastable metallic 1T phases. Recently, S vacancy-driven atomic diffusion has been studied to be an efficient approach for polymorphic transition from 2H-MoS_2 to 1T-MoS_2 by using carbon monoxide (CO)-mediated gas-solid reaction. Gas-solid reaction behaviors in nanomaterials can be predicted by their thermodynamic Gibbs free energy. The processing parameters of gas-solid reactions, such as the temperature and pressure, can be predicted using thermodynamic calculations that can be applied to drive targeted reactions. By using thermodynamic predictions and the properties of gas-solid reactions, the targeted reaction can be selectively induced among various competing reactions in multicomponent systems.
In this study, phase engineering of group VIB TMDs: WS_2 and MoS_2 was performed via CO-based gas-solid reactions with thermodynamic prediction. We predicted the thermal stability of chemical compounds corresponding to the process conditions and designed a process window map with the temperature and CO ratio. Each predicted phases appeared as oxides, sulfides, carbides and metals. In the synthesis of TMDs with precursors in a CO-mediated reaction environment, the metallic species exhibited a variety of phases within the quaternary-element system with Sulfur, Oxygen and Carbon. The trend of experimental fabrication was consistent with the prediction by the thermodynamic model. Synthesized TMDs exhibited 2H- to 1T-phase transition. 1T transition ratios was compared in two different TMDs according to the process parameters. The reaction between CO and S atoms became more active with increasing temperature, CO ratio, and calcination time that promote considerable S vacancy formation and cause phase transition. This revealed that gas-solid reactions-induced S vacancy formation triggered T-phase formation in not only MoS_2 but also WS_2.
This work presents the possibility of phase engineering TMDs through thermodynamic prediction, thereby helping to improve the synthesis efficiency of targeted materials and promoting expanded phase engineering of a variety of 2D nanomaterials as well.

12:05 PM EQ20.10.20
Late News: A Facile Strategy for the Synthesis of Tungsten Disulfide Monolayers from Solid Oxide Precursor Grown by Pulsed Laser Deposition Denys Miakota[1], Ganesh Ghimire[1], Raymond R. Unocic[2], Rajesh Ulaganathan[1], Fabian Bertoldo[1], Sara L. Engberg[1], Kristian S. Thygesen[1], David Geohegan[2] and Stela Canulescu[1]; [1]Technical University of Denmark, Denmark; [2]Oak Ridge National Laboratory, United States

Two-dimensional (2D) WS_2 is among the most intriguing representatives of the semiconducting transition metal dichalcogenide (TMD) family with a direct bandgap ~2 eV. WS_2 material shows extraordinary properties at the monolayer limit, such as strong light absorption, one of the lowest electron effective masses, high (>6.4%) photoluminescence yield (which can be further enhanced via doping), excellent thermal stability, mechanical flexibility and access to valley degree of freedom. Strong light absorption and emission at visible wavelengths opens great opportunities for its integration in ultrathin optoelectronic devices, such as light-emitting diodes, photodetectors, photovoltaic cells, and microcavity lasers.
However, for any practical application of WS_2, it is required to find a method to grow uniform and highly oriented WS_2 monolayers with a precise control over the layers number on a large scale. Tremendous efforts were devoted to study 2D TMD growth and examine their electronic and structural properties. Recently, several approaches were suggested to obtain a wafer-scale production of TMD monolayers. These methods include chemical vapor deposition (CVD), metal-organic chemical vapor deposition (MOCVD)[1], magnetron sputtering, and molecular beam epitaxy (MBE), etc. Pulsed laser deposition (PLD) is one of the prominent ways to synthesize TMD monolayers, which has demonstrated its potential for 2D materials synthesis both via direct growth[2] and two-step process[3].
In this paper, we report on two-step synthesis of WS_2 mono- and multilayers by high-temperature sulfurization of oxygen-deficient tungsten oxide films obtained by PLD on sapphire. PLD is an established method to grow high-quality oxides with sharp interfaces, and it offers great opportunities to control crystalline quality of the material and its composition. This is achieved by deposition of precursors at different substrate temperatures and background gases (oxygen and argon). The X-ray photoelectron spectroscopy (XPS) results reveal that by changing the growth conditions in the PLD process, the properties of WO_x precursors can be significantly varied.
Next, we unravel how the presence of intrinsic oxygen vacancies in the tungsten suboxide (WO_x) precursor leads to a more facile conversion from WO_x to WS_2 films in a CVD process. Our study suggests that native oxygen vacancies in the PLD-grown precursors can serve as niches through which sulfur atoms enters the lattice and facilitates the growth of WS_2 crystals with high photoluminescence (PL) emission and large domain size. Indeed, the overall PL emission increases ~40 fold while the full width of half maximum (FWHM) of the PL peak decreases significantly for WS_2 crystals synthesized from precursors with a high content of oxygen vacancies as compared to that obtained from nearly stoichiometric counterpart. Based on atomic resolution images we will discuss intrinsic, grain boundaries, bilayer WS_2 crystal orientation evolve from nearly stoichiometric oxides to highly reduced oxide

precursors.
Our studies reveals how the epitaxial WO_x precursors with tunable properties grown by PLD can be used to independently control the nucleation, lateral growth and ultimately the WS_2 domain size.

1:00 PM *EQ20.21.01
Challenges and Opportunities with 2D- Nanoporous Membranes Aleksandra Radenovic; Ecole Polytechnique Federale Lausanne, Switzerland

Atomically thin (2D) nanoporous membranes are an excellent platform for a broad scope of academic research. Their thickness and intrinsic ion selectivity (demonstrated for example, in molybdenum disulfide MoS2) make them particularly attractive for single molecule biosensing experiments and osmotic energy harvesting membranes. Currently, one of the significant challenges associated with the research progress and industrial development of 2D nanopore membrane devices is small scale thin film growth and small area transfer methods. This challenge has been recently tackled. Beyond large area growth and integration into devices, several other essential aspects such as mechanical stability and pore geometry, pore shape stability and its chemical termination require close attention from the community working with the 2D nanoporous membrane.

1:30 PM EQ20.21.02
Fingerprinting the Impact of p- and n-type Dopants on the Structural and Local Electrical Properties of Indium Selenide by Means of State-of-the-Art Transmission Electron Microscopy Abel Brokkelkamp[1], Sergiy Krylyuk[2], Laurien Roest[1], Isabel Postmes[1], Jaco ter Hoeve[3,4], Juan Rojo[3,4], Albert Davydov[2] and Sonia Conesa-Boj[1]; [1]TU Delft, Netherlands; [2]National Institute of Standards and Technology, United States; [3]Vrije Universiteit Amsterdam, Netherlands; [4]Nikhef, Netherlands

Indium Selenide (InSe) is a remarkable two-dimensional quantum material whose characteristic properties include a bandgap that increases with fewer layers and a high controllability of p- and n-type doping. Furthermore, its bandgap can lie in the near infrared region, depending on the specific crystalline phase adopted. Indium Selenide is known to crystallize in either the β(2H)-, γ(3R)- or the ε(2H)-phase. Of these three crystalline phases, only the β(2H) and γ(3R) ones exhibit a direct bandgap, which makes them particularly suitable for optoelectronic applications. However, while the β(2H)-phase can be easily disentangled from the other, the γ(3R)- and ε(2H)-phases are indistinguishable from the in-plane point of view and appear also very similar from the out-of-plane one. An attractive possibility to tailor the optoelectronic properties of InSe is based on the introduction of dopants, which leads to structural defects and can modify the crystalline structure and symmetry properties of the material. In this work, we investigate p- and n-doped (as well as undoped) Indium Selenide by means of Transmission Electron Microscopy and related techniques. We determine the crystalline phase present in these Indium Selenide specimens with High Resolution TEM by means of a systematic investigation of both in- and out-of-plane cross-sections, and compare the structural differences arising from different types and amounts of doping. We further assess the impact of dopants on the local electronic properties using Electron Energy-Loss Spectroscopy (EELS) by comparing how relevant features in the spectra (including surface- and edge-related properties) depend on the doping. Finally, we deploy Machine Learning techniques for a model-independent subtraction of the Zero Loss Peak, which makes possible identifying in an unbiased manner the impact of dopants in InSe in the ultra-low-loss region of the EELS spectra.

1:45 PM EQ20.21.03
***In Situ* Environmental Scanning Electron Microscopy of Aging Dynamics in 2D Materials** Ye Fan[1], Ryo Mizuta[1], Peter Voorhees[2] and Stephan Hofmann[1]; [1]University of Cambridge, United Kingdom; [2]Northwestern University, United States

2D materials have been under the spotlight for over a decade. Given the multitude of promising properties demonstrated at lab-scale, a host of disruptive technologies with exponentially improved performances were expected to revolutionise markets ranging from integrated electronics to catalysis. In reality, however, the emergence of such game-changers has been significantly delayed. One major reason is the aging and failure of 2D materials in real working environments [1,2], the dynamics of which remain poorly characterised.
Here, we present an *in situ* study of the thermal oxidation of transition metal dichalcogenide monolayers to foster a fundamental understanding of the corrosion and aging dynamics in 2D materials. The full corrosion process is monitored in real-time, from the nanometre to sub-millimetre scale, utilising a custom *in situ* environmental SEM (ESEM), permitting conventional theories of materials corrosion to be tested in the 2D limit. We focus on the emergence of corrosion pits in WS_2 monolayers during oxidation, leveraging the ESEM's large field of view to simultaneously track up to 10^3 to 10^4 pits. The corrosion kinetics are quantified by analysing the growth kinetics of individual pits, based on which the corrosion kinetics are found to transition from a reaction-limited to a diffusion-limited regime as a function of oxidation temperature. Moreover, an acceleration of corrosion is found to occur when adjacent corrosion pits coalesce with each other. All results are compared with phase field modelling, which provide a predictable model for the 2D thermal oxidation process. Our study demonstrate the power of the *in situ* ESEM in elucidating material aging mechanisms 2D materials at the nanoscale.

2:00 PM EQ20.21.04
Late News: 2D MXenes—Visible Black But Infrared White Materials Yang Li, Xiong Cheng, He Huang, Tianshou Zhao and Baoling Huang; Hong Kong University of Science and Technology, Hong Kong

In nature, most of the visible black materials have high absorption/emission in the mid-IR region (2.5-20 μm). Visible black materials with low infrared absorption/emission (or IR white) are rare but highly desired in numerous areas, such as solar energy harvesting, multispectral camouflage, thermal

insulation, and information security management. Due to the lack of wavelength selectivity in intrinsic materials, such counter-intuitive properties are generally realized by constructing complicated subwavelength metamaterials such as plasmonic nanostructures and photonic crystals with costly nanofabrication techniques. Here, for the first time, the intrinsically low mid-IR emissivity (down to 10%) of the black 2D $Ti_3C_2T_x$ MXene is reported. Associated with a high absorptance of 90% in average over the solar spectrun , it embraces the best wavelength selectivity among the reported intrinsic black solar absorbing materials. Its appealing potentials in multispectral camouflage, smart textiles, and anti-counterfeiting applications are experimentally demonstrated. First-principles calculations reveal that the IR emissivity of MXene relies on both the nanoflake orientations and terminal groups, indicating great tunability. The calculations also suggest more potential low-emissivity MXenes including Ti_2CT_x, Nb_2CT_x, and V_2CT_x. This work opens the avenue to further exploration of a family of intrinsically low-emissivity materials with over 70 members.

2:15 PM EQ20.21.05
Detecting Charge Dissipation and Conductance Switching in Graphene Nanodevices in a STEM Ondrej Dyck[1], Jacob L. Swett[2], Andrew R. Lupini[1], Jan Mol[2] and Stephen Jesse[1]; [1]Oak Ridge National Laboratory, United States; [2]University of Oxford, United Kingdom

Feedback-controlled electroburning of graphene nanoribbons has been shown to be effective at creating nanogaps within the ribbon.[1–3]Molecules introduced into these nanogaps form tunnel junctions which can form the basis for molecular rectifiers, switches, transistors, or sensors.[3] Secondary electron e-beam induced current (SEEBIC) is a technique that can be used to reveal sample conductivity and connectivity with high spatial resolution in a scanning transmission electron microscope (STEM).[4,5] Here, we use feedback-controlled electroburning *in situ* to observe the evolution of the sample while it is being burned. We leverage the SEEBIC technique to image conductive, connected regions of the sample and diagnose device failures. When a nanogap is formed, producing a non-ohmic device response, the SEEBIC signal is observed to display dynamic contrast variation. A significant component of this contrast variation can be attributed to conductance switching in the high resistance region of the graphene nanodevice as the beam differentially charges the substrate. These results suggest that the SEEBIC imaging technique can be leveraged to provide information about charge flow and dynamic variations in conductance at the nanometer scale.[6]

Infrared and Magnetic Study of the van der Waals Semiconductor $Co_2P_2S_6$ Ben Mallett[1,2], Kiri Van Koughnet[1], Shen V. Chong[1,2], Bob Buckley[1,2], Benjamin Conner[3] and Michael Susner[3]; [1]Robinson Research Institute - Victoria University of Wellington, New Zealand; [2]The MacDiarmid Institute for Advanced Materials and Nanotechnology, New Zealand; [3]Air Force Research Laboratory, United States

We report the results of a study of the temperature-dependent infrared spectroscopy and magnetism of single crystals of the antiferromagnetic semiconductor, $Co_2P_2S_6$. For comparison, we also report results on a second crystal substituted with 20% non-magnetic, closed-shell Zn. Concurrent with other, recent reports we observe a transition from a paramagnetic to antiferromagnetic state with a Neel temperature at $T_N \sim 120$ K. The magnetic transition is strongly reflected in differences between the infrared spectra taken above and below T_N. At 300 K we identify 4 relatively narrow phonon modes and a very broad mid-IR absorption while below T_N we observe that several new phonons appear, and a number alter their oscillator strength. The lowest energy mode exhibits significant asymmetry. With Zn doping significant changes occur at low energies where the motion is dominated by the transition metal atoms while the high energy modes, where motion is largely restricted to the sulphur atoms, are less affected.

A Clean TEM Sample Preparation Technique for CVD-Grown TMD Monolayers Shichen Fu, Mengqi Fang, Zitao Tang, Siwei Chen, Kyungnam Kang and Eui-Hyeok Yang; Stevens Institute of Technology, United States

Transmission electron microscopy (TEM) and scanning transmission electron microscopy (STEM) are extensively used to characterize chemical vapor deposition (CVD)-grown transition metal dichalcogenides (TMDs). To prepare the specimens for such an imaging, a polymethyl methacrylate (PMMA) assists wet-etching transfer technique is often used [1]. Here, PMMA residues can affect the TEM image quality, especially under high-magnifications. While thermal annealing under vacuum is typically performed to reduce the residue problem, the process can still damage TMD monolayers due to their poor in-air stability [2]. Here, we present an enhanced sample preparation technique for the TEM imaging of CVD-grown TMD monolayers, and the sample attachment onto a TEM grid, reducing TMD oxidation of monolayers. The new steps incorporated in this process include a thorough PMMA removal using acetone at 60 C followed by annealing at 350 C in 0.01 mTorr for 4 hours, which was corroborated by measuring Energy-dispersive X-ray spectroscopy (EDS). In addition, we dropped PMMA in a liquid form onto the TEM grid to fully cover the sample with the grid, ensuring a firm attachment of TMDs onto the grid during acetone washing. The sample was checked by scanning electron microscope (SEM), which confirmed that the TMD monolayers were successfully transferred onto TEM grids. Further, combining the EDS and EELS measurements, a significantly reduced carbon signal was observed. The high-resolution TEM (HRTEM) showed no polymer residues over the imaged regions, while the atomic structures were clearly seen. Several STEM images were also collected, and no e-beam radiation damage was observed.

***In Situ* Spectroscopic Ellipsometry for Monitoring Bi_2Se_3 Growth in Molecular Beam Epitaxy** Maria Hilse[1], Xiaoyu Wang[2], Phoebe Killea[2], Frank Peiris[2] and Roman Engel-Herbert[1]; [1]The Pennsylvania State University, United States; [2]Kenyon College, United States

Two-dimensional materials cover a large range of high-interest properties such as high mobility, piezo- and ferroelectricity, scalable band gap, and topological non-trivial band structures to name a few. The key to access and study those properties lies in high-quality materials synthesis, which in turn requires precise control over relevant growth parameters. The complex interplay of rate and relative flux ratio of the supplied constituents as well as substrate temperature at the growth front determines film growth rate, and stoichiometry. However, to date, there is no unifying method to measure these parameters in real time. Commonly used methods to monitor flux rates or film thickness and temperature differ in accuracy and applicability. Consequently, rather large unintentional deviations exist in reported values which presents a sizeable problem in the reproducibility of growth conditions, in particular for the growth temperature.
With our work, we propose in-situ spectroscopic ellipsometry (SE) as an alternative method that offers the potential for absolute temperature measurements and simultaneous determination of physical film thicknesses in-operando and non-destructively which furthermore can be used by any deposition technique. Using in-situ SE during molecular beam epitaxy (MBE) growth, we have developed a precise model for the dielectric function of Bi_2Se_3 thin films grown on Al_2O_3 substrates that allows to extract and thus monitor film thickness and growth temperature simultaneously. Throughout our work, we used an infrared (IR) camera system and X-ray reflectivity (XRR) to calibrate our SE measurements against absolute temperature in-situ and against physical film thickness ex-situ for which we capped Bi_2Se_3 films with an amorphous Se layer to protect them against oxidation under ambient pressure conditions.
In the first part we demonstrate the dielectric model for the Al_2O_3 substrate and the thickness dependence for the Bi_2Se_3 thin film model at the fixed growth temperature of 225 °C for 5 samples. The dielectric model obtained by in-situ SE proofed to be very sensitive to film thickness changes with a precision of about 1 %.
In the second part we show in-situ SE measurements performed on the same samples at different temperatures to demonstrate temperature dependent changes in the dielectric function of Bi_2Se_3 for fixed film thickness. Having thus decoupled thickness and temperature related changes in the dielectric function, we included temperature effects in our model, which allowed us to monitor the film temperature with a precision of about 10 K.
Based on the presented data, in-situ SE bears the potential to serve as an ultimate baseline for thickness and temperature calibration for two-dimensional materials, thus enhancing reproducibility and advancing material quality.

Unique 2D Metal Chalcogenide Material Synthesis by Molecular Building Blocks Veronika Brune, Fabian Hartl, René Weißing, Michael Wilhelm and Sanjay Mathur; University of Cologne, Germany

The lacking control of large scale and homogeneous preparation of well-known 2D van der Waals materials MS_2 (M= Mo^{IV}, W^{IV}, Ti^{IV}, Sn^{IV}), MS (M=Sn^{II}, Ge^{II}) for commercial application, motivated us to develop a unique synthetic approach to molecular precursors for layered 2D van der Waals materials. A uniform synthesis route of molecular building blocks for controlled formation of stable precursor class $[M(SEtN(Me)EtS)_x]$ (M = Mo^{IV}, W^{IV}, Ti^{IV}, x = 2; M = Ge^{II}, Sn^{II}, x = 1) was observed by using chelating SNS ligand systems and suitable metal precursors, which have been fully characterized by NMR, TG-DSC, mass spectroscopic and single crystal analysis. Following the simple synthetic protocol of new metal chalcogenide complexes isolation of (air)stable molecular precursors have been performed. These complexes enabled the targeted preparation of homogeneous crystalline 2D MoS_2, WS_2, TiS_2, SnS_2 and SnS by varying thermal based decomposition experiments as well as using wet chemical decomposition routs, resulting in SnS and SnS_2 particles. The as prepared 2D materials have been identified by XRD, XPS, SEM and TEM analysis.
The presented molecular building blocks provide an extraordinary synthetic approach to a unique molecular precursor class for 2D material preparation.

Band Engineering and Quantum Well Formation in Semiconducting Defective Graphene Multilayers—A First-Principles Study Yuta Taguchi, Masayuki Toyoda and Susumu Saito; Department of Physics, Tokyo Institute of Technology, Japan

Two dimensional van der Waals "heterostructures", which consist of two dimensional materials such as pristine graphene, hexagonal boron nitride and transition-metal dichalcogenides, have attracted much attention because they have various interesting electronic properties. The heterostructures are expected to be promising device materials in the next generation.Up to now, two dimensional materials without intentional defects have been used. However, periodically modified graphene with various types of defects, "graphene antidot lattices", are also expected to be the components of the heterostructures in the near future. Graphene antidot lattices have been studied theoretically for the last two decades and it is known that they can be semiconductors with the band gap values of 0 to 2 eV. We have studied the electronic properties of the graphene antidot lattices with the triangular defects in the super honeycomb arrangement. It is found that the band gap value can be tuned between 0.1 and 1.3 eV and the eigenvalue at the conduction band edge is nearly independent of the size of the defects while the eigenvalue at the valence band edge is strongly dependent on the size of the defects with the super-honeycomb-lattice-constant fixed. We should design both Type1 and Type2 quantum well structures by stacking the graphene antidot lattices with the triangular defects in the super honeycomb arrangement. From this background, we investigate the electronic properties of the trilayer systems consisting of the graphene antidot lattices with the triangular defects in the super honeycomb arrangement by performing first-principles electronic structure calculations within the framework of the density-functional theory. We study the stabilities, the electronic structures and the electronic states of the valence and conduction band edges. A graphene sheet with smaller band gap is sandwiched between two sheets with larger band gaps. It is found that electronic structures near the valence edge are independent of the stacking sequence while the electronic structures near the conduction band edge strongly depend on the stacking sequence. Interestingly, it is also found that both electrons and holes are expected to be confined in the middle layer for some cases. In other words, these types of trilayer graphene systems have Type1 quantum well structure. This result opens a new way of realizing a very thin quantum well laser of graphene antidot lattices. We will also report on the effect of the chemical doping and the electronic field.

4:10 PM EQ20.22.05
N,N'-Dimethylformamide Sensor in a Contaminated Solution Based on the Specific Interaction on Molybdenum Disulfide Akito Fukui[1], Hiroaki Onoe[2], Shun Itai[2], Keiko Ishikura[2], Hidekazu Ikeno[1], Yuh Hijikata[3], Jenny Pirillo[3], Takeshi Yoshimura[1], Norifumi Fujimura[1] and Daisuke Kiriya[1]; [1]Osaka Prefecture University, Japan; [2]Keio University, Japan; [3]Hokkaido University, Japan

N,N'-dimethylformamide (DMF) is one of the industrially important solvents. DMF is easily absorbed into the human body by inhalation or skin

absorption. DMF is metabolized to generate N-methylformamide (NMF), which is highly toxic for the human body[1]. In addition, DMF molecule shows cytotoxicity, and 50% inhibitive concentration is about 1 v/v% in a culture fluid[2]. Therefore, it is important to monitor DMF concentration at a scale of 0.1 % in a situation of contaminated solution. However, it is so far not easy to monitor DMF in solutions because of the low reactivity of DMF molecules, and the coexistence of polar molecules such as water prohibits the detection of DMF molecules. In this study, we examine the interaction between DMF molecules and transition metal dichalcogenides and found a specific interaction with DMF molecules on the surface. This specific interaction enables to generate DMF sensor to monitor the concentration even in a contaminated solution such as a cell culture fluid.
A metal-oxide-semiconductor field-effect transistor (MOSFET) was fabricated by a standard lithography process. The channel material is MoS_2 in this study. Transfer characteristic curves of MoS_2 MOSFET show usual n-type behavior with an average ON/OFF ratio of 10^5. By treating DMF solution, the drain current dramatically increases, and the MOSFET shows small electrostatic modulation by applying gate voltage. From the MOSFET characteristics, DMF molecules show n-type donor property to MoS_2 with achieving degenerate doping level. By using the strong donor ability of DMF molecules for MoS_2, we examined the DMF sensor in contaminated solutions. A microfluidic chamber was fabricated over the MoS_2-MOSFET device, and DMF-mixed solution in 0.15 M $NaCl_{aq}$ was introduced in the microchannel. MOSFET monitors the MoS_2 surface state and we found that the drain current can successfully distinguish the DMF concentration in NaCl solution at the concentration level of 0.1 v/v%.
To further investigate the mechanism of DMF-MoS_2 interaction, we calculated the frontier orbitals of DMF and band alignment with MoS_2 by DFT (B3LYP) method. From the calculation, we found that the location of the HOMO energy level of DMF molecule is under the conduction band of MoS_2, therefore, the n-type behavior would not be a usual electron transfer process. By further DFT calculation with the structural optimization of the interaction between DMF and MoS_2 and we found that the DMF molecules would be specifically oriented on the oxygen adatoms on MoS_2.

Nove Bipolar Exfoliated Graphene-Based Electrochemical Aptasensors for Sensitive Label-Free Detection of Cancer Biomarkers Shahrzad Forouzanfar, Iman Khakpour, Nezih Pala, Chunlei Wang and Borzooye Jafarizadeh; Florida International University, United States

Early detection of cancer can noticeably increase the survival chance of many cancer patients. Quantifying cancer biomarkers detectable from blood is an efficient way for the early detection of cancer diseases. In recent years, the application of synthetic DNA or RNA-based bio-recognizers (i.e., aptamers) in cancer biomarker sensor development has been vastly investigated. Electrochemical label-free aptamer-based biosensors (also known as aptasensors) are highly suitable for point-of-care applications. In this study, the application of bipolar exfoliated (BPE) graphene for developing cancer biomarker label-free aptasensors is explored. Graphene as a single, two-dimensional layer of carbon atoms has very remarkable features suitable for biosensor applications. The common graphene synthesis methods require complicated and costly processes and excessive use of harsh chemicals, as well as complex subsequent deposition procedures. In this study, a single setup has been used for exfoliation, reduction, and deposition of graphene nanosheets on a conductive electrode based on the principle of bipolar electrochemistry of graphite in deionized water. We investigated the properties of aptasensors based on graphene oxide (GO) deposited on a positive electrode feeding electrode and reduced-GO (rGO) deposited on a negative electrode feeding electrode. The PDGF-BB affinity aptamers were covalently immobilized by binding amino-tag terminated aptamers and carboxyl groups of GO and rGO surfaces. In this study, Fourier-transform infrared spectroscopy (FTIR) was used to study the surface characteristics of synthesized graphene and developed aptasensors. The scanning electron microscopy (SEM) was used to study the morphology of the bipolar exfoliated GO and rGO. The SEM study demonstrated that the rGO has a porous vertically aligned structure with pore sizes of around 100 nm, while GO has bulky flattened plates with random cracks. Cyclic voltammetry (CV) and differential pulse voltammetry (DPV) were used for characterizing the BPE graphene-based aptasensors in different stages of development and their sensing performances. The turn-off sensing strategy was implemented by measuring the peak-currents from DPV plots. The optimized aptasensor based on rGO showed a wide linear range of 0.75 pM-10 nM, high sensitivity of 7.83 A $Logc^{-1}$ (unit of c, pM), and a low detection limit of 0.53 pM. However, the optimized aptasensor based on GO reached its saturation point around 150 pM. This study demonstrated that bipolar electrochemistry is a simple yet efficient technique that could provide high-quality graphene for biosensing applications. Considering the BPE technique's simplicity and efficiency, this technique is highly promising for developing feasible and affordable lab-on-chip and point-of-care cancer diagnosis technologies. <!--

Tailoring Laser Induced Graphene Porosity for Pressure Sensing Tessa Van Volkenburg[1,2], Nick Kantack[1], Spencer Langevin[1] and Zhiyong Xia[1]; [1]Johns Hopkins University Applied Physics Laboratory, United States; [2]Johns Hopkins University, United States

Laser induced graphene (LIG) is a rapid fabrication technique for producing passive sensors that are lightweight, flexible, and tailored for applications ranging from biometric analysis to chemical detection. Through laser irradiation of a substrate surface, typically polyimide, a porous graphene can be formed whose electrical properties depend on the laser fluence, substrate composition, and atmosphere used. Though less conductive than traditional printed electronics, the porous nature has previously been leveraged to create piezoresistive sensors that change their conductivity in response to temperature, strain, or pressure. Additionally, the inherent robustness of polyimide substrates allows for application to extreme environments including space and ocean exploration. In this work, we expand on previous efforts to create LIG sensors for pressure measurement by correlating laser fluence and resultant graphene porosity to sensor hydrostatic response. The impact of laser fluence is investigated through changing speeds, powers, and density (pulses per inch) of the laser beam, and characterizing the porous structures formed with scanning electron microscopy. Hydrostatic testing at pressures up to 2,000 psi was also performed with supporting electronics to determine sensor response and validate the repeatability of the fabrication method. Through this work, we aim to demonstrate that by controlling the porosity of the graphene formed, and characterizing its piezoresistive response with respect to pressure, on demand passive pressure sensors can be fabricated for targeted pressure ranges and applications.

4:25 PM EQ20.22.09
Late News: Unusual-High Ion Conductivity in Large-Scale Patternable Two-Dimensional MoS2 Wonbong Choi[1], Sanket D. Bhoyate[1] and Juhong Park[1,2]; [1]University of North Texas, United States; [2]Ark Power Technology, United States

The advancement of ion transport applications will require the development of new materials with a high ionic conductivity that is stable, scalable, and micro-patternable. We report unusually high ionic conductivity of Li^+, Na^+, and K^+ in 2D MoS_2 nanofilm exceeding 1 S/cm, which is more than two orders of magnitude when compared to that of conventional solid ionic materials. The high ion conductivity of different cations can be explained by the mitigated activation energy *via* percolative ion channels in 2H-MoS_2, including the 1D ion channel at the grain boundary, as confirmed by modeling and analysis. We obtain field-effect modulation of ion transport with a high on/off ratio. The ion channel is large-scale patternable by conventional lithography, and the thickness can be tuned down to a single atomic layer. The findings yield insight into the ion transport mechanism of van der Waals solid materials and guide the development of future ionic devices owing to the facile and scalable device fabrication with superionic conductivity.

Investigating Effects of Graphene Layers on Photonics Properties in MoS_2/Graphene Heterostructure Ensemble Prepared by Dry Transfer Method for Optoelectronic Applications Sanju Gupta; University of Central Florida, United States

Two-dimensional layered materials that harvest or transduce light energy are of paramount interest. In this context, two-dimensional transition metal dichalcogenides such as molybdenum disulfide (MoS_2) are attractive for harnessing optoelectronics. In this work, we report the integration of MoS_2 with a strong electron accepting graphene yielding novel MoS_2 (1-2L)/graphene (1-2L) heterostructure ensemble by facile and efficient dry transfer method. We also found additional hetero-interfaces due to folded flakes such as MoS_2/MoS_2/graphene and MoS_2/MoS_2/Au hetero-interfaces. We characterized the heterointerfaces using correlated micro-Raman spectroscopy, photoluminescence (PL) spectroscopy, atomic force microscopy, Kelvin probe microscopy and conducting AFM, tip-enhanced Raman spectroscopy (TERS), and tip-enhanced photoluminescence (TEPL) techniques to gain insights into the structural quality, hetero-interfaces, and excitonic effects to elucidate the role of a number of graphene layers which are crucial in modulating the light emission. We studied the charge transfer in these vertical heterostructures unraveling the interlayer electronic coupling. We demonstrate strong evidence that the excitonic properties of MoS_2 are most effective for two layers of graphene layers underneath leading to a significant enhancement of the PL response as compared to MoS_2 supported on one-layer graphene and directly on the gold-coated substrate. We observed a marginal increase in work function with increasing MoS_2 layer as anticipated and for heterointerfaces which are indicative of electron injection. We measured C-AFM without light (dark) and with light in view of photoconducting properties of heterointerfaces and found a rectifying behavior with an apparent increase in current by almost twice for MoS_2/graphene heterostructures in contrast to MoS_2/Au which shows ohmic behavior. Our findings signify the importance of substrate engineering when constructing 2D multilayered architectures for harvesting or storing light energy. This work is financially supported in parts by NSF and NSF-MRI Grants.

4:35 PM EQ20.22.11
Late News: Dielectric and Substrate Engineered Tuning of Photoluminescence in Monolayer WS2 Tamaghna Chowdhury, Diptabrata Paul and Atikur Rahman; IISER Pune, India

The dielectric environment strongly influences the photoluminescence (PL) of transition metal dichalcogenide (TMD) monolayers. The PL spectra are usually modified by the defect states present in the monolayer and substrate interface. To study the effect of substrate defects on PL, we have gradually increased the separation between substrate and WS_2 by placing hBN of various thicknesses in between. Further dielectric engineering was done by patterning the substrate with holes and pillars. In this way, we were able to tune the contribution of trion and exciton in the PL of WS_2. An excitation power-dependent study was also done to understand the tuning mechanism of PL in various kinds of engineered substrates. The charge of the substrate defects is also important in determining the nature of the PL spectra in monolayer WS_2. This effect was also studied by treating the substrate with APTES which changes the nature of the charge carried by a SiO_2/Si substrate. This study will be important for the fabrication of valleytronic and excitonic interconnects.

6:30 PM EQ20.23.01
Heavy Ion and Laser Irradiation Effects on MoS_2 Memtransistors Christopher M. Smyth[1], John M. Cain[1], Eric J. Lang[1], Khalid Hattar[1], Xiaodong Yan[2], Jiangtan Yuan[2], Matthew Bland[2], Taisuke Ohta[1], Stanley Chou[1], Vinod K. Sangwan[2], Mark C. Hersam[2,2] and Tzu-Ming Lu[1]; [1]Sandia National Laboratories, United States; [2]Northwestern University, United States

Recently, a diverse range of memristive phenomena have been demonstrated in 2D transition metal dichalcogenides (TMD) in vertical and lateral device architectures. TMD-based memristors can exhibit unipolar and bipolar resistive switching, tunable set voltage, a resistance ratio as high as 10^5, endurance up to 10^7, thus, presenting a new opportunity for ultra-scaled memory cells [1-3]. The lateral architecture is implemented as a gate tunable memtransistor and relies on bias-induced Schottky barrier modulation, which either originates from defect migration or charge trapping/detrapping processes [4]. High performance is achieved in the lateral memtransistor architecture across an unusually wide defect density range up to ~50% [3]. Therefore, due to its inherent defect tolerance and ultrathin body [5], the TMD memtransistor may provide superior durability of in-memory computation in harsh radiation environments.

In this presentation, I will discuss the effects of 48 keV Au^+ irradiation and 532 nm laser irradiation on the physical and electrical properties of the MoS_2 memtransistor as a function of photon exposure or 48 keV Au^+ fluence. We employ X-ray photoelectron spectroscopy, Atomic Force Microscopy, Raman spectroscopy, and transmission electron microscopy to elucidate the structural and chemical effects of the radiation species and dose on polycrystalline MoS_2 grown by chemical vapor deposition. The V_G-dependent I_D-V_D response and gate-contact capacitance are measured ex-situ as a function of radiation dose to evaluate the radiation tolerance of the memtransistor and deconvolute the radiation effects in the gate oxide, respectively.

The S:Mo ratio of the MoS_2 decreases from 1.9 to 0.3 and the relative concentration of MoO_x increases from 0.1 to 0.5 after an ion fluence of 9E15 cm^{-2}. The E_{2g} mode exhibits a ~6 cm^{-1} red shift and the intensities of the LO(M) and TO(M) defect modes increase after an ion fluence of 1E14 cm^{-2}, which corroborates the significant increase in defect concentration in the MoS_2 with increasing ion fluence. The ON/OFF ratio of the memtransistor devices is reduced from ~10 to ~0 after serial exposure to an ion fluence of 1E13 cm^{-2} and a 532 nm laser. Interestingly, some memtransistor devices that are only ion irradiated retain initial electrical performance despite a significant increase in gate-contact capacitance. Our preliminary results suggest the MoS_2 memtransistor exhibits impressive tolerance to ionizing radiation.

This work was supported by a Laboratory Directed Research & Development program at Sandia National Laboratories. Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International, Inc., for the U.S. DOE's National Nuclear Security Administration under contract DE-NA-0003525. 6:45 PM EQ20.23.02
Xene Routes Towards Device Integration Christian Martella[1], Daya Sagar Dhungana[1], Chiara Massetti[1,2], Emiliano Bonera[2], Carlo Grazianetti[1] and Alessandro Molle[1]; [1]CNR Institute for Microelectronics and Microsystems, Italy; [2]Università degli Studi di Milano-Bicocca, Italy

Xenes, the two-dimensional (2D) monoelemental graphene-like materials, promise to open new research frontiers in the technological exploitation of atomically thin materials because of their scalability and of their rich physics varying from one member to another.[1,2] However, significant challenges are at stake when considering the Xenes synthesis, stabilization and manipulation. Because of their artificial nature, Xene deposition usually requires an extreme control of the experimental conditions including growth temperature and substrate choice, in particular when an epitaxial matching is necessary. Moreover, strategies for overcoming the stabilization issues related to their manipulation in ambient condition are to be implemented. Taking the silicene case, namely the 2D buckled form of silicon, as paradigmatic of the Xenes family, here we show that meeting these requirements is often a matter of adopting smart experimental solutions. For example, the use of single crystal metal films grown on cleavable mica substrates allows for the development of manipulation schemes enabling portability and transfer of the Xene layers by means of mechanical and chemical delamination.[3]In addition, the in-situ encapsulation of the silicene enables us to preserve the structural integrity against aging and degradation.[4] Here we demonstrate that, when disassembled from the substrate, silicene of different forms, i.e. single layer, multilayer or heterostructured layers,[5] can be bent by reshaping or rolling it around any macroscopic surface or object showing the emergence of a strain feature in its Raman response. Bendable silicene and Xenes may thus hold high potential for strain sensor devices. The work is within the ERC-COG 2017 Grant N0. 772261 “XFab”.

Achieving Open-Circuit Voltages Greater Than 500 mV by Applying Perovskite-Like Carrier-Selective Contacts to Transition Metal Dichalcogenide Solar Cells Cora Went[1], Joeson Wong[1], Phil Jahelka[1], Morgaine Mandigo-Stoba[2] and Harry A. Atwater[1]; [1]California Institute of Technology, United States; [2]University of California, Los Angeles, United States

Two-dimensional transition metal dichalcogenides (TMDCs) are promising candidates for ultrathin photovoltaics due to their high absorption coefficients and intrinsically passivated surfaces.[1] However, careful selection of carrier-selective contacts for efficient TMDC solar cells has never been seriously considered. Here, we demonstrate that open-circuit voltages greater than 500 mV are achievable in ultrathin (total cell thickness less than 150 nm) TMDC solar cells modeled on inverted perovskite device architectures. Currently, the highest efficiency inverted (p-i-n) perovskite solar cells employ the polymer hole-transporting layer PTAA as a bottom contact and the organic electron-transporting layer C60 as a top contact.[2,3] Following this inverted perovskite geometry, we fabricate carrier-selective contact TMDC solar cells. We start with a template-stripped gold substrate, spin coat 10 nm of PTAA, exfoliate 15 nm of tungsten disulfide, thermally evaporate 10 nm of C60, and finally thermally evaporate 20 nm of silver with a bathocuproine interlayer. These devices achieve open-circuit voltages greater than 500 mV even with nonideal optical design. Using transfer matrix calculations, we demonstrate that short-circuit current greater than 20 mA/cm^2 is possible in a similar electronic architecture illuminated from the bottom through an ITO-coated glass substrate, with a 100-nm silver top contact as a back-reflector. We fabricate these devices and characterize them for their optoelectronic properties using one-sun illumination in a solar simulator, absorption and quantum efficiency measurements, photocurrent mapping, and power-dependent current-voltage sweeps. Finally, we discuss pathways to greater than 10% one-sun power conversion efficiencies. Our work demonstrates the transferability of perovskite carrier-selective contacts to TMDC solar cells, opening up the possibility for TMDCs to become a new low-cost, high-efficiency photovoltaic technology.

Engineering the Electronic Structure of Two-Dimensional Materials with Near-Field Electrostatic Effects of Self-Assembled Organic Layers Qunfei Zhou[1], Bukuru Anaclet[2], Trevor Steiner[3], Michele Kotiuga[4] and Pierre Darancet[5]; [1]Northwestern University, United States; [2]Pomona College, United States; [3]University of Minnesota, United States; [4]Ecole Polytechnique Federale de Lausanne, Switzerland; [5]Argonne National Laboratory, United States

Engineering the electronic and physical properties, such as work function, band gaps and transport properties for two-dimensional (2D) materials is essential for their promising applications in advanced electronic and optoelectronic devices. In this work, we study the effect of experimentally self-assembled organic monolayers on the electronic properties of 2D materials using first-principles density functional theory calculations. Unlike surfaces of bulk materials, we find that 2D materials are strongly impacted by near-field electrostatic effects resulting from high multipoles of the organic layer electronic density. We show this effect can lead to significant (~0.5V) modulation of the in-plane potential experienced by the electrons within 4 Å of the molecular layer, with a transition between near- and far-field. We develop an electrostatic theory of this effect, showing that the effect of the molecular layer is akin to the one of a discretized planar charge density, which can be derived from the multipole moments of the molecules. Solving this model computationally and analytically, we propose implementations of this effect to generate novel electronic properties for electrons in 2D materials. As a proof of principle, we show that the near-field potential of phthalocyanine molecular monolayers deposited on graphene leads to bandgap opening.

Effects of Molecular Structure and Chemistry on Molecular Doping to MoS_2 Serrae Reed[1], Milad Yarali[1], Yifeng Chen[2], Yiren Zhong[1], David

Charboneau[1], Julia Curley[1], Fabian Menges[1], Nilay Hazari[1], Hailiang Wang[1], Su Ying Quek[2] and Judy Cha[1]; [1]Yale University, United States; [2]National University of Singapore, Singapore

Surface functionalization of 2D materials with organic electron donors (OEDs) is a powerful pathway to modulate the electronic properties of 2D materials. However, understanding of the doping mechanism is largely limited to categorization of molecular dopants as n- or p-type based on the relative position of the molecule's redox potential to the Fermi level of 2D host. Systematic studies to examine factors beyond redox potential for molecular doping are critically lacking. In our previous work, we showed that an organic dopant based on 4,4 bipyridine (DMAP-OED) has a doping power of 0.63-1.26 electrons per molecule to MoS_2 at maximum functionalization conditions.[1] We calculated the molecular doping by measuring the carrier density of functionalized MoS_2 field effect transistors and estimating the molecular surface coverage of DMAP-OED by atomic force microscopy. We also observed that the molecular arrangement and surface coverage greatly affects the doping power of the molecule.

In this study, we use monolayer MoS_2 as a model 2D system and two molecular dopants, Me- and ^{t}Bu-OED, which have the same redox potential but different ligand groups to probe the effects of molecular size and ligand chemistry on the molecular surface coverage and doping power to MoS_2. We show that, for the same functionalization conditions, the doping powers of Me- and ^{t}Bu-OED are 0.22-0.44 and 0.11 electrons per molecule, respectively, demonstrating that the molecular size and ligand chemistry critically affect molecular doping. Using the stronger dopant, Me-OED, a carrier density of 1.10 x 10^{14} cm^{-2} is achieved in MoS_2, the highest doping level to date in MoS_2 by surface functionalization. We thus show that proper tuning of the molecular ligand chemistry and size is essential in the rational design of powerful molecular dopants.

7:45 PM EQ20.23.06
***In Situ* Collecting Ultrafast Hot Carrier as Photocurrent in Monolayer WS_2** Pan P. Adhikari[1], Peijiang Wang[2], Chendi Xie[1], Hao Zeng[2], Victor Klimov[3] and Jianbo Gao[1]; [1]Clemson University, United States; [2]University at Buffalo, SUNY, United States; [3]Los Alamos National Laboratory, United States

Extracting hot carriers as a photocurrent remains a challenge in materials science and quantum devices because the hot carrier lifetime is within the range of ultrafast picosecond. A more profound challenge is to understand the hot carrier drift dynamics. Here, we collect hot carriers as a photocurrent *in-situ* 2D WS2 single layer photoconductor, characterized by the ultrafast photocurrent spectroscopy (UPCS). The hot carrier is induced by the rich exciton species interaction, attributed to the trion Auger recombination under low exciton density and biexciton Auger recombination at high exciton density, respectively. We further identify the hot carrier transport properties, manifested by the minimum mobility of ~ 10 cm^2/Vs and drift length of ~8 nm.

8:00 PM EQ20.23.07
Ultra-Thin Amorphous Boron Oxynitride Dielectric Produced by RF Magnetron Sputtering Corey Arnold[1], Chukwudi E. Iheomamere[1], Spencer Gellerup[1], Nicholas Glavin[2], Christopher Muratore[3], Nigel D. Shepherd[1] and Andrey A. Voevodin[1]; [1]University of North Texas, United States; [2]Air Force Research Laboratory, United States; [3]University of Dayton, United States

Advancement in flexible microelectronics based on 2D materials urgently needs reliable, high dielectric strength and chemically inert dielectric materials, which can be economically produced using large area and low-temperature synthesis techniques. Among possible candidate dielectric materials, ultra-thin amorphous boron oxynitride recently emerged as an attractive material, which can be synthesized at low temperatures using physical vapor deposition methods. In this study, amorphous boron oxynitride films were deposited at room temperature on rigid and flexible substrates using radio frequency magnetron sputtering of a hexagonal boron nitride target in various argon-nitrogen background gas ratios. The effect of nitrogen content in the sputtering gas, changes in target-to-substrate distance, and magnetron power density to the target on the film composition were investigated with X-ray photoelectron spectroscopy and correlated to the dielectric breakdown strength and bandgap obtained from current-voltage measurements and Tauc plots, respectively. Films grown in pure Ar atmosphere at a large target-to-substrate distance displayed compositions containing metallic boron, which led to a decrease in the dielectric breakdown strength. The use of Ar:N_2 mixtures and pure N_2 eliminated metallic boron bonding. Decreasing the target-to-substrate distance and target power density during reactive sputtering resulted in B:N stoichiometry ratio closer to one and about 25 – 30 at.% oxygen. Amorphous boron oxynitride films grown in pure N_2 at a small target-to-substrate distance exhibited dielectric breakdown strength of 2.1 – 2.4 MV cm^{-1}, smooth surface topography, and a bandgap of 5.4 eV. Charge transport was field-dependent, with field-enhanced Schottky emission, Frenkel–Poole emission, and space-charge-limited conduction being observed in various field ranges. Test MIS structures comprised of ~30 nm thick boron oxynitride insulator and transparent ZnO semiconductor also grown at room temperature revealed a low interface trap concentration N_{it} of 7.3×10^{10} cm^{-2}, and interface state density N_{ss} of 7.5×10^{12} eV^{-1} cm^{-2}. The results demonstrate the suitability of amorphous boron oxynitride for applications as an insulator or gate dielectric in flexible or transparent thin-film transistors and other electronics when a low processing temperature is required.

8:15 PM EQ20.23.08
Rapid Growth of Monolayer 2D Transition Metal Dichalcogenide Films for Large-Area Electronics Mengqiang Zhao[1], Danzhen Zhang[2], Chengyu Wen[3] and A T Charlie Johnson[3]; [1]New Jersey Institute of Technology, United States; [2]Drexel University, United States; [3]University of Pennsylvania, United States

The large-scale growth of semiconducting thin films on insulating substrates enables batch fabrication of atomically-thin electronic and optoelectronic devices and circuits without film transfer. Here we report an efficient method to achieve rapid growth of large-area monolayer $MoSe_2$ films based on spin coating of Mo precursor and assisted by NaCl. Uniform monolayer $MoSe_2$ films up to a few inches in size were obtained within a short growth time of 5 min. The as-grown monolayer $MoSe_2$ films were of high quality with large grain size (up to 120 μm). Arrays of field-effect transistors were fabricated from the $MoSe_2$ films through a photolithographic process; the devices exhibited high carrier mobility of ~27.6 $cm^2V^{-1}s^{-1}$ and on/off ratios of ~10^5. The growth method was also applicable to other 2D transition metal dichalcogenides (TMDs), and rapid growth of large-area monolayer MoS_2, WS_2, and WSe_2 films were all successfully achieved.Our findings provide insight into the batch production of uniform thin TMD films and promote their large-scale applications.

10:30 AM EQ20.24.02
Hexagonal Metal Oxide Monolayers Derived from the Metal-Gas Interface Bao Yue Zhang and Jian Zhen Ou; RMIT University, Australia

Metal oxides, which is one of the most abundant substances in nature, are rarely found to be layered crystal. This hinders their potential to form into two-dimension (2D) since the cleavage of weak, interlayer van der Waals bonds in layered bulk crystal serves as the benchmark to obtain the atomically thin high-quality 2D layers such as ZnO[1]. 2D-like non-layered metal oxides are usually created *via* a space-confined-growth[2-4] or soft-chemically exfoliation of unilamellar bulk crystal[5], in which external ionic groups may be induced to stabilize the crystals. In this talk, I will discuss our recent discovery of a series of the layered planar hexagonal phase of oxide from elements across the transition metals, post-transition metals, lanthanides and metalloids[6]. These oxides can be naturally formed from metallic surfaces under a controlled oxidation environment without involving sophisticated equipment or other chemicals. Subsequently, the hexagonal 2D metal oxide monolayers can be facilely exfoliated on a substrate in a mechanical manner, similar to the way of obtaining graphene and other layered metal chalcogenides. We have selected the hexagonal TiO_2 as a representative to reveal the distinct properties of such hexagon crystal coordinated oxides apart from their bulk counterparts. The monolayered and few-layered hexagonal TiO_2 shows p-typed semiconductor behavior with the hole mobility up to 950 $cm^2V^{-1}s^{-1}$ at room temperature. This research topic can possibly expand the exploration of metal oxides in the 2D quantum regime and initiate numerous applications in the future.

Universal Synthesis of Layered Materials by Microwave-Induced-Plasma Assisted Method Apoorva Chaturvedi and Edwin H. Teo; Nanyang Technological University, Singapore

Layered van der Waals (vdW) materials, consisting of atomically thin layers, are of paramount importance in physics, chemistry, and materials science owing to their unique properties and various promising applications. However, their fast and large-scale growth via a general approach is still a big challenge, severely limiting their practical implementations. Here, we report a universal method for rapid (~60 min) and large-scale (gram scale) growth of phase-pure, high-crystalline layered vdW materials from their elementary powders via microwave plasma heating in sealed ampoules. This method can be used for growth of 30 compounds with different components (binary, ternary, and quaternary) and properties. The ferroelectric and transport properties of mechanically exfoliated flakes validate the high crystal quality of the grown materials. Our study provides a general strategy for the fast and large-scale growth of layered vdW materials with appealing physiochemical properties, which could be used for various promising applications.

11:00 AM EQ20.24.04
Two-Dimensional Janus Nanomaterials for Controllable Delivery and Imaging Application Wei Wang and Sehoon Chang; Aramco Services Company, United States

Anisotropic nanomaterials composed of two halves with different structure, chemistry, or polarity, known as Janus nanomaterials, have distinct properties when compared to symmetrically functionalized analogues. These materials have recently gained significant attention in many applications such as electronic thin films, drug delivery, sensors, optics, oil/water separation membranes, photoactivated micromotors, photocatalysts, and interfacial modification. Two dimensional (2D) Janus nanosheets are especially intriguing considering their interfacial properties as well as their ability to assemble into higher order and hybrid structures. In this research, we describe an approach to mass synthesis of Janus nanosheets consist of graphene, metal and ceramic materials in highly controllable ways via a novel “Interfacial Nanoreactor” system. We have characterized and proven the asymmetric structures of the synthesized Janus graphene nanosheets by Langmuir-Blodgett (LB) surface pressure-area (π-A) curves, fluorescence spectroscopy, contact angle measurement and scanning electron microscope (SEM) characterizations. As an example of applications in oil and gas industry, we have demonstrated that the Janus nanosheets with proper hydrophilic/hydrophobic functionalization can be directed onto interface of aqueous-organic bi-phase system and significantly lower the interfacial tension (IFT) between aqueous and organic phases, which promotes the oil recovery process in oil reservoir. With loading of proper imaging contrast agents (dyes or quantum dots) on one side and controlled hydrophilicity or hydrophobicity on the other side, the Janus nanosheets can be directed to confined microporous area, which enables to probe structural microheterogeneity of geological samples such as shale rocks by optical or microscopic imaging techniques.

Late News: New Routes to Assessing and Enhancing the Yield of Hexagonal Boron Nitride Using Sustainable Liquid Phase Exfoliation Techniques Kai Ling Ng[1], Barbara M. Maciejewska[1], Zhicheng Xu[1], Dillon McGurty[1] and Nicole Grobert[1,2]; [1]University of Oxford, United Kingdom; [2]Williams Advanced Engineering, United Kingdom

The suitability of solvents for the efficient liquid phase exfoliation (LPE) to produce 2D materials such as hexagonal Boron Nitride (hBN) from their bulk starting materials is typically assessed by UV-Vis concentration measurements. However, UV-Vis concentration characterisation of liquid phase exfoliated 2D materials relies on good materials dispersibility within a given solvent for the data to reflect the actual solvent exfoliation efficiency.

‘Green’ solvents possess low boiling points and toxicity, which are the attractive solvent choice for LPE of 2D materials but the yield is low due to the limited materials dispersibility in these solvents. Therefore, the efficient liquid phase exfoliation to produce 2D materials is still largely relying on e.g., 1-Methyl-2-pyrrolidinone (NMP) which unfortunately is harmful to the environment and therefore hinders the large scale production. Here, to assess the exfoliation efficiency of 2D materials in ‘green’ solvents independently of their dispersibility, we performed dedicated exfoliation efficiency studies to enhance the yield of liquid phase exfoliated hBN and compared yields to the most studied 2D materials system to date, e.g. graphene.

We found that isopropanol (IPA) has the highest exfoliation efficiency (comparable to that of NMP), despite the poor dispersibility of graphene in IPA. We could also show that the dispersibility and concentration of layered materials in IPA is higher after a brief post-exfoliation sonication treatment without damaging the exfoliated 2D materials.

By studying shear-mixing processes and understanding the actual exfoliation efficiency of the solvents in detail, it is possible to double the hBN yield (and increase the graphene yield 10-fold) using IPA as the exfoliation medium. Our studies prove that the yield of hBN (and graphene) in green solvents is not limited by the exfoliation efficiency but it is due to its poor dispersibility in green solvents. Our findings pave the way for other post-exfoliation methods to optimise the yield through sustainable solvents exfoliation for industrial-scale, especially for hBN production.

11:30 AM EQ20.24.06
Late News: Synthesis of Two-Dimensional Silicon Carbide—Bridging Theory and Experiment Sakineh Chabi; University of New Mexico, United States

In the past decade, research in the field of two-dimensional materials has exponentially transitioned from fundamental studies to the development of complex 2D devices. While an increasing number of 2D materials, including graphene, and hexagonal-boron nitride, have been synthesized successfully in the lab, others have only been theoretically predicted. One very important example is two-dimensional silicon carbide (2D SiC). Theoretical studies have predicted that monolayer SiC has a stable planar graphene-like structure, a direct bandgap of about 2.58 eV, strong excitonic effects, and highly tunable electronic, optical, and magnetic properties. These characteristics are of great importance for many applications and make 2D SiC a potential game-changer for future energy-related technologies. Experimentally, however, the growth of 2D SiC has challenged scientists for decades, mainly because unlike graphite or other layered materials, bulk SiC is not a van der Waals layered structure. Bulk SiC is a covalently bonded material, and it is one of the strongest materials. Further still, bulk SiC exists in more than 250 polytypes, further complicating the synthesis efforts. Importantly though, our group has made groundbreaking progress on the synthesis of 2D SiC. We successfully grow the first monolayer SiC by adopting a unique wet exfoliation method, in which 6H-SiC was used as a precursor. The exfoliated 2D SiC nanosheets, are 100% stable in air and show visible light emission at around 480 nm (2.58 eV), which is in good agreement with theoretical predications.
As a stable atomic thick semiconducting material, 2D SiC has the potential to bring revolutionary advances across various technological fields ranging from power electronics, and optoelectronics to quantum information processing and beyond.2D SiC can address countless drawbacks associated with the gapless nature of graphene, silicon semiconductors (narrow band gap and low voltage breakdown), environmental instability of silicene and few-layer black phosphorous and the indirect bandgap of bulk SiC.

11:45 AM EQ20.24.07
Patterning Laser Induced Graphene on Flexible Substrates with Spatial Control of Morphology Moataz Abdulhafez, Ki-Ho Nam, Golnaz Najaf Tomaraei and Mostafa Bedewy; University of Pittsburgh, United States

Laser induced graphene (LIG) is an emerging technique that enables directly patterning conductive carbon electrodes for a plethora of flexible devices, including supercapacitors and sensors. While the morphology and chemistry of the porous three-dimensional graphene produced by this method were previously shown to be tunable, the ability to create functional gradation wherein different parts of the patterned graphene exhibit different morphology and/or chemistry on the same flexible substrate has not been previously achieved. Here, we present a new methods for creating functionally graded LIG based on utilizing controlled gradients of optical energy flux to create spatial gradients of LIG morphologies having different electrical conductivities. Importantly, we demonstrate the seamless transition between neighboring regions having different porosity and conductivity. To demonstrate the morphology transitions in the LIG, we developed a method to continuously sweep laser fluence values by controlling the defocus level of the sample surface. This sweep enabled identifying the precise fluence thresholds that correspond to morphological transitions: first, from isotropic porous morphology to anisotropic networks at 12 J/cm^2; second, from anisotropic networks to aligned nanofibers at 17 J/cm^2. Hence, our results provide new insights into the fluence-dependence of the physicochemical processes underlying LIG formation. Moreover, our approach enables generating a morphology diagram for LIG, which facilitates precise tunability of both the morphology, electrical and electrochemical properties of LIG patterns, based on easy-to-control processing parameters, such as laser power and degree of beam defocusing. In addition, this unprecedented ability to create spatially varying morphologies opens the door for one-step fabrication process of complex flexible devices with high surface area electrodes that are integrated with relatively denser and more electrically conducting traces.
Here, we present two methods for creating functionally graded laser induced graphene materials: The first method utilizes controlled gradients of optical energy flux to create spatial gradients of LIG morphologies having different electrical conductivities. The second approach creates spatially controlled surface functionalization through relasing the LIG in vacuum, nitrogen or oxygen environment in a controlled chamber. Through the second lase, patterned LIG surfaces can be created, leading to patterned surface properties and electrochemical properties.

Forming Input/Output (I/O) Interfaces with Excitable Cells and Tissue Using Nanocarbons Tzahi Cohen-Karni; Carnegie Mellon University, United States

We focus on developing a new class of nanoscale materials and novel strategies for the investigation of biological entities at multiple length scales, from the molecular level to complex cellular networks. Our highly flexible bottom-up nanomaterials synthesis capabilities allow us to form unique hybrid-nanomaterials that can be used in various input/output bioelectrical interfaces, i.e., bioelectrical platforms for chemical and physical sensing and actuation. We developed a breakthrough bioelectrical interface, a 3D self-rolled biosensor arrays (3D-SR-BAs) of either active field effect transistors or passive microelectrodes to measure both cardiac and neural spheroids electrophysiology in 3D. This approach enables electrophysiological investigation and monitoring of the complex signal transduction in 3D cellular assemblies toward an organ-on-an-electronic-chip (organ-on-e-chip) platform for tissue maturation investigations and development of drugs for disease treatment. Utilizing graphene, a two-dimensional (2D) atomically thin carbon allotrope, we demonstrated a new technique to simultaneously record the intracellular electrical activity of multiple excitable cells with ultra-microelectrodes that can be as small as the size as an axon ca. 2µm in size. The outstanding electrochemical properties of our hybrid-nanomaterials allowed us to develop electrical sensors and actuators, e.g., sensors to explore the brain chemistry and sensors/actuators that are deployed in a large volumetric muscle loss animal model. Finally, using the unique optical properties of nanocarbons, e.g., graphene-based hybrid-nanomaterials and 2D nanocarbides, we have formed remote, non-genetic bioelectrical interfaces with excitable cells and modulated cellular and network activity with high precision and low needed energy. In summary, the exceptional synthetic control and flexible assembly of nanomaterials provide powerful tools for fundamental studies and applications in life science and potentially seamlessly merge nanomaterials-based platforms with cells, fusing nonliving and living systems together.

2:00 PM *SB01.01.02
Computer Designed Organisms Built from Embryonic Amphibian Cells Douglas Blackiston[1,2], Sam Kriegman[3], Josh Bongard[3] and Michael Levin[1,2]; [1]Tufts University, United States; [2]Wyss Institute, United States; [3]The University of Vermont, United States

The fields of biology and robotics have seen an emergence of interdisciplinary work aimed at building machines that contain biological components, designed to solve a wide variety of problems that challenge traditional robots including; robustness to damage, increased biocompatibility, and a programmable internal biochemistry. These efforts have largely coalesced around biohybrid designs, combining synthetic scaffolds or components alongside living cells and tissues. In complement to this approach, we have developed methods for constructing fully biological machines from embryonic amphibian cells, engineered to exhibit a specific behavior. As part of these studies, we demonstrate a scalable pipeline for creating functional computer designed organisms: AI methods automatically design diverse candidate lifeforms in silico to perform some desired function, and transferable designs are then created using a cell-based construction toolkit to realize living systems with the predicted behaviors. Although some steps in this pipeline still require manual intervention, complete automation in future would pave the way to designing and deploying unique, bespoke living systems for a wide range of functions.

2:30 PM SB01.01.03
Stress-Induced Electrical Signaling in Microalgae Cohorts Paulo R. Rocha[1], Lode Vandamme[2] and Ricardo Leite[3]; [1]University of Coimbra, Portugal; [2]Eindhoven University of Technology, Netherlands; [3]Instituto Gulbenkian de Ciência, Portugal

Diatoms are early Jurassic microalgae, a photosynthetic group with a major environmental role on the planet due to the biogeochemical cycling of silica and global fixation of carbon. However, they can evolve into harmful blooms through a resourceful communication mechanism, not yet fully understood. Harmful algae blooms in water supply reservoirs must be eradicated due to unwanted toxin production and filter blocking at water treatment works. Until now there has been no efficient consensus that harmful microorganisms such as diatoms communicate with each other and no accurate and self-sustained tool to monitor such communication.

Here, we demonstrate the ability to electrically monitor a diatom cohort. The breakthrough is realized by means of a unique measurement setup based on low impedance electrodes that exploit the large Helmholtz-Gouy-Chapman double-layer capacitance. The sensing system comprises a transducer based on a metal/Si/SiO_2/Au electrode. Small extracellular voltages of diatoms adhered to the electrode induce a displacement current that is enhanced by a gain factor proportional to the double-layer capacitance.

The origin is paracrine signalling, which is a feedback, or survival, mechanism that counteracts changes in the physicochemical environment. The intracellular messenger could be related to Ca^{2+} ions since spatiotemporal changes in their concentration match the characteristics of the intercellular waves. Our conclusion is supported by using a Ca^{2+} channel inhibitor. The transport of Ca^{2+} ions through the membrane to the extracellular medium is blocked and the intercellular waves disappear. The translation of microalgae cooperative signalling paves the way for early detection and prevention of harmful blooms and an extensive range of stress-induced alterations in the aquatic ecosystem

2:45 PM *SB01.01.04
Synapse- and Neuron-Inspired Biomolecular Materials and Devices Joseph S. Najem; The Pennsylvania State University, United States

The rise of Artificial Intelligence and the Internet of Things applications in biological domains poses questions about the best way to build computing devices that are biocompatible, low-power, and adaptable. We believe an approach that takes inspiration from the brain could grant an answer. For instance, biological neurons process signals and compute by integrating incoming stimuli and initiating action potentials to convey information within the nervous system without loss. The process from generation to propagation is regulated by membrane potential and voltage-activated sodium and potassium channels. Moreover, synaptic plasticity is responsible for learning, processing, and information retention. These key features inspire and guide the design of neuron-and synapse-like materials for applications in signal processing, computing, and lossless propagation of information. To this end, we have recently

demonstrated that lipid bilayer membranes formed between two lipid-encased water droplets in oil (i.e., droplet interface bilayers or DIBs) can exhibit memcapacitive and memristive properties, suitable for emulating synapse and neuron functions. Here, we describe a dynamic neuristor consisting of two biomolecular memristors in parallel, while operating according to the same principles as the Hodgkin-Huxley model. The biomolecular memristors consist of insulating biomembrane doped with voltage-driven, pore-forming alamethicin peptides. To capture the switching dynamics of the sodium and potassium channels, we used DPhPC- and BTLE-based memristors, which can offer fast and slow switching dynamics, respectively. The neuristor exhibits a firing behavior similar to a biological neuron and a power efficiency that far exceeds metal oxide-based memristors. This novel neuristor can be implemented in applications ranging from adaptive nonlinear control to signal processing. Additionally, we will discuss our approach to scaling up networks of biomolecular synapses and neurons using microfluidic crossbar array devices. We describe how these devices can be implemented in online learning and reservoir computing applications. These results serve as a foundation for a new class of low-cost, low-power biomolecular materials to support neuromorphic computing applications in biological environments.

3:15 PM SB01.01.05
A Microfluidics-Based *In Vitro* Model of Anterior-Posterior Gut Patterning Kiara W. Cui, Leeya Engel, Kevin J. Liu, Kyle M. Loh, Lay Teng Ang and Alexander Dunn; Stanford University, United States

In this work, we demonstrate, for the first time, spatially controlled differentiation of human pluripotent stem cells (hPSCs) into the anterior foregut (AFG) and mid/hindgut (MHG) cell types within a single cell monolayer using chemical gradient-generating microfluidics. This result represents an advance in the ongoing efforts to harness the processes by which complex tissues arise during embryonic development *in vitro*—a long-standing goal of tissue engineering and regenerative medicine. In embryos, uniform populations of stem cells are exposed to spatial gradients of diffusible extracellular signaling proteins, known as morphogens. Varying levels of these signaling proteins induce stem cells to differentiate into distinct cell types at different positions along the gradient, thus creating spatially patterned tissues.

To accomplish this spatially controlled differentiation, or patterning, we combined principles of engineering and biology to develop a novel, reproducible, and easily accessible method for the anterior-posterior patterning of hPSCs. We performed a 6-day, on-chip differentiation protocol within a commercially available microfluidic chip. We used finite element analysis to model the distribution of morphogens within the microfluidic device and determined that the chip can generate two stable and opposing linear morphogen gradients. Quantitative analysis of immunofluorescence data showed that expression of AFG and MHG markers is localized to their respective morphogen sources and that both display a decreasing linear profile with increasing distance from their sources. This platform thus allows us to explore fundamental questions about how a single population of stem cells differentiate into multiple cell types along a body axis in response to exposure to morphogen gradients, such as whether the response in marker expression is graded or discretized as well as the influence of neighboring cells on cell fate decisions. Our *in vitro* model contributes to the stem cell and developmental biology toolkit and may eventually pave the way to create increasingly spatially patterned tissue-like constructs *in vitro*.

3:30 PM *SB01.01.06
Remodeling of Biological Membranes Adsorbed to Crumpling 2D Materials Devices Cecilia Leal, Marilyn Porras-Gomez, Hyunchul Kim, Nurila Kambar, Mohan Teja Dronadula, Narayana Aluru and Arend van der Zande; University of Illinois at Urbana-Champaign, United States

We study the structural evolution of biologically relevant phospholipid membranes adsorbed onto deformable 2D substrates. We introduce a novel way to remodel lipid bilayers using polydimethylsiloxane substrates or graphene, which can be uniaxially stretched and wrinkled on demand. X-ray, microscopy and simulation data revealed that phospholipid membranes undergo restructuring at the nano and molecular scale. These observations have repercussions on membrane order, permeation, and directing the insertion of proteins for applications in biotechnological applications such as biosensing.

***In Vitro* Neuronal Network-on-a-Chip Technology—From Millimeter to Centimeter-Scale Networks** Yoonkey Nam; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

In vitro neural cultures have been used as an experimental model system to study basic neuroscience, design advanced cell-based biosensing platform, and utilize as testbeds for novel neurotechnology. Many types of primary cultured neurons (e.g. rat/mouse cortical or hippocampal neurons) go through developmental processes (neurite outgrowth, axon/dendrite formation), and form a matured neuronal network with functional synapses during the extended cultivation period. To investigate the functional developments during the network formation, neurons are cultivated on a planar-type microelectrode array (MEA) chip, and electrophysiological activity is measured from multiple sites in the network. Conventional MEA chips provide a few millimeter-sized recoding area with sparse or dense microelectrodes, which limits the physical size of the cultured neuronal networks under the investigation. Large-scale neuronal networks on the order of a few centimeters are rarely investigated by the limited availability of the MEA chips that provide recording electrodes distributed over a large area. This talk introduces a scaling up the network size to centimeter scale on a microslide-sized MEA chip. The chip is equipped with 256 channels which are subdivided into 16 millimeter-sized recording areas with 16 channels. The large-scale MEA chips were fabricated by conventional microfabrication processes, and recording sites were made of low-impedance electropolymerized conductive polymers (PEDOT:PSS). On this large-scale MEA chip with clustered recording areas, we designed an ultra-large-scale, modular neuronal network connected by biological connections (e.g. axons). Neuronal network modules, composed of primary cultured neurons, were patterned on the MEA chip using soft-lithography, and each module was connected later by removing alginate hydrogel mask. The alginate hydrogel was used as a removable cell-repulsive surface to temporarily limit the cell adhesion and neurite outgrowth. Using this method, the development of network activity could be more precisely measured and analyzed. The emergence of synchronized, propagating network bursts were readily measured, and their time course could be analyzed. We found network-size dependent signal propagation properties in the cultured neuronal networks.

Emerging Technology for Biohybrid Systems Shoji Takeuchi[1,2]; [1]The University of Tokyo, Japan; [2]Kanagawa Institute of Industrial Science and Technology, Japan

While manufacturing is evolving and new devices are coming out one after another, it is still difficult to artificially create functions such as molecular recognition, material production, and self-organization that are found in living organisms. We have developed a biohybrid device that combines living organisms and machines. The biohybrid devices can be categorized into 4 groups: (i) biohybrid-sensors that can detect target molecules at highly selective and sensitive manner, (ii) biohybrid-reactors that mimic biological reaction in our body, and thus are useful for drug testing or tissue transplant for cell therapy, (iii) biohybrid-actuators that shows highly energy efficient motion and (iv) biohybrid-processors that achieve low-energy and highly parallel computing like our brain. Here, I would like to talk about a couple of our recent results regarding biohybrid sensors and actuators.

9:00 AM SB01.02.03
Rapid and Simple Antibiotic Susceptibility Testing by Monitoring Bacterial Extracellular Electron Transfer Zahra Rafiee and Seokheun Choi; Binghamton University, The State University of New York, United States

A rapid and simple antibiotic susceptibility testing (AST) is critical to provide valuable information on the antibiotic efficacy and their right doses for treatment against bacterial infections. Although emerging genotypic ASTs are very useful and fast, it is difficult to characterize unknown bacteria. Even "gold standard" phenotypic ASTs require a relatively long time for culturing and monitoring. This work creates a powerful yet simple method to assess antibiotic effectiveness against electrogenic bacteria, which enables rapid, high-throughput, and real-time monitoring. The proposed AST approach continuously monitors extracellular electron transfer by bacterial cells, parallelly and controllably formed on a paper-based sensing array. The transferred electrons are based on microbial metabolic activities and are inversely proportional to the concentration of potential antibiotics, leading to the early detection of antimicrobial drug resistance in bacteria.
Extracellular electron transfer (EET) is a remarkable bioelectrochemical process used by certain microorganisms for growth, overall cell maintenance, and information exchange with surrounding microorganisms or environments. Almost all environments, even those involving harsh conditions, host microorganisms performing EET. Recent studies have demonstrated electrogenicity by even Gram-positive microorganisms, which have thick cell walls that limit effective electron transfer. Other microorganisms have demonstrated weak electrogenic capacity in microbial consortia, involving direct interspecies electron transfer (DIET) and EET-involved cell-to-cell communications. Even many microbial pathogens such as *Pseudomonas aeruginosa* use quorum sensing inter-cellular communication by producing diffusible signaling molecules (e.g., autoinducers) and redox active compounds to control virulence during infections and defend their immediate niche against competing microorganisms and environmental stresses. The redox-active compounds can also serve as extracellular soluble mediators for microbial EET. Therefore, the electrical outputs from the bacterial EET can be used as a measurement to evaluate the antibiotic efficacy. When the antibiotics are effective against those pathogenic exoelectrogens, their metabolic activities can be inhibited, thus decreasing their electron transfer reactions. The changes in electrical outputs can be measured to assess the antibiotic effectiveness against the pathogen.
In this work, a paper-based 8-well sensing array offers a rapid and simple approach to characterize bacterial electrical response in the different concentrations of antibiotics. A common Gram-negative pathogenic bacterium *Pseudomonas aeruginosa* wild-type PAO1 and first-line antibiotic gentamicin (GEN) are used in our experiments. Eight different concentrations of antibiotics (1, 2, 4, 8, 16, 32, 64, and 128 ug/ml) are pre-loaded and dried on the sensing units. When bacterial samples are loaded into the array, antibiotic exposures allow sufficient inhibition to the bacterial metabolisms, and the readout becomes sensitive enough to show small variations in electric output caused by changes in antibiotic effectiveness. The result generates quantitative, actionable minimum inhibitory concentration (MIC) values within an hour by measuring electricity produced by bacterial metabolism instead of the days needed for growth-observation methods. This work will explore the viability of this system as a practical and reliable AST tool. The project outcomes will address grand challenges in microbial infections critical to U.S. healthcare and the economy, through enabling sensors that will augment human health, safety, and well-being by providing information to effectively treat the infections and better control the spread of the antibiotic resistance.

9:15 AM SB01.02.04
Late News: Cardiac Muscle-Cell-Based Coupled Oscillator Network for Vertex Coloring Problems Jiaying Ji[1], Xiang Ren[1], Jorge Gómez[1], Mohammad K. Bashar[2], Shukla Nikhil[2], Suman Datta[1] and Pinar Zorlutuna[1]; [1]University of Notre Dame, United States; [2]University of Virginia, United States

Inspired by the natural biological system's efficiency and complexity, biocomputing that utilizes or mimics natural information processing inherent in living organisms provides a new computational approach that performs computing in a massively parallel way with energy efficiency. Here, we present a new biocomputing platform, a cardiac muscle-cell-based bio-oscillator network, for solving computationally hard problems such as vertex coloring problems, which entail computing the minimum number of colors required to assign colors to all vertices in a graph such that every adjacent vertex have a different color. The computing components of the network are composed of bio-oscillators, cardiomyocytes (CMs), and coupling elements, cardiac fibroblasts (CFs). We aim to harness the unique phase ordering produced by the coupled bio-oscillators to approximate the optimal solution to the vertex coloring problem. We first studied the synchronization behavior of a pair of coupled bio-oscillators that exhibited stable phase delays caused by the time lag in transporting electrical signals through the coupling elements. Such delays can be exploited to build up the phase ordering in multi-node oscillators. Then, we aimed to use the bio-oscillator network to solve multi-node vertex coloring problems (9 nodes and 64 nodes) through mapping the vertices and edges onto the CMs and CFs. The micropatterning method based on topographic features and mobile blockers was implemented for creating the controlled cell distribution. On the theoretical front, we developed a polynomial-time post-processing scheme that uses the bio-oscillator solution as a starting point to improve the solution to be comparable to the heuristic algorithm. Moreover, the bio-oscillator-based computational model can have a performance advantage at large nodes compared to the heuristic algorithm. We also benchmarked the energy and latency for graph coloring using coupled bio-oscillators and conventional CMOS oscillators. The energy consumption of the cardiac-cell and CMOS oscillators for networks of different sizes indicated that cardiac cells consume lesser energy in computing the graph coloring solution which can lead to significant energy savings in larger networks.

Paper-supported 3-D Cell Culturing, Sensing and Biofabrication for Exploring Research Frontiers in Electromicrobiology Anwar Elhadad and Seokheun Choi; Binghamton University, The State University of New York, United States

Electromicrobiology is a discipline emerging from studies of microbial electron exchange with external electrodes and of novel electrochemical properties of microorganisms. Intensive study in electromicrobiological engineering has created a plethora of new concepts and potential applications, offering

sustainable environmental solutions for the production of energy as well as valuable products. However, the microbial electrochemical technique has not yet been leveraged for practical applications. Several significant research gaps must be addressed before electromicrobiology is viable and scalable, and the need to address these gaps is growing more urgent with the increasing concerns over the energy-climate crisis and environment pollution. For example, researchers do not yet fully understand the interplay between electrodes and active microbes, and factors controlling the rate and extent of the exchange process are still ill-defined. Additionally, more research is needed to ascertain which microbial species or consortia of species are best suited for efficient electron transfer.

The overarching purpose of this work is to pursue advanced, innovative approaches that elucidate/maximize microbial electron exchange with electrodes, and translate basic findings within the field of electromicrobiology into practical, real-world applications that support environmental sustainability. In this work, a range of innovative approaches are investigated with the major goals of investigating fundamental factors responsible for determining efficient electron exchange with external devices, and exploring three-dimensional biofabrication and engineering of synthetic polymicrobial biofilms. This research provides a foundation for enhanced performance in electromicrobiology. The project uses the new field of 3D, paper-based cell culturing, sensing and biofabrication platforms that mimic microbe-electrode interactions in biofilms. In particular, stacks of patterned papers provide creative and unique solutions for 3D bacterial cultures of controlled biofilm geometry, high-throughput monitoring of microbial electrical properties and layer-by-layer construction of an artificial biofilm. This research addresses key issues in electromicrobiology: (i) promote/accelerate the discovery and characterization of customized and novel exoelectrogens, (ii) establish fundamental knowledge to determine critical factors in electron transfer at the microbial/anode interface, and (iii) optimize bacterial synergistic interactions in synthetic bacterial communities.

Multiple layers of paper containing bacterial cells can be stacked to form a layered 3D model of the overall biofilm construct and mass transport of nutrients/oxygen into this 3D system can be regulated to explore the microbial energy production within controlled biofilms. Different stack configurations allow us to generate many different experimental setups to better understand key mechanisms underlying electron harvesting from microorganisms and other fundamental factors determining their electron-generating capabilities. De-stacking the multi-layered biofilm construct also allow layer-by-layer analysis for pH distribution and cellular viability. In this 3D model system, Synechocystis sp. PCC 6803 on the top layer exploits photosynthesis to produce carbohydrates, which are used as a carbon source by other microbial communities. Then, the facultative aerobe Bacillus subtilis are inserted into the middle layer of the co-culture to produce riboflavin as an electron shuttle, which significantly improves power generation of exoelectrogens, Shewanella oneidensis, on the bottom layer. Furthermore, Bacillus subtilis can remove oxygen and thus maintain an anaerobic condition for the optimized electrogenic process of Shewanella sp. This 3D system demonstrates a significantly increased power output.

10:45 AM SB01.03.02

A Three-Dimensional Blood-Brain Barrier Model Using *Ex Vivo* Brain Tissue Brian O'Grady[1], Alexis Yates[1], Michael Geuy[1], Hyosung Kim[1], John Wikswo[1], Matthew Schrag[1,2] and Ethan Lippmann[1]; [1]Vanderbilt University, United States; [2]Vanderbilt University Medical Center, United States

Introduction: Dysfunction of the blood-brain barrier (BBB) is implicated in several neurological disorders. As such, it is highly desirable to develop new models to study BBB pathology. However, these studies are hampered by the complex multi-cellular hierarchy and cellular interactions that are required to create a physiologically relevant model that accurately depicts the structure and function of the BBB. To address these limitations, we have been developing a vascularized, anatomically-representative three-dimensional (3D) model of the BBB in a perfusable, 3D printed microfluidic chip using *ex vivo* mouse and human tissue embedded in a biomimetic hydrogel. Overall, our 3D BBB model provides a unique system that allows for dynamic interrogation of the BBB in healthy and diseased tissue.

Methods and Materials: Microfluidic devices were fabricated using a stereolithographic 3D printed mold. This mold was vapor deposited with Parylene C to provide a physical barrier to prevent cytotoxic leaching into the casted polydimethylsiloxane and hydrogel. Fresh mouse and/or human brain tissue were collected and minced in a 1mL conical tube filled with 500µL of Hank's Balanced Salt solution for 5 minutes. The vial was then centrifuged at 2500 rpm. After centrifugation, the vial was tilted and the liquid top layer was aspirated. Then, 100µL of minced tissue was transferred to 1mL of 10% gelatin conjugated with an N-cadherin biomimetic peptide and thoroughly mixed. Subsequently, microbial transglutaminase was added to the hydrogel for crosslinking (2% final solution), mixed and poured into the microfluidic device. The hydrogel was cured for 30 minutes at 37°C, followed by immediate perfusion of the peripheral channels. Vascular growth in the hydrogels was imaged with confocal immunofluorescence 7 days following tissue embedding.

Results and Discussion: We established a neurovascular *ex vivo* model using mouse and human brain tissue embedded in a hydrogel containing a peptide from the extracellular epitope of N-cadherin. This tissue spontaneously sprouts vasculature in our microfluidic platform to form a perfusable vascular network. The two flanking perfusion channels are independently perfusable with media and growth factors to direct vascularization to the channels, while the middle channel was designed for 3D hydrogels impregnated with tissue. Neovascularization could be observed in real-time from the embedded tissue, and immunostaining revealed vessels that were several millimeters in length and consisted of anatomically correct positioning of endothelial cells and pericytes separated by a collagen IV basement membrane. Excitingly, human brain tissue from a patient with CAA, a disease characterized by the accumulation of amyloid-β deposition in the vascular walls, could grow vasculature that exhibited hallmarks of the disease including amyloid accumulation and arterioles devoid of smooth muscle cells.

Conclusions: We have shown that human and mouse brain tissue in our hydrogel exhibits continuous vascular growth with anatomically correct hierarchy and expression of characteristic markers of vascular cell phenotypes. This new platform also supports the use of diseased primary human tissue to produce brain vasculature with alterations characteristic of the underlying cerebral vascular architecture pathology. Thus, we believe this new tool will be a powerful platform for building more complex brain models with proper organization and assessing therapeutic efficacy of drugs for a broad range of neurological disorders.

11:00 AM SB01.03.03

On-Demand Paper Biobatteries Activated by Human Body Fluids Mya Landers and Seokheun Choi; Binghamton University, The State University of New York, United States

With the growing demand for point-of-care (POC) and in-field diagnostic testing, paper attracts significant attention as a substrate for simple, low-cost, and disposable analytical devices. A porous, hydrophilic network of intertwined cellulose fibers promotes excellent mechanical, dielectrical and fluidic properties in paper. These properties mean microfluidic assays and electronic/mechanical components can be built into paper, offering the transformative potential of generating important function for POC diagnostic devices. Recent advances in paperfluidic and papertronic technologies offer more decentralized diagnostic analyses with portability, automation, and the capacity to produce test results in shorter times at a reduced cost. However, there has been a significant challenge in realizing a truly stand-alone and self-sustainable diagnostic platform that does not rely on a competent laboratory service or smartphone's built-in functions. The key challenge is to develop a miniaturized on-chip power source for those paper-based POC devices in a more effective and efficient way. Power autonomy is one of the most critical requirements for the devices so they can work independently and self-sustainably in limited-resource and remote regions, where a stable electrical supply is not available. Even standard batteries are not suitable in those areas because of their cost, incompatibility with paper, and potential danger to the environment. Smartphone built-in batteries are not always available. Also, conventional energy harvesting technologies (e.g. solar, thermal, mechanical, chemical energy) are too overqualified and expensive as a power source for single-use, disposable POC tests, which require relatively small power consumption for only a couple of minutes. What is needed is a low-cost, disposable, and eco-friendly micro-power source that can be easily integrated with paper-based devices and be readily activated even in those challenging field conditions.

Here we provide a realistic and accessible solution as a novel power source that can enable a self-powered paper-based diagnostic test for anyone,

anywhere, and anytime. The work creates a paper-based microbial fuel cell (MFC) device that is pre-inoculated with *Bacillus subtilis* endospores and can be activated with a drop of human body fluids, such as sweat or saliva. *B. subtilis* endospores are a resilient, desiccation-resistant state of the bacteria that can develop in a nutrient-deficient environment. These endospores are pre-loaded into the anode of the device and begin germination and electricity generation once nutrients become available. Dropping bodily fluids onto the device's inlet introduces these nutrients to the endospores and activates the biobattery. The design consists of several individual MFC units that can be easily connected through a simple folding mechanism to achieve a higher output power.
Since they are low-cost, fast-acting, and disposable, paper-based MFCs have shown potential for applications in powering a variety of low-power, POC diagnostic tools, especially in resource-limited environments that lack dependable access to other forms of power. Conventional MFC operation often requires exoelectrogen-containing or nutrient-rich water from the environment to be applied to the MFC for activation, but access to such a water source may not always be available. Using bodily fluids to activate the device allows for it to be readily used even in dry climates without access to nutrient-rich environmental water. Since local bacteria may also be incapable of generating electricity, some previous MFC devices have included pre-inoculated, lyophilized exoelectrogens, but lyophilized bacteria have been shown to suffer from significant performance decline over time during storage. Using dehydrated *B. subtilis* endospores instead extends the durability and shelf-life of the MFC, while still allowing for rapid, on-demand electricity generation once activated.

11:15 AM *SB01.03.04
Soft Reconfigurable Electronics Through Tunable Percolation Networks Carmel Majidi; Carnegie Mellon University, United States

Nervous tissue has the extraordinary ability to reconfigure the synaptic connections between its neurons and form new neural pathways. This mechanism of neuroplasticity allows for dynamic adaptations in reponse to learning or to repair tissue damaged by injury. Achieving this reconfigurability in engineered systems could allow future machines and electronics to be more adaptive, sustainable, and robust to damage. Such capabilities will be especially critical in emerging fields like soft robotics and stretchable electronics, which are designed to match the versatility and rich multifunctionality of soft natural organisms and tissue. In this talk, I will highlight progress in creating bioinspired circuits that are soft, stretchable, and electrically reconfigurable. This includes recent work on electrically conductive hydrogel composites in which a soft hydrogel is embedded with percolating networks of silver flakes that reversibly reconfigure under hydration, heat, and electrical stimulation. I will also present our ongoing work on creating self-reconfigurable soft circuits using liquid metal (LM). Eutectic gallium indium (EGaIn) is selected as the LM alloy due to its enabling combination of high electrical conductivity and fluidic deformability. When embedded in soft elastomer, microscale droplets of EGaIn can be selectively connected to form electrically conductive pathways that reconfigure in response to mechanical loading and damage. To demonstrate their potential role in future soft material technologies, I will present examples of how these Ag-hydrogel and LM-elastomer composites can be used for sensing, power transmission, and actuation in soft robotics and stretchable electronics applications.

Tough Hydrogel Coatings via Diffusion-Mediated Redox Polymerization Elizabeth Cosgriff-Hernandez and Megan Wancura; The University of Texas at Austin, United States

Our lab has developed hydrogel coatings for electrospun vascular grafts that resist platelet adhesion and promote endothelial cell adhesion for acute and sustained thromboresistance.[1] To improve homogeneity of the coating, we developed a diffusion-mediated redox polymerization method to generate conformal hydrogel coatings with improved thickness control.[2] Reduced thickness of the hydrogel coating resulted in reduced damage due to forceps gripping; however, these coatings still displayed damage due to twisting and torqueing associated with implantation that exposed the underlying thrombogenic substrate.[3] In this study, we developed a new hydrogel chemistry based on interpenetrating networks of polyether urethane diacrylamide

(PEUDAm) and poly(*N*-acryloyl glycinamide) (pNAGA) with improved damage resistance. Investigation of the redox hydrogel coating methodology was then used to identify parameters that enabled fabrication of hydrogel-mesh vascular grafts with requisite laminate strength.
First, the reducing agent, iron gluconate (IG), was adsorbed onto the electrospun mesh substrate, then the coated substrate was immersed in an aqueous macromer solution with the initiator, ammonium persulfate (APS). IG diffusion from the mesh substrate into the APS solution results in the formation of persulfate radicals and crosslinking of the PEUDAm hydrogel. The hydrogel coating thickness was controlled with incubation time. The effect of solution viscosity and rate of crosslinking on hydrogel coating laminate strength was studied by systematically tuning molecular weight and APS concentration to identify parameters for suitable coating application. A second network was introduced by swelling in NAGA and photopolymerization with the total hydrogel coating thickness set by the first PEUDAm hydrogel coating.

Our studies identified key parameters necessary to apply these coatings using redox diffusion-mediated crosslinking with improved control of hydrogel thickness. Reducing initiator concentration was necessary to slow cure rate to promote better penetration of higher molecular weight macromers and prevent swelling-mediated delamination; however, reduction of initiator concentration also required additional consideration of gelation time to achieve sufficient crosslink density. The resulting hydrogel coatings were resistant to damage from suturing and torqueing of coatings under 180° twisting with hemostat gripping. We hypothesized that the increased molecular weight between crosslinking points facilitated greater elongations and the additional hydrogen bonding motifs dissipated fracture energy to increase the resistance to hydrogel coating damage with handling. These results demonstrate the improved damage resistance of PEUDAm-NAGA hydrogels and the potential of this hydrogel design for coating vascular grafts.

Establishing Rules for How N- and O- Glycans Modify Interfacial Phenomena at Biological Surfaces Anjolaoluwa L. Bamtefa, Elbethel L. Damtae and Preethi Chandran; Howard University, United States

The surfaces of host cells and pathogens are covered with short polymers of sugars known as glycans attached to the proteins and lipids in the biological membranes. There are two predominant types of glycans - N and O glycans. N-glycans have a highly conserved structure, constitute greater than 50% of the glycosylation type in secreted proteins. O-glycans have a more varied structure and are present in the mucins of host cells. Among the five sugars typically present in N- and O- glycans, four are common to both. The goal is to determine if there are clear rules for how the interfacial phenomena on biotic and abiotic surface varies with the sugar composition of the glycans present, particularly their terminal sugar profile. Terminal sugars on N- and O-glycans were systematically removed and the changes in aggregation and adhesion patterns were monitored. Rules of adhesion and aggregation between different combinations of terminal glycan sugars were verified in multiple systems. Mannore sugars consistently showed short-range 'Velcro-like' adhesions with other mannose sugars, whereas SA residues showed long-range 'slime-like' adhesions with other terminal SA sugars in the presence of salt. The adhesion patterns were not sensitive to the structure of sugar presentation - they existed irrespective of whether the sugars were present in abiotic monolayers or in N-glycans or in O-glycans. In addition to these sugar-sugar self-adhesions, cross-adhesions were observed only between specific pairs of sugars. N-glycans abound on the surfaces of viruses such as HIV, Ebola, Dengue, SARs, and Influenza. O- glycans abound on mucins present in the mucus gel within respiratory, gastric, and vaginal cavities. Rules for which sugars on these glycans will self- and cross-adhere would enable predicting when pathegens will self-aggregate, when mucins will adhere to pathogens, how glycosylated abiotic surfaces will behave in host environment, and how changes in glycosylation that occur with age, race, and chronic conditions will alter the interfacial phenomena on biotic and abiotic surfaces.

11:30 AM SB02.01 .03
Polyanion Induced Phase Separation of Resilin-Based Intrinsically Disordered Proteins—Applications in Microstructured Hydrogels Cristobal Garcia and Kristi Kiick; University of Delaware, United States

Resilin-like polypeptides (RLPs) are intrinsically disordered proteins (IDPs) that may undergo liquid-liquid phase separation (LLPS). This IDP property is involved in the control of the formation and dissolution of membraneless organelles inside cells through interactions between the IDP amino acids or interactions with polyanions such as RNA. Polyphosphate is a polyanion that is capable of promoting the LLPS of resilin-based IDPs, emulating the behavior observed between other IDPs and RNA in living cells. By regulating the concentration and localization of polyphosphate deposited over acrylamide functional RLP solutions, transition temperature gradients are generated, allowing the creation of different types and sizes of microstructures upon crosslinking of the resulting emulsions. These studies help us to take advantage of a phenomenon naturally occurring in cells and utilize it for making RLP-based hydrogels with controlled microstructures with potential applications in fields such as tissue engineering and drug delivery.

11:45 AM SB02.01 .04
Additive Manufacturing of Shape-Changing Engineered Living Materials Laura K. Rivera Tarazona[1], Tarjani Shukla[2], Kanwar A. Singh[1], Akhilesh Gaharwar[1], Zachary T. Campbell[2] and Taylor H. Ware[1,1]; [1]Texas A&M University, United States; [2]The University of Texas at Dallas, United States

Shape transformation in response to changes in environmental conditions is a prevalent function observed in living systems, from the blooming of flowers to muscle actuation. Current shape-changing synthetic materials that mimic this behavior typically respond to non-specific stimuli such as pH, light, or temperature. Nevertheless, these stimuli are not specific to the material and may affect various components of the surrounding environment. New materials are needed that respond mechanically in a programmed manner by detecting specific biochemical cues. In this work, we develop 3D-printable engineered living materials (ELMs) capable of responding to very specific and pre-determined biochemical stimuli. We synthesize shape-changing ELMs from living probiotics embedded in cellulose nanocrystal (CNC)/polyacrylamide hydrogels. The effects of CNC at concentrations between 5-14 wt% and 11-22 wt% were studied to evaluate ELM volume expansion in active (with yeast) and passive (cell-free) composites respectively. Using direct ink write printing, we spatially patterned cellular proliferation within a monolith to induce complex shape transformations. By encapsulating genetically engineered probiotics (*Saccharomyces boulardii*) that proliferate only in the presence of specific biochemical cues, ELM capsules were designed that deliver a model drug. To create these drug delivery devices, structures composed of cell-free and yeast-embedding materials were printed to obtain hollow capsules containing a hydrophobic model drug. In this device, the ELM portion, containing an engineered *S. boulardii* strain, only changes in volume in the presence of a particular amino acid, which leads to expansion of one portion of the capsule. This expansion ruptures the device and releases 11 % ± 3 % of the total model drug to the surrounding environment within 48 h of growth. The use of genetically modified probiotics enables devices that respond to subtle biological cues found in the surrounding environment. Our study may enable new opportunities to develop drug-delivery devices for the diagnosis and treatment of gastrointestinal disorders.

SESSION SB02.02: 3D Printing and Hydrogel Characterization
Session Chair: Orlin Velev
Tuesday Afternoon, November 30, 2021
Sheraton, 2nd Floor, Republic A

1:30 PM *SB02.02.01
Design of 3D Printable Homocomposite Hydrogels with Synergistically Reinforced Molecular-Colloidal Networks Orlin D. Velev; North Carolina State University, United States

We report the design and properties of a new class of self-reinforced homocomposite hydrogels (HHGs) comprised of interpenetrating networks of multiscale hierarchy. They are made possible by the introduction of novel soft matter called soft dendritic colloids ("dendricolloids"). The dendricolloids are fabricated by a process of the eddy-guided polymer precipitation in turbulently sheared liquid medium. They have hierarchical morphology similar to molecular-scale polymer dendrimers, but two orders of magnitude larger in scale [Nature Mater. 18:1315, 2019]. The branched dendricolloids have very large excluded volume, and are surrounded by a corona of polymer nanofibers, which are highly adhesive due to van der Waals forces. Dendricolloids made of alginate can serve as reinforcement networks of molecular alginate, forming jointly homocomposite hydrogels [Nature Comm. 12:2834, 2021]. The reinforcement of the molecular gel with the nanofibrillar colloidal network of the same biopolymer results in a remarkable increase in the mechanical properties of the homocomposite hydrogels. The HHG's show >3× larger storage modulus and >4× larger Young's modulus than either constitutive network at the same concentration. The synergistically reinforced colloidal-molecular HHGs open numerous opportunities for formulation of biocompatible gels with robust structure-property relationships. They can be used in 3D printing with Homocomposite Thixotropic Paste (HTP), a method that was originally developed in our group for 3D printing with ultrasoft silicone HTP [Adv. Mater. 29:1701554, 2017]. The homocomposite hydrogels enable the making of thixotropic pastes for precise and efficient 3D printing via extrusion. We will demonstrate how the ratio of the HHG precursors facilitates precise control of the yield stress and timed rate of self-reinforcement. The resulting hydrogel architectures have excellent mechanical properties and potential for broad range of biomedical and soft robotics applications.

2:00 PM SB02.02.03
Design Polyrotaxane-Based 3D Printing Hydrogels for Direct Ink Writing Chenfeng Ke; Dartmouth College, United States

Natural materials are programmed hierarchically to form homo- and heterogeneous three-dimensional (3D) architectures, yielding intelligent systems that can complete complex tasks. Designing artificial materials that mimic and even improve upon natural systems requires the precise spatiotemporal control of molecular entities' chemical structures, assemblies, homo- and heterogeneous placements, and macroscale 3D architectures. My research aims to develop next-generation responsive polymers by integrating cyclodextrin (CD)-based polypseudorotaxanes with the direct ink writing technique. The understanding and control of the molecular-to-macroscopic hierarchical assembly within in a pre-designed 3D geometry enables the fabrication of responsive polyrotaxanes to complete complex tasks.
In this presentation, I will introduce our development of a CD-based sidechain polypseudorotaxane system and the synthesis of 3D-printable hydrogels with spatiotemporally programmable shape morphing and dynamic mechanical properties. We demonstrated a *de novo* molecular design to synthesize sidechain polypseudorotaxanes with tunable nano-to-macroscale properties for multi-material 3D printing. These sidechain polypseudorotaxanes were formed by copolymers with PEG sidechains and α-CDs. When α-CDs fully covered the PEG sidechains, the rod-like polypseudorotaxane sidechains acted like rigid collagen helices at the nanoscale to aggregate in water, forming crystalline bundles at the mesoscale. We revealed that longer copolymer chains formed disordered polypseudorotaxane crystalline aggregates through systematic variations of the copolymer chain lengths, which exhibited physically crosslinked 3D networks with good 3D printability. Shorter copolymer chains favored ordered lamella crystalline aggregates. Upon α-CD threading and dethreading, copolymers with varied PEG grafting densities showed different stiffness. When these sidechain polypseudorotaxane networks were covalently crosslinked, they were transformed into α-CD-responsive mechanically adaptive hydrogels, featuring more than 100 times elastic moduli change and multi-stage shape persistence. By incorporating a slide-ring crosslinker in the hydrogel, we achieved large tensile strain and significant elastic-to-plastic property variation upon α-CD (de)threading. These discoveries enabled us to integrate two α-CD-responsive hydrogels through multi-material 3D printing and fabricate a sea cucumber mimic possessing multi-stage stiffness change and shape morphing. Our demonstration of designing a macroscale multi-responsive system directly from simple molecular entities showcased an integrated nano-to-macroscale design.

Late News: 3D Printing of Living Microbial Fuel Cell Anode Megan Freyman, Tianyi Kou, Shanwen Wang and Yat Li; University of California, Santa Cruz, United States

3D printing helps to provide further control on electrode design. By using 3D printing to tune the geometry, porosity and dimensions of the structure mass transport to functional microbes or sites in the structure can be improved. By embedding living microbes directly into the ink, we can create 3D printed structures to help harness the activity of microbes and use them in functional devices. Here we demonstrate the incorporation of the living bacteria *Shewanella Oneidensis* MR-1 (*S. Oneidensis* MR-1) directly into an ink used for creating 3D printed structures. *S. Oneidensis* MR-1 has been commonly used in microbial fuel cells (MFC). By incorporating *S. Oneidensis* MR-1 into a sodium alginate-cellulose ink we showed that *S. Oneidensis* MR-1 survives the 3D printing process through the prominent degradation of methyl orange azo dye from the surrounding solution in the presence of the living 3D printed structure. The viability was further confirmed using confocal microscopy. By incorporating carbon black into this ink we further demonstrate the direct printing of a living MFC anode. Electrochemical measurements showed there was good charge transfer between the *S. Oneidensis* MR-1 and the electrode surface. To our knowledge, this is the first report on implementing 3D printed bacteria structure as a living electrode for an MFC system. The capability of printing living and functional 3D bacterial structure could open up new possibilities in design and fabrication of microbial devices as well as fundamental research on the interaction between different bacterial strains, electrode materials, and surrounding environments.

Microgel Building Blocks Control Granular Hydrogel Mechanics Börte Emiroglu, Andrew J. deMello and Mark W. Tibbitt; ETH Zurich, Switzerland

Traditional polymeric hydrogels are often static in nature with nanoscale pores, which can limit cell infiltration, spreading, and extracellular matrix deposition. Granular hydrogels overcome these limitations, due to their macroporous structure [1]. Composed of micro-scale building blocks (microgels), granular hydrogels can undergo a glass transition into a jammed state, giving rise to macroscale elasticity. The resulting voids between microgels form a

three-dimensional interconnected network of pores. Recent studies have exploited granular hydrogels to meet the complex demands of cell culture [2] and regenerative medicine [3,4]. Despite the wide interest in granular hydrogels, the mechanism by which the properties of the building blocks control the rheological behavior of these systems remains largely unexplored and is essential to ensure robust translation.

In this work, we relate the emergence of granular hydrogel mechanics to building block properties and provide in depth understanding of the dynamic rheology of soft and jammed granular systems. Thiol–ene based microgels were formed leveraging microfluidic templating for precise synthesis of the building blocks. The microgels were then jammed to produce macroscopic materials that behave like an elastic solid at low strain, but also exhibit shear-thinning and self-healing properties. Oscillatory shear rheometry showed that the mechanical properties of granular hydrogels can be tuned over several orders of magnitude through the control of microgel stiffness and size. To unveil the emergence of the macroscale behavior of granular hydrogels, we computationally generated jammed hard sphere packings and simulated the three-dimensional soft microgel scaffolds. We leveraged contact mechanics principles to establish predictive descriptions of the mechanical response. The model revealed that the extent of contact deformation is proportional to the size and inversely proportional to the stiffness of the microgels, which dictates the linear viscoelastic plateau moduli and zero shear viscosity [5]. With our predictions of the contact landscape of the building blocks, we further explained the differences in the non-linear rheology of granular hydrogels. The results expand our ability to tailor the material properties of granular hydrogels toward a range of biomedical applications and enable advanced engineering of granular hydrogels of complex architecture.

We are translating our study on the relationship between building block properties and the macroscopic response into rational design of granular hydrogels for the development of in vitro models and the engineering of regenerative biomaterials. We present additional results on the effects of controlled microgel environments that enable cell spreading, proliferation, and differentiation.

Multiphysics Modeling of Ionically Conductive Hydrogels Nikola Bosnjak, Max Tapermeister, Hongyi Cai and Meredith N. Silberstein; Cornell University, United States

Recently there has been an increase in demand for soft and biocompatible electronic devices capable of withstanding large stretch. Conductive hydrogels present a promising class of soft materials for the emerging applications due to their ability to realize charge transport across wet and swollen polymer networks, while preserving the desired mechanical and chemical features. As opposed to electron transfer in traditional electrical conductors, the charge transport across a polymer swollen with an electrolyte solution is achieved through ion migration – such materials are therefore known as ionotronic. The applications of ionically conductive hydrogels are vast, from healthcare and soft robotics to sensors. Moreover, the ability to successfully predict ion migration in soft and wet materials opens the door for implementation of biocompatible hydrogels as an interface between living tissue and external devices.

Hydration level and water diffusion through the polymer network have a significant impact on both the conductive and mechanical behavior of hydrogels. In addition to water molecules and mobile ionic species, fixed charge groups might be tethered onto the polymeric backbone. As a consequence of variation in pH, the ions might interact with the fixed groups through association/dissociation chemical reactions, thus changing the overall electrolyte strength. This significant environmental responsiveness of hydrogels identifies them as active materials with highly tunable properties, and therefore front-runners for implementation in soft electric circuits and devices.

Ionotronic materials and systems are characterized primarily through DC measurements, electrochemical impedance spectroscopy (EIS), and thermo-mechanical testing. EIS consists of applying a time-varying voltage across the material while measuring the corresponding current, and provides insights into the underlying electrochemical mechanisms driving the ion transport. Despite the rapid increase in the number of potential applications and experimental procedures, there is a lack of overarching design tools, hindering the further advance of ionotronic technology. The main challenge in developing reliable simulation capabilities is the complex and coupled electro-chemo-mechanical behavior of ionically conductive hydrogels.

In this work, we propose a multiphysics framework involving the coupled effects of ion transport, electric fields, network hydration, and large deformation. In addition, the developed constitutive model takes into account the difference in conductivity at various hydration levels, along with association/dissociation chemical reactions triggered by pH variations. The model also provides capabilities for computing current generated by the time-varying voltage, and prediction of EIS results based on material microstructure and environmental conditions. We numerically solve this multiphysics system by employing the finite element method. Such an approach will enable quantitative evaluation of material design and ionotronic devices. The accuracy of the developed model and numerical method is ensured through validation against the EIS data. The usefulness of the developed multiphysics model is showcased by simulating the representative ion transport problems and the operation of a soft ionotronic device.

Gel Spiderweb Robots Younghoon Lee, Won Jun Song and Jeong-Yun Sun; Seoul National University, Korea (the Republic of)

Spiders possess fascinating multi-feats with spiderweb for maximizing adhesion force. Here, we explore an approach to behavioral characteristics of *cyclosa japonicas* inspired ionic spider webs (ISWs), which is capturable, self-powered sensible and vibrationally dust-cleanable, all of which the principles are solely based on electrostaticity in a single platform [1]. It was made with ionically conducting organogels capsulated with dielectric elastomers as a strand shape. Its thinness and transmittance led ISWs could be camouflageable. Plasma etching and (heptadecafluoro-1,1,2,2-tetrahydrodecyl)trichlorosilane treatment on dielectric elastomer readily boosted cleanability and it even prevented the evaporation of organogel, which led increase of durability of ionic spider web. Its high stretchability and translucency led it endure applied strain upto 50 % to capture targets larger than ISWs, which cannot be realized by rigid one, and realized it can be camouflageable, respectively. The ISW robustly captured a wide range of materials including a leaf, acryl, glass, and aluminum of which weight is 50 times heavier than its own weight. The capturability was ensured with its additional feats including electrostatic sensing ability and resonance cleanability.

Micellar Hybrid Nitric Oxide-Scavenging and Sequential Drug-Releasing Hydrogel for Combinatorial Treatment of Rheumatoid Arthritis Taejeong Kim and Won Jong Kim; Pohang University of Science and Technology, Korea (the Republic of)

Selective depletion of overproduced nitric oxide (NO) with nanoscavengers is a promising approach for treating rheumatoid arthritis (RA), preventing both oxidative/nitrosative stress and the upregulation of immune cells. However, its practical applications are limited owing to the minimum time interval between intra-articular injections and unwanted off-target NO depletion. At an appropriate level, NO plays a crucial role in modulating various biological functions. To address this issue, we herein report the rational design of an injectable in situ micellar hybrid NO-scavenging and sequential drug-releasing (M-NO) gel platform for the combinatorial treatment of RA by incorporating a “clickable” NO-cleavable cross-linker (DA-NOCCL). This network is held together with micellar structures to achieve a self-healing capability for visco-supplementation and on-demand dual drug (both hydrophilic and hydrophobic)-releasing properties, depending on the NO concentration. Moreover, consecutive NO-scavenging action reduces pro-inflammatory cytokine levels in LPS-stimulated macrophage cell lines in vitro. Finally, the intra-articularly injected M-NO gel with anti-inflammatory dexamethasone significantly alleviated the symptoms of RA, with negligible toxicity, in animal models.
This proposed concept and the platform with favorable results showed promising application potential for the combinatorial treatment of various NO-related diseases, delivering various hydrophobic and hydrophilic drugs in a single platform with a consecutive NO-scavenging action.

Late News: Enhanced Strength and Shape Memory in Microgel Filled Biopolymer Networks Vignesh Subramaniam and Thomas E. Angelini; University of Florida, United States

Biopolymer networks comprise an essential and substantial proportion of 3D bioprinting materials because of their abundance and role in living tissues. While biopolymers serve to strengthen tissues in vivo, biopolymer networks in vitro are notoriously soft and weak; bioprinted structures made from biopolymer networks exhibit the same limitations. To stiffen and strengthen printable in vitro biopolymer networks, we developed a biomaterial made from collagen-1 in which the polymer mesh-space is filled with micron-scale microgel particles made from polyethylene glycol (PEG). We find that this combination of material components synergistically enhances the system material properties. For example, by filling in the mesh space of the polymer networks with low volume fraction microgels, the elastic modulus can increase by more than an order of magnitude. By packing the microgels into the polymer network at volume fractions approaching jamming, the material takes on a shape-memory property, where the material will spontaneously lock-in deformations at intermediate strain levels; reversal of these strains requires a stress-reversal and results in the material resulting to its original deformation state. This new class of materials opens up wide possibilities in its capacity as a 3D bioprinting material and has potential applications in fabrication of model tissues.

4:30 PM SB02.02.10
Stretchable Anti-Fogging Tapes for Diverse Transparent Materials Shaoting Lin, Yueying Yang, Jiahua Ni, Xuanhe Zhao and Gang Chen; Massachusetts Institute of Technology, United States

Surface wetting prevents surface fogging on transparent materials by facilitating filmwise condensation with specific chemistry but suffers from material and geometry selectivity. Extreme environments associated with high humidity and mechanical loading further limit their anti-fogging persistence. Here, we report a stretchable anti-fogging tape (SAT) that can be applied to diverse transparent materials with varied curvatures for persistent fogging prevention. The SAT consists of three synergistically combined transparent layers: i) a stretchable and tough layer with large elastic recovery, ii) an endurant anti-fogging layer insensitive to ambient humidity, and iii) a robustly and reversibly adhesive layer. The SAT maintains high total transmittance (>90%) and low diffuse transmittance (<5%) in high-humidity environments, under various modes of mechanical deformations, and over a prolonged lifetime (193 days tested so far). Two applications are demonstrated, including the SAT-adhered eyeglasses and goggles for clear fog-free vision, and the SAT-adhered condensation cover for efficient solar-powered freshwater production.

4:45 PM SB02.02.11
Fracture and Fatigue of Ideal Polymer Networks Shaoting Lin, Jiahua Ni, Dongchang Zheng and Xuanhe Zhao; Massachusetts Institute of Technology, United States

Soft materials have enabled diverse modern technologies, but their practical deployment is usually limited by their mechanical failures. Fracture and fatigue of polymer networks are two important causes of mechanical failures of soft materials. A soft material fails by fracture when a monotonic load reaches its *fracture toughness* or fails by fatigue when a cyclic load reaches its *fatigue threshold*. Fracture toughness is usually much larger than fatigue threshold for randomly crosslinked polymer networks (e.g., elastomers and gels). This work systematically studies the fracture and fatigue of ideal polymer networks with controlled densities of dangling-chain defects. We show that the fracture toughness and fatigue threshold of an ideal polymer network almost without defects are the same. After introducing a low density of dangling-chain defects into the ideal polymer network, its fracture toughness and fatigue threshold still maintain approximately the same. The fracture toughness of the ideal polymer network is also independent of the loading rate. We further use the recently developed defect network model to explain the fatigue threshold (*i.e.*, intrinsic fracture energy) of ideal polymer networks with controlled densities of dangling-chain defects.

Thermosensitive Hydrogel-Based Desalination System Driven by Diurnal Temperature Variation Hoyeon Kim and Jonghwi Lee; Chung-Ang University, Korea (the Republic of)

Solar desalination system has been considered as an effective method to address the global water scarcity, which thanks to its eco-friendliness and sustainability. However, the heat loss of evaporation surface to water reservoir, fouling due to the formation of salt crystals on evaporation surfaces and

water channels, and the difficulty of continuous brine supply without external power are the major obstacles in the practical use of the solar desalination. Herein, through the separation of water pumping and evaporation part, a novel solar desalination system showed no heat loss during evaporation and had an antifouling property. Moreover, using thermosensitive hydrogel composites, a solar desalination system could work by diurnal temperature variation. An irreversible water flow was achieved by using composites of thermosensitive poly(N-isopropylacrylamide) (PNIPAm) hydrogel and hydrophobic polydimethylsiloxane (PDMS), which have fast deswelling kinetics responsive to temperature above 32 °C (LCST). The composites were made by directional melt crystallization (DMC) of solvent. By the DMC method, a porous PNIPAm having aligned and continuous three-dimensional pores was prepared. The structure enables a combination of two different materials. It can be achieved by the infiltration of PDMS to the aligned pores of PNIPAm. Anisotropic composites have PNIPAm/PDMS phase at the bottom of the composites, which has a faster deswelling rate than pure PNIPAm phase. As temperature rises above the LCST of PNIPAm, water can be released from the top surface of the PNIPAm, and this water pumping could be repeated by the diurnal temperature variance. Average pump efficiency of our composites is 88%. Between the pumping composite and the water reservoir, porous polyethylene glycol (PEG) was placed for the water channel. PEG can absorb brine from the water reservoir and diffuse brine into the entire phases of PNIPAm/PDMS composite. Water from the pumped brine evaporates on the surface of reduced graphene oxide (rGO) coated cellulose paper, which showed broad range of light wavelength. When brine is released, the rGO coated cellulose paper float, and salt accumulation is formed at the bottom of the paper. This crystallized salt is dissolved in the next pumped water. Our three-dimensional solar desalination system was operated stably in several cyclic tests in one-sun condition. Diurnal operating strategy makes the solar evaporator eco-friendly, and the antifouling properties increase the sustainability of solar desalination.

SB02.03.02
Injectable and Conductive Alginate and Poly (3,4-Ethylenedioxythiophene) (PEDOT) Based Soft Electrodes for Neural Regenerative Applications Ivana Perkucin, Tianhao Chen, Kylie Lau, Cindi M. Morshead and Hani E. Naguib; University of Toronto, Canada

Electroconductive biocompatible polymers have been of interest for use in a wide range of biomedical applications such as biosensors, regenerative therapeutics and protheses. This surge of curiosity has sparked the development of soft functional materials to meet these demands. In the field of neural regenerative medicine, we have demonstrated that resident brain neural precursor cells are electrosensitive cells that respond to electric field application by proliferating, differentiating and migrating in a rapid and directed fashion. Harnessing these properties can potentially be used to facilitate neural regeneration following injury or disease. The design of current electrodes, typically made of conductive metals, are stiff and result in additional tissue injury as a result of implantation. The mechanical mismatch of these materials to the soft and wet physiological conditions that they would be subjected to in their use in the brain, presents significant limitations of this technology as a potential therapeutic. Recently, there has been interest in using biologically derived polymers for their relative abundance and consequently, economic feasibility. Sodium alginate is an attractive example of such and can be used to form hydrogels whose soft and flexible nature as well as functionality in aqueous environments presents a potential solution to this issue of mechanical mismatch. We have fabricated a novel conductive and biocompatible hydrogel that more closely mimics the modulus of the brain as a solution to this problem. By designing a hydrogel based system comprised of alginate and conductive polymer, poly(3,4-ethylenedioxythiophene (PEDOT), we propose an innovative new material for use in the development of novel neural regenerative therapeutics. These alginate/PEDOT blends exhibit sheer thinning behaviour at both ambient and body temperatures as well as exhibit satisfactory conductivity for their intended therapeutic application.

SB02.03.04
Heterotypic Supramolecular Hydrogels Formed by Noncovalent Interactions in Inflammasomes Adrianna Shy, Huaimin Wang, Zhaoqianqi Feng and Bing Xu; Brandeis University, United States

Inspired by the work of Stupp and colleagues on the supramolecular exchange of oppositely charged molecules, we used two complementary peptides derived from ASCPYD inflammasomes. The addition of the positive and negatively charged complements in water produced heterotypic hydrogels dependent on ratio and the use of N-terminal acetyl or naphthalene capping groups. We found that mixing one naphthalene capped positively charged peptide at 0.5wt% with an acetyl capped negatively charged complement created hydrogels across all ratios of 0.5, 1, 2, 3, and 4 times the amount of positively charged peptide. The addition of the peptides of the oppositely charged peptides in solution produces heterotypic hydrogels. Rheology measurement shows that ratios of the complementary peptides affect the viscoelasticity of the resulted hydrogel. Circular dichroism indicates that the addition of the complementary peptides results in electrostatic interactions that modulate self-assembly. Lastly, transmission electron microscopy reveals that the ratio of the complementary peptides controls the morphology of the heterotypic peptide assemblies. This work illustrates a rational, biomimetic approach that uses the structural information from the protein data base (PDB) for developing heterotypic peptide materials via self-assembly.

SB02.03.05
Leveraging LCST Behavior in Thermoresponsive Polymers to Enable Reliable Cooling-Triggered Reactions Romario Lobban and Leon Bellan; Vanderbilt University, United States

Much work has been done on the use of heating to trigger reactions via the temperature-dependent removal of a barrier or constraint separating reagents. An example of this method is the use of wax microbeads to encapsulate reagents which are only liberated to react with each other when the wax is melted by heating. Far less work, however, has been done on the use of cooling to achieve a similar goal. Numerous applications, such as those involving components or materials susceptible to persistent low temperatures and cases in which energy for heating is not available would benefit from this inverse approach. Hence, in this study we explore whether LCST polymers can be reliably used as thermoresponsive constraints that allow reagents to react only upon cooling. We aim to achieve this by loading reagents into separate adjacent blocks of thermoresponsive polymer gels- in this case, 400 cP methylcellulose- and showing that said reagents can only react with each other after the temperature of the polymer falls below its LCST. Additionally, to demonstrate generalizability and the innate robustness of the concept, we explore situations involving radically different reaction types: one reaction based on a colorimetric enzyme assay (using a colorless HRP solution to oxidize a colorless TMB substrate, resulting in a soluble blue reaction product), and another based on a change in pH (using basic colorless NaOH solution to change colorless slightly acidic phenolphthalein solution from colorless to pink). Finally, to explore the tunability of the process, we alter the LCST of the polymer and observe the resulting change in the extent of cooling necessary to allow a chemical reaction to occur. This change in LCST is achieved by adding different quantities of NaCl to methylcellulose and is corroborated by rheology.

At elevated temperatures (above the LCST), the reagents remain sequestered in separate gels and no reaction occurs. We have demonstrated that this “OFF” state is stable for extended periods of time. When the system is allowed to cool, the gels liquify and flow into each other, allowing mixing of the embedded reagents (“ON” state). By quantitatively assessing the progress of the stated color change reactions over time, we determine that these reactions are triggered reproducibly at different temperatures based on the polymer’s tuned LCST (determined by the NaCl content of the methylcellulose), as well as the proximity of the reagent-laden gels and viscosity of the liquified materials after cooling. With no NaCl present, reactions are triggered 18 minutes (the time required for the gels to liquify and flow into each other) after cooling below 50 degrees Celsius. With 1.5% and 2% NaCl, reactions are triggered 18 minutes after cooling below 36 and 30 degrees Celsius, respectively. In all three cases, the same geometry is used (to maintain the same gel proximity) and the viscosity of liquified materials is similar. We therefore conclude that thermoresponsive polymers can, in fact, act as reliable temperature-sensitive

constraints that allow reagents to react only upon cooling. We successfully demonstrate that this method can be applied to a variety of reactions and that the temperature required for triggering a reaction can be predictably and reproducibly tuned.

SB02.03.06
High Elastic Modulus, Ion-Responsive Hydrogel with Controlled Response Abhishek Pachauri and Jeffrey Bates; University of Utah, United States

Hydrogels possess outstanding biocompatibility and swelling properties and thus find extensive applications in fields such as biomedical devices and soft robotics. Here, a high elastic modulus hydrogel with improved strength and toughness is synthesized. The hydrogel can be stretched many times its initial dimensions, where the material returns to its original shape in a reversible manner. Glucose solution is used as the chemical stimulus and the hydrogel swells several times its initial size when immersed in glucose solution and shrinks when it removed from the solution. This swelling and deswelling behavior of the hydrogel can be used to perform useful work. The swelling behavior of the hydrogel as a function of the amount of glucose in the solution is studied. Rheology of hydrogel material is investigated so that the material has desired properties for 3 D printing. Mechanical and viscoelastic properties of hydrogel before and after swelling are tested. The swelling kinetics are analyzed, so that swelling and deswelling behavior can be precisely controlled.

SESSION SB02.05: Biological Gels
Session Chairs: Alan Grodzinsky and Nir Kampf
Wednesday Morning, December 1, 2021
Sheraton, 2nd Floor, Republic A

10:30 AM *SB02.05.01
Hydration Lubrication by Polymer Assemblies and Hydrogel Composites Nir Kampf[1], Weifeng Lin[1], Monika Kluzek[1], Somasundaram A. Angayarkanni[2], Noa Iuster[1], Eyal Shimoni[1], Ronit Goldberg[3] and Jacob Klein[1]; [1]Weizmann Institute of Science, Israel; [2]SRM Institute of Science and Technology, India; [3]Liposphere Ltd., Israel

About 20% of the world's total energy consumption spent to overcome friction. Friction is also present in biological systems such as in hips and joints, and correlated with joint diseases such as osteoarthritis. Due to the molecular complexity of the biological systems, the mechanism of lubrication is still not clear. Apart from our efforts to find the major components responsible for the low friction in biological systems, we also try to exploit nature's solution for lubricating interfaces such as cartilage by mimicking nature's strategies of boundary lubrication, which lead to an extreme reduction of friction in aqueous environments. In my talk, I will present several examples of bio-inspired lubrication by polymers and in polymer networks. We carried out systematic investigations from the molecular to the macroscopic level, demonstrating excellent lubrication by polymer assemblies (1) and hydrogel composites (2), attributed to the hydration lubrication mechanism acting at highly-hydrated boundary layers.

11:00 AM *SB02.05.02
A Human Microphysiological System to Model Breakdown of Hydrogel-Like Cartilage Caused by Osteoarthritis Alan Grodzinsky; Massachusetts Institute of Technology, United States

Traumatic joint injuries can initiate early cartilage degeneration in the presence of elevated levels of inflammatory cytokines, leading to post-traumatic osteoarthritis (PTOA). There are currently no disease modifying drugs for osteoarthritis, and a major challenge is the ability to achieve sustained levels of potential therapeutics *inside* a target tissue, with no side effects, after intra-articular delivery. We have developed a human in vitro microphysiological system (MPS) for studies of drug discovery for OA/PTOA as well as drug delivery into cartilage. Human knee osteochondral plugs subjected to a single impact mechanical injury are co-cultured with joint capsule synovium. Cytokines secreted mainly from the synovium emulate the inflammatory component of the response to joint injury. Combination therapeutics (e.g., glucocorticoids, growth factors) are tested which can inhibit matrix degradation and cell death in cartilage. Experiments involving this human knee MPS were recently launched on SpaceX-21 to the International Space Station to study the effects of microgravity and radiation on disease-like progression and the effects of selected therapeutics. Parallel *in vitro* and animal studies are aimed at approaches to targeted tissue drug delivery. For these studies, electrostatic interactions involving cationic nanoparticles to which drugs are functionalized are found to augment transport into and through the cartilage tissue. Thus, the transport properties of the negatively charged gel-like extracellular matrix of cartilage, even during initial degradative stages of the disease model, can provide benefit to enhance drug delivery.

11:30 AM SB02.05.03
Towards Hydrogel-Capped Titanium Implants for Cartilage Repair Jiacheng Zhao, Feichen Yang, William Koshut, Alina Kirillova, Cambre Kelly and Heng Xu; Duke University, United States

There are approximately 900,000 people in the US suffering from damage to the articular cartilage, with the knee being most commonly affected. Articular cartilage lacks a vasculature and has a limited ability to heal. A variety of surgical treatments have been developed to repair cartilage lesions. Current strategies for cartilage repair include microfracture, autologous chondrocyte implantation (ACI) and osteochondral allograft transfer (OAT). These strategies suffer from high failure rates (25-50% at 10 years), long rehabilitation times (more than 12 months) and decreasing efficacy in patients older than 40-50 years. Focal joint resurfacing with traditional orthopedic materials is being explored as an alternative strategy, but due to their high stiffness and coefficient of friction relative to cartilage, these implants may ultimately contribute to joint degeneration through abnormal stress and wear. A focal joint resurfacing method that is widely available, allows immediate weight bearing, has short recovery times and has low long-term failure rates remains an unmet need.
Our strategy to address this need is to (1) develop a material that mimics the properties of cartilage and (2) attach this material to a titanium base to enable integration with bone. We developed the first hydrogel to achieve the strength and modulus of cartilage in both tension and compression. This hydrogel also exhibits cartilage-equivalent tensile fatigue at 100,000 cycles. The hydrogel was created by infiltrating a PVA-PAMPS double-network hydrogel into a bacterial cellulose (BC) nanofiber network. The BC provides tensile strength in a manner analogous to collagen in cartilage. The PAMPS provides a fixed negative charge and osmotic restoring force similar to the role of aggrecan in cartilage. The hydrogel is not toxic, has the same aggregate modulus and permeability as cartilage, has a coefficient of friction 45% lower than cartilage, and is 4.4 times more wear-resistance than a PVA hydrogel. These properties make the BC-PVA-PAMPS hydrogel an excellent candidate material for the replacement of damaged cartilage.
Current strategies for adhering hydrogel to a surface are 10 times weaker than the shear strength with which cartilage is attached to the bone. The

osteochondral junction is characterized by collagen nanofibers anchoring cartilage to bone. We sought to mimic this strategy by bonding freeze-dried BC to porous titanium with a hydroxyapatite-forming cement. The cement penetrates about 10 microns into the bacterial cellulose, forming a nanofiber-reinforced zone of adhesion. The PVA-PAMPS hydrogel is then infiltrated into the bonded bacterial cellulose. This strategy achieved a shear strength of attachment three times greater than the state of the art. Such improved strategies for attaching hydrogels to a titanium surface with sufficient strength to allow for weight-bearing can enable the creation of hydrogel-capped titanium implants for cartilage repair.

11:45 AM SB02.05.04
Chemistry of Metal-Organic Frameworks as Hydrogels and Silicone Patches in Wound Healing UnJin Ryu and Kyung Min Choi; Sookmyung Women's University, Korea (the Republic of)

Metal-organic frameworks, called MOFs, are crystalline porous materials constructed by repeating metal clusters and organic linkers thus having permanent porosity. The structure and characters of MOF libraries have been widely reported and some MOFs have been applied to the wound healing process by using the porosity to release drugs, gases, and metal ions promoting the wound healing process. However, our research focused on removing substances from living organisms, and these studies have not been reported before.
In the wound healing process, the important mediators that lead to inflammation and scar formation are nitric oxide, cytokines, and reactive oxygen species (ROS). However, the overproduction of these inflammatory agents causes abnormal inflammation and excessive scarring, so it is challenging to control adequate amounts of mediators to complete wound healing with barely scarred.
In this study, MOF was introduced to suppress the excess nitric oxide, cytokines, and ROS, that based on their MOF's own structure such as micropores, surface, and catalytic activities. we systemically devised and applied a MOF hybrid hydrogel (and silicone patch) that optimizes the wound healing performance by removing excess immune mediators with MOF as well as simultaneously supplying moisture and uniformly applying MOF by hydrogel matrix. After the removal of excess mediators was experimentally analyzed based on MOF chemistry, the wound healing process of MOF was analyzed through cell-derived substances, and finally applied the MOF to animal testing for a real actual wounded environment. It was confirmed that the wound recovered rapidly within 14 days after the introduction of MOF-hydrogel, which showed that the system incorporating MOF is effective in wound healing.

SESSION SB02.06: Gels and Applications

1:30 PM SB02.06.01
Strength and Toughness of Stochastic Networks: Dependence on Structural Parameters and Network Architecture Catalin R. Picu, Sai Deogekar and Shengguang Jin; Rensselaer Polytechnic Institute, United States

Network materials are encountered broadly in the engineering and natural worlds and gels are an important subset of this broad class. These materials have a molecular or fiber network as their main structural component and perform various functions of which the most prevalent is structural. The integrity of network materials is critical in many applications. Therefore, it is of interest to determine ways to control their strength and toughness. This work focuses on the relation between structural parameters of the network, the network architecture and its strength and toughness. We report the dependence of the strength on network density, crosslink density and strength, and fiber properties. We also investigate the toughness of networks without pre-existing defects and report its dependence on the same set of structural parameters. We observe and characterize the intermittent dynamics of rupture in networks and relate it to similar processes in other materials with stochastic structure. Network design rules emerge from these results. Numerical results are compared with equivalent experimental data.

Anomalous Collagen Fiber Reorientation in the Facet Capsule Ligament: Mechanism and Implications Jacob Merson, Mark Shephard and Catalin R. Picu; Rensselaer Polytechnic Institute, United States

Multiscale models are employed to study how the microscopic and tissue scale properties of the facet capsule ligament of the spine combine to cause anomalous collagen fiber realignment (AR). The facet capsule ligament, located between the spinal processes, is primarily made up from type I collagen. Fiber reorientation in the FCL has been linked to neck and back pain and it is therefore a critical phenomenon to understand. Anomalous realignment is experimentally observed in the FCL using quantitative polarized light imaging (QPLI). However, no experimental techniques are currently available to probe the root causes of anomalous realignment. This talk will discuss how the interplay of tissue scale collagen orientation, fiber scale instabilities, and fiber failure can cause anomalous realignment in the facet capsule ligament.

Developing a Platform to Evaluate Photoswitches and Their Mechanical Work Friedrich Stricker, Jesus G. Campos, Minwook Park, Kyle Clark and Javier Read de Alaniz; University of California, Santa Barbara, United States

Materials adapting their shape reversibly to external stimuli have gathered increasing attention for a range of applications in medicine and robotics. In particular, photoresponsive systems have shown promise through the facile and benign nature of the trigger. However, most photoresponsive molecules, which can be used to convert light into mechanical work, are susceptible to decomposition upon conditions commonly used in preparation of polymeric systems. In this work we present new light-responsive liquid crystalline network (LCN) systems using benign Diels–Alder chemistry and employ this novel platform to compare a range of different photoswitches from the well-established azobenzene scaffold to the novel Donor-Acceptor Stenhouse adducts.

Thermal Stabilisation of Biologics Using Reversible Dynamic Covalent Hydrogels Bruno Marco Dufort and Mark W. Tibbitt; ETH Zurich, Switzerland

Biologics—including peptides, therapeutic proteins, enzymes, monoclonal antibodies, vaccines, and viral vectors—comprise the majority of new drugs entering the market. However, biologics are highly susceptible to thermal fluctuations during storage and transport, as aggregation, denaturation, and oxidative degradation render them ineffective. In order to guarantee their quality and safety, biologics must be maintained within a tight temperature window (2–8 °C) from manufacture to point of use. This global 'cold chain' infrastructure cost over 17 billion USD in 2020 and poses significant health

risks as failures in the cold chain can lead to community health outbreaks, as in the case of ineffective vaccines. An emerging strategy to impart thermal stabilisation is to immobilize biologics directly within a protective matrix that can hold the molecules in place to resist conformational changes and prevent translation. One of the major challenges for these matrix-based approaches, however, is to achieve on-demand release of the biologics from the protective matrix.

To meet these challenges, we designed a safe and easy-to-use synthetic reversible hydrogel for the encapsulation and stabilisation of a broad range of biologics against thermal stress [1]. Our approach is based on the use of dynamic covalent boronic ester cross-links that enable on-demand recovery through network dissolution upon addition of sugars [2, 3]. Using these reversible hydrogels, we thermally stabilised a wide range of biologics, starting with model enzymes (β-galactosidase, leucine aminopeptidase, and alkaline phosphatase). We attributed protection to the formation of polymer networks around the biologics, which restricted their mobility and physically restrained them from interacting with each other, reducing aggregation and activity loss after exposure to heat. In addition, we showed that the gels could be used to protect extremely heat sensitive therapeutic enzymes, such as *E. coli* DNA gyrase and human topoisomerase I. Both enzymes could be stored within the gels for months at room temperature without significant activity loss, vastly outperforming the unencapsulated (free) enzymes.

Finally, we present our results on the thermal stabilisation of vaccines. We stabilised a protein-based vaccine, recombinant influenza A H5N1 hemagglutinin, and a live virus, adenovirus Type 5 (Ad5). Viral vectors, such as Ad5, are central to gene therapy and genome editing techniques (i.e., CRISPR-Cas9), and are becoming increasingly important for use in vaccine development (i.e., COVID-19 vaccines). Live viruses such as Ad5 present a particular challenge for thermal stabilisation because both protein conformation and nucleic acid integrity must be preserved to retain viral infectivity and immunogenicity; even simple drying of live viruses is often challenging. Gel-encapsulated Ad5 outperformed free Ad5 at all tested temperatures (4 °C to 65 °C) and retained close to 100 % activity after 4 weeks at 27 °C, while the infectivity of free Ad5 decreased by 3 logs. In total, our work demonstrates that reversible hydrogels are suitable for the thermal stabilisation of multiple classes of biologics, with little formulation work required to stabilise each type of biologic. The ability to protect biologics from thermal stress with a simple material solution offers a useful approach to mitigate the costs and risks associated with reliance on a continuous cold chain for biologic transport and storage.

Digitally Programmable Living Materials from Biowaste Suitu Wang, Laura K. Rivera Tarazona, Mustafa K. Abdelrahman and Taylor H. Ware; Texas A&M University, United States

Materials manufacturing strategies that use little energy, valorize waste, and result in degradable products are urgently needed. Strategies that transform abundant biomass into functional materials form one approach to new manufacturing, but the resulting products of the biomass are often dictated by the organisms. From a biology standpoint, morphogenesis of biological tissues is a “manufacturing” mode without energy-intensive processes, large carbon footprints, and toxic wastes. However, most living organisms cannot form materials that are suitable for engineering applications. Inspired by biological morphogenesis, we have proposed a manufacturing strategy by embedding living *Saccharomyces cerevisiae* (baker’s yeast) within a synthetic acrylic, such as poly(2-hydroxyethyl acrylate), hydrogel matrix. The resulting living composites derive functionality from both the biological activity and material properties. By culturing the living composites in media derived from bread waste, encapsulated yeast cells can proliferate resulting in a dramatic dry mass and volume increase of the whole living composite. After growth, the final composite is up to 96 wt% biomass and 590% larger in volume than the initial object. By spatial-patterning the cell viability through UV irradiation or photodynamic therapy, the living composites can also form complex user-defined relief surfaces or 3D objects during growth. The resulting living composites also have tunable mechanical properties by controlling the extent of the cell growth or the selection of polymer matrix. After growth and drying, the modulus of the composites can be tuned from 290 MPa to 856 MPa. Ultimately, the grown structures can be degraded into water-soluble polymers and yeast. The accelerated degradation of the living composites can be tuned by changing the molecular weight of polyester crosslinkers from 4 to 8 days. The proposed living composite strategy cultured from biowaste may pave the way for future ecologically friendly manufacturing of materials.

Design and Use of a Thermogelling Methylcellulose Nanoemulsion to Formulate Nanocrystalline Oral Dosage Forms Liang-Hsun Chen and Patrick Doyle; Massachusetts Institute of Technology, United States

Oral drug products have become indispensable in modern medicine because of their exceptional patient compliance. However, poor bioavailability of ubiquitous low-water-soluble active pharmaceutical ingredients (APIs) and lack of efficient oral drug formulations remain as significant challenges. Nanocrystalline formulations are an attractive route to increase API solubility, but typically require abrasive mechanical milling and several processing steps to create an oral dosage form. Using the dual amphiphilic and thermoresponsive properties of methylcellulose (MC), a new thermogelling nanoemulsion and a facile thermal dripping method are developed for efficient formulation of composite particles with the MC matrix embedded with precisely controlled API nanocrystals. Moreover, a fast and tunable release performance is achieved with the combination of a fast-eroding MC matrix and fast-dissolving API nanocrystals. Using the versatile thermal processing approach, the thermogelling nanoemulsion is easily formulated into a wide variety of dosage forms (nanoparticle suspension, drug tablet, and oral thin film) in a manner that avoids nanomilling. Overall, the proposed thermogelling nanoemulsion platform not only broadens the applications of thermoresponsive nanoemulsions but also shows great promise for more efficient formulation of oral drug products with high quality and tunable fast release.

Late News: Digital Lensless Holographic Traction Force Microscopy in Alginate Hydrogels Optimized for Additive Manufacturing Sebastian Ocampo Gutierrez, Brayan Patiño-Jurado, Carlos Paucar and Claudia Garcia; Universidad Nacional de Colombia, Colombia

The general knowledge of many cell-based processes comes from experimentation on flat surfaces, mainly in culture wells made of either a polymer or glass. These are 2D, stiff and non-physiological environments, which are simple for experimentation, yet do not replicate all the conditions a cell experiences in vivo.
In this work a methodology to develop an alginate hydrogel based material with calcium phosphate particles suspensions is presented. This material has the potential to act as a scaffold with a complex architecture processed via additive manufacturing, and is shown in the shape of a triply periodic minimal surface. Being a known biocompatible material, and formed in a shape suitable for cell culturing, a method to capture information from this scaffold is presented.

The formed hydrogel shows elastic properties suitable to implement traction force microscopy (TFM), a computational technique to compute force fields exerted on the substrate. This is achieved using digital lensless holographic microscopy, a holographic technique that vastly reduces costs, experimental setup and permits the analysis of transparent objects with sizes in the range of a few micrometers. The calcium phosphate particles in the hydrogel are used as fiducial markers to calculate displacement in TFM. This way, a complex, more physiological environment can be achieved, and the means to recover information such as traction forces are shown to work, facilitating acquisition to offer biological insight.

SESSION SB02.07: Hydrogel Characterization and Application

Surface Morphology Changes and Micromechanics in PNiPAAm Based Micro- and Nanogels Particles Fabio Domenici[1], Elisabetta Tortorella[1], Barbara Cerroni[1], Yosra Toumia[1], Letizia Oddo[1], Sharad Pasale[1], Ester Chiessi[1], Mark Telling[2], Sarah Rogers[2] and Gaio Paradossi[1]; [1]Università degli Studi di Roma Tor Vergata, Italy; [2]STFC ISIS Facility, United Kingdom

Gels thermal responsivity is usually associated to a Volume Phase Transition, VPT. However, different and equally relevant for biomedical applications, responsive behaviors to temperature can be found in micro- and nanogel particles.
In this contribution we report on the morphological changes around physiological temperature of hybrid nanogel particles made by crosslinking via click chemistry an azido-derivative of hyaluronic acid, HA, and a derivative of poly(N-isopropyl acrylamide), PNiPAm, having propargyl functions at both ends, with interesting fallouts concerning targeting and drug delivery. In *in vitro* tests, doxorubicin loaded nanoparticles with a PNiPAAm/HA ratio of 33 % (w/w) increased its cytotoxicity on HT-29 tumor cells over the NIH 3T3 healthy fibroblasts, by a factor of two.
In this HA/PNiPAAm nanogel, the hydrophobic – hydrophylic interplay of the two crosslinked polymer components gives rise to a reshuffling of the surface composition passing a quite narrow threshold around 33 °C, taken as the VPT temperature, VPTT, of the system. In this process, the room temperature surface structure is a collection of PNiPAAm and hyaluronate patches. Approaching the VPTT, the PNiPAAm hydrophobicity promotes the interparticle aggregation. Above the VPTT, the NiPAAm residues self-segregate in the particle core, leaving the charged HA moiety on the surface. This moieties redistribution, and not the size reduction, within the microgel particle, assessed by an atomic force microscopy, AFM, study of the surface, dynamic light scattering, DLS, zeta potential analysis and small angle neutron scattering, SANS, is at the base of the recognition of tumor cells via the interaction HA/receptors of overexpressed CD44 transmembrane proteins and of the specific drug delivery mechanism.

In PNiPAAm hydrogels, drug release has been often coupled with the temperature response of the matrix. However, besides the temperature, responsiveness to other state variables, such as pressure, or to the combination of both temperature and pressure can be considered. Two microgels having PNiPAAm as the only polymer component but different architectures, obtained by precipitation polymerization, were investigated: a morphology with (i) an un-crosslinked core and a crosslinked shell of PNIPAM chains and a softer one, (ii), having crosslinked PNIPAM chains as particle core with a shell of tethered un-crosslinked PNIPAM chains to the core. Confocal microscopy was a useful tool to validate the different morphologies. Differential scanning calorimetry, DSC, and DLS were used to follow the microgels as a function of temperature, pressure and both, pressure being osmotically controlled with a high molecular weight non-interacting polymer. Under osmotic stress, soft microgels can be compressed above the VPTT, reaching extremely low hydration degrees. The microgel volume behavior as a function of pressure and temperature allowed to estimate the isothermal compressibility and thermal expansion coefficients for the different morphologies. The VPT enthalpy is scarcely affected by the network architecture, whereas the work on osmotically stressed PNiPAAm is strongly influenced by the morphology. As biological counterpart, a very low cytotoxicity was highlighted by MTT tests of all morphologies on HaCAT cell line, while it is noteworthy that the softer morphology (ii) of microgels enhances the phagocytosis by RAW 264 macrophages.

Biopolymer-Particle Composites Designed to Match the Mechanical Properties of Soft Biological Tissues Paul A. Janmey; University of Pennsylvania, United States

Fibrous networks are ubiquitous in biology. The mechanical properties of the biopolymer fibers, the way in which the fibers are linked into networks, and the types of cells or particles within the network mesh all affect the macroscopic mechanical response of the material. Filamentous polymer networks containing volume-conserving particles are found in the cytoskeleton and extracellular matrix of animal cells and tissues, bacterial biofilms, fungal mycelia, and other structures spanning multiple biological kingdoms. The responses of biomaterials to uniaxial and shear deformations depends critically on the volume fraction of particles within networks and on the binding of particles to the network, but current data suggest that the mechanical properties of the particles themselves have only minor effects on the response of the composite material. Controlling biopolymer network connections and incorporation of appropriately sized particles within them can lead to viscoelastic properties that mimic those of biological tissues more closely than polymer networks alone.

11:30 AM *SB02.07.03
Mapping the Mechanics of Cartilage Matrix, Nature's Almost Perfect Hydrogel Emilios K. Dimitriadis[1], Preethi Chandran[2], Edward Mertz[1], Ferenc Horkay[1] and Peter Basser[1]; [1]National Institutes of Health, United States; [2]Howard University, United States

Cartilage matrix is composed of a dense collagen mesh within which the highly charged glycoprotein, aggrecan, is produced by chondrocytes and remains entangled in high concentrations. The inclusion and entanglement of large complexes of aggrecan molecules attached to long hyaluronic acid chains is responsible for matrix osmotic swelling that profoundly affects the behavior of the composite tissue. The equilibrium between the swelling and the mechanical constraints imposed by the collagen matrix is what provides cushioning of bones at load bearing joints. The relationship between osmotic and mechanical properties on one hand, and matrix composition and architecture on the other, is poorly understood. The composition of the tissue changes through tissue depth. Moreover, in growing cartilage, the relative composition and organization of the different components changes with time and along the bone axis and in the vicinity of chondrocytes, the pericellular matrix (PCM). Axial mapping of the mechanics is further complicated due to the need to physically section the tissue to gain access.
Here we study mouse cartilage. Even though mice are extensively used as model systems for a wide range of pathologies including arthritis, there are limited studies mapping matrix mechanics across different regions. Newborn mouse cartilage adds the complication that the tissue is densely populated with chondrocytes creating a complex 3-D composite that is continuously varying both in space and time. Nanomechanical studies, typically performed by

indenting tissue sections, are subject to errors due to matrix collapse, surface roughness and loss of aggrecan from the section surface by diffusion and degradation. Furthermore, data interpretation often poses its own challenges not least because of the natural inhomogeneity of the tissue.

Here, we performed high-resolution (1um) elasticity mapping of the knee cartilage matrix of newborn mice. The indentations were performed on thin (~12um) cartilage sections that were cut parallel to the bone longitudinal axis and mildly fixed to minimize loss of aggrecan. We chose the diameter of the microspheres used as indentation probes and we applied indentations that were large enough as to minimize the effects of surface roughness and geometric inhomogeneities. To consistently analyze the data, we developed a novel method for obtaining an effective contact point on the tissue surface. Our model fitting protocol ensures that we are probing bulk matrix properties and minimizes the effects of surface damage, tissue inhomogeneity and finite sample thickness. Matrix regions were extracted by correlation with optical images. Our results show interesting variation of properties between different regions and large variations in the vicinity of chondrocytes. The latter presented an additional challenge because the septa between chondrocytes are often very narrow adding to the difficulty of interpretation. Further modeling and analysis points to continuously and strongly varying properties of the PCM. The variability of matrix elasticity across the growing cartilage will be described and possible correlations with composition will be discussed.

12:00 PM *SB02.07.04
Bio-Inspired Hydrogels as Superglue in Seawater Hailong Fan and Jian Ping Gong; Hokkaido University, Japan

Many efforts have been made on developing adhesives for the marine environment that are inspired by organisms that fix themselves to underwater surfaces, like mussels. These catechol-based glues are easily oxidized and so eventually lose their adhesiveness, making them less than satisfactory for their intended purpose. Recently, we explored the possibility of developing adhesives that utilize electrostatic interaction to stick to negatively charged surfaces such as rocks, glass, and metals under the sea [1]. We built polymer chains made from two types of monomers as building blocks. One contains a positively charged “cationic” residue and the other contains an “aromatic” ring. In biosystems, adjacent cationic-aromatic amino acid sequences in proteins are known to facilitate electrostatic interactions in saline water. It has been challenging, however, to introduce such sequences in synthetic polymers due to difficulties in controlling monomer sequences. We discovered that the synthetic polymers with adjacent cationic-aromatic sequences could easily be manufactured using a highly scalable, cost-effective method through cation–π complex-aided free-radical polymerization. We found that the two residue types in polymers bonded together to form a hydrogel that stuck well to negatively charged solid surfaces in saltwater. Hydrogels composed of a variety of cationic-aromatic monomer combinations exhibited fast, strong, but reversible adhesion to the surfaces. Adhesion was largely thanks to the electrostatic interaction between the positively charged residues on the polymers and the negatively charged surfaces. But, interestingly, polymers made from these cationic - aromatic monomers without adjacent sequences weren’t nearly as adherent, indicating that adjacent aromatic residue enhances electrostatic interaction in high ionic strength environments. Based on the above result, we also developed hydrogel adhesives working in pure water [2].

3D Printable Hybrid Hydrogels with Hierarchical Structure Pramod Dorishetty, Rajkamal Balu, Naba Dutta and Namita Choudhury; RMIT University, Australia

The development of protein-based 3D printable hydrogels with required physicochemical and structural tunability is a critical challenge. One of our major focus is to design and develop novel 3D printable hydrogels that must possess both appropriate mechanics to be printable, are both shear-thinning and self-healing, and possess appropriate biocompatibility to support cellular interaction. Many widely used bioinks do not currently allow for this flexibility. By expanding the number and tunability of materials that are available for 3D printing, we aim to fabricate complex, multi-material constructs [1-7] and use of customizable, engineered scaffolds to support cell or microbiota growth with controlled porosity, elasticity, water absorption characteristics and mechanical properties. This presentation will highlight the effects of different types of nanocellulose on the hierarchical structure (nano-micro), mechanical properties (compression and shear), cellular response, and the printability of the fabricated protein/polysaccharide biomimetic hydrogels. The incorporation of fibrous polysaccharide significantly increased the toughness of the hydrogel without compromising cellular activities. The extrusion-based 3D printing of protein based hydrogels photochemically co-crosslinked between globular protein and fibrous protein has also been investigated in this work. The hierarchical structure of hybrid inks and their organizational transition during printing condition (shear) was investigated using small-/ultra-small-angle neutron scattering combined with rheology (Rheo-SANS/USANS). The properties of fabricated hydrogels was investigated using photorheology and atomic force microscopy; where, the hybrid hydrogels exhibited tuneable storage and Young’s modulus. The 3D printed hybrid hydrogels showed micropore size significantly higher than their solution casted counterparts. Moreover, the fabricated hybrid hydrogels show good mouse fibroblast cell attachment, viability and proliferation demonstrating their potential for tissue engineering applications.

1:30 PM *SB02.08.02

Desolvation Induced Shape Change for 4D Printing Hang (Jerry) Qi; Georgia Inst of Technology, United States

3D printing of structures and devices with shape or property change, or 4D printing, are highly desirable in many applications such as mechanical actuators, soft robotics, and artificial muscles. Early work in 4D printing used shape memory polymers (SMPs) as the shape change mechanism, but SMPs require complicated thermo-mechanical loading and most SMPs do not have reversible shape change capability. It is still a challenge to develop simple methods to freestanding, reversible, shape changing structures and devices. Desolvation is a novel method for shape changing devices where polymers with different crosslinking densities can absorb different amount of water or solvent to create different deformation. In recent years, our group has explored using the desolvation concept as a means for 4D printing. We first found that the light intensity gradient along the thickness direction created by photoabsorbers can be used to generate bending deformation. The level of the bending deformation depends on the light irradiation dose, which can be further controlled by light intensity. Therefore, by controlling light intensity pattern, we could create different bending distributions, or origami. This concept was further used to create reversible origami-based shape transformations. We then further developed such method to print 3D structures with rapid shape transformation by carefully managing the light penetration among different layers. Finally, we applied this method to extrusion based DIW printing of inks with high short fiber glass content to create shape-changing stiff structures. The design of all these desolvation-based 4D printing methods were guided by the theoretical modeling to achieve more accurate control of shape transformation.

2:00 PM SB02.08.03
3D Printing MRI Phantoms for Microscopic Anisotropy Velencia Witherspoon[1], Nickolay V. Lavrik[2], Michal Komlosh[1] and Peter Basser[1]; [1]National Institutes of Health, United States; [2]Oak Ridge National Laboratory, United States

One major challenge facing the advancement of diffusion-weighted imaging (DWI) methods is phantom development and fabrication. Isotropic diffusion phantoms are not sufficient to validate and calibrate more advanced DWI sequences that aim to distinguish between isotropic hindered diffusion and anisotropic randomly oriented restricted diffusion. Enhancing the contrast between these descriptions of diffusion regimes is the goal of most diffusion MRI method development teams. In reality, the size of the microstructural features that exhibit this behavior in biological tissue is on the order of 1-10 μm, while the features of the most commonly used phantoms are on the order of 20-100 μm. We plan on addressing the technical challenge of fabricating a 3D phantom that contains both randomly oriented highly anisotropic and isotropic structural features. We hope to reach high aspect ratios for these features to better resemble the target brain tissue. We tested this 3D Printed MRI phantom using DWI that reproduced the size and orientation distribution of the 3D printed pores. A portion of this research was conducted at the Center for Nanophase Materials Sciences, which is a DOE Office of Science User Facility.

2:15 PM SB02.08.04
3D Bioprinted Inflammation Modulating Polymer Scaffold for Chronic Wound Healing Aparna Adumbumkulath[1], Crystal S. Shin[2], Richard Lee[2], Adam Nelson[1], Ghanashyam Acharya[2] and Pulickel Ajayan[1]; [1]Rice University, United States; [2]Baylor College of Medicine, United States

Wound healing is a complex, highly organized biological and physiological process comprising of four overlapping phases: hemostasis, inflammation, re-epithelialization, and remodeling. A standard wound healing process is dependent on leukocyte recruitment and a cascade of pro- and anti- inflammatory cytokine responses. Over expression of the inflammatory cytokines such as interleukins (IL-1, IL-6) and tumor necrosis factor (TNF-α) as well as excessive recruitment of neutrophils and macrophages arrests the healing process in the chronic inflammatory phase. Once the wound is stalled in this phase, it becomes chronic or non-healing and is prone to infections. Chronic foot ulcers are one of the most common chronic wound condition arising from complication of diabetes, suffered by ~25% of diabetic patients. These confer a high-risk prognosis for lower extremity amputation to prevent the spread of infection. Current standard of care for chronic foot ulcer includes wound debridement, wound dressings for moisture balance, revascularization procedures to treat ischemia and improve blood flow, and hyperbaric oxygen therapy. Pharmacological treatments include using biological actives like topical formulations of growth factors or anti-inflammatory cytokines. The efficacy of topical formulations is hindered by their proteolytic breakdown in the hostile environment that results in therapeutically ineffective concentration and prevents their diffusion into deeper wound layers. Moreover, these approaches are labor intensive, expensive and focus on treating the symptoms of inflammation rather than the inflammation itself. Thus, it is important to develop de novo multivalent materials that can unlock the local inflammatory phase by extracting the molecular drivers of inflammation in a highly selective and concerted fashion and aid in the reparative phase. In this work, we developed a novel non-pharmacological approach to modulate chronic inflammation. A 3D-bioprinted polymer scaffold was fabricated by in-situ phosphate crosslinking of a poly (vinyl alcohol) polymer, that when applied on the wound, can modulate local inflammation by sequestering pro-inflammatory cytokines from the wound site via physicochemical and electrostatic interactions. Moreover, this polymer scaffold also contributes to the rapid wound healing by disrupting the constant recruitment of leukocytes to the wound site. We demonstrated the therapeutic efficacy of the polymer scaffold in a skin excision mouse model by applying the gel directly on the wound. The ability of the scaffold to capture the positively charged pro-inflammatory cytokines were evaluated by Luminex assay on the scaffold removed from the mice. Compared to the controls (PVA crosslinked with glycidyl methacrylate), the polymer scaffold was more effective in capturing the pro-inflammatory cytokines (IL-1α , IL-6 and TNF-α). Furthermore, flow cytometry studies showed that leukocytes were captured by the scaffold. These studies support that the polymer scaffold enhanced wound healing by trapping the excess pro-inflammatory cytokines and leukocytes in a tightly controlled manner and disrupting the chronic inflammatory cycle in wounds.

2:30 PM *SB02.08.05
3D Bioprinting—What Cells Find Attractive in a Gel Gordon Wallace; University of Wollongong, Australia

3D Bioprinting enables the fabrication of structures with living cells, biomaterials and other active ingredients (e.g. drugs and/or growth factors) strategically arranged in three dimensions. The biomaterials used are traditionally hydrogels since these provide adequate mechanical support to ensure structure integrity along with a cytocompatible environment.

The engagement of cells with the biomaterial (gel or the precursors) during and after printing determines the success or otherwise of any 3D Bioprinting strategy.

The interaction of gel or the precursors and cells determines the ability to retain viable suspensions in bioink reservoirs.

The rheological properties of the gels used determines how they behave and how they might protect cells during printing.

The modulus and porosity of gels determines the capacity of cells to interact with each other and the immediate environment.

Using several 3D bioprinting case studies aimed at meeting clinical challenges we will explore the critical properties of gels for such applications.

The clinical challenges include:
- cartilage regeneration in the knee (1,2)

- islet cell transplant ion to treat diabetes (3,4)
- skin regeneration (5,6)

With a view to developing protocols that are implementable in the clinic we will also review some of the additional requirements such gels must meet. These include the availability of a reliable and reproducible source material and compatibility with sterilisation methods traditionally used.

The cell - gel engagement is short lived and the temporal dimension is critical to a successful relationship. The role of the gel as a function of cell and tissue development time will be discussed.

Biocompatible Fluidic Device Formed Through the Buckle-Delamination of Hydrogel Films Riku Takahashi[1], Hiroki Miyazako[2], Aya Tanaka[1] and Masumi Yamaguchi[1]; [1]NTT Basic Research Laboratories and Bio-Medical Informatics Research Center, NTT Corporation, Japan; [2]NTT Basic Reserach Laboratories, NTT Corporation, Japan

Biocompatible fluidic systems play a vital role in a wide range of biological applications, such as tissue engineering, biochemical sensing, cell-to-cell interaction studies, microfluidic bioreactors and so on. Hydrogels are one of the best candidates to use as a base material when fabricating the above systems due to their characteristic properties, including compliance similar to biological tissues, permeability to small molecules, biocompatibility with most cells and optical clarity under visible light. On the other hand, the swelling properties (volume change) of hydrogels is considered to be a negative factor in flow channel design, and therefore non/less-swellable hydrogels tend to be used to fabricate hydrogel-based fluidic systems. By leveraging the swelling properties of hydrogels, we can turn this disadvantage into a unique, new method to create fluidic devices from various functional hydrogels.
In this study, we demonstrate the use of swelling-driven buckle-delamination, a physical phenomenon observed in hydrogel/solid substrate bilayer composites, for fabricating fluidic channels.[1] By spatially controlling the interfacial bonding between a thin polyacrylamide (PAAm) gel film and a glass substrate, swelling-driven compressive stress induces the formation of channel architectures through a buckle-delamination process. Connecting flow tubes to the channels with a 3D printed connecter results in a fluidic device, enabling pressure-driven flow without leakage or rupture. Furthermore, by stacking less-swellable bulk gels on the device, we obtained a tough, permeable, and biocompatible fluidic device, which successfully demonstrates the use of both swellable and less-swellable hydrogels as base materials for developing fluidic systems. Finally, we performed cell cultures with the device and applied chemical stimulation to cells through diffusion of molecules from the fluidic channels. [2] This work should shed light on the design of diverse hydrogel-based fluidic systems and may be useful for applications in the fields of bioanalysis, tissue-engineering and cell biology.

Late News: Capsule-Shaped Self-Oscillating Gel with Cell-like Surface Fluctuation Won Seok Lee, Takafumi Enomoto, Aya M. Akimoto and Ryo Yoshida; The University of Tokyo, Japan

[Introudction]
The fluctuation of biological membranes has fascinated scientists and engineers with various backgrounds. The membrane fluctuation induces essential features for life, such as cell compartmentalization, cell motility, cell division, and vesicle trafficking. The membrane fluctuation is derived from the following parameters: the thermal fluctuation of phospholipids in the membrane layer, ATP-dependent conformational changes of transmembrane proteins. Mimicking the membrane fluctuation using artificial active matters is important to understand the origin of the dynamic behavior of life.
In this context, our group has developed self-oscillating gels with living organism-like functions. The self-oscillating gel shows dynamic behavior by chemo-mechanical motion, driven by a Belousov-Zahbontinsky (BZ) reaction. The self-oscillating gel is fabricated by introducing a tris(2,2'-bipyridine)

ruthenium ($Ru(bpy)_3^{2+}$), a metal catalyst for the BZ reaction, into a thermoresponsive hydrogel network. Cyclic redox changes of $Ru(bpy)_3$ ($Ru(bpy)_3^{2+} \leftrightarrow Ru(bpy)_3^{3+}$) during the BZ reaction lead the gel to present periodic and autonomous swelling-deswelling oscillation without any external stimuli.[1]
Here we present a self-oscillating capsule-shaped gel that shows the cell-like membrane fluctuation. Self-oscillating gels are one of the promising materials for mimicking the membrane fluctuation because the gels show the regional deformation randomly and spontaneously in various regions. We fabricated a capsule-shaped hollow structure using the self-oscillating gel, which provides a structural resemblance compared with biological cells. The capsule-shaped gel exhibits the surface fluctuation by the propagation of the BZ reaction wave similar to the shape fluctuation of the living cells.

[Materials and Method]
The capsule-shaped hollow self-oscillating gel was fabricated by four processes described below: (1) An alginate/calcium (Alg/Ca) spherical bead, which is a template of the capsule-shaped gel, was fabricated by adding sodium alginate solution to $CaCl_2$ solution. (2) Poly ((*N*-isopropylacrylamide)-*co*-(*N*-(3-aminopropyl)methacrylamide)) (poly(NIPAAm-*co*-NAPMAm) layer was synthesized by immersing the Alg/Ca gel into ammonium persulfate (APS) solution and monomer solution, in a sequence. (3) The Alg/Ca template was dissolved by putting the gel into a sodium citrate solution. (4) $Ru(bpy)_3$-NHS was conjugated to capsule-shaped hollow gel. The gel surface fluctuations by volumetric oscillation during the BZ reaction were evaluated.

[Result and Discussion]
The cross-sectional images of the gels in each fabricating process show that the capsule-shaped hollow structure was successfully formed. On a millimeter scale, the volumetric oscillation of the self-oscillating gel appears with a spreading chemical signal by the BZ reaction.[2] Therefore, in this study, the chemical signals of the BZ reaction run along to the surface of the entire gel, causing the surface fluctuating phenomenon like a living red blood cell. Moreover, it becomes clear that the amplitude of fluctuation increases as layer thickness grows. The thickened self-oscillating gel layer leads to improved local deformation, which brings about the more intense surface fluctuation phenomenon. The thickness deformation-induced surface fluctuation could correspond to the effect of the ATP-driven conformational change of protein, which induces the shape fluctuation in the living cells. We expect that this study can be utilized to realize the artificial cell which shows various cell-like functions.

Fabrication of Porous PDMS Sponges Using Spontaneously Self-Removing Sacrificial Templates Alex Keller, Khalid Zainulabdeen, Holly Warren and Marc In het Panhuis; University of Wollongong, Australia

Poly(dimethylsiloxane) (PDMS) sponges are an emergent technology, garnering much attention in recent years due to their unique mechanical properties, high surface area and hydrophobicity/oleophilicity. In this work, a hydroscopic calcium chloride hard template is used to prepare a PDMS sponge in 6 hours, faster than previously reported template removal methods. Furthermore, the unique deliquescent properties of the calcium chloride are harnessed to provide a spontaneously self-removing sacrificial template within 4 days. The resultant PDMS sponges displayed excellent mechanical robustness, exhibiting maximum tensile and compressive stress values of 110 ± 20 kPa and 2.8 ± 0.1 MPa, respectively. The PDMS sponges displayed far greater preferential absorption of toxic solvents over simulated gastric fluid.

9:15 PM SB02.09.04
Living Hydrogels as Toxicity Indicators Kharina Fenton and Marc In het Panhuis; University of Wollongong, Australia

Living hydrogels were made by embedding microalgae of the species *Chlorella vulgaris* in alginate-based hydrogels. It was shown through detection of chlorophyll-a content that these algal cells were able to grow as expected within the hydrogel matrix. This system was formed the basis for a *Chlorella vulgaris* algal (hydrogel) sensing system for the detection of the exposure to toxic compounds. For example, exposure to dichloroethane resulted in a 43% decrease in *Chlorella vulgaris* growth. This work demonstrates that living hydrogel materials containing *Chlorella vulgaris* cells can successfully act as toxicity indicators. This could suggest their suitability in applications of living hydrogels in water quality assessment.

9:20 PM SB02.09.05
Synthesis and Characterisation of a 3D-Printable Gelatin—Epoxy Amine Double Network Hydrogel Anne Kelly and Marc In het Panhuis; University of Wollongong, Australia

There is a current need for the development of robust smart materials for a variety of medical, consumer, and manufacturing applications. In addition, these materials require the ability to act as 3D printable inks to undergo rapid prototyping. A UV curable gelatin-epoxy amine double network hydrogel with water content of 80% can be simply produced by a one-pot synthesis. This synthesis method can be performed by methacrylating the individual networks by either a one-step process (simultaneously) or a two-step process (independently). It was found that the two-step process is more effective in producing a mechanically robust material, capable of exhibiting a compressive stress at failure of 2.5 ±0.2 MPa. Significantly, a new 3D printing method has been developed to allow the material to be cured post printing resulting in no significant loss in mechanical strength compared to gels prepared by casting. This method uses the entanglement of gelatin (below 37°C) to give support to the individual printed layers of the structure eliminating the need for UV curing after each layer is printed. Post printing, the structure can be UV cured to increase the mechanical strength of the material to that of the hydrogels prepared by casting. It is envisage that this new printing method in conjunction with new hydrogel chemistries can be utilised to fabricated new materials for applications ranging from biomedical devices to soft robotics.

9:25 PM SB02.09.06
3D Printed Living Hydrogels Mohammed Al-Mossawi, Paul Molino, Holly Warren and Marc In het Panhuis; University of Wollongong, Australia

In this presentation the 3D printing of living hydrogels based on alginate-gelatin gels embedded green algae *Chlorella Vulgaris* is presented. It is shown that alginate-gelatin gels crosslinked with 0.05M CaCl2 displayed excellent mechanical properties whilst still allowing for suitable algal cell growth. The latter was determined using dissolved oxygen ratio.

The rheological flow behaviour of these hydrogels systems was investigated to assess their potential for extrusion printing. Our results indicated that a combination involving 4% (w/w) alginate and 4% (w/w) gelatin resulted in a mechanically robust 3D structure that maintained algal cell viability. 3D printed living hydrogel with excellent mechanical stability offer new possibilities to connect the inorganic and biological worlds.

9:30 PM SB02.09.07

3D Printing of Surgical Staples Osama Al Takhayneh, Holly Warren and Marc In het Panhuis; University of Wollongong, Australia

There are several techniques used in the manufacturing of bone implants such as 3D printing. Rapid prototyping/3D printing is an important process in the development of implants used in bone fixation surgeries, its importance lies within the ability to customize and create patient specific systems to increase the efficiency of bone fixation surgeries. The main aim of this study was to develop and test new (and softer) materials for the purpose of surgincal staples using 3D printing. Our results indicate that the mechanical characteristics of staples is suitable to enable their use in low impact locations within the body (such as upper extremities). This study demonstrated that biocompatible polymers are a viable alternative for metal alloys in the use of surgical staples.

9:35 PM SB02.09.08
Cartilage Hierarchy and Function Ferenc Horkay[1], Peter Basser[1] and Erik Geissler[2]; [1]National Institutes of Health, United States; [2]Universite Grenoble Alpes, France

The biochemistry of cartilage has been extensively studied in the last couple of decades. The major proteoglycan component of catilage extracellular matrix is the high molecular weight ($1x10^6 < M < 3x10^6$) bottlebrush shaped aggrecan. In the presence of hyaluronic acid (HA) and link protein, aggrecan self-assembles into a supramolecular structure with as many as 100 aggrecan molecules attached as side chains on a filament of HA. This supramolecular array yields a hydrated, viscous gel that provides the osmotic properties necessary for the cartilage to resist deswelling under compressive load. In cartilage these complexes are interspersed in the collagen matrix.
Imaging techniques (electron microscopy, atomic force microscopy, etc) have revealed the size and structural pattern of large distinct aggrecan-HA acid complexes. Such methods yield detailed information on the morphology within a selected area of the sample. However, the interactions that govern the morphology and dynamics of aggrecan-HA assemblies in solution remained poorly understood. Owing to the complexity of the aggrecan-HA system the determination of the relationship between its structure and function requires a range of experimental approaches combining both physical and biochemical techniques.
We investigate the spatial organization both in solutions of aggrecan and aggrecan-HA complexes over a length scale range between 1 and 500 nm. The static properties are studied by small angle neutron scattering (SANS) and static light scattering (SLS), while the dynamics are probed by dynamic light scattering (DLS). The length scale range probed by scattering methods detects changes in the architecture on the supramolecular scale. Changes at the molecular level are detected by virtue of the average effect that they exert on the larger scale structures. Better understanding of the organization of aggrecan assemblies and their effect on cartilage mechanical properties is essential to advance our knowledge of arthritiis and develop treatment strategies.

9:40 PM SB02.09.09
Structural Change of Colloidal Silica Solution Under Shear Stress Keishi Akada[1], Soichiro Okubo[2], Kazuya Tokuda[2], Koji Yamaguchi[2], Takamasa Onoki[2], Tatsuya Yamada[3], Ryota Jono[3], Hiroshi Ushiyama[3], Syogo Tejima[3] and Jun-ichi Fujita[1]; [1]University of Tsukuba, Japan; [2]Sumitomo Electric Industries, Ltd., Japan; [3]Research Organization for Information Science & Technology, Japan

Background:
In some colloidal suspensions, viscosity increases (shear thickening) or decreases (shear shining) when shear stress is applied. The shear thickening material is a candidate for wide range applications such as damper systems in machinery, and such phenomena can cause a flow to be obstructed. However, these viscosity changes occur in a dynamic process in which shear is applied, and the viscosity returns to its original state when the shear stress is removed. Therefore, it has been difficult to measure the dynamic microstructural changes that lead to the shear thickening phenomena. In this study, we performed simultaneous measurements of solution viscosity and small-angle X-ray scattering (SAXS) using an X-ray transmission solution cell. By observing the structural changes of colloidal particle clusters under shear stress in real time, we investigated the aggregation process of colloidal particles responsible for the phenomenon.

Experiment:
The silica colloid sample was prepared by dispersing a silica sol (Snowtex ST-S, Nissan Chemical) with a particle size of 8 nm in a 0.8 wt% PEG solution [1]. The viscosity and SAXS were measured simultaneously using a rheometer (ONRH-1, Ohna Tech Inc.) in combination with a polycarbonate X-ray transmission Couette cell. The obtained spectra were divided into perpendicular and parallel components with respect to the direction of the cylinder rotation, and it was plotted against the scattering vector Q. The experiments were performed at the Sumitomo Electric Beamline BL16 at the Kyushu Synchrotron Light Source Center and Spring-8 BL40XU.

Results:
The viscosity measurement results of the silica colloidal solution showing shear thickening properties. This property was observed at a shear rate of 10 [1/s], where the viscosity increased rapidly. SAXS spectra were acquired while rotating at a constant speed at the shear rate before and after the viscosity change, and the spectra in direction of perpendicular and parallel to the rotation were compared.
In both directions, a characteristic peak at about 3.4 [1/nm] was observed, which is attributed to a particle cluster spacing and reflects an isotropic cluster dispersion. The anisotropic shift of the peaks were observed after viscosity increase. The spacing of the parallel to the shear direction decreased, while that of perpendicular increased, suggesting that a compressive force was applied to the cluster in the direction of rotation. These results suggest that the application of shear stress caused an aggregating cluster and an increasing viscosity [2]. These results demonstrated an effectiveness of the viscosity-SAXS measurement method.

3D Printing of Tough and Stretchable Hydrogels Kusuma Betha Cahaya Imani and Jinhwan Yoon; Pusan National University, Korea (the Republic of)

Tough and stretchable hydrogels are highly studied in recent years, due to its promising potential applications in various field such as for actuators, wearable electronic devices, and soft robotics. To have a hydrogel with improved mechanical property, its viscoelastic dissipation needs to be enhanced, which is difficult to be obtained in a hydrogel containing of covalent bonds only. To overcome this problem, in this study, physical interaction in form of ionic bond and micelles incorporations are used. For the micelles, Pluronic F-127 micelles was chosen, other than for mechanical enhancement, it also has the capability to have a quick viscosity sift depending on temperature. This capability is generated owing to its structure, a triblock copolymer which consists of hydrophobic poly (propylene oxide) (PPO) core block and hydrophilic poly (ethylene oxide) (PEO) side blocks. At elevated temperature, the hydrophobic core block dehydrates, which leads to micelles formation and increasing its viscosity. The controllable viscosity is highly useful for 3D

printing, as it is important to prevent the spread of the ink upon deposition to a substrate. The Pluronic F-127 was also synthesized to have methacrylate group to allow photo-polymerization after printing, to have immediate permanent shape. With this method, hydrogels with complex shapes in various toughness and stretchability could be achieved, and it opens the possibility for further applications.

9:50 PM SB02.09.11
Reversible Clustering Dynamics of Thermo-Responsive Hydrogel Micropillar Arrays by Capillary Force and Temperature Jiseong Choi, Suim Lim and Seongmin Kang; Chungnam National University, Korea (the Republic of)

High aspect ratio pillar structure was suitable for implementing various functional surfaces due to the easy shape transform. The high aspect ratio pillars composed of elastomers or rigid polymers were unstable and easily clustered by external forces such as capillary forces. This clustering property was used in various field. However, easy clustering property of the high aspect ratio pillars posed an obstacle to apply functional surfaces because special treatment was essential for high aspect ratio pillars to return to their original state from clustering state. Therefore, we reported reasonable criteria to control the clustering phenomena in high aspect ratio pillar arrays. We adjusted two main factors that were the crosslinker density of thermal-responsive hydrogels and the temperature of the surrounding environment to control the elastic modulus, which was the most important characteristic for clustering property of high aspect ratio pillars. Experimentally, the clustering behavior of the high aspect ratio pillars was respectively analyzed by changing the mechanical property according to the water content and temperature. In addition, theoretical analysis supported the criteria for controlling condition with clustering and de-clustering phenomena of the high aspect ratio pillars.

9:55 PM SB02.09.12
Late News: Modeling the Behavior of Hydrogel Modified Pore Fluids for Geotechnical Applications Varun Nimmagadda[1], Albert Tam[2,3], Shoumik Saha[2] and Dilip Gersappe[2]; [1]University of Michigan–Ann Arbor, United States; [2]SUNY-Stony Brook, United States; [3]Lynbrook High School, United States

Recent advances in bioremediation techniques in geotechnical engineering has pioneered the replacement of pore water in soil by biopolymers to improve the physical and hydraulic properties of soils. In determining the type of biopolymer additive that will not reduce the soil strength, several factors need to be considered. Ideally, the biopolymer-based pore fluid needs to be self-assembling and can recover after deformation. Recent advances in geotechnical engineering have shown hydrogels as a soil additive to improve soil stability. Hydrogels, particularly with clay additives, can help mitigate soil erosion, reduce soil swelling, and optimize soil near building foundations. While experiments have successfully demonstrated the effect of hydrogels on soil strength, these studies depend on trial and error to identify the suitable biopolymer and type and concentration of clay fillers.

This study analyzes hydrogel systems consisting of two types of polymer chains and clay nanoplatelets dispersed in an explicit solvent and assesses the effect of clay filler structure, filler amount, and polymer-polymer attraction on the mechanical and structural properties of the hydrogel. To simulate the formation and behavior of the hydrogel, the systems were studied using coarse-grained molecular dynamics. A series of simulations were run using various combinations and concentrations of clays and the different polymers. We analyzed the effect of including interactions between the clay and the polymers and polymer – polymer interactions. Mechanical properties were measured via viscosity and stress autocorrelation (SAC) calculations, while the radial distribution function (RDF), was used to measure degree of phase separation or random mixing of polymers.

Our results show that by changing the polymer-polymer interaction we observed morphologies ranging interpenetrating networks to single polymer networks. Higher percentage of clay fillers and larger values of attraction between the polymers allows us to tailor the viscosity of the hydrogel pore fluid. High shear rates lowered viscosity values, leading to the pore fluids being shear thinning in nature. Overall, our results show that by choosing the hydrogel components and the nanofiller, the properties of the pore fluid can be controlled. These results will allow better design and selection of the biopolymer-based pore fluids for various biogeotechnology applications.

10:00 PM SB02.09.13
Dynamically Changing the Transmission Property of Hydrogel using Metal Microstructures Fabricated by Multi-Photon Photoreduction Hirofumi Tomikawa, Kaneto Tsunemitsu, Yo Nagano and Mitsuhiro Terakawa; Keio University, Japan

All-optical switching, or dynamically changing optical properties by light stimulation, has received much attention because of its capability of non-contact controlling. Volume phase transition of temperature-responsive hydrogel causes change of optical transmittance, and metal nanoparticles embedded in the hydrogel can enhance the transmittance change by light stimulation, owning to photo-thermal conversion via the localized surface plasmon resonance (LSPR). In this study, we propose a method to control spatially-localized optical transmittance of temperature-responsive hydrogel by external light stimulation, by the use of the metal microstructures fabricated with multi-photon photoreduction (MPR) method. MPR is the reduction of metal ions induced by ultrashort laser pulses which enables direct writing of metal microstructures composed of the nanoparticles. Grating microstructures with different line spacing were fabricated inside poly(N-isopropylacrylamide) (PNIPAm) hydrogel containing gold ions by computer-aided femtosecond-laser scanning. Since the gold microstructures formed in the hydrogel showed an absorbance peak around 520 nm, 520 nm laser diode (maximum laser power: 50 mW) was used as the light source of stimulation. As a result, decrease in the transmittance (more than 66 %) was observed at laser powers higher than 7 mW for the light stimulation, when hydrogel with line spacing of 5 μm was used. The threshold of the laser power that required to decrease the transmittance became higher as hydrogel with wider line spacing was used, demonstrating transmission property can be easily changed with the same materials and the fabrication method. Our results indicate the potential to fabricate all-optical switching devices with hydrogel.

10:05 PM SB02.03.03
Functionalized Conductive Hydrogels Applied to the Discriminative Detection of Heavy Metals João P. Braga[1], Guilherme R. De Lima[1], Giovani Gozzi[2] and Lucas Fugikawa-Santos[2]; [1]São Paulo State University – UNESP, Brazil; [2]São Paulo State University - UNESP, Brazil

Ionic conductive hydrogels can be used in many sensing and actuators applications, including chemical detection, artificial skin, and biosensors. We report herein the development of a discriminative sensor array used to detect heavy metals commonly found dissolved in waters in aquatic ecosystems. Each sensing unit is comprised by 4 interdigitated electrodes on which poly(ethylene glycol):poly(ethylene glycol) diacrylate (PEG:PEG-DA) films were formed by UVA (370 nm) curing. After crosslinking, the hydrogels were washed and functionalized by drop casting solutions of 3 different organic semiconductors: poly(3-hexathiophene) (P3HT), poly(o-methoxy anyline) (POMA) and a poly(vinyl carbazole):2-(4-biphenylyl)-5-(4-tert-butylphenyl)-1,3,4-oxadiazole (PVK:PBD) blend. The resulting sensor array was formed by 3 electrodes with organic semiconductor functionalized hydrogels, in addition to a “blank” hydrogel film, used as reference. Water solutions of iron (Fe), manganese (Mn) and molybdenum (Mo), at concentrations varying from 20 ppm up to 200 ppm were used to demonstrate the discriminative capability for heavy metal detection by using the global electrode response extracted from electrical impedance/capacitance measurements. The frequency-dependent response of the electrodes was analyzed by considering a generalized Warburg impedance model to extract the electrical response parameters. The electrical characteristics of the functionalized hydrogels were compared to the changes in the morphological, thermal and physio-chemical properties of the films, analyzed via scanning electron microscopy,

thermogravimetry analysis, FTIR and Raman spectroscopy.

10:30 AM *SB02.10.01
Evidence of Many-Body Interactions in the Virial Coefficients of Polyelectrolyte Gels Jack F. Douglas[1] and Ferenc Horkay[2]; [1]National Institute of Standards and Technology, United States; [2]National Institutes of Health, United States

The phase behavior of materials ranging from gases to polymer solutions can often be understood semi-quantitatively in terms of their first few virial coefficients that quantify intermolecular interactions in the limit of low molecular concentration. The second (A_2) and third (A_3) virial coefficients, or their equivalent *chi*-interaction parameters in a polymer solution context, have correspondingly been adopted as fundamental measures of intermolecular interaction having fundamental significance for materials classification, design and characterization. It is often implicit in this type of description of phase behavior that the interactions between the molecules can be described by *pairwise decomposable interactions* and it is not clear if patterns of phase behavior applies to complex liquids, such as ionic and polyelectrolyte solutions, polyelectrolyte gels, etc. in which many-body interactions associated with polymer and ion solvation, and hydrogen bonding interactions of the water molecules, and the associated "hydrophobic effect" governing solvation of charged molecules or uncharged moieties in water, might lead to entirely different patters of phase behavior. Along this lines, simulations of simple hydrophobic solutes (modeled as Lennard-Jones molecules or simple molecules such as methane or noble gases) in water at ambient temperatures have indicated that while the interaction of two particles may be predominantly repulsive, corresponding to a positive second virial, the interactions between many particles can become attractive, corresponding to higher virials being negative, and this can lead to phase separation.This pattern of phase behavior is exhibited experimentally by all the polyelectrolyte gels that we study. We thus observe clear evidence of many-body interactions on the solution properties of polyelectrolyte gels.

11:00 AM *SB02.10.02
Imaging Cells and Tissues in 3D at the Nanoscale with Electron Probes Richard D. Leapman and Maria A. Aronova; National Institutes of Health, United States

Microscopies based on focused electron probes allow the cell biologist to image the 3D ultrastructure of eukaryotic cells and tissues extending over large volumes, thus providing new insight into the quantitative relationship between cellular architecture and function of organelles. Here we compare three such techniques: (i) electron tomography in conjunction with axial bright-field scanning transmission electron microscopy (BF-STEM), (ii) serial block face scanning electron microscopy (SB-SEM), and (iii) focused ion beam scanning electron microscopy (FIB-SEM). The advantages and limitations of each approach are illustrated by their application to determining the 3D ultrastructure of human blood platelets, and insulin-secreting beta cells of mouse pancreatic islets of Langerhans. In comparing the three methods, we consider specimen geometry, specimen preparation of stained polymer embedded cells and tissues, beam damage and automated segmentation methods. Many features of the organelles contained in blood platelets can be visualized using all three approaches, but STEM tomography offers an almost isotropic resolution of ~ 3 nm, compared with ~5 nm in FIB-SEM, and an anisotropic resolution of ~5 nm in the block-face plane and ~30 nm perpendicular to the block-face in SB-SEM. In this regard, we demonstrate that STEM tomography is advantageous for visualizing the platelet canalicular system consisting of interconnected membranous cisternae. In contrast, SB-SEM enables visualization of large numbers of complete platelets, each of which extends ~2 µm in minimum dimension, whereas an electron tomogram acquired in the BF-STEM can typically only visualize about half of a platelet volume due to a rapid non-linear loss of signal in specimens of thickness greater than ~1.5 µm. Although cellular and tissue volumes acquired by FIB-SEM are typically smaller than those acquired by SB-SEM, the improved spatial resolution perpendicular to the block-face in FIB-SEM facilitates more accurate 3D segmentation of the ultrastructure.

11:30 AM *SB02.10.03
Photo-Crosslinkable Polymer Platform—From Bioinks to Shape Memory Polymers Sandra Van Vlierberghe[1,2]; [1]Ghent University, Belgium; [2]Vrije Universiteit Brussel, Belgium

Biofabrication is a specific area within the field of tissue engineering which takes advantage of rapid manufacturing (RM) techniques to generate 3D structures which mimic the natural extracellular matrix (ECM). A popular material in this respect is gelatin, as it is a cost-effective collagen derivative, which is the major constituent of the natural ECM. The material is characterized by an upper critical solution temperature making the material soluble at physiological conditions. To tackle this problem, the present work focusses on different gelatin functionalization strategies which enable covalent stabilization of 3D gelatin structures [1, 2].
In a second part, synthetic acrylate-endcapped, urethane-based precursors (AUP) based on polyethers and polyesters, will be discussed with exceptional crosslinking behaviour and CAD-CAM mimicry compared to conventional materials [3]. Within this synthetic material class, also insight will be provided on the shape memory properties of polyester-based AUPs (two filed patents). Both chain growth and step growth polymerization mechanisms (see figure) along with their mechanical properties and processability potential will also be addressed.
Several polymer processing techniques will be covered including conventional 3D printing using the Bioscaffolder 3.1 and two-photon polymerization [4, 5]. A number of biomedical applications will be tackled including adipose tissue engineering [6, 7], vascularization [8], ocular applications [9], etc. In a final part, attention will be paid to the valorization of our biomaterial platform technology through the launch of our spin-off company Xpect-INX. The results show that chemistry is a valuable tool to tailor the properties of (bio)polymers towards processing while preserving the material biocompatibility.

Osmotic and Load-Bearing Properties of Cartilage Peter Basser; National Institutes of Health, United States

Cartilage is a load-bearing tissue that derives its stiffness from a fibrous network, mainly consisting of collagen type II, which is pre-stressed by the osmotic swelling pressure of negatively charged proteoglycan assemblies imbedded in the collagen matrix[1]. Changes in the relative amounts of the main constituents will affect the macroscopic properties of cartilage. A decrease in tissue water content that might occur in some disease states could alter these properties and lead to impaired joint function. For example, previous findings indicate that osteoarthritic cartilage contains more water than healthy cartilage and exhibits poorer load-bearing properties.[1]
We intend to determine how the interactions of the major biochemical constituents of articular cartilage influence its osmotic and mechanical behavior. One of the basic challenges of existing biomimetic cartilage models and modeling is that the pre-stress is largely ignored. However, in cartilage pre-stress exists even in the absence of external loading and plays an important role in defining the load-bearing properties of this tissue[1]. Recently, we developed a pre-stressed biomimetic composite gel system consisting of a relatively stiff poly(vinyl alcohol) (PVA) matrix which encloses weakly cross-linked poly(acrylic acid) microgel particles. This model allows us to explore how changes in composition affect the swelling and mechanical behavior. There are three major determinants of the biomechanical behavior of articular cartilage. The first is the osmotic swelling pressure that reflects the interactions between the polymeric components of the tissue and the ions. The second is the elastic resistance of the cartilage matrix itself, and the third is the fluid-solid interaction that can affect hydration. It is demonstrated that our model satisfactorily describes the osmotic and swelling properties of healthy and osteoarthritic cartilage.[2]

Multifunctional Hydrogels from Mechanistic Design to Practical Applications Jie Zheng; University of Akron, United States

Nature designs a vast library of soft materials in living bodies to fulfil many unique and specific functions, including strong mechanics, high actuation and sensitivity, better biocompatibility, and fast self-healing property. Sure nature soft materials offer a rich reservoir for rational design and engineering of synthetic soft materials (polymers and hydrogels). Herein, we uniquely integrate theoretical models, molecular simulations, and biophysical experiments to conduct fundamental and applied research at the interface of computational structural biology, biophysics, biomaterials, and nanotechnology, with the goals of better understanding of biophysicochemical interactions at the biological interfaces and rationally engineering biomolecules for practical applications in biomaterials and medicine. In this talk, I will show different general strategy to design soft living materials with extraordinary properties. Guided by our computational theory, I will demonstrate the design of synthetic polymers and peptides for antifouling coatings, smart hydrogels, and amyloid inhibitors. The interplays between theory, experiments and design will be emphasized throughout the talk.

2:00 PM *SB02.11.03
Genipin Crosslinked Networks—From Bioplastics and Biogels to Next-Generation Embolization Coils Emily Augustine, Spencer Matonis, Gaurav Balakrishnan, Durva Naik and Christopher J. Bettinger; Carnegie Mellon University, United States

Genipin is a naturally occurring small molecule that has been used extensively as a protein crosslinker for engineering application-specific biomedical materials. Genipin crosslinked proteins have been used for applications ranging from tissue engineering scaffolds to drug delivery matrices. Here, we will discuss the use of genipin as an enabling additive to improve the mechanical properties and processability of both collagen-based networks for medical devices and fibrin-based networks for use as a strategy for reinforcement after embolization. In the first part of the talk, we will describe structure-processing-property relationships in genipin/collagen hybrids. The composition and processing history of these precursor materials can be controlled to produce materials ranging from rigid bioplastics to compliant hydrogel-based networks. Applications as structural materials in biomedical devices and bioelectronics will be discussed. In the second part of the talk, we will describe the use of genipin as a crosslinker to improve the robustness of fibrin networks in the context of embolization devices. Specifically, we will describe genipin-eluting polymer fibers as an approach to improve the efficacy of embolizing intracranial aneurysms. Diffusion-reaction kinetics of genipin released from polymeric fibers within fibrin hydrogels using an in vitro aneurysm flow model will be described. Taken together, this talk will elaborate on the use of genipin as an enabling component of protein-based hydrogels as biomedical materials.

2:30 PM SB02.11.04
Synthesis of Polymer Nanoparticles and Their Assemblies Nikunjkumar Visaveliya; The City College of New York, United States

When two or more nanoscale components assemble, they create new, advanced, and multifunctional composite systems. The assembly systems reveal advanced property/function that is not possible to achieve by individual types of nanoparticles alone. A wide range of various assemblies can be prepared such as self-assembly, templated assembly, directed assembly, etc. Considering the chemical nature of polymeric materials which are soft and flexible, it is more challenging and interesting to create the engineering architectures of nanoscale assemblies in hierarchical order. In general, the engineering of polymer nanoparticles with controlled properties is very promising for various applications. Polymer nanoparticles' interior is mainly made up of the cross linked network. On the other side, the surface of polymer nanoparticles can be tailored with soft, flexible, and responsive molecules and macromolecules as potential support for the controlled particulate assemblies. Molecular surfactants and polyelectrolytes as interfacial agents improve the stability of the nanoparticles whereas a swellable and soft shell like cross linked polymeric layer at the interface can significantly enhance the uptake of guest nano constituents during their interactions to form the assembly architectures. Moreover, layer by layer surface functionalization holds the ability to provide a high variability in assembly architectures of different interfacial properties. Based on these aspects, various assembly architectures of polymer

nanoparticles of tunable size, shapes, morphology, and tailored interfaces together with controllable interfacial interactions are presented here. The microfluidic supported platform has been used for the synthesis of constituent polymer nanoparticles of various structural and interfacial properties, and their assemblies are prepared in batch or flow conditions.

2:45 PM SB02.11.05
Messy to Ordered—Fiber Diameter Controls the Shape-Morphing Behavior of 2D Networks of Mesoscale Responsive Fibers Shiran Ziv Sharabani and Amit Sitt; Tel Aviv University, Israel

In recent years, there has been a continuous endeavor to develop synthetic shape-morphing materials of different architectures and scales and to decipher the underlying principles that govern their behavior and functionality. Here, we present 2D highly ordered shape-morphing networks of interconnected mesoscale fibers, constructed of a thermoresponsive copolymer. The networks are fabricated using the jet writing approach, which enables a high spatial precision over fiber deposition, a well-defined long-range order, and high control over the fiber diameter.
When immersed in a hot aqueous environment, the networks maintain their ordered as-spun morphology. However, upon cooling below, the fibers swell and the networks shape-morph, exhibiting two distinct morphing behaviors that are determined by the diameter of the diameter and the mesh density. In the case of thick fibers or dense networks, the networks swell while preserving their original ordered morphology and expands homogeneously. In the case of thin fibers and sparse networks, upon swelling the fibers exhibit significant in-plane buckling, and the network loses its ordered morphology. However, regardless of the morphing mode, the networks exhibit memory and return to their originally ordered, as spun, configuration upon heating. Simulations of the morphing of the network using a mesh-of-springs model indicated that for mesoscale hydrogel fibers, the change in the mechanical properties during the swelling process can induce a transition between the two morphing modes as a function of the fiber diameter.
The morphing behavior exhibited for networks of mesoscale morphing fibers differs significantly from bulk systems and macroscale networks of similar compositions, and hence demonstrates a novel structure-and-function relationship, which was not exhibited in other 2D morphing systems. Such meshes may be used in novel applications, ranging from artificial micro-muscles to shape-morphing optical devices, and may provide insights into the morphing mechanisms of complex biological filament networks such as actin-myosin and microtubules networks.

SESSION SB02.12: Structure Property Relationships in Gels II

Pushing the Boundary of Thermally Responsive Hydrogel in Osmotic Processes via Materials Designs Nupur Gupta, Yen Nan Liang and Xiao Hu; Nanyang Technological University, Singapore, Singapore

Stimuli-responsive hydrogels forms an interesting class of crosslinked hydrophilic polymeric materials, capable of absorbing large amount of water without dissolving. Their physical properties can be easily tuned to different external stimulus such as heat, light, pressure, pH, ionic strength, etc., by careful selection of functional groups and proper molecular design. This has in turn rendered their tremendous potential use for a wide array of applications such as biosensing, actuation, smart electronics, sensing and as osmotic agents.

Our research group has demonstrated previously use of thermally responsive hydrogels as smart regenerable draw agents for quasi-continuous forward osmosis (FO) where the swelling pressure of hydrogel drives the water permeation across the semi-permeable membrane [1, 2]. Hence, it can easily overcome reverse solute diffusion, one of the major drawbacks using conventional draw solutes and provide direct water recovery by heating the hydrogel above its volume phase transition temperature. High water recovery using N-isopropylacrylamide based hydrogels has gained special attention as its hydrophilicity can be tuned at physiological temperature i.e., 32 °C. On heating above this temperature, the change in the polymer solvent interaction results in conformational change of the polymer resulting in water release. However, its slow response and low absorption capacity has left them obscure to be used as draw agents.

To overcome the low absorption capacity and enhance the water release kinetics semi-IPN architecture of the hydrogel was previously proposed by our research group. By dispersing a hydrophilic polyelectrolyte, like poly sodium acrylate (PSA), within the PNIPAM network not only the water absorption capacity of the hydrogel can be improved but also fast water release was also observed. Yet only low water flux was achievable using the above system when used for FO. Although semi-IPN hydrogel is widely studied, yet there is no systematic study done regarding retention of polyelectrolyte within the gel network. Based on our recent work we have found that a number of factors play a critical role in defining the morphology of the semi-IPN hydrogel and also for enhanced retention of PSA in PNIPAM network[3]. Using a series of model PNIPAM/PSA semi-IPN hydrogel we not only determined the optimum synthesis conditions for higher retention of PSA within the PNIPAM network but also decoupled the swelling/deswelling kinetics from the measured swelling ratio. Using a lower polymerization temperature, more dense and homogenous structure is formed resulting in faster water uptake whereas higher polymerization temperature results in more porous fibrillar like structure with faster water release kinetics. By optimising the polymerization temperature, PSA concentration and Mw we were able to synthesize PNIPAM/PSA semi-IPN hydrogel with swelling ratio as high as 260 g/g with fast swelling kinetics. The ongoing work in this direction entails on tailoring compositional and morphological properties for enhancing interaction between hydrogel and membrane surface to improve the water flux and permeation.

Negatively Charged Hydrogel Microfibers for Three-Dimensional Cell Culture Scaffolds Sungrok Wang, Jongwon Lee, Sangwoo Lee and Myung-Han Yoon; Gwangju Institute of Science and Technology, Korea (the Republic of)

Polymeric microfibers have been utilized as porous scaffolds for various types of three-dimensional (3-D) cell cultures but there still exist practical issues

such as limited bioactivity, unfavorable mechanical stiffness, poor dimension controllability, etc. In this research, we developed water-soluble polymer(e.g., polyvinyl alcohol, hyaluronic acid and gelatin)-based negatively-charged hydrogel microfibers with enhanced bioactivity and adjustable mechanical properties. In order to increase dimensional controllability of hydrogel microfibers, we homogenized these microfibers and precipitated them by adding cationic polyelectrolyte, leading to the entangled hydrogel microfibrillar network with microscale porosity. Furthermore, because those fibers were made by combination with natural polymers, the hydrogel microfibrillar network was degradable by enzyme treatment (>95% by hydrolase such as collagenase or hyaluronidase). Also following the degree of crosslinking, the degradability and size of entangled hydrogel microfibrillar network were well modulated by controlling their composition and fiber diameters. Finally, we demonstrated that these colloidal hydrogel microfibers mixed with cells could be patterned by using a conventional 3D printer, suggesting that resultant hydrogel microfiber scaffolds are suitable for various types of 3-D cell cultures.

4:30 PM SB02.12.03
Late News: Ultra-Tough and Stiff Ionogels by *In Situ* Phase Separation Meixiang Wang and Michael Dickey; North Carolina State University, United States

Ionogels are compelling materials for energy storage devices, ionotronics, and actuators due to their excellent ionic conductivity, thermal and electrochemical stability and nonvolatility. However, most existing ionogels suffer from low strength and toughness. Here, we report a simple one-step method to achieve ultra-tough and stretchable ionogels by randomly copolymerizing two common monomers in ionic liquid. Copolymerization leads to a single covalent network with controllable polymer- and solvent-rich phases that form in situ due to the phase behavior of the polymer in ionic liquid. The polymer-rich phase forms hydrogen bonds that dissipate energy and thereby toughen the ionogel during extension, while the solvent-rich phase remains elastic to enable large strain. The copolymer ionogels composed of acrylamide and acrylic acid exhibit extraordinary mechanical properties, including fracture strength (12.6 MPa), fracture energy (~24 kJ m-2), and Young's modulus (46.5 MPa), setting new records among reported ionogels. The tough ionogels are highly stretchable (~600% strain) and possess good self-recovery, as well as excellent self-healing and shape-memory properties. This concept extends to other monomers and ionic liquids, which offers a promising and general way to tune microstructure in situ during one-step polymerization that solves the longstanding mechanical challenges in ionogels.

Controlled Delivery Technologies for Modulating the Immune System to Engineer Potent and Durable Vaccines Eric A. Appel; Stanford University, United States

Vaccines can take one of several forms, but those based on subunit antigens (representative subunits of the pathogen for which immunity is desired) offer the greatest safety profile and scalability, but generally elicit weaker and less durable immune responses. Failure to elicit a sufficiently strong response likely arises from inappropriate temporal control over antigen/adjuvant presentation and immune cell activation. Either short-term presentation of these signals, or misalignment of their presentation along different timelines, results in poor affinity maturation of antibodies and poor immune memory responses. When considering the iterative selection process occurring during somatic hypermutation and antibody affinity maturation in B lymphocytes, it is intuitive that prolonged lymphocyte activation and antigen exposure would lead to the generation of higher-affinity antibodies. Moreover, the immune system is highly spatially organized and so spatiotemporal control over vaccine exposure is crucial to potent and safe responses. In this work we will discuss novel technologies for improving the spatiotemporal presentation of vaccine components to the immune system. In particular we will describe an injectable hydrogel platform providing unique drug delivery capabilities for the long-term co-delivery of antigen and adjuvant in subunit vaccines and discuss the impact of prolonged vaccine delivery on humoral immune responses. We demonstrate that prolonged hydrogel-based immunizations greatly enhance the magnitude and duration of antibody responses, enhance and prolong germinal responses, and lead to 1000-fold enhancement in antibody affinity maturation when compared to the same vaccine delivered in bolus. These advanced materials technologies, therefore, have the potential to provide

vastly superior vaccine performance through the precise and sustained delivery of subunit vaccines that take advantage of natural immune mechanisms for building long-lasting and potent immunity.

11:00 AM SB03.01.02
Delivering an Antibody Against SARS-CoV-2 from a Subcutaneous Supramolecular Hydrogel Depot Catherine Meis and Eric A. Appel; Stanford University, United States

Supramolecular hydrogels are promising materials to address challenges associated with the formulation of biotherapeutic drugs, such as antibodies, which often suffer from a lack of stability in formulation and poor pharmacokinetics. To address these challenges, we have developed an injectable polymeric materials platform to encapsulate and deliver macromolecular drug cargo. Our modular, tunable supramolecular hydrogel system is comprised of a polymer matrix that is physically cross-linked by polymeric nanoparticles, resulting in a material which exhibits shear-thinning and self-healing properties, both desirable characteristics for an injectable drug delivery vehicle. In vitro drug release assays and diffusion measurements indicate that our materials dramatically prolong the release of antibodies and improve formulation stability under severe stressed aging conditions. To investigate the performance of these materials in vivo, antibodies against SARS-CoV-2 were delivered in mice to assess the pharmacokinetics of an antibody delivered in our hydrogel compared to standard routes of administration. In addition, a model was implemented to further understand how the materials design impacts the ability of the hydrogel to modulate pharmacokinetics in vivo, enabling customization of the hydrogel properties to achieve the target pharmacokinetic profile based on properties of both the hydrogel formulation and the specific antibody drug. The model will help inform future materials design efforts to generate long-acting antibody-based drug products for a variety of important therapeutic applications.

Therapeutic Targeting of lncRNAs for Cancer Therapy Jan M. Hoelzl[1,2] and Ralph Weissleder[1,3]; [1]Massachusetts General Hospital Research Institute, United States; [2]Heidelberg University Medical Center, Germany; [3]Harvard Medical School, United States

Long non-coding RNAs (lncRNAs) are emerging as a new player in the field of cancer research. They show tissue -and sometimes even cell-specific expression and have potential in therapeutic and diagnostic settings. Whilst research in this area is still in its early stages, promising lncRNA candidates have been identified. Therapeutically, the most widely used approach is to silence cancer-associated lncRNAs with RNAse H competent antisense oligonuclotides (ASOs). While this approach is promising, in vivo ASO delivery to tumors remains a hurdle. Different advances in nano compositions of lipid nanoparticles (LNPs), lipoplexes and exosomes offer some possibilities to maximize tumoral and minimize hepatic delivery. Here, I will present on the role that these nanotechnologies, specifically LNPs, could play in the development of novel ASO-based cancer therapeutics and will also discuss remaining problems with this approach and next steps that have to be taken in order to move such novel drugs towards the clinic. I will also explore possibly targetable lncRNAs associated with different cancers. It is expected that collaborative efforts in nanotechnology and cancer biology may lead to therapeutic platforms that could usher in a new era of therapeutics.

11:30 AM SB03.01.04
Late News: Development of a Polymer-Lipid Core-Shell Nanoparticle for Improved Drug Loading and Layer-by-Layer Functionalization Emily Han[1], Joelle L. Straehla[1,2] and Paula Hammond[1,1]; [1]Massachusetts Institute of Technology, United States; [2]Dana-Farber/Boston Children's Cancer and Blood Disorders Center, United States

Introduction: Efficient encapsulation of therapeutic agents is a key factor when designing a nanoparticle (NP) drug delivery platform. For some hydrophobic small molecules, encapsulation within polymer-lipid core-shell NPs is more efficient than polymer- or lipid-based NPs. Most well-studied core-shell formulations incorporate poly(ethylene glycol) (PEG) as a stealth molecule to extend circulation time, but there are disadvantages to PEG as well, including limited uptake into cancer cells and the potential for allergic reactions. In addition, surface PEG limits the ability to perform layer-by-layer (LbL) functionalization.
Objectives: We sought to develop a stable core-shell NP without PEG that can efficiently load hydrophobic drugs and serve as a biocompatible anionic substrate for layer-by-layer (LbL) functionalization. LbL assembly involves the iterative adsorption of oppositely charged polyelectrolytes onto charged NP cores in a simple and scalable water-based system. LbL NPs have key advantages including preserving the biological activity of therapeutic agents, controlling drug release behavior, and adding functional targeting groups to the surface. Here we report a new polymer-lipid core-shell NP formulation with a poly(lactic-co-glycolic acid) (PLGA) core and a lipid shell, with the eventual goal of loading a class of poorly soluble small molecule inhibitors for a targeted cancer application.
Methods: We first tested a suite of lipids with anionic head groups for solubility in water-miscible organic solvents to maintain compatibility with the nanoprecipitation method. Next, lead lipid candidates were combined with soy lecithin in the aqueous phase, and a panel of core-shell NPs were formed via nanoprecipitation with 50:50 esterified PLGA in the organic phase (protocol adapted from Chan et al. Biomaterials, 30, (2009), 1627). NPs were characterized for dynamic light scattering size, polydispersity, and zeta potential. Transmission electron microscope (TEM) imaging was used to investigate NP morphology. Finally, lead formulations were used as core templates for layering, with cationic poly-L-arginine (PLR) as the first layer and anionic poly-L-aspartic acid (PLD) as the terminal layer.
Results: We identified two lipids with anionic head groups that were soluble in ethanol, 1,2-dipalmitoyl-sn-glycero-3-phospho-(1'-rac-glycerol) (16:0 PG) and 1-palmitoyl-2-oleoyl-sn-glycero-3-phospho-(1'-rac-glycerol) (16:0-18:1 PG), making them ideal for the nanoprecipitation method. They had higher solubility than analogously structured phosphoethanolamine (PE)-based lipids, likely due to the PG head group bearing more negative charge. Incorporating 16:0 PG and 16:0-18:1 PG with soy lecithin at a molar ratio of 3:7, we were able to form NPs with favorable properties for drug delivery. The z-averaged diameter, number mean diameter, and zeta potential of the formulations are as follows: 186 nm, 130 nm, -53 mV (16:0 PG formulation); 175 nm, 117 nm, -61 mV (16:0-18:1 PG formulation); 157 nm, 89 nm, -52 mV (1,2-Distearoyl-sn-glycero-3-phosphoethanolamine-Poly(ethylene glycol) (DSPE-PEG) control). 16:0-18:1 PG was chosen as the lead candidate after dry-state TEM imaging confirmed the core-shell structure. This formulation also formed stable LbL NPs, with surface charge reversal after layering with PLR (63 mV) and PLD (-56 mV).
Discussion: Our data suggests that polymer-lipid core-shell nanoparticles without PEG are a promising formulation to improve hydrophobic drug loading, avoid clinical disadvantages of PEG, and take advantage of the layering capabilities of LbL technology. Ongoing work with this formulation includes drug loading, release characterization, and the generation of an expanded LbL NP library with functionalization for specific cancer applications.

11:45 AM SB03.01.05
Multimodal Nanotracking for Exosome-Based Therapy in DMD Valeria Secchi[1], Chiara Villa[2], Yvan Torrente[2] and Angelo Monguzzi[1]; [1]University of Milano-Bicocca, Italy; [2]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Italy

Duchenne Muscular Dystrophy (DMD) is one of the most common forms of muscular dystrophy caused by mutations in the dystrophin gene that result in absent or insufficient functional dystrophin, a cytoskeletal protein that enables the strength, stability, and functionality of myofibres. Progressive muscular damage and degeneration occurs in people with DMD, resulting in muscular weakness, associated motor delays, loss of ambulation, respiratory impairment, and cardiomyopathy. Up to now there is no cure for DMD.

Recently, promising outcomes are revealed from the therapeutic use of exosomes: small extracellular vesicles secreted by cells and found in body fluids. Exosomes can be seen as exciting biological carriers, thanks to their ability to traverse biological barriers, to transport functional RNAs between cells and to be better tolerated by the immune system. They can be considered as surrogate for cell-based therapy with a stronger safety, for their well-documented active therapeutic role.
In this context, our aim is the development of a stable, therapeutic, tissue-specific exosome-based approach in the field of DMD, supported by the use of advanced multimodal probes, in order to track and specifically direct the exosomes to dystrophic muscles. For this reason, we combined fluorescent, labeling and ferromagnetic functionalities on single nano-object through self-assembly interactions to obtain a multimodal probe for high contrast non-invasive in vitro imaging and efficient in vivo tracking of exosomes in dystrophic mice. The multimodal probe is made of inert and biocompatible chrysotile nanotubes (NTs). The positive surface potential of NTs could be exploited for anchoring anionic species, exosomes included, in aqueous environment, following an ionic self-assembly scheme. A magnetic functionality is introduced through the interaction of NTs with anionic functional groups of the TAU capping ligand of ferrite magnetic nanoparticles (MAG NPs). Moreover, the fluorescent functionality is introduced by a red emitting chromophore. Side-by-side fluorescence imaging and magnetic resonance (MRI) experiments have confirmed the effectiveness of fluormagnetic Nanotubes as multimodal contrast agents.
In particular, the strong ferromagnetic properties of these probes will enable the driving of regenerative exosomes under high magnetic field by a clinically applicable permanent magnet, for a specific targeted in vivo delivery towards interested tissue. The possibility to specifically direct exosomes to dystrophic muscle will allow the development of a controlled release of sufficient exosome amount at disease target site for a clinical outlook of personalized highly efficient and safe nanomedicine.

1:30 PM *SB03.02.01
Coupling Pro-Apoptotic TRAIL Factor to Superparamagnetic Iron Oxide Nanoparticles to Build Efficient Nanohybrid Drugs for Cancer Therapy Hanene Belkahla[1,2,2], Andrei Alexandru Constantinescu[2], Tijani Gharbi[2], Florent Barbaut[1], Miryana Hemadi[1] and Souad Ammar[1]; [1]Universite de Paris, France; [2]Université Bourgogne Franche-Comté, France

TRAIL (Tumor Necrosis Factor-related apoptosis-inducing ligand), a cytokine belonging to the TNF superfamily, attracted major interest in oncology owing to its selective antitumor properties [1]. Therapeutic clinical trials using soluble TRAIL or antibodies targeting the two main agonist receptors (TRAIL-R1 and TRAIL-R2) have, however, failed to demonstrate their efficacy [2]. Attempts to increase its antitumor activity include, amongst others, its functionalization by nanoparticles [3], particularly magnetic nanoparticles (MNPs). Such carriers allow concentrating TRAIL [4] which can be driven to a defined target site by local application of an external DC-magnetic field. They also offer the possibility of monitoring TRAIL delivery by magnetic resonance imaging (MRI) and the possibility to increase antitumor TRAIL functionality by magnetic hyperthermia [5]. Magnetic iron oxide MNPs, magnetite and maghemite, have the right magnetic properties [6] and exhibit relatively low toxicity [7]. For this reason, they were specifically produced with different average sizes, i.e. 10 and 100 nm (magnetic single core versus magnetic multicore) [4], and were attached to TRAIL through peptide coupling, engaging respectively carboxylic or amino protein group to evaluate both the effect of their size and their chemical bounding on TRAIL antitumoral activity on malignant mammal cells. They were also subsequently submitted to an external AC-magnetic field to confirm their capability to eradicate residual TRAIL resistant tumoral cells through local heating [5]. Clearly, the properties of TRAIL and the multimodal characteristics of MNPs hold great promise for the treatment of cancer and pave the way for the generation of new and efficient drugs.

2:00 PM SB03.02.02
Design of Luminescence and Surface Chemistry of Hafnia Nanoparticles for Biological Applications Xavier H. Guichard and Alessandro Lauria; ETH Zurich, Switzerland

Luminescent materials are used in a variety of applications, from lighting and display technologies to scintillators for high-energy radiation detection. [1] A particular interest has grown towards nanoscale phosphors, proposed also for innovative bio-imaging excited by infrared radiation or photosensitizers for cancer self-lighting photodynamic therapy. [2]
The employment of nanoparticles in these applications relies on the ability to tailor their photo-physics, which is based on the control over structural features like their size, composition and crystal symmetry able to impact their optical properties. Moreover, to be suitable for specific applications, the surface chemistry of these materials must be adapted to provide homogeneous stable dispersions/inks and thus facilitate handling and deposition, as well as efficient cellular uptake.
Colloidal nanocrystals of HfO_2 can be synthesized from molecular precursors by a solvothermal route, where both fluorescence and structural control can be achieved thanks to the multifunctional role of rare earth (RE) doping. [3] While RE dopant ions activate the visible luminescence of nanocrystals, at the same time, their incorporation can also stabilise the cubic polymorph of HfO_2 at room temperature. Such a structural change can significantly affect the optical quality of sintered polycrystalline scintillator ceramics as well as the performance of RE-based upconversion. In addition, the native surface chemistry of such nanoparticles allows their further adaptation to either organic solvents or, alternatively, to aqueous biological environments, enabling cellular uptake and making them suitable as non-toxic probes for optical imaging, and possibly therapy. [4]
In this talk the control over the structure/function relationship in HfO_2 doped nanoparticles is discussed, together with its implications towards and

functional inks for innovative deposition/assembly of nanoparticle based optical materials as well as for advanced bio-imaging.

Modulating Neuronal Signaling with Magnetic Nanotransducers Polina Anikeeva; Massachusetts Institute of Technology, United States

The mammalian nervous system spans spatial scales from centimeters to nanometers, and functions at time scales from microseconds to decades. To access this spatiotemporal complexity, we envision tools capable of modulating individual receptors at the nanoscale in behaving organisms at the macroscale. Weak magnetic fields offer unprecedented access to the arbitrary locations within the body due to the low conductivity and negligible magnetic permeability of biological matter. To convert weak magnetic fields into biological signals, we design and synthesize a range of nanotransducers. Based on their composition and geometry, these nanotransducers can be tailored to dissipate heat or apply force or torque. We leverage magnetothermal and magnetomechanical transduction mechanisms to enable wireless remote control of a variety of receptors in neurons and thus modulate animal behavior and physiology.

Development of Colloidal Magnetic Nanoparticles with Strong Liquid-Phase AC Field Response for Remote Thermometry and Sensing Applications Adam Biacchi, Thinh Bui, Eduardo Correa, Cindi Dennis, Solomon Woods and Angela Hight Walker; National Institute of Standards and Technology, United States

Colloidal magnetic nanoparticles (MNPs) are an important class of nanomaterials being investigated for use in a host of therapeutic and diagnostic modalities such as medical imaging, remote sensing, drug delivery, and hyperthermia. These applications exploit the very soft magnetic behavior found in certain materials, often ferrites, when they are confined in size to tens of nanometers in diameter or less. Such nanoscale magnets produce a strong collective response to applied alternating (AC) magnetic fields, while simultaneously remaining dispersed in heterophasic liquid media. Further, the synthesis of these magnetic colloids employs inexpensive, scalable, highly tailorable solution chemistry routes that both allow fine control of their properties and afford a practical route to commercialization.

Recently, we have been developing remote magnetic thermal imaging as a potential diagnostic application of colloidal MNPs. This measurement will employ dispersed particles to construct a 3D visual representation of temperature throughout a volume. The technique is based on the temperature-dependent collective response of MNPs to applied AC magnetic fields coupled with simultaneously applied DC fields to afford spatial control over the region in which the measurement is conducted. However, significant challenges remain in the development of this metrology, including a need to increase both the MNPs' magnetic thermosensitivity and magnitude of AC field response.

Here, we report on our development of MNPs with a robust liquid-phase response to applied AC magnetic fields, specifically for solution-phase remote thermometry and other sensing applications. First, a series of colloidal nanocrystals based on ferrites were synthesized *via* solution routes in a variety of sizes and compositions. These MNPs were then systematically investigated using liquid-phase AC and DC field magnetometry measurements. An arbitrary-wave magnetic particle spectrometer was employed to measure magnetic AC susceptibility, allowing for a rigorous analysis of the temperature- and frequency-dependent AC response from 1 Hz to 30 MHz. These results were cross-correlated with detailed structural characterization, including electron microscopy, optical spectroscopy, and X-ray/electron diffraction, which underpins the inherent magnetic properties of the particles.

We find the relaxation dynamics in solution are strongly dictated by the structural and compositional properties of the MNPs. Specifically, particle size and compositional doping act as levers to optimize the liquid-phase AC response through the manipulation of interparticle and intraparticle magnetic spin interactions. Using these guidelines, we find the set of structural parameters that produce the most robust thermosensitive magnetic response. Collectively, these studies illuminate the complex behavior of MNPs under AC driving fields, reveal extensive correlations between nanoscale atomic structure and their liquid-phase magnetic response, and provide guidelines for the design of MNPs used in magnetic thermal imaging and other remote sensing applications.

3:00 PM SB03.02.07
Magnetic Silica-Coated Particles with Enhanced Brightness (MagSiGlow) Isabel Gessner[1,2], Elias A. Halabi Rosillo[1,2,3], Katherine S. Yang[1,2] and Ralph Weissleder[1,2]; [1]Massachusetts General Hospital, United States; [2]Harvard Medical School, United States; [3]Swiss National Science Foundation, Switzerland

Magnetic nanoparticles are extremely useful tools for purifying biological targets in complex mixtures. Magnetofluorescent nanoparticles have additional benefits allowing for sensing and multiplexing. Although the chemical coupling of conventional organic dyes to silicon dioxide shells is straightforward, densely packing can lead to quenching and non-radiative decay pathways. These unwanted side effects, significantly reduce the overall brightness of a given particle. To circumvent this issue, we implement a new method to sparsely distribute dye labeling on multiple coating layers, yielding distinctively bright magnetic silica-coated fluorescent particles, which we termed MagSiGlow. In this study, we describe the design and synthesis of MagSiGlow particles using novel and commercially available fluorophores detectable in different color channels. Additionally, we discuss experiments where implementing MagSiGlow particles facilitates detection of extracellular vesicles and visualization of living cells using flow cytometer and confocal microscopy.

3:45 PM SB03.02.08
Opto-Thermo-Electrohydrodynamic Tweezers (OTET) for On-Chip Trapping and Analysis of Single Extracellular Vesicles Justus C. Ndukaife, Chuchuan Hong and Sen Yang; Vanderbilt University, United States

The year 2018 Nobel Prize in Physics was awarded for Optical Tweezers and their application in biological systems. Optical tweezers have emerged as a powerful tool for the non-invasive trapping and manipulation of colloidal particles and biological cells. However, the stable trapping of nanometer-scale biological objects such as proteins, small extracellular vesicles, and virions has been met with challenges due to the diffraction limit of light. Significantly increasing the laser power can provide sufficient trapping potential depth to trap nanoscale objects. Unfortunately, the significant optical intensity required predisposes the trapped biological specimens to photo-toxicity and thermal stress. I will discuss a new paradigm for optically controlled nanotweezers termed Opto-Thermo-Electrohydrodynamic Tweezers (OTET) that enables the stable trapping and dynamic manipulation of nanoscale biological objects such as EVs with negligible photothermal heating and light intensity. The OTET platform employs a finite array of plasmonic nanoholes illuminated with light in conjunction with an applied a.c. electric field to create the spatially varying electrohydrodynamic potential that can rapidly trap single nanoscale

EVs on-demand. I will also discuss potential translational biomedical applications of this new technology for early cancer detection via EV-based liquid biopsy. This novel non-invasive optical nanotweezer is expected to open new horizons in life science and medicine by offering an unprecedented level of control of tiny nano-sized biological objects in solution without photo-induced damage.

Carbon Nanotubes Based Hydrogels for Transdermal Drug Delivery Juliette Simon[1,2,3], Georgios Kougkolos[1,2,4], Bastien Jouanmiqueou[3], Muriel Golzio[3], Emmanuel Flahaut[2,1] and Zarel Valdez-Nava[4,1]; [1]University of Paul Sabatier, France; [2]CNRS / CIRIMAT, France; [3]CNRS / IPBS, France; [4]CNRS / LAPLACE, France

Large molecules such as insulin are too big to be able to cross the skin and reach the blood flow through passive diffusion, unlike smaller molecules such as nicotine for example. Needles are thus usually required to cross this natural barrier. In order to improve the life quality of patients using regular hypodermal injections, alternative delivery methods are needed. Carbon-based nanoparticles, free or associated with a polymer matrix, are increasingly used in innovative biomedical applications [1]. We are developping a non-invasive transdermal delivery route, using a two-in-one nanocomposite device and the reversible permeabilisation of the skin, thanks to electroporation. The device is a nanocomposite with a biocompatible hydrogel matrix containing carbon nanotubes (CNTs), which combines both purposes of assisting the permeabilisation and storing the molecule to be delivered. The inclusion of CNTs in the hydrogel matrix is also intended to prevent their release during operation of the device, with a safe(r) by design strategy in mind. Previous work from our group described an enhanced drug delivery of dextran FITC through permeabilised skin for devices containing CNTs [2]. Later, the electrical characterisation of those devices was performed [3]. However, although the proof of concept was validated, such devices are still far from practical applications and the optimisation of electroporation parameters, depending on the intended use, is still in progress. We will describe and discuss our most recent advances.

Injectable Nanoparticle-Based Hydrogels Improve the Safety and Efficacy of Potent Immunostimulatory CD40 Agonist Antibodies Santiago Correa, Juliana Idoyaga and Eric A. Appel; Stanford University, United States

When properly deployed, the immune system can render deadly pathogens harmless, eradicate even metastatic cancers, and provide long-lasting protection from diverse diseases. However, realizing these remarkable capabilities is inherently risky, as disruption to immune homeostasis can lead to dangerous complications and autoimmune disorders. While current research is continuously expanding the arsenal of potent immunotherapeutics, there is a technological gap when it comes to controlling when, where, and how long these drugs act on the body. We previously described a polymer-nanoparticle (PNP) based hydrogel that is biocompatible, long lasting, and injectable[1, 2], traits that we hypothesized would improve controlled local delivery of immunotherapy.

To test this hypothesis, we explored PNP hydrogel-mediated delivery of CD40 agonist antibody (aCD40), a potent immunostimulant that has been shown to improve outcomes in combination immunotherapy, but poses considerable dose-limiting toxicity.[3] PNP hydrogels were formed by mixing CD40 agonist antibody (CD40a), dodecyl-modified hydroxymethylcellulose (HPMC-C_{12}), and poly(ethylene glycol)-b-poly(lactic acid) nanoparticles (PEG-PLA NPs) to generate gels with 2 wt% HPMC-C_{12}, 10 wt% PEG-PLA NPs, and the desired dose of CD40a (ranging from 10-100 mg). HPMC-C_{12} and PEG-PLA NPs were prepared as described previously[1].

Using positron emission tomography (PET) imaging, we quantitatively tracked how delivery strategy (e.g., hydrogel vs. local bolus) shaped aCD40 pharmacokinetics over the course of 12 days. PET studies demonstrated that hydrogels substantively altered antibody pharmacokinetics to favor drug exposure in target tissues. Our data indicate that hydrogels increased exposure at the injection site by 96 ± 13% (q = 4 x 10-6) and at the tumor draining lymph node by 35 ± 19% (q = 5 x 10^{-3}) over the course of the 12-day study. Locoregional hydrogel delivery also circumvented dose-limiting toxicity commonly associated with aCD40 therapy (*e.g.*, acute weight loss and hepatotoxicity). Using Luminex multiplexed cytokine assays, we also evaluated how delivery strategy shaped the induction of effector cytokines in systemic circulation and in tumor draining lymph nodes. We found that hydrogels substantively attenuated the induction of systemic cytokines, particularly across a number of pro-inflammatory cytokines (IFNy, TNFa, IL6, and IL1b) commonly associated with cytokine storm syndrome, another common side effect of aCD40 therapy. Despite reducing cytokine levels systemically, hydrogel delivery generated a more potent immune response, as measured by effector cytokine (IFNy, CXCL10) levels within tumor-draining lymph nodes (TdLN). Correspondingly, hydrogel-mediated locoregional aCD40 therapy was more tolerable and effective than even locoregional bolus injections, and synergized with PD-L1 blockade (40% survivors in combo-therapy arms vs. 0% survivors in monotherapy arms, n=10, p_{adj}<0.03).

Overall, this study provides compelling evidence that PNP hydrogels can improve aCD40 pharmacokinetics and pharmacodynamics, leading to greater tolerability and therapeutic efficacy in the B16F10 model of melanoma. Notably, PNP hydrogels mediated these effects without the need to modify their cargo in any way. Therefore, we anticipate that this approach may also improve the safety of other potent immunostimulants, and is thus a highly translatable solution to the problem of immune-related adverse effects.

Enzyme-Triggered Depolymerization of Polymeric Micelles for Targeted Anticancer Therapy Jaehyun Park, Seokhee Jo, Junseok Lee and Won Jong Kim; Pohang University of Science and Technology, Korea (the Republic of)

The high activity of specific enzymes in cancer has been utilized as tumor-specific trigger for anticancer drug delivery. NAD(P)H:quinone oxidoreductase-1 (NQO1), an overexpressed enzyme in certain tumor types, maintains homeostasis and inhibits oxidative stress caused by elevated reactive oxygen species (ROS) in tumor cells. The activity of NQO1 in certain types of cancer cells is increased compared to that in normal cells. Interestingly, NQO1 catalyze the reaction of trimethyl-locked quinone propionic acid (QPA) to a lactone-based group via intramolecular cyclization. Toward this objective, we synthesized amphiphilic block copolymer (QPA-P) composed of QPA-locked polycaprolactone (PCL) as a hydrophobic block and poly(ethylene glycol) (PEG) as a hydrophilic block. This polymer formed a self-assembled micelle via hydrophobic interaction. QPA-locked PCL block was depolymerized by NQO1 via a cascade two-step cyclization process, which eventually mediated the disassembly of micelle and released anticancer drugs at the target cancer cells. The micelles showed NQO1-responsive intracellular drug release and enhanced anticancer effects in vivo. These results indicate that enzyme-responsive depolymerization process could be a promising strategy for improving therapeutic efficacy of polymer-based anticancer drug delivery carrier.

SESSION SB03.04: Transformative Nanostructures with Therapeutic and Diagnostic Modalities IV
Session Chairs: Souad Ammar and Eric Appel
Wednesday Afternoon, December 1, 2021
Sheraton, 2nd Floor, Independence East

1:30 PM SB03.04.02
H_2O_2 Detection with Silver-Platinum Core-Shell Nanowires Serkan Koylan[1], Sensu Tunca[1], Gokhan Polat[2], Mete Batuhan Durukan[1,1], Dongkwan Kim[3], Yunus E. Kalay[1], Seung H. Ko[3] and Husnu E. Unalan[1,1,1]; [1]Middle East Technical University, Turkey; [2]Necmettin Erbakan University, Turkey; [3]Seoul National University, Korea (the Republic of)

Detection of hydrogen peroxide (H_2O_2) possess an essential role in both analysis and applications (chemical synthesis, cosmetics, biology, medicine, food, paper and textile industries) in bioelectronics. Electrochemical detection of H_2O_2 seems to be the highly promising due to its simplicity, fast response and low cost. Enzyme-free electrochemical sensors were demonstrated utilizing metal nanostructures, particularly silver (Ag) based nanostructures, for the detection of H_2O_2. Oxidation tendency of Ag together with its degradation in the presence of H_2O_2 necessitates use of a protective coating for Ag based amperometric sensors. In this work, a platinum (Pt) shell layer was deposited onto Ag NWs to improve the oxidation stability so then they can be used for the detection of H_2O_2. Ag-Pt core-shell NW electrodes were used for the detection of H_2O_2 with different concentrations (10, 50, 100 mM) at an applied potential of +0.8 V (vs. Ag/AgCl). The fabricated Ag-Pt core-shell NWs electrode showed a high sensitivity of 0.04 μA/μM over a wide linear range of concentrations (16.6 - 990.1 μM) with a low detection limit (10.95 μM). the regression equation was determined as $I\ (\mu A) = 1.61 + 0.04 \times [H_2O_2]/\mu M$ with a correlation coefficient R^2 of 0.9947. Using the 90% initial step change in the current, the response time of the sensor was 4.74 seconds. Fabricated sensors gave response only to H_2O_2 which proved interference selectivity. A simple and highly reproducible method for the fabrication of H_2O_2 sensors with highly repeatable response was demonstrated, which can be further expanded to other bioelectronics applications requiring electrochemical stability.

This work was supported by the Scientific and Technological Research Council of Turkey (TUBITAK) under grant no 117E539.

1:45 PM SB03.04.03
Probing Peptide Conformation on Carbon Nanotube for Volatile Organic Compound Sensors Daniel Sim[1,2], Zhifeng Kuang[1], Nicholas Bedford[3], Jorge L. Chávez[1], Jennifer A. Martin[1], Ahmad Islam[1], Benji Maruyama[1], Rajesh Naik[1] and Steve S. Kim[1]; [1]Air Force Research Laboratory, United States; [2]UES, Inc., United States; [3]University of New South Wales, Australia

Ubiquitous, autonomous, and real-time chemical sensing can provide abundant information related to the warfighter health and performance status. For example, volatile organic compounds (VOCs) found in exhaled breath are critical biomarkers for assessing human health and physiological status. Biorecognition elements (BREs) are biological materials exhibiting specific affinity to the target molecules. Short peptides (generally composed of 5-15 amino acid residuals) are promising BREs for selective VOC detection. They provide chemical stability and design flexibility to sensing the targeted biomarker. Peptide BRE-coated CNT chemiresistor has emerged as a miniaturized sensor platform for wearable applications. Previous peptide-functionalized CNT gas sensors have shown detecting explosives and bacterial food contamination byproducts. However, the peptide sensing mechanism of a peptide-CNT pair is yet unclear. We presumed that the conformation of the peptide on the CNT surface affects the molecular accessibility to the BRE-CNT interface. Here, we present a peptide conformation model to investigate peptides' affinity towards VOC on a CNT chemiresistor platform. This model predicts the conformation of the peptide on the CNT surface using peptide-CNT interaction energy obtained from a molecular dynamics simulation. A near-edge X-ray absorption fine structure (NEXAFS) spectroscopy experimentally validates the peptide conformation model by observing the peptide alignment to the CNT. Then, a peptide-functionalized CNT chemiresistor was tested to various gases to investigate how the conformation affects VOC sensing. The result shows that the vertically oriented peptide on the CNT surface hinders VOC access to the peptide-CNT interface, resulting in a significantly low sensor signal than the CNT chemiresistor with the horizontally oriented peptide. Our results strongly indicate that molecular accessibility is a key factor detrimental to the VOC sensing from peptide-CNT devices. This finding is crucial for designing the peptide sequence specific to target VOC, and ultimately, developing sensitive CNT-based VOC sensors.

Late News: Biomimetically Self-Assembled DNA—Inorganic Hybrid Nanoarchitectures for Quantitative Intracellular Aptasensing Nayoung Kim, Eunjung Kim, Hyemin Kim, Michael R. Thomas, Adrian Najer and Molly Stevens; Imperial College London, United Kingdom

Aptamers, nucleic acid analogs of antibodies, have shown promise in molecular diagnostics capitalizing on their programmable nature and high affinity/selectivity towards cognate ligands. Despite the breadth of biomolecular targets ranging from biofluid biomarkers to cellular analytes, a biologically deliverable aptasensor that enables to accurately monitor endogenous biomolecular abundance still remains elusive. DNA nanoassembly

aptasensors built from short staple DNA stands have shown particular success based on their precise Förster resonance energy transfer (FRET)-based operations; nonetheless, challenges are often associated with relatively low structural stability, its labor-/time-intensive fabrication, and the complex sensor operations that limit the design generalizability and necessitate computational modeling. Here, we present high-throughput biomimetic crystallization-driven DNA self-assembly as a route to tackle the challenges and produce a highly programmable and agile intracellular ratiometric aptasensor.[1] The probes are formulated by rolling circle amplification (RCA), whereby multifunctional elements-encoded polymeric DNA strands are enzymatically produced and self-compacted into DNA–inorganic hybrid nanoarchitectures. Harnessing the programmability of RCA template, the obtained DNA nanoparticles are intrinsically encoded with three functional features: 1) Tumor targetability using cell-targeting aptamer, 2) Ratiometric aptasensing of cellular analytes empowered by a tripartite duplexed aptasensor and 3) Synergistic assistance of cellular internalization by cholesterol decoration. The resultant probes possess biocompatibility, structural integrity and sequence-driven multifunctionalities which can be readily customized using the template without the need of computational modeling or any modification of fabrication procedures. Taking LNCaP human prostate adenocarcinoma cells and intracellular adenosine triphosphate as an exemplar target system, we illustrate the targeted delivery of our probe and subsequent ratiometric signaling triggered by intracellular target analyte recognition events. The limitations often associated with intensiometric-signaling intracellular probes are elegantly leveraged by our approach, where the quantitative detection is demonstrated with drug-treated cells and corresponding ratiometric FRET signal changes from internalized aptasensors. To the best of our knowledge, this represents the first demonstration of harnessing biomimetic crystallization to construct a DNA nanosensor that is capable of target-responsive biomolecular detection within intracellular environments. We envision that the proposed probe has substantial promise as a biologically deliverable probe that can be readily tailored across wide-ranging target systems, being capable of the quantitative monitoring of biomolecular profiles.

PDMS Composites with Photostable NIR Dyes for Multi-Modal Ultrasound Imaging and Optical Ablation India Lewis-Thompson, Shaoyan Zhang and Richard J. Colchester; University College London, United Kingdom

All-optical ultrasound imaging has emerged as an imaging paradigm well-suited for minimally invasive surgical procedures. With this modality, ultrasound is generated when pulsed or modulated light is absorbed within a coating material. The ensuing heat rise causes a corresponding pressure rise which propagates as ultrasound. Using optic fibres to deliver light for ultrasound generation and reception allows complementary therapeutic and imaging modalities to be integrated to create highly miniaturised devices. One area of interest for these devices is combined imaging and optical ablation, to provide real-time monitoring of ablation lesion depth. However, combining modalities requires carefully engineered composite materials with wavelength-selective absorption. Previous research has demonstrated the use of gold nanoparticles and crystal violet dye for co-registered ultrasound and photoacoustic imaging [1]. However, these materials were limited by material degradation with prolonged exposure and limited ultrasound pressures and bandwidths.

We present the optimisation of a nanocomposite material that comprises a near infrared absorbing dye in a polydimethylsiloxane (PDMS) host on the distal tip of optical fibres. The optical absorption of this composite has a pronounced peak at 1064 nm, allowing the absorption of laser light for ultrasound generation. Optical transmission through the composite was low for wavelengths below 900 nm allowing for the transmission of laser light at 808 nm for tissue ablation. Crucially, the composite demonstrates a high photostability to laser exposure, allowing continuous ultrasound imaging for larger periods of time (several hours). Varying the dye concentration allows for strong optical absorption for ultrasound generation, whilst maintaining higher transmission at shorter wavelengths for complementary modalities.

Our studies demonstrate that ultrasound pressures in excess of 1 MPa can be generated, sufficient for M-mode imaging at centimetre scale depths and consistent with other ultrasound generating materials [1,2]. Further, the corresponding ultrasound bandwidths (25 MHz), will enable high resolution imaging. We have used this composite to provide ultrasound imaging for the monitoring laser ablation of tissue in real-time, allowing the tracking of lesion depth. By optimising the optical absorption of the composite, light delivery for laser ablation is possible through the same optical fibre used for ultrasound generation. This would allow for device miniaturisation and coaxially aligned imaging and tissue ablation.

Late News: Glutathione-Depleting Nanocomposites for Amplification of Oxidative Stress in Sonodynamic Therapy Wooram Um, Yeari Song and Jae Hyung Park; Sungkyunkwan University, Korea (the Republic of)

The upregulation of glutathione (GSH) in cancer contributes to the resistance of cancer cells against oxidative stress and apoptosis. Thus, it is considered a crucial barrier that inhibits the therapeutic efficacy of reactive oxygen species-mediated cancer therapy. Herein, we develop glutathione-depleting nanocomposites (dGSH-NC) for amplifying the oxidative stress in sonodynamic therapy of cancer. dGSH-NC is composed of titanium dioxide nanoparticles and manganese dioxide surface for providing ultrasound-responsive ROS generation and GSH depletion. Further, GSH reduces manganese dioxide to manganese(II) ion that induces additional intracellular ROS generation. In SCC7 cells, dGSH-NC remarkably inhibits GSH of SCC7 cells and produces reactive oxygen species to amplify the cellular oxidative stress. In the presence of ultrasound, dGSH-NC exhibited an improved cytotoxic effect than that of bare titanium dioxide nanoparticles, and exposed cells presented necrotic cell death features.

SB03.05.04
Late News: Impact of Surface Properties on Nanoprobe-Analyte Interaction Kaleigh M. Ryan, Ajita Nair, Zelin Wang, Yuxuan Wu, Lu Wang and Laura Fabris; Rutgers University, United States

Surface enhanced Raman spectroscopy (SERS) is gaining popularity as a diagnostic technique, due to its ability for multiplexed detection and ultra-high sensitivity. So far, in the majority of its clinical applications, it has relied on the use of nanoprobes for indirect detection. In general, the nanoprobe brightness decreases exponentially as the Raman reporter molecule moves away from the nanoparticle surface, and local enhancement factors can vary dramatically on specific locations of the nanoparticle due to the presence of "hot spots". In order to develop a SERS based diagnostic platform with maximum sensitivity and reliability, it is imperative to understand the orientation and binding behavior of the Raman reporter on the nanoparticle surface, as well as under what conditions its orientation may change. Herein, we investigate analyte orientation and interaction on the nanoparticle surface using two different nanostar morphologies, surfactant-free nanostars and 6-branched nanostars, and three different analytes, thiophenol, 4-aminothiophenol, and crystal violet. Nanoprobe-analyte interactions are characterized by Raman spectroscopy and nanostar morphologies by transmission electron microscopy (TEM). Molecular dynamics simulations were conducted to verify the changes in analyte-nanoprobe interaction. It was found that signal amplification provided by surfactant-free nanostars and 6-branched nanostars can follow dramatically different trends depending on the analyte molecular structure. Molecular orientation on the nanoprobe surface was demonstrated to vary with changing analyte concentration.

SB03.05.05
Drug Delivery via Surface Modified Scintillating Nanoparticles Jeremy M. Quintana[1,2], David Arboleda[1], Isabel Gessner[1,2], Miles Miller[1,2] and Ralph Weissleder[1,2]; [1]Massachusetts General Hospital, United States; [2]Harvard Medical School, United States

Antibody and nanoparticle mediated drug delivery to solid tumors can improve pharmacokinetics and dynamics of local payloads and decrease systemic toxicity. Despite these obvious advantages, there remains considerable room for improvement. We have previously shown that localized bursts of radiation can enhance local myeloid cell delivery and result in improved anti-tumor effects. To further enhance target specificity, we hypothesized that radiation induced drug release could represent a powerful complementary approach. Here, we developed scintillating yttrium oxide nanoparticles that emit UV light upon excitation with external X-ray irradiation, resulting in the release of attached UV-activatable prodrugs. Using Fourier-transform infrared spectroscopy, zeta potential and dynamic light scattering measurements, we have demonstrated and optimized the covalent modification of the nanoparticle surface with a prodrug. The release kinetics and total drug release were then observed by X-ray irradiation, followed by drug quantification using liquid chromatography. Likewise, the *in vitro* activation of the prodrugs has been demonstrated in culture, following X-ray irradiation. We show that these X-ray activatable nanoparticles efficiently release active cytotoxic agent with revise control due to the external radiation beam.

SB03.05.06
Anatase TiO_2-Coated Gold Nanobipyramids for Combinational Photothermal and Photodynamic Therapy Dohyub Jang[1,2], Subin Yu[3], Dong June Ahn[2], Sehoon Kim[1] and Dong Ha Kim[3]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Korea University, Korea (the Republic of); [3]Ewha Womans University, Korea (the Republic of)

Photodynamic therapy is increasingly being recognized as a non-invasive feature and local treatment. Especially, inorganic photocatalysts, such as titanium dioxide (TiO_2), are regarded alternative materials for organic photosensitizer due to their high photo-stability, biocompatibility and significant photocatalytic ability. However, inorganic photocatalysts have critical threshold in the absorption of low energy photons to introduce in cancer therapy owing to their large band gap.
Meanwhile, plasmonic noble metal-based nanomaterials has drawn important attraction in recent years due to their broadly tunable localized surface plasmon resonance properties derived from the collective oscillation of surface free electrons under incident light. According to recent studies, anisotropic gold nanomaterials with tunable aspect ratio can generate strong electric fields at their tips. Particularly, gold nanobipyramids possessing sharp-tip morphology induce much stronger electric fields against gold nanorods commonly used in photothermal therapy. With suitable biocompatibility, plasmonic gold nanomaterials were investigated for cancer treatment and became a promising candidate to redeem the limitations of TiO_2 in biomedical applications. Upon strategic coupling with TiO_2, LSPR-induced hot carriers of plasmonic Au nanomaterials are injected into the conduction band of TiO_2 over the Schottky barrier, which can be consumed for the reduction of oxygen.
Despite of these advantages, Au NBP is hard to utilized due to their low thermal stability. To date, the synthesis of Au/TiO_2 heterostructures with crystalline TiO_2 requiring annealing steps at high temperature after amorphous TiO_2 coating. In order to convert the amorphous phase of TiO_2 to anatase phase, high temperature treatment is necessary. However, sharp tip gold nanomaterials such as Au NBP lose their tip during annealing process. Therefore, undesirable morphological disruption is occurred during annealing step, leading to LSPR peak changes. Moreover, TiO_2 shell agglomeration could not be avoided. These leads to low photocatalytic effects during NIR laser irradiation.
Herein, we newly developed anatase TiO_2-decorated Au NBP (Au NBP/a-TiO_2) as a novel metal/semiconductor core/shell colloidal heterostructure for NIR-responsive phototherapy. This is the first time that introducing low temperature hydrothermal method to crystalline anatase TiO_2 onto Au NBP surface, while preserving a well-defined Au NBP/a-TiO_2 morphology with sharp-metal tips without any aggregation. Strategically, the highly energetic LSPR-derived hot electrons generated by incident NIR light were injected directly into the conduction band of the anatase TiO_2 nanoclusters, inducing the reduction of oxygen to superoxide and finally producing hydroxyl radical species. Simultaneously, the LSPR-induced photothermal effect was investigated for combinational photothermal and photodynamic cancer therapy. Our work emphasizes the facile and mild fabrication of anatase TiO_2 decorated anisotropic plasmonic nanostructures, while expanding the promise of novel NIR-responsive nanostructures with remarkably superior efficiency for synergistic photo-induced cancer treatments.

SB03.05.07
Plasmon-Triggered Upconversion Luminescence and Hot Carrier Injection in Novel Au NR@TiO_2@UCNP Nanostructures—Mechanism and Application in Photothermal and Photodynamic Cancer Therapy Subin Yu[1], Dohyub Jang[2], Hong Yuan[3], Wen-Tse Huang[3], Minju Kim[1], Filipe Marques Mota[1], Ru Shi Liu[3], Hyukjin Lee[1], Sehoon Kim[2] and Dong Ha Kim[1]; [1]Ewha Woman's University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of); [3]National Taiwan University, Taiwan

Lanthanide-doped upconversion nanoparticles (UCNP) have been attracted great attention with the unique ability to convert low-energy NIR radiation to high-energy UV-vis light in biomedical applications. UCNP additionally possesses unique properties, including good photostability with biological transparent excitation wavelength, tunable emission band, and low cytotoxicity. However, the UCNP showcases the intrinsic low quantum efficiency for practical applications as a result of insufficient absorption cross-section area and surface defects. To overcome this limitation, the incorporation of localized surface plasmon resonance (LSPR) has been suggested as a promising way. In this work, anatase titania-coated gold nanorods (Au NR@aTiO_2) were decorated with UCNP. aTiO_2 was integrated as a spacer between plasmonic Au NR and UCNP to avoid the quenching of UCL. Au NR and UCNP components showed characteristic absorbance in the NIR region, detailed characterization of the resulting core@shell nanostructures revealed enhanced UCNP-derived UV-vis emission due to the plasmonic properties of Au NR.[1] In presence of UCNP, the emitted UV light was proposed to excite the aTiO_2 semiconductor and play a key role in the generation of reactive oxygen species (ROS). In addition, emitted visible light from UCNP was re-absorbed

by Au NR which was well matched with the transverse absorption peak of Au NR to further generate the hot carriers. The resultant hot carriers could inject into the conduction band of $aTiO_2$ to further generate the ROS. LSPR-induced photo-thermal effect was also investigated by temperature-rise profile. *In vitro* and *in vivo* phototherapy effect was induced on U87MG (Glioblastoma astrocytoma). Interestingly, the overall therapeutic effects of our hybrid nanostructures were enhanced under laser irradiation, confirming the combinational photothermal and photodynamic effects. Thus, serving as a multifunctional phototherapy agent, the hybrid nanostructures herein introduced are suggested to be a valuable addition in deep-range noninvasive cancer phototherapy studies.

A Feasible Phenylboronic Acid-Based Delivery Platform of Anti-PD-L1 Antibody for Effective Cancer Immunotherapy Junha Lim, Junseok Lee, Sungjin Jung and Won Jong Kim; Pohang University of Science and Technology (POSTECH), Korea (the Republic of)

The immune checkpoint blockade (ICB) for tumor therapy is promising in the clinic. Among some ICB drug, Anti-PD-L1 antibody (aPD-L1 antibody) blocks the overexpressed PD-L1 of the tumor cell membrane and enhance the antitumor effect of cytotoxic T cell. However, these antibody therapies still have several challenges of poor delivery efficiency and immune-related adverse events. Herein, we designed the delivery platform for systemic controlled release of aPD-L1 antibody. Through the formation of pH-responsive phenylboronic ester between PBA group on polymeric phenylboronic acid (pPBA) and diol on inherent glycosylation site of the antibody, a polymeric phenylboronic acid-antibody (pPBA-Ab) nanocomplex was prepared by simply mixing pPBA and antibody. As the basic key point of effective delivery, we focused on the property of antibody nanocomplex, which are protection from external attack and release at tumor lesion. In various in vitro assays, Our antibody nanocomplex protected antibody by shielding effect of polymer shell and released antibody from acidic pH which are known as hallmarks of tumor. Furthermore, antibody complex exhibited longer circulation and enhanced tumor accumulation in vivo, which led to a significant antitumor effect when compared to free antibody. Overall, we propose the potential of our antibody nanocomplex platform as a successful delivery system for a therapeutic application that improved antitumor immunity.

Novel $CuInS_2$ Quantum Dot-PDMS Nanocomposites for All-Optical Multimodality Imaging Semyon Bodian[1], Richard Colchester[1], Thomas J. Macdonald[2], Sunish J. Mathews[1], Edward Z. Zhang[1], Paul C. Beard[1], Ivan P. Parkin[1], Adrien Desjardins[1] and Sacha Noimark[1]; [1]University College London, United Kingdom; [2]Imperial College London, United Kingdom

Highly optically absorbing nanocomposites have broad versatility with applications ranging from solar cell technology to biomedical imaging. One area in which these nanocomposites have shown particular promise, is optical ultrasound generation. We report the development of $CuInS_2$ quantum dot (CIS QD)-polydimethylsiloxane (PDMS) nanocomposites with wavelength-selective optical absorption properties for all-optical multimodality imaging. Using bottom-up fabrication methods, micron-scale thickness CIS QD-PDMS nanocomposites were created on highly miniature optical fibre substrates. These nanocomposites were engineered to exhibit high optical absorption (> 90%) at 532 nm for optical ultrasound generation and high optical transmission (> 95 %) at wavelengths greater than 700 nm, enabling other modalities such as photoacoustic imaging and spectroscopy.

Pulsed laser excitation light at 532 nm transmitted by the optical fibre was absorbed by the coating and ultrasound generation was achieved *via* the photoacoustic effect. These CIS QD-PDMS nanocomposites generated high ultrasound pressures of up to 3.7 MPa (laser fluence: 153.4 mJ/cm^2, distance: 1.5 mm) with corresponding -6 dB ultrasound bandwidths of 18 MHz. Using 532 nm and 1064 nm laser excitation sources for ultrasound and photoacoustic imaging respectively, a co-registered image of a carbon black ink-filled tube gel wax phantom was obtained with good correspondence between the ultrasound image and photoacoustic signals. Due to their wavelength-selective optical absorption properties, these high-performance fibre-based ultrasound transmitters show promise for diagnostic and therapeutic clinical applications such as the imaging of atherosclerotic plaques in coronary arteries, or use in photodynamic therapy for cancer treatment.

8:00 AM *SB03.06.01
Nanostructure of NIR-Excited Photo Dynamic Therapy for Killing Three Birds with One Stone Kohei Soga[1], Masakazu Umezawa[1], Kyohei Okubo[1], Masao Kamimura[1] and Hsin-Cheng Chiu[2]; [1]Tokyo University of Science, Japan; [2]National Tsing Hua University, Taiwan

Photo dynamic therapy (PDT) is one of the important therapeutic methods for cancer treat especially for skin cancer. Currently, a sort of dye, such as chlorin e6, are used for generating singlet oxygen for killing cancer by irradiating visible light. However, the penetration depth of the visible excitation light is only limited to be less than a millimeter. We proposed to use near infrared (NIR) light for the excitation to penetrate into tissues with centimeter order depth. Upconversion (UC) luminescence is a specific phenomenon observable for the rare-earth ions in ceramic hosts to emit green and red visible light under NIR excitation. We had reported a nano-structure by combining the UC ceramic nano phosphors with red emission (660 nm) to generate singlet oxygen by exciting the chlorin e6 on the surface. Simultaneous emission of NIR luminescence (1550 nm) can be used for NIR fluorescence imaging for diagnosis. The structure can kill two birds with one stone [M. Kamimura et al., Chem. Lett. 2017, 46, 1076−1078(doi: 10.1246/cl.170322)]. Rose Bengal (RB) is another known dye for the PDT to be excited with green light. The UC nano phosphor can also be designed to emit 550-nm green light efficiently. Here, we designed a new nanostructure for using the RB for the NIR-excited PDT agent. Basically the position of the RB is important. The RB is known to have toxicity. If the RB is exposed to the surface of the structure, the toxicity cannot be avoided. We designed to form a nano micelle structure with hydrophobic core with PLGA and PEGylated hydrophilic shell. The RB was installed to the border position of the border of the PLGA core and PEG shell. For installing the RB at a proper position, C_{18}RB was used for sticking the C18 part to the hydrophobic core to locate the RB on the border. Singlet oxygen generation effectively killed cancer cells with 980-nm NIR excitation. As well, NIR imaging was successfully performed by observing 1550-nm luminescence. Also, the toxicity of the RB was effectively suppressed. Therapy, diagnosis and toxicity suppression are the three birds. One stone killed three birds [K. Tezuka et al., ACS Appl. Bio Matter, 2021, 4 4462-4469 (doi: 10.1021/acsabm.1c00213)]! The nanostructure for utilizing the merits of transparency of the NIR photonics [K. Soga et al. ed., “Transparency in Biology,” Springer, 2021(doi: 10.1007/978-981-15-9627-8)] will be furthermore discussed.

8:30 AM *SB03.06.02
Multimodalities of Diamond Nanoparticles for Imaging and Drug Delivery in 3D Cellular Models Elena Perevedentseva[1,2], Y.-C. Lin[1], Z.-R. Lin[1], C.-

C Chang[1] and Chia-Liang Cheng[1]; [1]National Dong Hwa University, Taiwan; [2]Russian Academy of Sciences, Russian Federation

Nanoparticles (NP) exhibit some interesting bio-medical applications and the development are in high degree determined by new facilities opened by the NP's multifunctionalities. Among all developed nanoparticles, nanodiamond (ND) and ND-based hybrid complexes are promising due to their biocompatibility, variable sizes, structure, surface chemistry, and physical properties. Recent works have demonstrated exciting advantages of ND for theranostic applications, including bio imaging and drug delivery. ND's surface chemistry allows advanced methods of functionalization with the molecules of interest extending the applications, for example, ND enhanced drug delivery and efficiency has been observed, including effects on chemoresistant tumors and direct delivery across blood-brain barrier.
In this presentation, nanodiamond-gold core-shell (ND@Au) hybrid nanoparticles are synthesized combining properties and advantages of Si-doped nanodiamond and nanogold. It is shown that the ND@Au nanoparticles are biocompatible. NDs are demonstrated as imaging agent for Raman mapping, one-photon Fluorescence imaging, two-photon Fluorescence Lifetime Imaging, and high-resolution X-ray microscopy utilizing absorption properties of Au in the nanoshell. This demonstrated the synergistical effects of combining gold and nanodiamond render then useful markers in bio tracing and imaging. When drug molecules are conjugated onto ND, the composed ND-X complexes are demonstrated in a 3D cellular model (multicellular tumor spheroid, MCTS), consisted of large collection of cells in a three dimensional format extend about 0.7 mm in diameter; resemble the configuration of a tumor, ideal for evaluating the cytotoxicity and cytotoxicity mechanism of ND-drug complex and their efficacy. The drug molecules can be released in a pH dependent manner and enhanced drug efficacy can be achieved. Although this work presents only few examples, they demonstrate wide perspectives of development of NP with new synergy properties and of their use.

9:00 AM *SB03.06.04
Tailoring the Bioactivity of Inorganic Nanomaterials Inge K. Herrmann[1,2]; [1]ETH Zurich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

The well-controlled synthesis of nanoscale materials is arguably one of the most important achievements of material science in the past decades. With the push to simplify biomedical material designs, inorganic nanomaterials have regained interest. Especially metal and metal oxide nanomaterials have attracted significant attention due to the scalability and robustness of their synthesis and their tailorable composition and architecture. While fascinating results have been achieved by loading inorganic nanoparticles with organic molecules, my presentation will focus on purely inorganic systems.
In the first part, I will present an approach to unite tissue adhesion, based on nano-bridging, with bioactivity for wound healing applications. Uniting these properties requires control over nanoparticle architecture and freedom of choice in materials. Liquid-feed flame spray pyrolysis (LF-FSP) fulfills these requirements, while offering scalable and sterile synthesis. By utilizing the versatility of LF-FSP, we have united the wound closure properties of bioglass with the anti-inflammatory properties of ceria in one nanoparticle hybrid system. Careful selection of the bioglass composition and the hybrid architecture gives access to hard and soft tissue healing properties. In addition, by adjusting LF-FSP process parameters, we are able to control the oxidation state of the ceria, which governs anti-oxidative and anti-microbial properties of the hybrid. By tailoring the architecture of the hybrid nanoparticles, temporal control of the material bioactivities can be achieved in order to optimally address the different phases of the wound healing cascade.
In the second part, I will show how LF-FSP gives assess to ultra-small, near-monodisperse hafnium dioxide nanoparticles with excellent radio-enhancement properties. Such radio-enhancers can be employed to increase the x-ray absorption cross-section of tumor compared to healthy tissues. Direct benchmarking of the LF-FSP-made hafnia against gold nanoparticles, the current gold standard in the field, rationalizes their use based on their superior radio-enhancement performance. The competitive radio-enhancement properties for near-monodisperse nanoparticles produced by scalable and sterile flame spray synthesis offer a route to overcoming key roadblocks in the translation of nanoparticle-based radio-enhancers.

9:30 AM SB03.06.05
Polymeric Matrices for High-Resolution Dual-Mode MALDI MS and MS Imaging of Low Molecular Weight Compounds Franziska Lissel[1,2]; [1]Leibniz Institute of Polymer Research, Germany; [2]Dresden University of Technology, Germany

Matrices for matrix assisted laser desorption/ionization mass spectrometry (MALDI MS) is a standard tool to investigate high molecular weight (HMW) compounds, e.g. proteins and polymers. Small organic matrices (SOMs) generally consist of an aromatic ring to absorb the laser energy and transfer it to the HMWC analyte, and an ionizing functional group to transfer charge. Now the MALDI analysis of low molecular weight (LMW) compounds is coming into focus [1], to use this fast and reliable method to e.g. trace metabolomic changes in tumor development. Here, SOMs are problematic as they give rise to noise in the LMW part of the spectrum (are not "MALDI-silent"), are generally not "dual mode" (i.e. supporting measurements in both ion modes) and in MALDI MS imaging (MSI), their uneven surface coverage limits spatial resolution.

We develop polymeric matrices to enable MALDI analytics of LMW compounds, thereby turning the initial MALDI MS concept of "small matrices – big analytes" on its head.

For conjugated polymers (CPs), the conjugated backbone translates into a strong optical absorption, alkyl side chains make the CPs solution-processable and allows to coat uniform thin films. We tested several CPs as matrices and found that they are MALDI silent in the full measurement range (>m/z= 150k) except at high laser intensities, when fragmentation of the solubilizing sidechains starts [2]. Most importantly, the CPs allow the analysis of noise-free analysis of LMW analytes. Also, the CPs are dual-mode matrices, and the analyte ionization ability is competitive to standard SOMs in both positive and negative mode. MALDI MSI experiments were carried out visualize morphologies of rat brain sections, and the uniform thin films allowed a spatial resolution of 10 mm, which is high for MSI and was limited by the resolution of the instrument. SEM analyses of the films indicates that using more advanced instruments, even higher resolutions are possible using CPs.

It is a general assumption that high crystallinity is a crucial prerequisite for MALDI matrices. Yet polymers are only capable of adopting a semi-crystalline morphology, i.e., forming crystalline and amorphous domains. The analytes are therefore expected to be incorporated in the crystalline domains, and efficiency is expected to depend on the polymer's degree of crystallinity. To explore this, we synthesized two fully amorphous NDI(T2) and fluorene co-polymers carrying long and branches sidechains on both monomers [3]. Both turned out to be excellent MALDI silent dual-mode matrices, suggesting that in CP matrices analyte incorporation takes place in the amorphous phase.

Finally, the polymerization of high-performing SOMs can retain the advantageous properties of the SOM while increasing their vacuum stability and making them MALDI silent in the LMW area. The polymerized SOMs were used in MALDI MSI measurements of breast cancer xenografts, and showed excellent ion extraction abilities [4].

Multistage Signal-interactive Nanoparticles Improve Tumor Targeting Through Efficient Nanoparticle-Cell Communications Hélder A. Santos[1,2]; [1]The University Medical Center Groningen, Netherlands; [2]University of Helsinki, Finland

Communication between biological components is critical for homeostasis maintenance among the convergence of complicated bio-signals. For therapeutic nanoparticles (NPs), the general lack of effective communication mechanisms with the external cellular environment causes loss of homeostasis, resulting in deprived autonomy, severe macrophage-mediated clearance, and limited tumor accumulation. Here, we develop a multistage signal-interactive system on porous silicon particles through integrating the Self-peptide and Tyr-Ile-Gly-Ser-Arg (YIGSR) peptide into a hierarchical chimeric signaling interface with ''don't eat me'' and ''eat me'' signals. This biochemical transceiver can act as both the signal receiver for amantadine to achieve NP transformation and signal conversion as well as the signal source to present different signals sequentially by reversible self-mimicking. Compared with the non-interactive controls, these signal-interactive NPs loaded with AS1411 and tanespimycin (17-AAG) as anticancer drugs improve tumor targeting 2.8-fold and tumor suppression 6.5-fold and showed only 51% accumulation in the liver with restricted hepatic injury.
Here, we demonstrate that constructing a signal-interactive NP system improves NP-cell communication efficiency. Moreover, we show that the functional chimeric peptide design enables orderly integrating of multiple signal modules and the signal-interactive NPs reduce liver accumulation and promote tumor targeting in an animal cancer model.

11:00 AM SB03.07.02
Mesoporous NiO Electrodes for Enzymatic Electrochemical Sensing of Xanthine Anuja Tripathi[1,2], Natasha Singer[2], Anastasia L. Elias[1], Abebaw B. Jemere[2] and Kenneth D. Harris[2,1]; [1]University of Alberta, Canada; [2]National Research Council Canada, Nanotechnology Research Centre, Canada

The freshness of fish meat is the most important criterion in the pre-consumption quality control process. Complex microbiological processes lead to the loss of freshness and subsequent spoilage. Six hours after death, autolytic decomposition of adenosine triphosphate (ATP, the energy-storing molecule found in cells) leads to xanthine (XA) production. XA concentration increases with storage time, and thus it can be used as an indicator of fish freshness. Current analytical methods of XA determination that are based on chromatography, colorimetry, spectrophotometry or mass spectrometry are time consuming, expensive and require experienced operators. Electrochemical sensor platforms on the other hand are attractive due to their simple operation, low cost, low sample volume requirements, and speed of analysis. In recent years, enzyme-based electrochemical biosensors, employing xanthine oxidase (XO) for selective recognition and catalysis of XA, have become promising for XA determination in fish and meat samples because of their low detection limits, high selectivity and sensitivity.
The working electrode material is a key factor affecting the analytical performance of electrochemical biosensors, and integration of nanomaterials in the working electrode has previously improved sensor performance. Though carbon based nanomaterials, metal and metal oxide nanostructures that have favorable electrical properties and biocompatibility have been reported for enzymatic biosensor fabrication, mesoporous NiO electrodes are rarely used for electrochemical enzymatic detection of XA. Mesoporous NiO electrodes are ideal for electrochemical biosensor fabrication owing to their large surface area for enzyme immobilization, high isoelectric point, biocompatibility, chemical stability and fast electron transfer features. Moreover, NiO has a redox couple of its own (Ni^{3+}/Ni^{2+}), paving the way for reagentless biosensing. In this work, we fabricate mesoporous NiO electrodes to immobilize XO, and we demonstrate sensitive and selective amperometric determination of XA. Electrodes were formed using the glancing angle deposition (GLAD) technique, and the large surface area and internal porosity of the GLAD films should allow immobilization of large quantities of the XO enzyme, which combined with the excellent electrical properties of the GLAD electrode allowed amperometric detection of XA at +0.5 V vs Ag/AgCl with excellent sensitivity, detection limit and response time. The sensor was also used to measure XA in a fish sample.
Sensor fabrication and performance
Nanocolumnar and mesoporous NiO films (thickness ~500 nm) were deposited on ITO using GLAD. XO was physisorbed into the pores of activated GLAD NiO electrode by incubating in XO-loaded PBS buffer, pH 7.4. In brief, the NiO electrode was first electrochemically activated using 0.1 N NaOH for 25 cycles at 10 mV/s. 20 µl 0.18 U/mg XO was then immobilized in the activated NiO electrode for 4 hours at room temperature. The modification of the NiO GLAD film with XO was characterized by electrochemistry and FTIR techniques. XO catalyzes the oxidation of XA to uric acid and hydrogen peroxide (H_2O_2), and therefore, using an optimized measurement condition, current was monitored by applying +0.5 V vs Ag/AgCl to the electrode. This current was proportional to the concentration of XA. The amperometric sensor rendered a dynamic range of 60 nM to 3.5 µM, with a limit of detection of 2 nM, limit of quantitation of 6 nM and a sensitivity of 0.01 µA/nM. The sensor showed little interference from common fish sample matrices (such as glucose, uric acid, hypoxanthine) and the common fish preservative (sodium benzoate). The sensor could also be stored in buffer at 4ºC for over a week without losing its performance.

11:15 AM *SB03.07.03
Carbon Dots—Multinfunctional Nanomaterials for Bioimaging and Biosensing Applications Rafik Naccache; Concordia University, Canada

In recent years, nanomaterials (defined as materials < 100 nm in a single dimension) have garnered significant interest for the development of novel applications in the physical and life sciences. This is especially true for luminescent nanoparticles, which have been investigated for the development of sensors, imaging and diagnostic probes. Recently, a relatively new class of luminescent nanomaterials, namely carbon dots, has come to light. Carbon dots, sometimes known as carbongenic dots, are carbon, oxygen, nitrogen and hydrogen containing materials that are typically water dispersible and can be prepared from an abundant number of inexpensive sources including small molecules such as citric acid, amino acids and sugars. Of particular interest are their optical properties, which can be tailored via careful selection of the starting precursors and the desired synthesis route resulting in the ability to generate fluorescence from the blue to the near infrared regions of the spectrum. In addition to their versatile optical properties, these carbon dots are generally known to have low cytotoxicity and good biocompatibility. Combined with their small size and versatile optical properties, developing carbon dots as a nanoplatform can be achieved as these nanodots lend themselves for integration in a myriad of applications most notably in bio-imaging, sensing and drug delivery, among others. Our work focuses on achieving a fundamental understanding of the synthesis of these carbon dots in order to control their size and achieve homogenous surface chemistry and optical properties. We can also endow them with chirality during synthesis opening up novel avenues for chiral sensing applications. As they are fluorescent, we have investigated their development as bimodal imaging probes for optical and magnetic

resonance imaging applications. We have also exploited their temperature and pH dependent optical properties in order develop novel tools that can be used for intracellular sensing applications.

11:45 AM *SB03.07.04
Dual Action Chemo-Radio Labeled Targeted Nanocarriers with High Efficacy Against Triple Negative Breast Cancer Shaista Ilyas[1], Annika Szymura[1], Sabri Sahnoun[2], Pardes Habib[3], Felix Mottaghy[2] and Sanjay Mathur[1]; [1]Institute of Inorganic and Materials Chemistry, University of Cologne, Germany; [2]Department of Nuclear Medicine, University Hospital RWTH Aachen, Germany; [3]Department of Neurology, RWTH Aachen University, Germany

The therapeutic index of established nuclear medicine procedures for an aggressive type of cancer such as triple negative breast cancer, (TNBC, lacking estrogen, progesterone receptors, and excess HER2 protein) is typically low due to the lack of targeted therapies and limited stability of radiolabeled carrier molecules in physiological environment. In this study, we developed a potential dual-purpose therapeutic nanocarrier (mesoporous silica particles) by integrating complementary functionalities (folate ligand, DOTA chelator) and payloads (doxorubicine, radionuclides ^{68}Ga/^{177}Lu) into one nanocarrier through covalent conjugation strategies.The nanocarriers, [^{68}Ga]Ga-DOTA-FA and [^{177}Lu]Lu-DOTA-FA demonstrated an outstanding radiochemical yield of > 98 % showing successful incorporation of radionuclides to DOTA cavity. Moreover, radiolabeled nanocarrier exhibited excellent stability in PBS and human serum during 3 h (^{68}Ga) and 120 h (^{177}Lu). In addition, the labeled FA-DOTA@mSiO_2 exhibited a favorable partition coefficient (log P) of -3.29 ± 0.08, suggesting highly hydrophilic carriers. *In vitro* studies using 3 different TNBC cell lines with FA-DOTA@mSiO_2 carriers demonstrated a significant cell internalization suggesting specific targeting of folate receptor in TNBC cells. Interestingly, FA-capped nanocarrier revealed a significant time dependent cell uptake after labeling with ^{177}Lu in SUM149PT (33 %) MDA-MB-231 (9%), BT20 (28%) compared to nanocarrier without FA. In Annexin-V based apoptosis studies, combined delivery of ^{177}Lu radiations and DOX induced significant cell death to TNBC cells earlier at different time points. In ovo studies using fertilized chicken eggs, exhibited higher uptake of dual-purposed nanocarriers (PET imaging). Our data suggests that dual functions nanocarriers has great potential in delivering radiation and drug doses for TNBC tumor treatment and highlight further studies to evaluate its preclinical therapeutic efficacy.

1:00 PM SB03.08.02
Formation and Stability of Dendronized Vesicles Akash Banerjee[1], Acacia Tam[2] and Meenakshi Dutt[1]; [1]Rutgers, The State University of New Jersey, United States; [2]Cornell University, United States

Nanoparticles that block fundamental bacterial functions like quorum sensing could potentially replace conventional antibiotic therapies. Vesicles that bind interfacially to charged biomolecules could be used to block these quorum sensing pathways. Towards this goal, dendronized vesicles (DVs) consisting of polyamidoamine dendron-grafted amphiphiles (PDAs) and dipalmitoyl-sn-glycero-3-phosphocholine lipids are investigated. The molecular dynamics simulation technique in conjunction with an explicit solvent coarse-grained force field is employed. The key physical factors responsible for the stability of DVs as a function of the dendron generation and relative concentration are identified. The threshold concentration of each dendron generation that yields stable DVs is determined. Lower dendron generations rupture the DVs at high relative concentrations due to the electrostatic repulsions between the terminally protonated amines. Whereas, intermediate dendron generations demonstrate a mushroom-to-brush transition. Such conformational changes in the dendrons expand the outer DV surface, resulting in instability in the DV bilayer. DVs encompassing dendrons with higher generations incur stresses on the bilayer due to their high charge density and spontaneous curvature. Minimization of asymmetric stresses across the bilayer are understood by studying the self-organization of PDAs on the DV surface. A conducive set of conditions is determined for the formation of a single cluster of PDAs that decorates the DV surface like a mesh. Results from this study can potentially guide the design and synthesis of nanoparticles which target quorum sensing pathways in bacteria. Beyond applications in prevention of bacterial infections, these nanoparticles can be used in diverse applications, e.g. biomedicine, energy or bioelectronics, that require synthetic dendronized cells or the adsorption and transport of charged species.

1:15 PM *SB03.08.03
Combinatorial Immunotherapies and Treatment Response to Immunotherapies with Nanoscale Probes Rizia Bardhan[1,2]; [1]Iowa State University, United States; [2]Nanovaccine Institute, United States

Immunotherapies have driven a paradigm shift in the landscape of cancer treatment and currently many immune active drugs are in FDA trial for cancer therapies. Yet, the distribution of many of these drugs remains low in the tumor due to rapid in vivo degradation or low accumulation. Further, which patients are good candidates for immunotherapies remains a challenge incurring high costs of unsuccessful therapies and unnecessary side effects. In this talk I will show the utility of inorganic nanoprobes (gold nanostars) designed in my lab for rapid and noninvasive detection of multiple immunomarkers of cancer to enable patient selection for immunotherapies, as well as response to treatment after immunotherapy. We combined a clinical and pre-clinical imaging technique, positron emission tomography with surface-enhanced Raman spectroscopy (ImmunoPET-SERS) in vivo by labeling gold nanostars with radiolabels, Raman reporter molecules, and targeting antibodies. Multimodal ImmunoPET-SERS seamlessly integrates depth-resolved whole-body imaging and high sensitivity of PET with high spatiotemporal resolution and multiplexing of SERS providing dynamic immunomarkers profiling in vivo. ImmunoPET-SERS was used to determine the immunomarker status of mice treated with combinatorial immunotherapy; we demonstrated real-time feedback of CD8+ infiltration and PD-L1 status in tumors which was confirmed with IHC ex vivo. We are also tracking both CD8+ T cells and Natural Killer (NK) cells in vivo to examine repose to immunotherapies. I will also show the utility of organic nanoprobes (liposomes) for highly effective combinatorial immunotherapies integrating mild hyperthermia and hypoxic drugs with immune checkpoint blockade for enhanced treatment outcome in aggressive breast tumors. In summary, my talk will show nanoscale probes can be engineered to have multifunctional properties from therapeutic response to monitoring treatment efficacy *in vivo*.

1:45 PM SB03.08.04
Domain Aggregation and Associated Pore Growth in Lipid Membranes Yue Liu[1,2], Guijin Zou[3] and Huajian Gao[1,3,4]; [1]Brown University, United States; [2]University of Michigan, United States; [3]Institute of High Performance Computing, Singapore; [4]Nanyang Technological University, Singapore

Recent experiments have shown that certain molecular nano-agents can selectively penetrate and aggregate in bacterial lipid membranes, leading to their

permeability and rupture, and as such can effectively address the looming crisis on antimicrobial resistance by killing bacteria even in their dormant state - the so-called “persisters”. So far, the discovery of these agents is still mainly restricted to empirical screening with limited physical understanding. To help reveal and understand the underlying mechanisms, here we establish a theory to show that the deformation energy of the membrane tends to limit the growth of molecular domains on a lipid membrane, resulting in a characteristic domain size, and that the domain aggregation significantly reduces the energy barrier to pore growth. Coarse-grained molecular dynamics simulations are performed to validate such domain aggregation and associated pore formation. This study sheds light on how lipid membranes can be damaged through molecular domain aggregation and contributes to establish a theoretical foundation for the next-generation membrane-targeting nanomedicine to effectively target bacteria with high antimicrobial resistance against conventional antibiotics.

4:00 PM *SB03.09.01
Beyond Cryo-Microscopy—Current-Controlled Transmission Electron Microscopy for Beam-Sensitive Material Imaging Petra D. Specht[1] and Christian Kisielowski[2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Since the DoE funded TEAM project ended in the United States with the development of spherical and chromatic aberration correction in 2009 single atom sensitivity is established for transmission electron microscopy (TEM) imaging. Theoretically, every material could be imaged in full atomic resolution, and every atom could be resolved within all material structures. In an experimental setup, however, electron beam sensitivity of a given material determines which original structures can be resolved in reality. Therefore, our focus in the last decade has been on minimizing electron beam induced material damage, and to find alternative ways to image beam sensitive materials without altering its original structure. At least, if a material is altered under the electron beam the dynamics of this behavior should be recorded, too. Such dynamic considerations led to the development of current-controlled TEM.

Low dose rate and pulsed electron beams were applied to image pristine properties of $MgCl_2$, a Ziegler-Natta catalyst which is both air and electron beam sensitive. The particular choice of pulse and delay times allowed to mitigate damage caused by phonon accumulation. The total electron dose can be extended more than ten times before material alterations set in. Changing electron currents while imaging polymers or various catalytic nano-crystals by varying dose rates and / or the irradiated areas had similar effects. Using direct electron detectors facilitated those experiments, and allowed for the use of ultra-low currents where single electrons are delivered to interact with the material under investigation. We find that the beam current limits material alterations in the ultra-low current regime rather than the deposition of electron charge.

With the application of current-controlled TEM the onset of material changes is found to be generally delayed. The experimental setup may be used in combination with cryo-microscopy, and could further postpone material alterations, even in soft materials.

Work at the Molecular Foundry was supported by the Office of Science, Office of Basic Energy Sciences, of the U.S. Department of Energy under Contract No. DE-AC02-05CH11231.

Plasmon-Mediated Optical Biosensing and Photodynamic Therapy Nianqiang Wu; University of Massachusetts Amherst, United States

Surface plasmon resonance (SPR) is characteristic of strong light harvesting, enhanced localized electromagnetic filed and tunable energy donation. As a result, SPR has a great potential in biosensing, drug delivery and theranostics. In this work, SPR has been used to develop new fluorescence and surface-enhanced Raman scattering (SERS) sensors. In particular, SPR enables sensitive detection of analytes in human fluidic samples in the biological transparency window in the near-infrared spectral range. In addition, SPR can be incorporated with inorganic semiconductors to create new stable agents for photodynamic therapy.

5:00 PM SB03.09.03
Intracellular Trafficking Study and Rapid Purification of Lysosomes Using Magnetic Plasmonic Nanoparticles The Son Le[1], Mari Takahashi[1], Yuichi Hiratsuka[1], Kazuaki Matsumura[1], Tomohiko Taguchi[2] and Shinya Maenosono[1]; [1]Japan Advanced Institute of Science and Technology, Japan; [2]Tohoku University, Japan

The rapid and efficient purification of lysosomes is the key to uncover the mechanistic insights of lysosomal activity using proteomics analysis. The traditional method for isolating lysosomes such as the density-gradient ultracentrifugation technique often takes a long time and the intact structure of lysosomes is not preserved.[1] Therefore, it may lead to a change of protein composition in labile lysosomes as well as detach and/or denature of membrane proteins on it. Recently, the nanoparticle-based fractionation method which uses superparamagnetic iron oxide nanoparticles (SPIONs) for targeting lysosomes through the endocytosis pathway has been used for the isolation of lysosomes to identify disease-related alternation in protein composition.[2] The versatility of SPIONs together with the quick and gentle nature of magnetic isolation are advantages of this technique. However, to obtain a highly-purified lysosomal fraction with high yield, it is important to determine the appropriate timing for performing magnetic separation, since the time-dependent localization of SPIONs in different organelles (*i.e*. early endosome, late endosome, and lysosome) depends on cell type, loading condition, incubation time, *etc*. To screen localization of SPIONs in a large number of cells, they are often labeled with the fluorescent dye to be monitored by fluorescent microscopy. However, besides the photobleaching problem, dye labeling of nanoparticles could have dye-leaking or influence on nanoparticle uptakes.[3] Therefore, to further sophisticate the SPIONs-based isolation technique, it has been demanded to develop a new type of magnetic probes with intrinsic imaging capability to both precisely visualize the intracellular transport and quickly obtain high purified isolation fraction.
Herein, to satisfy those requirements, we have developed magnetic-plasmonic Ag/FeCo/Ag core/shell/shell nanoparticles (MPNPs) for lysosome isolation. Since dextran has been well-known as a fluid phase cargo, which is internalized *via* pinocytosis rather than receptor-mediated endocytosis and eventually delivered to lysosomes. In this study, the MPNPs were encapsulated in phospholipid micelles followed by conjugation with amino dextran (aDxt). The hydrodynamic size of aDxt-conjugated MPNPs (aDxt-MPNPs) was ~50 nm at pH in the range of 4~10, which is suitable for efficient cellular uptake through various pathways. Owing to plasmonic property, the intracellular trafficking of aDxt-MPNPs could be simply visualized by confocal laser scanning microscopy (CLSM). After determining the intracellular fate of aDxt-MPNPs, lysosomes were quickly isolated using a MACS separator (Miltenyi Biotec). The purity and the intactness of the lysosome fraction were confirmed by western blot and CLSM images. Furthermore, we will discuss

the influence of the elapsed time from homogenization to the magnetic separation on the protein composition in lysosomes.

Nano-Analytical Characterization of Metal-Organic-Framework Biotransformation Anna Neuer[1,2], Alexander Gogos[2], Alexandre Anthis[1,2] and Inge K. Herrmann[1,2]; [1]ETH Zurich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

In biomedical research, metal-organic-frameworks (MOF) have attracted increasing interest over the past decade. MOFs hold promises as drug delivery agents, radioenhancers and application in theranostic and personalized medicine. Zeolite-imidazole-framework-8 nanoparticles (ZIF-8) are amongst the most extensively studied MOFs featuring anti-inflammatory and anti-microbial properties when doped with ceria.[1,2] Alternatively, hafnium-based MOFs have been shown to enhance radiation therapy damage in tumor cells via reactive oxygen species creation.[3] However, clinical translation for such novel materials remains challenging and tight control over nanomaterial chemistry during nanomedical life-cycle is needed. While stability and dissolution have been studied in the past for several MOFs, a detailed understanding of the intracellular behaviour and potential phase-transformation and/or generation of secondary nanomaterials is missing. Compared to their metal oxide counterparts, MOFs typically exhibit higher instability, making them prone to degradation/biotransformation. For biomedical applications, the fate of these new materials is, next to efficacy and toxicity, a major determinant of clinical success.

To overcome the gap between material engineering and medical application, and enable more rationalized safe-by-design material development, we investigated the environment-dependent biochemical-transformation of different nano-particulate MOFs containing essential (Zn, Fe) and non-essential (Hf, Ce) metal ions in physiologically relevant liquids and *in-vitro* systems. We present biotransformation kinetics of a biomedically relevant set of MOFs, including findings of particle transformation with changes in elemental distribution and morphological appearance with potential formation of nanomaterial from degradation products. Taken together, our nano-analytical characterization approach offers a route to follow the biological fate of MOF-based nanomedicines.

An Interdisciplinary Approach to Biosensors to Meet the Market Need for Faster Diagnosis in Health Care Laure Abensur Vuillaume[1], Thierry Leichle[1,2], Mathieu Grajoszex[3], Marie-Pia d'Ortho[3], Paul Voss[1,4], Jean-Paul Salvestrini[1,5] and Abdallah Ougazzaden[1,4]; [1]IRL 2958 GeorgiaTech CNRS, France; [2]LAAS-CNRS, Université de Toulouse, France; [3]DMH – APHP and Université de Paris, France; [4]Georgia Institute of Technology, School of Electrical and Computer Engineering, United States; [5]Georgia Tech Lorraine, France

To improve the efficiency of current medical practices, more significant data from technology is needed. One lever to optimize medical decision time is to shorten the delay from biological test to results. In the field of fast biological tests, biosensors have received increasing attention over the last decades and several technologies have been developed to deliver portable, cheap and sensitive analytical systems. Nevertheless, two main obstacles prevent the marketing of these biosensors: 1) an accurate analysis of the market in terms of real needs for medical practices and 2) perfect matching with current medical recommendations We identify several obstacles that prevent the marketing of biosensors today: 1/ prior precise study of the market (needs for medical practices that fit perfectly into the current recommendations); 2/ technological realization that can meet this need; 3/ Knowledge of standards and validation and calibration procedures. Our study is divided into 5 phases: 1/ Determination of the use case(s) and the biomarkers of interest with an international opinion survey of physicians from all specialties; 2/ Design of a laboratory prototype; 3/ Manufacturing of a more advanced prototype suitable for the first steps of clinical validation phase; 4/ Interconnection with artificial intelligence and biological gold standard; 5/ Multicentric study for validation as a medical device. For this purpose, we have assembled an interdisciplinary team with medical doctors, engineers, and experts on market validation with the goal of identifying the most promising use cases in human medicine and creation of the most suitable biosensors anchored in medical practices.
In this work, we first determine the use case(s) and the biomarkers of interest through an international opinion survey conducted among physicians from a broad range of specialties. We distributed a questionnaire via our networks and professional social networks for a voluntary survey of physicians about existing needs for rapid biological diagnosis and what this might change in their daily practice. More than 200 physicians from 10 different countries and 19 different medical specialty responded to our survey. 48,5% of participants think that it would save medical time (fluidity in the hospital environment, saving time in ambulatory care), 55,5% think it could improve their medical practice (guide a course of action, help a therapeutic decision, avoid unnecessary treatment) and 31,5% think that this could lead to faster and easier patient referrals.
As a result, the main biomarkers of interest identified by our panel are troponin (50%), PCR (30,5%), d-dimères (26,5%), BNP or NT-proBNP (12,5%), and respiratory viruses (9,5%).
Our study is based on the creation of biosensors, in a trans and interdisciplinary manner, so that they can be perfectly integrated into daily medical practice and respect all the issues at stake, in terms of diagnostic sensitivity, cost/efficiency and service to the patient. The biosensors are based on AlGaN/GaN High Electron Mobility Transistors (HEMTs). GaN-based HEMTs have demonstrated high sensitivity as detectors, sensors and biosensors and have the advantage of extreme chemical stability and are biocompatible. Furthermore, the basic technology is widely commercialized and mature, making for rapid industrial upscaling
In this presentation, we will describe the interest of the various biomarkers that were identified in our study and we will compare medical practices, literature, recommendations of good practices and technological possibilities, in order to define the best use case for biosensors.
This study is of importance in terms of future public health, making it possible to provide the medical community and the patient with one or more relevant tools for the fluidity of care.

6:30 PM SB03.10.01
Engineering Nano-Architected Surfaces to Steer Soft and Hard Tissue Interactions on Tissue Level Dental Implants Judith Ng[1,2], Martin Tobias Matter[1], Kerda Keevend[1], Stefanie Guimond[2], Markus Rottmar[2] and Inge K. Herrmann[1,2]; [1]ETH Zurich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Dental implant failures arise from poor integration of the implant with surrounding soft and hard tissues. Osseointegration and periointegration are crucial to their prevention. A persistent challenge is the inconsistency between tissue surrounding an implant and natural periodontal tissue around natural teeth. This increases vulnerability to peri-implant diseases, affecting soft and hard tissue integration and highlighting the need for implants with improved osseointegration and periointegration potential. Implant surface nanostructures promote osseointegration; however, designs which improve the soft tissue response have yet to be identified. We present novel nanoparticle coatings applied to surfaces in a single step technique driven by liquid-feed flame spray pyrolysis, which uniquely permits the construction of bespoke nanoparticle architectures from a breadth of inorganic precursors. This highly scalable technique has the potential to create multi-layer nanostructures of differing thicknesses, diverse patterns, and pore sizes – qualities as diverse as the inorganic building blocks of which these nanoparticle layers are composed. Novel nanoparticle-based coatings with bioactive inorganic architectures can enhance osseointegration, reduce the inflammatory response, and possess exemplary process versatility and stability, permitting precise control over the synthesis process, and so too, evaluation of the concomitant soft tissue bioresponse.

6:35 PM SB03.10.02
Late News: Facile Fabrication of Silk Protein for a Versatile Drug Carrier Anh T. Dao, Farsai Taemaitree, Motohumi Nakamura, Ryuju Suzuki, Yoshitaka Koseki and Hitoshi Kasai; Tohoku University, Japan

Drug delivery technologies have been quickly innovated in the last few decades, especially in aspect of combination with nanotechnology to advance into multifunctional drug carriers, which can accomplish targeting a tumor, delivering therapeutic molecules, imaging and monitoring drug response. Many models were built and tested; still the challenge is at the choice of the appropriate materials and the facilitation of carrier preparation to achieve both safety and efficacy. Reflecting such needs, silk protein was chosen to provide a biodegradable and biocompatible matrix for carrying drug molecules. Such system with controllable structures and compositions can be an advanced type of drug carriers and further contribute to the improvement of cancer therapy. Silk protein originated from *Bombyx mori* silkworm was dissolved in various types of aqueous solution, including LiBr [1], $CaCl_2$/Ethanol [2], and formic acid solutions. In this research, the fabrication of silk NPs from the obtained silk protein solution was carefully monitored to achieve various morphologies and structures, through the reprecipitation method. Silk NPs were obtained in narrow size distribution, with the average diameter can be tuned from 10 to 100 nm. The surface charges of as-synthesized silk nanoparticles can be either negative or positive, depending on preparation conditions, brings out the possibility of loading different types of drugs. The obtained silk NPs showed good drug uptakes, adequate stability in aqueous and almost no toxicity at cellular level. The research also provides a NP library with diverse structures and properties, which can be used to manipulate the drug delivery performance. The results are discussed in terms of UV-Vis, DLS, XRD, TEM, XPS, and CLSM.

Study of the Interaction of Human Serum Albumin with β-Cyclodextrin Modified Gallium Oxide Nanoparticles Using Fluorescence Spectroscopy Nitza Falcón-Cruz and Rolando Oyola-Martínez; University of Puerto Rico-Humacao, United States

Gallium oxide nanoparticles (GaO-(OH)) have been proposed for biomedical applications such as diagnostics and therapeutic approaches, like cancer treatments. Understanding its interaction with biological components, like proteins, is an important factor for the development of new nanomaterials. Gallium oxide nanoparticles conjugated with β-cyclodextrin (GaO-CD) were synthesized using a wet-chemical route, characterized by molecular spectroscopic and imaging techniques, and further used to probe equilibrium interactions with human serum albumin (HSA). In this work, we have used the sensitivity of the single tryptophan (Trp) fluorescence of HSA to monitor the interaction between GaO-CD and the protein at different temperatures. The binding and quenching constants were determined using Stern-Volmer analysis. Also, the thermal stability of the complex was followed by fluorescence spectroscopy using a simple two-state model. A weak interaction of HSA with GaO-CD, relative to other nanomaterials, like gold nanoparticles, was observed. In addition, results show no change in temperature of unfolding (T_m) of the protein, implying that GaO-CD does not affect HSA tertiary structure.

SESSION SB03.11: Transformative Nanostructures with Therapeutic and Diagnostic Modalities IX

Rare-Earth-Based Nanoparticles—From Microwave-Assisted Synthesis to Multimodal Bioprobes Eva Hemmer; University of Ottawa, Canada

The remarkable optomagnetic properties of the rare-earths (RE) make RE-based materials ideal for biomedical applications, including diagnostic (e.g., imaging, nanothermometry) and therapeutic (e.g., drug delivery, photodynamic therapy) approaches. This is due the unique electronic properties of the f-elements allowing for upconversion and near-infrared emission under near-infrared excitation as well as high magnetic moments.
Yet, challenges remain; low emission intensity and efficiency of small nanoparticles (NPs), and reliable, fast synthesis routes. As material chemists, we tackle these challenges with new designs of RE-NPs by chemically controlled synthesis, application-oriented surface chemistry, and understanding of structure-property-relationships. Sodium rare-earth fluorides ($NaREF_4$) are our favorite materials, and we developed a fast and reliable microwave-assisted synthesis approach allowing crystalline phase and size control in the sub 15nm realm. Such control is crucial for the understanding of fundamental structure-property relationships and to optimize their optical and magnetic properties, when aiming for the design of next-generation optical probes or contrast agents for magnetic resonance imaging. For instance, $NaGdF_4$ NPs are gaining interest as alternative MRI contrast agent, while co-doping with RE^{3+} ions renders them excellent candidates for photoluminescent optical probes. The hexagonal crystalline phase of $NaGdF_4$ is known as the more efficient host material for upconversion emission, yet interestingly, it was found that its cubic counterpart shows superior performance as MRI contrast agent. Having a fast and reliable synthesis route towards $NaREF_4$ NPs on hand, we now explore various nanoparticle architectures and compositions with

the goal to optimize their optomagnetic properties, ultimately resulting in the design of biocompatible multimodal bioprobes.
This presentation will shed light on recent results and remaining challenges in the field of RE-based nanostructures with respect to their microwave-assisted synthesis as well as structural and optomagnetic properties, seeking biomedical application, while also touching on hyperspectral imaging as an emerging analytical tool offering spatio-spectral information about RE-based materials.

1:30 PM SB03.11.02
Tuning the In-Plane Anisotropy of CoFeB Films for Disk-Shaped Nanoparticles for Biomedical Applications Subas Scheibler[1,2], Oguz Yildirim[2], Mihai Gabureac[2], Inge K. Herrmann[1] and Hans J. Hug[2]; [1]ETH Zürich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Magnetic separation offers an elegant and efficient route to selectively capture and remove specific compounds from blood (or other body fluids), which are inaccessible to current blood cleansing technologies, such as dialysis and hemosorption [1]. However, currently available superparamagnetic iron oxide nanoparticles (SPIONs) impose significant performance limits arising from their physical properties. Their low saturation magnetization coming from their oxidic nature results in a poor magnetic response, which severely limits performance.
The development of disk-shaped nanoparticles fabricated by lithographic methods and thin film deposition enables a precise control of size, geometry, material composition and magnetic properties such as interlayer exchange coupling and magnetic anisotropies.
In this work, we develop magnetic thin film systems for synthetic antiferromagnetic (SAF) coupled disk shaped particles with tunable in-plane anisotropies. The antiferromagnetic coupling is obtained by the stray field interaction of the two ferromagnetic layers. These SAF particles are designed to show zero net-magnetization in absence of a magnetic field – hence allowing perfect colloidal stability. Upon application of a magnetic field overcoming the antiferromagnetic coupling, a high net-magnetization can then be obtained, which translates into a large magnetic moment and magnetic force, acting on the particles in a gradient field allowing efficient capturing.
In order to synthesize such synthetic antiferromagnets, we evaluated strategies to obtain the required magnetic anisotropies. We report results obtained by deposition of soft magnetic CoFeB layers on Ta seed layers grown by oblique sputtering and compare the resulting anisotropies to those obtained by deposition of the magnetic layer in an applied field. Moreover, for the CoFeB layers on the oblique-sputtered seeds we compare the anisotropies obtained for different CoFeB-thicknesses to distinguish between a surface or interface induced anisotropy or a bulk anisotropy term. While with oblique sputtering, a wide range of in-plane anisotropies can be achieved (2kJ/m3 – 25kJ/m3), the anisotropy remains much smaller when CoFeB films are deposited in field(1.35kJ/m3).
Our work shows that in-plane anisotropies in magnetically soft systems can be tuned over a wide range by oblique seed-layer depositions or in-field depositions. These thin film systems open up the path for a new kind of magnetic disk shaped nanoparticles for prospective use in magnetic blood purification.

Self-Organization of Iron Sulfide Nanoparticles into Multi-Compartment Supraparticles as Artificial Viruses for DNA Delivery Emine S. Turali-Emre, Ahmet Emre, Kadiyala Usha, Scott J. VanEpps and Nicholas Kotov; University of Michigan, United States

Gene and gene editing therapies have been widely investigated for the treatment of inherited or acquired genetic diseases. Efficient delivery of therapeutic agents has become a significant barrier in clinical applications due to the toxicity and instability of the vectors in the complex intracellular environment. Among non-viral vectors, individual inorganic nanoparticles (NPs) have become a popular strategy for nucleic acid delivery. However, the nanoshell geometry of viruses that creates a compartment to protect the cargo from its environment is still advantageous. Recreation of these compartments' formation has both technological and fundamental importance. In this study, we show that *L*-cysteine stabilized iron sulfide NPs can self-assemble into multi-compartment supraparticles (SPs) with nanoshell geometry. The transmission electron microscopy results showed that constituent NPs initially form ~55nm cup-like structures and then mature into positively charged ~75nm SPs with *ca.*190 interconnected compartments. The results of selected area electron diffraction and energy dispersive X-ray spectroscopy confirm SPs are formed from FeS_2 and Fe_2O_3 NPs. Elemental mapping showed that Fe_2O_3 NPs are located on the surface of the SP and protecting FeS_2 and compartments from the surroundings. DNA was loaded in the compartments during the formation of supraparticles. We tested these complexes in circular dichroism, UV-Vis spectroscopy, electrophoretic mobility shift, and protection assays. Our results show successful DNA encapsulation in compartments. These pDNA-SP complex protect DNA against degradation, penetrate through cellular membranes and facilitate endolysosomal escape. Therefore, the development of these particles can be used as an effective cargo delivery tool for gene and gene-editing therapies.

2:00 PM SB03.11.04
Mixed-Halide Nanocrystals—From NIR-to-Vis Upconverters to Luminescent Thermometers Federico A. Rabuffetti; Wayne State University, United States

Bulk mixed halides constitute an important class of optical materials used as detection and storage phosphors in medicine. However, the potential of their nanocrystalline counterparts in biophotonic applications such as imaging and sensing is largely unexplored. In this talk I will highlight the potential of mixed-halide nanocrystals as luminescent thermometers capable of operating in a broad temperature range, from cryogenic to physiological temperatures. First, I will describe the chemistry that enables the synthesis of size- and shape-controlled mixed-halide nanocrystals with sizes ranging from 20 to 100 nm. Then, I will show how controlled amounts of rare-earth ions may be incorporated into these nanocrystals to generate a family of color-tunable NIR-to-visible upconverters. Finally, I will demonstrate that rare-earth-doped mixed halide nanocrystals serve as optical temperature sensors in the 100–400 K range. These luminescent thermometers can be excited within the first biological window.

SESSION SB03.12: On-Demand
Sunday Morning, December 5, 2021

8:00 AM SB03.02.03
Late News: Design of Theranostic Nanocomplex for Drug Delivery and Photodynamic Therapy Against HER2+ Breast Cancer Elder De la Rosa[1], Gonzalo Ramirez[2], Sandeep Panikar[3], Tanya Camacho[4] and Pedro Salas[2]; [1]Universidad De La Salle Bajio, Mexico; [2]CFATA-UNAM, Mexico; [3]UNAM,

Mexico; [4]CIATEJ, Mexico

Design of theranostic nanocomplex has gained a lot of attention because its capability for simultaneous imaging, detection and therapy. In particular, high selectivity nanocomplex for photodynamic therapy and drug delivery are important tools to fight the cancer problem. Here, we report recent results on the design of theranostic complex based on the use of upconversion nanoparticles (UCNP) which convert near infrared (NIR) excitation at 970 nm into blue, green, red and NIR emission tuned with the lanthanide doping ion. Such nanoparticles are ideal for overpassing the limited penetration depth of conventional photodynamic therapy (PDT), also useful for imaging and detection. Green and red emissions were obtained with the introduction of Er^{3+} ion. The green and red emission is used as an excitation source for zinc phtalocyanine (ZnPc), a photosensitizer (PS) bounded to the surface of UCNP. PS transfers energy to molecular oxygen in the surroundings to produce reactive oxygen species (ROS) able to induce death of breast cancer cells (BCC). Selectivity was obtained by the conjugation with Trastuzumab (Tras), a specific monoclonal antibody for selective detection and treatment of HER2-overexpresing malignant BCC. With the use of nanocomplex UCNP-ZnPC-Tras, was observed selective tracking of SKBR-3 HER2+ BCC by using a confocal microscope and reducing cells viability to 80% upon 200mg/ml load and 5 minutes of irradiation. Furthermore, PS was replaced for a photocatalytic TiO_2/ZrO_2 shell which is excited with blue light coming from Tm^{3+} ions enhancing the ROS production and then killing cancer cells up to 88%. In this case, emission band at 801 nm was used for tracking cells at deep tissue. Indeed, we report the fabrication of inmunoliposomes nanocomplex loaded with UCNP, PS for PDT and drugs for chemotherapy. Results shows a combined chemo-photodynamic synergistic effect killing cells up to 80% after 10mM load and 5 minutes of irradiation. The specificity of our nanocomplex was achieved by conjugating a newly discovered anti-HER2 peptide screened from a phage display peptide library. The high selectivity of the peptide-conjugated was confirmed by confocal imaging of SKBR-3 (HER2-positive) and MCF-7 (HER2-negative) breast cancer cell lines, illustrating its target-specific nature. Results suggest great potential for multifunctional theranostic nanocomplex for detection, imaging and therapy of cancer.

We acknowledge financial support from UDLSB and CONACYT through grant 259192.

8:15 AM SB03.05.10
Stimuli-Responsive Mesoporous Silica Nanoparticles for Applications in Cancer Theranostics Nikola Knezevic, Minja Mladenovic, Mirjana Mundzic and Aleksandra Pavlovic; University of Novi Sad, Serbia

Mesoporous silica nanoparticles (MSN) exhibit highly beneficial features for devising nanosystems applicable in cancer therapy, imaging, or diagnostics. The high surface area of MSN, which can be easily postsynthetically functionalized with different organosilanes, in addition to their structured porosity available for loading cargo molecules, allows plethora of opportunities for devising multifunctional and multipurpose nanostructures.
In this context, our research focuses on devising MSN-based cancer theranostics, containing different modalities for targeting specific cancer microenvironment, and the capabilities for delivering cargo therapeutic molecules upon exposure to the specific conditions of this environment, such as tissue acidosis or elevated concentration of glutathione and other cancer-related biomolecules. Thus, specific surface modification and controlling the release process of therapeutic molecules enables utilization of MSNs as unique facilitators toward enhancing the efficacy and precision of cancer treatment, imaging and sensing.

Using New Materials for Brain-Like Computing—From Fundamental Mechanisms to High-Performance Devices Alberto Salleo; Stanford

University, United States

The brain can perform massively parallel information processing while consuming only ~1- 100 fJ per synaptic event. I will describe an electrochemical neuromorphic device that switches at low energy (~80 fJ), and displays a large number of distinct, non-volatile conductance states within a ~1 V operating range. The tunable resistance behaves very linearly, allowing blind updates in a neural network when operated with the proper access device. These devices also display outstanding endurance achieving over 10^9 switching events with very little degradation. I will describe our recent efforts at scaling and materials selection, allowing us to reach 20 ns write pulses and operation at high temperature (up to 120°C). In particular, we developed a fully lithographic process that allowed us to demonstrate sub-µm channel devices, opening the door to integration with Si driving circuitry. By carefully deuterating the electrolytes, we provide strong evidence that the secret to the high speed and low energy switching properties of these artificial synapses is the combination of electronic and protonic transport. Finally, we demonstrate that the working mechanism is quite general by fabricating and operating high-performance synapses based on MXenes. This generality is promising in terms of monolithic integration as MXenes can be chosen to be BEOL compatible with Si.

11:00 AM *SB04.01.02
Large-Scale Crossbar Arrays of Analog Memristors for In-Memory Computing Qiangfei Xia; University of Massachusetts, United States

It becomes increasingly difficult to improve the speed-energy efficiency of traditional digital processors because of limitations in transistor scaling and the von Neumann architecture. Computing systems augmented with emerging devices such as memristors offer an attractive solution. A memristor, also known as a resistance switch, is an electronic device whose internal resistance state is dependent on the history of the current or voltage it has experienced. Because of its small size and fast switching speed, a memristor consumes a small amount of energy to update the internal state (training). Within large-scale crossbar arrays, memristors perform in-memory computing by utilizing physical laws, such as Ohm's law for multiplication and Kirchhoff's current law for accumulation. The current readout (inference) at all columns is finished simultaneously regardless of the array size, offering massive parallelism in vector-matrix multiplication and accelerating neural computing. This talk will first introduce an analog memristor that meets most requirements for in-memory computing in artificial neural networks. We will then showcase the integration of large-scale crossbar arrays of these memristors and the implementation of multilayer neural networks for several machine learning applications.

11:30 AM SB04.01.03
Oxygen Vacancy Based Electrochemical Memory Yields Deterministic Analogue Switching and Nonvolatile State Retention Yiyang Li; University of Michigan, United States

In-memory computing with combined logic and memory functionality is a promising energy-efficient solution for data-intensive processes like machine learning. A crucial component towards in-memory computing is the analogue nonvolatile resistive memory element. Two-terminal filamentary valence-change memory (VCM) based on metal oxides are extremely difficult to control due to the formation of a nanosized filament. On the other hand, more predictable and deterministic solutions like electrochemical random-access memory (ECRAM) based on the intercalation of lithium and proton ions have poor state retention when scaled to nanosized dimensions, and often utilize materials that are difficult to integrate into CMOS processes. A memory solution possessing all of these requirements have been elusive.

In this work, we combine the VCM and ECRAM concepts by replacing the highly mobile lithium and proton ions in ECRAM with less mobile oxygen vacancies. As a three-terminal ECRAM cell with a solid electrolyte, it possesses highly desireable linear and deterministic analogue switching at moderately elevated temperatures (~100-150C). On the other hand, the low mobility of oxygen vacancies at room temperatures provide nonvolatile state retention for days and weeks at scale without a selector, while also enabling the use of CMOS-compatible transition metal oxides. We further show how the switching and retention time are related to fundamental material properties like ionic resistance and chemical capacitance, and how changes in material processing conditions can be used to control the switching and retention properties.

11:45 AM SB04.01.04
Reliability of ZrO_2-ReRAM Based Memristive Crossbars in Inference Dominated Applications Johannes Mohr[1], Christopher Bengel[1], Stefan Wiefels[2], Rainer Waser[1,2], Stephan Menzel[2] and Dirk J. Wouters[1]; [1]RWTH Aachen University, Germany; [2]Forschungszentrum Jülich GmbH, Germany

In recent years, many novel computing paradigms have emerged that promise to complement the classic von-Neumann architecture, such as artificial neural networks and computation-in-memory. It is expected that these will enhance the functionality of everyday devices, such as in edge-AI and the internet of things as well as in datacenters for green-IT.
Analog accelerators based on crossbar arrays of non-volatile memristive devices (such as resistive switching ReRAM) are believed to be well suited for many of these applications, as they offer efficient (i.e., fast parallel and low power) operation and high integration densities. However, because of their high write energy and limited write count, applications of interest are limited to read-dominated ones, such as ANN inference or database queries. Yet, the effect of ReRAM device reliability issues as variability and drift on the crossbar operation needs to be explored.
To characterize the reliability of the crossbar, a representative computation is needed. The vector dot-product was chosen here because it can serve as a computational primitive for constructing more complicated operations such as matrix or tensor multiplications, which are among the most utilized operations in neural networks. Therefore, it can reveal the key behaviors, while still being sufficiently simple to allow for easy interpretation of the results. We fabricated crossbar structures based on a ZrO_2/Ta ReRAM device stack. These feature a number of cells connected with one electrode to a common bitline, and can be viewed as a column of a passive memory array. The measurements presented were performed on 8-bit words stored in these. To perform a computation, an input voltage vector is applied to the block, the sum of the currents through all memristive devices is then the calculated dot-product. Using this configuration, we experimentally demonstrated the feasibility of the operation. From these experiments, a number of important conclusions could be drawn regarding the memristive device characteristics. For example, it was found (using binary weights) that the spread in current levels depends strongly both on the accuracy of the programmed low resistance state value and on the resistance level of the high resistance state.
Furthermore, we identified typical failure mechanisms, such as read disturb, which is a change or drift in the device resistance caused by repeated reading of the cells or random bit-flips. We show how these are influenced by the magnitude of the applied voltages, and compare the behavior to that expected from the characterization of single cells. We demonstrate how they can be understood based on the material properties, such as the non-linear device kinetics being a key driver of low resistance state degradation. This allows us to identify the best operating conditions.
In a real world application the crossbar does not operate as a standalone device, but in conjunction with CMOS periphery. This periphery is needed to convert between the analog domain of the crossbar and the digital domain of the rest of the system. The impact of the measured device level failures on this interfacing between the analog and digital world is investigated through simulation. For these, we fitted our physics based compact model JART VCM v1b to measured data from the cells, which is able to describe the device-to-device and cycle-to-cycle variability, as well as mechanisms such as read disturb and random telegraph noise.

SESSION SB04.02: Biointerfacing and Biosensing

1:30 PM *SB04.02.01
Translational Neuroelectronics Dion Khodagholy; Columbia University, United States

As our understanding of the brain's physiology and pathology progresses, increasingly sophisticated technologies are required to advance discoveries in neuroscience and develop more effective approaches to treating neuropsychiatric disease. To facilitate clinical translation of advanced materials, devices, and technologies, all components of bioelectronic devices have to be considered. Organic electronics offer a unique approach to device design, due to their mixed ionic/electronic conduction, mechanical flexibility, enhanced biocompatibility, and capability for drug delivery. We design, develop, and characterize conformable organic electronic devices based on conducting polymer-based electrodes, particulate electronic composites, high-performance transistors, conformable integrated circuits, and ion-based data communication. These devices facilitate large-scale neurophysiology experiments and have led to discovery of a novel cortical oscillation involved in memory consolidation as well as elucidated patterns of neural network maturation in the developing brain. The biocompatibility of the devices also allowed intra-operative recording from patients undergoing epilepsy and deep brain stimulation surgeries, highlighting the translational capacity of this class of neural interface devices. In parallel, we are developing the high-speed conformable implantable integrated circuits and embedded acquisition and storage systems required to make high channel count, chronic neurophysiological recording from animals and human subjects possible. This multidisciplinary approach will enable the development of new devices based on organic electronics, with broad applicability to the understanding of physiologic and pathologic network activity, control of brain-machine interfaces, and therapeutic closed-loop devices.

2:00 PM *SB04.02.02
Stable Self-Healing Neural Circuits in Millimeter-Sized Animal Jacob T. Robinson; Rice University, United States

By understanding the self-healing properties of biological systems it may be possible to build robust artificial systems with similar stable operation. Here we discuss how the nervous system of the Hydra - a millimeter-sized aquatic cnidarian - can reorganize itself in a matter of hours to regain function after half the neurons are lost. By studying how this simple nervous system confined to two layers of cells achieves this robust control of the body we hope to reveal ways we may be able to design and build robust, soft, biological neural control systems.

2:30 PM SB04.02.03
Polymeric Thin–Film Memristor Integration with Sensors onto Reconfigurable Structures for *In Situ* Processing of Tactile Inputs Subhadeep Koner[1], Yongchao Yu[1], Katherine Riley[2], Juan C. Osorio[2], Carlos Montenegro[2], Janav Udani[2], Harith Morgan[2], Andres F. Arrieta[2] and Stephen Sarles[1]; [1]University of Tennessee, United States; [2]Purdue University, United States

In animals, and especially humans, trained neural networks form associative learning patterns that allow rapid classification and decision making (e.g. object identification via touch sensing). In contrast, current engineered systems are unable to sense and classify information without significant instrumentation and software. But this might be possible in hardware alone if a system were constructed in a way that combines materials for distributed sensing, intrinsic computing (for classification), and memory (for learning). Only a handful of research works by Bao et.al, Lee et.al, Zhu et.al have tried to explore the artificial sensory nervous system, mostly using transistors, with just one work by Zhang et.al used threshold dependent switching devices for data processing.
Recently, Arrieta, et al demonstrated thin, flexible dimpled sheets, comprised of planar arrays of bi-stable domes, which reconfigure their global shapes in emergent forms when specific domes are inverted. The global shape of the sheet is dictated by both the local pattern and sequence of dome inversions. We propose to leverage the complex mechanics of these dimpled sheets combined with polymeric thin film non-volatile memristors to provide a novel foundation for combining autonomous reconfiguration with distributing sensing and embedded memory—akin to a peripheral nervous system—for onboard classification in engineered structures.
In this study, we demonstrate that dome inversion events can be sensed and remembered by integrating resistive strain sensors connected electrically to memory storage elements. The former is achieved by printing conductive traces into the dimpled sheets at positions near the individual domes, while the latter consists of polymeric thin-films that function as memory resistors. When the two are connected in series and biased with voltage, a transient change in sensor resistance caused by deformation of the dome encodes a permanent change in the resistance of the memristor. Through fabrication and experiments, we study the design and integration of both the sensor and memory storage elements for effective operation. An amplification circuit is used to magnify the changes in sensor resistance occurring during dome deformation, which allows the memristor voltage to eclipse the switching threshold. Using 1 sensor:1 memristor pairs, we demonstrate spatially distributed transduction and memory of dome inversions, and by applying a pulsatile voltage, we demonstrate incremental changes in the state of the memristor, which allows for temporal encoding of dome inversion events. These capabilities set the stage for an era of smart sensing and memory (via memristors) applications with emerging systems (reconfigurable sheet) that interact with the world for autonomous classification of tactile information.

2:45 PM SB04.02.04
Organic Electrochemical Networks for Brain-Inspired Computation and Classification Tasks of Biosignals and Biofluids Matteo Cucchi, Hans Kleemann and Karl Leo; TU Dresden, Germany

Early detection of malign patterns in patients' biological signals can save millions of lives. In this regard, artificial intelligence and machine learning can be used to detect patterns with super-human abilities. However, the practical clinical application of these methods is mostly constrained to an offline evaluation of the patients' data. In-vivo and real-time use of machine learning is so far only a vision, hampered by the difficult integration of traditional electronics and dedicated hardware into the human body.
Previous studies have identified organic electrochemical transistors (OECTs) as ideal candidates in bioelectronics for biosignal monitoring and sensing. However, using them for pattern recognition in real-time has so far not been achieved. Likewise, OECT-based artificial synapses have been proposed, but never integrated into networks.
In the present study, we produce and characterize brain-inspired random networks composed of OECTs and employ them for time-series predictions and classification tasks using the machine learning framework known as reservoir computing.
Due to their biocompatibility and low energy consumption, these networks could serve in implantable devices to carry out real-time on-chip computation. We successfully pattern these networks on flexible and biocomptaible substrates and we apply them to learning tasks with classical databases (classification of flowers and time-series predictions).
Furthermore, we show the potential use of the networks for biofluid monitoring and biosignal analysis. For this purpose, we classify 4 classes of arrhythmic

heartbeats with an accuracy of 88%. Each measurement is performed in PBS solution, in order to mimic the interface between the polymer and the biological cellular environment.
The results of this study introduce a novel paradigm for biocompatible computational platforms and may enable the development of ultra-low power consumption hardware-based artificial neural networks capable of interacting with body fluids, sensing chemicals, and monitoring biological tissues.

3:00 PM SB04.02.05
An Organic Artificial Synapse Coupling Optical and Electronical Readouts to Replicate Multiple-Neurotransmitters-Based Learning and Forgetting Patterns Giovanni Maria Matrone[1,2], Csaba Forro[1,3], Claudia Lubrano[1], Ugo Bruno[1], Bas de Jong[4], Stefano Cinti[5], Yoeri van de Burgt[2] and Francesca Santoro[1]; [1]Istituto Italiano di Tecnologia IIT, Italy; [2]Technische Universiteit Eindhoven, Netherlands; [3]Stanford University, United States; [4]Cicci Research, Italy; [5]University of Naples Federico II, Italy

In biological neural networks communication relies on electric signals in the form of action potentials (APs) that trigger the release of neurotransmitters at the synapses, thus influencing the mechanisms of synaptic plasticity that regulates over time the transmission efficiency across the synaptic cleft. Neuromorphic computing and its progress intrinsically depend on faithfully replicating the communication mechanisms of biological neural networks. As such, electrical to chemical signal transduction is essential to fully mimic brain functions and establish in future an active interaction with biological tissues[1]. The potential transition from fully artificial to bio-hybrid, integrated synapses is only enabled by neuromorphic systems that display synaptic conditioning based on biochemical signalling activity which typically involves more than one neuromodulator.
The conductive polymer mixture PEDOT: PSS can be exploited for the electrochemical detection of electroactive neurotransmitters[2] (i.e. dopamine, serotonin, ascorbic acid) through redox reactions while providing a suitable biocompatible interface with cells and neurons[3].
Here, we report the first demonstration of a neuromorphic platform recapitulating the synergetic concourse of multiple neurotransmitters (NTs) that control synaptic weight modulation. This novel symmetric electrochemical neuromorphic organic device (SENODe) is capable of identifying three neurotransmitters that are simultaneously present and through modular microfluidic channels to mimic the recycling machinery of the synaptic cleft and control the output to replicate exocytosis-driven synaptic potentiation and depression[4].Hence, the platform allows to transduce the neurotransmitters-mediated chemical signal, eliciting an output that is stored and read as a change in the polymer's conductance, a reversible neuromorphic phenomenon that replicates neuronal's short-term and long-term plasticity[5].Moreover, by exploiting PEDOT:PSS electrochromism, the system's readout is alternatively monitored as a variation of the polymer's transmittance. The combination of the two readout mechanisms allows to emulate high order biological processes such as intrinsic forgetting, memory consolidation and NTs co-modulation, while also classic conditioning processes are replicated. Hence, the possibility to combine different NTs and input stimuli enableto program the synapse weights opens the way to the integration of array of devices which recreate complex, more refined brain's learning processes.

Sheraton, 2nd Floor, Liberty B

4:00 PM *SB04.03.01
Evolvable Organic Electronics Based on *In Situ* Polymerization Magnus Berggren; Linkoping University, Sweden

Neuromorphic electronics is a promising approach to enable dedicated computing at the site of sensing and actuation at the same time it offers new strategies to perform signal processing. Neuromorphic devices and systems combine signal processing and memory functionality in a manner to enable "training" and "evolution" of hardware to improve its performance for identification, perception and/or quantifying data and information. Our approach takes use of operating organic electrochemical devices and systems in electrolyte media containing electroactive monomers. This approach allows us to evolve the actual physical dimensions of devices while operating and performing signal processing. Organic electronic materials are unique in the sense that they can operate and be manufactured at the same conductions, which here allow us to make novel neuromorphic technology that relies on evolving critical device parameters of organic electrochemical transistors. We will report on device architectures, manufacturing approaches, materials and system design for organic evolvable electronics.

4:30 PM SB04.03.02
Particulate Composite Anisotropic Ion Conductor Richard Yao and Dion Khodagholy; Columbia University, United States

Ions are the primary charge carrier in physiological environments. Conventional inorganic electronic materials used in bioelectronic devices rely on surface capacitance for conversion of ionic potentials to electrons at the tissue interface for electrophysiological sensing and stimulation. In contrast, conducting polymers have mixed ion and electron conductivity that enables ion-based modulation of electronic charge carriers. However, it is not possible to individually control the properties of these polymers' ion and electron conducting domains. Mixed-conducting particulate composites are an emerging material that allows precise tuning of ionic and electronic conduction states by varying particle size and density in a scaffolding matrix. We hypothesized that a similar strategy could be used to create an anisotropic ion conductor by controlling the particle path (ionic mean free path) length to allow ion conductivity only within the lateral plane. To test our hypothesis, we synthesized anisotropic ion conducting films composed of biocompatible ion conducting particles and organic dielectric materials. Electrochemical impedance spectroscopy and scanning electron microscopy measurements were performed to characterize the degree of anisotropy and mean free path of particles. We showed that such composites have uniformly distributed particles, hydration stability over weeks, scalable thickness, tunable out-of-plane conductivity, and consistent anisotropy for various particle and scaffold materials. Additionally, an anisotropic ion conductor can be designed as a soft, stretchable, and conformable transducer that directly interfaces with the skin for neural

interface applications. We demonstrated the application of this material by acquiring biological signals via electrocardiography. Furthermore, we applied this ion membrane in organic electrochemical transistors (OECTs) to eliminate crosstalk between transistors, which is conventionally caused by the use of a shared electrolyte. This enables the fabrication of high-density transistor arrays, opening the avenue for organic integrated circuits and OECT-based neuromorphic computing devices. The development of this novel anisotropic ion conducting film has a wide range of implications and potential applications, ranging from anisotropic interfaces with biological tissue for high-resolution electrophysiology recordings and large-scale integration of ionic circuits, to directional control and programming of synaptic weights for artificial neural network and neuromorphic devices.

4:45 PM SB04.03.03
Biomembrane-Based Reservoir Computing for Image Classification Joshua Maraj, Jessie Ringley and Stephen Sarles; The University of Tennessee, Knoxville, United States

Biomembrane-based devices exhibit unique capabilities in the realm of neuromorphic applications. Doping model lipid membranes with voltage-active species transforms them into low voltage volatile memristors that dynamically and nonlinearly process incoming signals in a manner consistent with sensory synapses in the retina and olfactory systems. Unlike the brain however, volatile memristor networks do not have a built-in method to interpret processed signals. Reservoir computing (RC) may be one such way to interpret the nonlinear, history-dependent outputs from such networks. In the simplest terms, a reservoir is a network of nodes with inputs and outputs whose connection topology and weights do not change. Classification can be performed on reservoir outputs using supervised learning techniques to train a “readout layer” of artificial neurons, independent of the internal connectivity that defines the reservoir itself. Recently, volatile, solid-state memristors have been successfully used to create a reservoir for enbling image classification and chaotic temporal forecasting tasks. Low voltage, organic, and biocompatible materials, including those that more faithfully emulate the short-term plasticity of biological synapses, however, have not yet reported these capabilities but have the necessary properties to show similar success.

Herein, we propose the use of monazomycin-doped droplet interface bilayers (MzDIB) as candidates for reservoir computing nodes. We hypothesize that this material composition has unique properties that can reduce the overall size of the reservoir which will reduce footprint and energy expenditure. Using physical modeling, numerical simulation, and image classification tasks, we show that MzDIBs can accurately classify handwritten numbers digitized as small (5x5) or large (20x22) pixel representations of digits with appropriately sized reservoirs. A custom 5x5 pixel digit dataset consisting of ten distinct representations of each integer 0-9 is tested as proof of concept, with the larger 20x22 images consisting of the MNIST handwritten digit dataset with black borders removed. To process images using voltage-activated MzDIBs, pixel rows of image are converted into time varying voltage inputs fed at different rates into the reservoir. The voltages cause bi-directional, time-varying changes in membrane conductance due to Mz channel formation, such that the simulated final conductance states are then used as inputs to a 196x10 readout layer for image classification. We show that classification using a MzDIB reservoir network is feasible. Fully realized arrays with more complex connectivity have the potential to be hardware based reservoir computers due to their low operation voltage, biocompatibility, and ease of assembly.

5:00 PM SB04.03.04
Independent Impact of the Electrode Thermal Environment on the Analog Response of HfO_x-Based Filamentary Neuromorphic Devices Matthew P. West[1], Robert H. Montgomery[1], Georges Pavlidis[2], Riley Hanus[1], Fabia Farlin Athena[1], Andrea Centrone[2], Samuel Graham[1] and Eric M. Vogel[1]; [1]Georgia Institute of Technology, United States; [2]National Institute of Standards and Technology, United States

Filamentary adaptive oxides operate on nanosecond time scales, with local temperatures as high as 1000 K, yet the impact of the thermal environment on their analog operation is often ignored. These devices are a promising new technology for neuromorphic and biomimetic computing applications, which require linear, analog resistance changes. Filamentary oxides can be set to a continuum of resistance states based on the amount of oxygen ions within a nanosized area, called a filament. If the maximum current is well controlled, the oxygen deficient region can be partially re-oxidized by reversing the bias, thus increasing the resistance of the device. The resistance is modulated by applying voltage pulses for times varying many orders of magnitude, from seconds to nanoseconds. The ability to realize these devices in neuromorphic computing models such as spike timing dependent plasticity or pattern recognition relies on achieving a repeatable, linear resistance change. Understanding the role that the thermal environment has on the distribution of oxygen ions will inform material choices for the electrodes, substrates, and packaging of neural network chips.

The main mechanisms that drive the oxygen ions in and out of the filament are drift, diffusion, and thermophoresis [1]; all of which are heavily influenced by the temperature. Temperature gradients are the driving force for thermophoresis, which is very strong in these devices due to a localized high temperature region where all the current passes. Previous work showed changing the thermal conductivity of the substrate by an order of magnitude, from 138 W/m-K to 1.2 W/m-K, increased the percent change in the resistance of a single pulse from 150% to 450% [2]. It was determined that when the substrate thermal conductivity was low, the electrode acted as a heat sink. To influence the thermal environment of the switching oxide more directly, this work focuses on changing the thermal properties of the electrodes while maintaining the same chemical environment near the filament. Previous studies have explored the impact of the electrodes in direct contact with the filament [3], however, this layer also alters the bonding and release of oxygen ions, and thus these experiments did not independently change the thermal environment. In this study, the thermal environment imposed by the electrodes will be independently changed by surrounding the filamentary HfO_x active layer with thin, 5 nm gold layers. The bulk of the electrodes will then be varied between silver, platinum, and TiN having thermal conductivities of ~429, 72, and 25 W/m-K. Initial finite element modeling suggests that increasing the thermal conductivity of the electrodes reduces the initial resistance change to the first pulse. This is important because these devices typically have a large initial resistance change that quickly levels off, instead of the desired linear change with the number of pulses. The digital, analog, and operation temperature of these devices are compared and supported by modelling work. By tailoring the thermal environment of the device, the temperature gradient is manipulated thus altering relative magnitudes of three main thermal driving forces, drift, diffusion, and thermophoresis. Fundamentally understanding how the electrode materials influence the local temperature distribution will lead to more reliable and repeatable filamentary devices for neuromorphic applications.

SB04.04.01
Impact of Oxygen Concentration at the HfO_x/Ti Interface on the Behavior of HfOx Filamentary Memristors Jinho Hah, Matthew P. West, Fabia Farlin Athena, Riley Hanus, Eric M. Vogel and Samuel Graham; Georgia Institute of Technology, United States

Towards future computing and nonvolatile memory (NVM), memristors have gained wide attention for their in-memory computing and neuromorphic computing applications [1, 2]. The resistive switching (RS) dynamics in memristors rely critically on oxygen ions and their recombination with oxygen vacancies to partially rupture and form the conductive filament (CF) [3] for modulating the device between the low resistance state (LRS) and high resistance state (HRS).

In this study, we investigated the effect of oxygen ion concentration at the HfO_x/Ti interface on set and reset operation, LRS, and HRS characteristics in HfO_x-based filamentary memristors. Devices with higher oxygen ion concentrations at the interface were fabricated by performing oxygen plasma treatment at varying times on the as-grown ~5 nm HfOx active layer via atomic layer deposition (ALD). Detailed x-ray photoelectron spectroscopy (XPS) analysis and its depth profile results verify the excess oxygen ion present at the HfO_x/Ti interface, and thin TiO_x layer has been formed between the HfO_x and Ti layers, resulting in a HfO_x/TiO_x/Ti structure. This change in interface chemistry at the active layer and capping layer near the top electrode have impacted the set transition behavior more gradual, favorable for analog logic computation. This work demonstrates the importance of oxygen ion concentration and motion in controlled growth of CF during memristor set operation.

SB04.04.02
Artificial Synapse with Neurotransmitter and Spike-Timing Dependent Plasticity (STDP) Modulation for Neuronal Micro-Circuitry Charles-Théophile Coen, Setareh Kazemzadeh, Aref Saberi and Yoeri van de Burgt; Technische Universiteit Eindhoven, Netherlands

For more than a decade, a shift of paradigm has taken place within neural implant engineering with the idea of implementing active components and bringing out modalities capable of modulating the biological surroundings. Examples span from integration of micro-LED for photostimulation of cells, to microfluidic systems for local drug delivery.

This shift has been a cornerstone in neuroengineering that allowed to move from a passive monitoring to a dynamic modulation of the nervous system. Nonetheless, one of the missing parts is the ability to emulate certain functions of the neural system, such as neuronal connectivity, network plasticity or local computing. Indeed, to achieve a biologically relevant modulation, it is crucial to mimic as closely as possible neuronal processes happening in the body. The next generation of devices needs thus to focus on implementing biomemetic aspects to not only interface with the nervous system, but recreate these biological functions to locally sense, process and modulate it.
The central nervous system is at the essence of our ability to learn, memorize and compute information and at the core of this intricate and complicated network lays the synapse and its capacity of passing information from one neuron to another. The first building blocks to recreate the functions of this key element have already been developed with a non-volatile electrochemical neuromorphic organic device (ENODe)[1] which showed short- and long-term plasticity, laying down the foundation of neuromorphic devices for bio applications. Another important milestone has been the modulation of a biohybrid synapse through the inhibitory neurotransmitter dopamine released by neuron-like cells[2].
In this work, we propose to further develop these technologies and to create an artificial synapse capable of creating neuronal micro-circuits. In its nature, the synapse can strengthen or weaken over time and different mechanisms cooperate to achieve this plasticity, such as the release of neurotransmitters by the presynaptic neuron or the time difference of firing between the pre- and postsynaptic neurons. We are therefore investigating the modulation of an artificial synapse trough the presynaptic release of inhibitory or excitatory neurotransmitters and through a spike-time dependent plasticity (STDP) phenomenon. An unconnected pair of neurons is coupled together thanks to this artificial synapse showing a plasticity at the chemical level, with the neurotransmitters, and in the time domain, with the STDP, allowing a more truthful modulation.
This work thus aims at creating an artificial synapse that emulates as closely as possible its biological counterpart and presents a platform capable of creating a closed-loop neuronal micro-circuit based on neuromorphic devices.

SESSION SB04.05: Materials and Devices for Neuromorphic Computing and Learning
Session Chair: Robert Nawrocki
Wednesday Morning, December 1, 2021
Sheraton, 2nd Floor, Liberty B

10:30 AM *SB04.05.01
Novel Organic Materials and Architectures for Neuromorphic Computing George G. Malliaras; University of Cambridge, United Kingdom

The realization of bioinspired circuits that mimic the signal processing capabilities of the brain demands the reproduction of both short- and long-term aspects of synaptic plasticity on a single device level. The emergence of organic electronics has made available a host of new materials and devices with properties that are well-suited to address this challenge. We show how mixed conductivity in organic semiconductors can be leveraged to control neuromorphic functions similar to the basic short-term and long-term synaptic plasticity. Namely, we demonstrate that the timescales for functions such as depression, adaptation and dynamic filtering can be controlled by tuning the ratio of electronic/ionic mobility. We further show that 3D printing can be leveraged to develop new architectures for neuromorphic computing.

11:00 AM *SB04.05.02
Control of Ion Trapping for Non-Volatile Electrochemical Transistors Jonathan Rivnay; Northwestern University, United States

Materials processing and synthetic design serve as ideal avenues to control the transport properties of polymer-based mixed ionic/electronic conductors. Small changes in chemistry can affect the materials electronic mobility, swelling, ion uptake and stability. Devices based on these materials have thus opened up new opportunities in bioelectronics, energy, and neuromorphic computing. Associative learning, a critical learning principle to improve an individual's adaptability, has been emulated by few organic electrochemical devices. However, complicated bias schemes, high write voltages, as well as process irreversibility hinder the further development of associative learning circuits. Here, we present a non-volatile organic electrochemical transistor (OECT) based on a poly(3,4-ethylenedioxythiophene):tosylate (PEDOT:Tos)/ Polytetrahydrofuran (PTHF) composite. This device can continuously and reversibly change its conductance state at a write bias less than 0.8 V and the state retention time can be longer than 200 min without decoupling the write and read operation. By incorporating a pressure sensor and a photoresistor into the gate terminal of volatile and non-volatile OECTs, a neuromorphic circuit is demonstrated with the ability to associate two physical inputs (light and pressure), which may have implications for biomimetic devices like electronics-skin and neuroprosthetics. To unravel the non-volatility of this material, UV-Vis-NIR spectroscopy, X-ray photoelectron spectroscopy (XPS) and grazing-incidence wide-angle X-ray scattering (GIWAXS) are used to characterize the oxidation level variation, compositional change and the structural modulation of the PEDOT:Tos/PTHF films in various conductance states. These studies support the finding that non-crystalline PTHF retains injected cations, and thus allowing for the non-volatile memory behavior of the composite OECT devices. The implementation of the associative learning circuit as well as the understanding of the non-volatile material represent critical advances for organic electrochemical devices in neuromorphic applications.

11:30 AM SB04.05.03
Organic Neuromorphic Electronics for Local Control and Learning—Path Planning Robot in a Maze Imke Krauhausen[1,2], Dimitrios Koutsouras[1], Armantas Melianas[3], Scott T. Keene[4], Katharina Lieberth[1], Hadrien Ledanseur[1], Rajendar Sheelamanthula[5], Alexander Giovannitti[3], Fabrizio Torricelli[6], Iain McCulloch[5,7], Paul Blom[1], Alberto Salleo[3], Yoeri van de Burgt[2] and Paschalis Gkoupidenis[1]; [1]Max Planck Institute for Polymer Research, Germany; [2]Technische Universiteit Eindhoven, Netherlands; [3]Stanford University, United States Minor Outlying Islands; [4]University of Cambridge, United Kingdom; [5]King Abdullah University of Science and Technology, Saudi Arabia; [6]University of Brescia, Italy; [7]University of Oxford, United Kingdom

Artificial intelligence applications have demonstrated their enormous potential for complex processing over the last decade. However, they are mainly based on digital operating principles while being part of an analogue world. Moreover, they still lack the efficiency and computing capacity of biological systems. Neuromorphic electronics emulate the analogue information processing of biological nervous systems.[1] Organic artificial synapses exhibit volatile as well as tunable/non-volatile conductance states that replicate the behavior of their biological counterparts.[2-6]
In this work we present a path planning robot that uses a small-scale, locally-trained organic neuromorphic circuit to navigate through a maze. The neuromorphic circuit responds and adapts to environmental stimuli directly, as it is integrated with the robot sensors. The on-chip integration of sensor signals together with low-power organic neuromorphic electronics paves the way toward stand-alone, brain-inspired computing circuitry in autonomous and intelligent robotics.[7]

Smart and Adaptable Biosensor Based on Organic Neuromorphic Circuit Eveline van Doremaele[1,2] and Yoeri van de Burgt[1,2]; [1]Eindhoven University of Technology, Netherlands; [2]Institute for Complex Molecular Systems, Netherlands

Traditional computing systems are unable to capture the capability of the brain in real world information processing as evidenced by the anticipated end to Moore's law. Neuromorphic computing aims to mimic the efficiency of the brain in complex classification tasks by applying learning directly in hardware and is promising for local edge computing applications such as smart point-of-care devices (1). However, straightforward tuneability, low power consumption and high accuracy are necessary for successful implementation of such applications (2). Recently, organic materials have emerged as building blocks for neuromorphic systems due to their low operation voltage, biocompatibility and excellent tunability properties (3). Nevertheless, fully autonomous bioelectronic applications demand not only the acquisition of biological signals, but also local data processing, storage and the extraction of specific features of merit (4). Here we show a smart biosensor based on organic neuromorphic devices that can be fully trained in hardware to classify a model disease (e.g. cystic fibrosis). We use ion selective electrodes that are able to detect physiological levels of potassium and chloride and serve as the input to the hardware-implemented neural network. We demonstrate the flexibility and versatility of the neuromorphic system by on-chip retraining with different input signals as well as by classification of logic gates. These results pave the way for adaptive biosensors, smart point-of-care devices and personalized healthcare.

High-Aspect-Ratio Nanoelectrodes for the Recordings of Neuronal Signals with Sub-Threshold Signal Resolution Andreas Offenhaeusser[1], Pegah Shokoohimehr[1], Bogdana Cepkenovic[1,2] and Vanessa Maybeck[1]; [1]Forschungszentrum Julich, Germany; [2]RWTH Aachen University, Germany

Silicon-based microstructures are gaining importance in fundamental neuroscience and biomedical research. Precise and long-lasting neuro-electronic hybrid systems are at the center of research and development in this field. Nowadays, the best approach to study the electrophysiological activity of neurons in vitro and in vivo is based on planar microelectrode arrays (MEA) or field-effect transistors (FET) which can be integrated with microfluidic devices. However, the weak coupling between cell membrane and electrode surface is one of the major limiting factors and technology of 3D nanostructures for cell-chip coupling is currently a vivid field of investigation. Our present study focuses on the investigation of cell-chip interfaces with 3D nanoelectrodes for extracellular recordings. In particular 3D nanostructures with a high aspect ratio have become a suitable interface between neurons and electronic devices, since the excellent mechanical coupling to the neuronal cell membrane allows very high signal-to-noise ratios. In the light of an increasing demand for a stable, non-invasive and long-term recording at subthreshold resolution, we present a combination of vertical nanostraws with nanocavities. These structures provide a tight coupling with rat cortical neurons, resulting in high amplitude sensitivity and post-synaptic resolution capability, as directly confirmed by combined patch-clamp and MEA measurements.

Sensing, Thresholding and Associative Memory in Multistable Metasheets Juan C. Osorio[1], Carlos Montenegro[1], Katherine Riley[1], Harith Morgan[1], Subhadeep Koner[2], Yongchao Yu[2], Stephen Sarles[2] and Andres F. Arrieta[1]; [1]Purdue University, United States; [2]The University of Tennessee, Knoxville, United States

Organisms display a remarkable ability to perform complex functions in unstructured settings thanks to their co-evolved neuromechanical systems. Filtering, thresholding, and nonlinear amplification are common features found in organisms' mechanosensing. In contrast to engineering systems that rely on electrical filtering, organisms often employ distributed mechanical filters intimately integrated within their material architecture to extract only the necessary information from the environment. Filtering and signal thresholding are often achieved by careful positioning of geometrical features in the form of hairs or cilia spiders' legs, bats' wings, and fish's skins to sense the surrounding conditions mechanically.
An equally important aspect in neuromechanical systems is the capacity to form and retain memory that classifies different external stimuli. A crucial such mechanism is the ability to recall events from partial information, often described as associative memory. Integrating mechanosensing and memory formation as intrinsic properties in soft systems constitutes a new frontier in the development of engineered materials with potential applications in robotics, morphing structures, and wearables.
We report on multistable metamaterial architectures exhibiting hybrid units that enable filtering, thresholding, transduction, and associative memory formation, providing a route to synthetic neuromechanical systems. Our hybrid constitutive units collocate a geometrically bistable structure, a piezoresistive sensor, and a polymeric memristor. Specifically, we leverage the local bistability of constitutive units to filter external inputs, which are only transduced once the specific force threshold required to induce unit inversion (snap-through) is reached. The resulting unit inversion causes a nonlinear strain field that amplifies the external input, subsequently inducing transduction into an electrical signal leveraging collocated piezoresistive strips. The transduced signals trigger memristance changes which allow for memory retention. Notably, successive transduced signals accumulate changes of memristance, thereby enabling the formation of associative memories following a Hebbian rule within the paradigm of Hopfield networks. We demonstrate that the final accumulated signal on our memristors can be used to recall several spatiotemporal forcing patterns acting on metasheet featuring *N* hybrid units. Our metamaterials offer the rudiments of neuromechanical systems while requiring minimal external power and digital electronics, opening a route to engineered structures with organism-inspired functionality.

4:00 PM *SB04.07.01
Spiking Organic Electronics Synaptic Circuits Mohammad Javad Mirshojaeian Hosseini[1], Elisa Donati[2,3,4], Giacomo Indiveri[2,3,4] and Robert A. Nawrocki[1]; [1]Purdue University, United States; [2]Institute of Neuroinformatics, Switzerland; [3]University of Zurich, Switzerland; [4]ETH Zurich, Switzerland

Spiking Neural Networks (SNN), provide distributed computational capability and emulate the brain processing principles. Compared to conventional Artificial Neural Networks (ANN) that encode the information in the magnitude of the signal, SNN function based on modulation of spike frequency and pulse width [1]. Due to intrinsic compatibility with brain signaling, one of the target applications of SNN hardware implementation, known as neuromorphic systems [2], are Brain-Computer Interfaces (BCI) [3]. With a handful of exceptions [4], such implementations are typically implemented using silicon technology, which is physically hard and rigid, and non-biocompatible, resulting in a permanent damage to the brain's soft tissue. Organic electronics are physically soft and flexible, biocompatible, and offer low-cost, large-area fabrication, for direct interface with biological tissues [5].

Synapses play a crucial role in neural networks by interfacing between adjacent neurons [1]. They are responsible for tuning the neural signals and, as such, are critical in memory, learning, and cognition.

We report on the fabrication of a physically flexible organic electronics, spiking synaptic circuits. Organic Field-Effect Transistors (OFETs) were fabricated on rigid glass and physically flexible 50 µm thin Polyimide substrates. OFETs' architecture was bottom-gate top-contact, and fabricated through thermal deposition of Cr (3 nm)/Au (50 nm) as the gate electrode, 400 nm of Parylene diX-SR as the dielectric, 30 nm of dinaphtho[2,3b:2',3'-f]thieno[3,2-b]thiophene (DNTT) as the p-type and N,N'-bis(n-octyl)-x:y,dicyanoperylene3,4:9,10-bis(dicarboximide) (PDI8-CN2, also referred to as N1200) as the n-type organic semiconductors. A 50 nm layer of Au served as the source and the drain electrodes. A layer of Parylene encapsulated the structure. Non-fabrication-integrated commercial capacitors were used to accelerate the fabrication and the characterization process. Future work will include all

integrated, all-organic circuits.

The results demonstrate that the fabricated log-domain integrator synapse [6], a variant of the linear charge-and-discharge synapse, can implement a true linear integrator circuit. The circuit exploits the logarithmic relationship between subthreshold OFET gate-to-source voltages and their channel currents. It provides proportional output current based on continuously tunable synaptic weights. We also demonstrate the effects of synaptic weighting voltage, synaptic capacitance, and disparity in pre-synaptic signals on circuit time constant.
Crucially, we show that our organic synaptic circuits can provide time constants that are more than 200 times longer compared to silicon-based synaptic circuits, recorded in excess of 6 seconds. Also, theoretical calculations are commensurate with empirically recorded time constants.

We believe that this work is the first demonstration of a spiking organic electronic synaptic circuit. Time constants in the range of seconds are considered critical for future integration of synaptic neuromorphic circuits with biological neurons, for future implantable BMIs. Furthermore, with our previously demonstrated spiking organic electronic Axon-Hillock somatic circuits [7], it paves the way for future all-organic, flexible and biocompatible neuromorphic computing.

Solid-state Organic Electrochemical Transistor with Adjustable Biomimetic Properties for Spiking Neurons Hsin Tseng[1], Anton Weissbach[1], Lukas M. Bongartz[1], Laurie E. Calvet[2], Karl Leo[1] and Hans Kleemann[1]; [1]Technische Universität Dresden, Germany; [2]C2N, Université Paris-Saclay-CNRS, France

Neuromorphic devices and circuits offer huge potential for hardware-based neuromorphic computing and next-generation, power-efficient artificial intelligence (AI). Organic electrochemical transistors (OECTs) and related devices emerged as an interesting class of devices for neuromorphic computing as the interplay between ions and electrons in OECTs can be considered biomimetic. The research on OECTs mainly focuses on developing powerful and versatile artificial synapses for conventional AI paradigms, e.g., feed-forward neural networks. However, because of their biomimetic operation, OECTs might also be used to build bio-inspired spiking neurons for next-generation power-efficient computing. Here, we show an OECT with photo-patternable solid electrolyte advancing towards the integration of bio-inspired neurons. We discuss how the neuromorphic properties of OECTs, i.e. the time constants of the ionic and electronic subcircuit of the device, can be controlled by process and device parameters. We also demonstrate the first step towards the integration of Morris-Lecar inspired neurons, which offer type-I and type-II excitability in their spiking behavior. In particular, we discuss how the specific properties of the solid-state electrolyte OECTs, such as threshold voltage, subthreshold slope, hysteresis, and off-current leakage, influence the function of the subcircuit of our biomimetic neuron. The solid-state electrolyte OECT paves the foundation towards the integration of neuromorphic devices beyond artificial synapses, and the small-scale integration of OECTs exhibit potential for building blocks of next-generation spiking neuron circuits.

4:45 PM SB04.07.03
Neuromorphic Memory with Hydrogen Doped Rare-Earth Perovskite Nickelates Tae Joon Park, Hai-Tian Zhang and Shriram Ramanathan; Purdue University, United States

Strongly correlated perovskite nickelates ($RNiO_3$) have attracted great interest in condensed matter sciences due to its unique electrical properties such as metal-to-insulator transition. Hydrogenation induced electron doping leads to a phase transition in this material system independent of temperature. The electrical conductivity of $RNiO_3$ is extremely sensitive to the electron occupancy of Ni 3d orbitals. The electron from hydrogen occupies Ni eg orbital and results in remarkable resistance change by several orders of magnitude. The proton resides on interstitial sites of NiO_6 octahedra and can be mobile under electric fields. In this work, we applied high-speed voltage pulses and measured the resistance changes of hydrogen doped $NdNiO_3$ devices fabricated with conducting oxide (FTO) electrodes. We will discuss the effect of voltage pulses on proton migration in the nickelate device, which enables thousands of analog states with highly tunable electronic structures. Interestingly, non-volatile memory trees can be demonstrated in perovskite nickelate device at room temperature by applying consecutive positive or negative voltage pulses emulating synaptic weight branching noted in animal brains. This behavior is akin to magnetic frustration in spin-glasses at low temperatures. The complex synaptic behavior in perovskite nickelate devices can open up new avenues for design of memories for neuromorphic computing.

5:00 PM SB04.07.04
Stochastically Switching HfO_2/TiO_x ReRAM Devices for Spiking Neural Network Synapses Felix J. Cüppers[1], Christopher Bengel[2], Melika Payvand[3], Rainer Waser[1,2], Stephan Menzel[1] and Susanne Hoffmann-Eifert[1]; [1]Forschungszentrum Jülich GmbH, Germany; [2]RWTH Aachen University, Germany; [3]ETH Zürich, Switzerland

In today's computing architectures, fundamental physical limits are increasingly prohibiting performance improvements. At the same time, the amount of data, recorded by an ever rising number of sensors in various applications, is growing rapidly. In order for computers to keep up with this contradiction, new computing paradigms are required. Neuromorphic technologies are seen as key solutions as they can be employed at the edge of the sensors, rendering the need for storing the data or sending them to remote clouds. Augmenting these devices with emerging memory technologies empowers them with non-volatile and adaptive properties, which are desirable for low power and online learning requirements at the edge, independently from remote cloud computers. However, an energy- and area-efficient realization of such systems requires disruptive hardware and algorithm changes. Solutions based on memristive devices are in the focus of research and industry due to their low-power and high-density online learning potential. Specifically, the filamentary-type valence change mechanism (VCM) memories have shown to be promising candidates. Because of CMOS compatibility, HfO_2-based cells are among the most researched devices and are nearing industrial maturity. In consequence, physical models capturing a broad spectrum of experimentally observed features such as the pronounced cycle-to-cycle and device-to-device variability are required for accurate evaluation of the proposed concepts.
In this study, we present an in-depth experimental analysis of device-to-device and cycle-to-cycle variability of filamentary-type bipolar switching HfO_2/TiO_x nano-sized crossbar devices. A match of the experimentally obtained statistics and variabilities to our physically motivated, variability-aware JART VCM compact model [1] is established. The high degree of agreement between model and experiment allows us to evaluate the concept of parallel memristive devices forming a single synapse. Both experimental and theoretical results are presented and conditions for favorable properties of such synapses are defined. The interplay of cycle-to-cycle and device-to-device variability is analyzed in detail and descriptive figures of merit are defined, since the proposed concept should retain its functionality in case of devices with lower variability.

These parallel compound synapses form a synaptic array which is at the core of many neuromorphic chips. We exploit the cycle-to-cycle variability of the single devices for stochastic online learning which has shown to increase the effective bit precision of the synapses [2]. Finally, we demonstrate the stochastic switching operation as synapse update method in a Spiking Neural Network which classifies two patterns. In this small scale demonstrator, perfect accuracy is achieved, proving the feasibility of this alternative synapse concept. [3]

Monday Morning, December 6, 2021
SB04-Virtual

10:30 AM *SB04.08.01
"Lithionics"—On the Design of Lithium Oxides for Novel Neuromorphic Computing Functions Jennifer L. Rupp; Massachusetts Institute of Technology, United States

Next generation of energy storage may largely benefit from fast Li^+ ceramic electrolyte conductors to allow for safe and efficient batteries. With recent discoveries in thin film processing solid-state lithium ion conductors, such as Li-garnets and LIPON or LiSICON-based solids, have been recently considered as candidate materials not only for next-generation solid-state batteries but also for neuromorphic computing via memristors owing to the fast ionic transport in the solid-state electrolyte.
In the first part of this talk, we review current needs and challenges in the field of solid state batteries. We underline the advantages of various Li solid-state conductor materials and reflect on opportunities of thin film processing, being a requirement to define precisely the Lithium stoichiometries and related electronic state changes for transition metal ions, miniaturize the device, and reach high energy/information densities for energy storage, computation, and sensing.
In the second part, we focus on Li-film processing and controlling Lithium stoichiometries to reach fast conductive phases for Li garnets and Li titanates as solid state battery components, and memristive neuromorphic computing units. Insights on structure-phase-transport interaction and implications on performances will be exemplified for energy storage aiming high energy densities, and modulations of synaptic artificial weights through lithium induced metal-to-insulator transitions in lithium titanate memristors.

11:00 AM SB04.08.02
Ruthenium Prussian Blue Analogue for Electrochemically Programmed Artificial Synapses Donald A. Robinson, Austin Bhandarkar, Elliot J. Fuller, Vitalie Stavila, David Ashby, Catalin Spataru, Christopher Bennett, Matthew Marinella, Mark D. Allendorf and A. A. Talin; Sandia National Laboratories, United States

Artificial neural networks based on electrochemical random-access memory (EC-RAM) represent an emerging strategy for low power analog computing. EC-RAM synapses operate by virtue of linear/symmetric resistance tuning through electrochemically gated control of the charge state of a resistive channel. The exploration of promising active materials for EC-RAM functionality was previously limited to semiconducting organic polymers and metal oxides. Here we demonstrate a Ru-based Prussian Blue Analogue (RuPBA), an electroactive mixed valence semiconductor with a cyanide-bridged framework structure, as a new candidate material for EC-RAM devices. Our fabrication method employs inkjet printing to prepare both the RuPBA and ionogel electrolyte films. The RuPBA channel resistance depends on the electrochemically tunable ratio of Ru^{II} to Ru^{III} and the degree of cation intercalation in the micropores of the material. The relationship between charge state, resistance, and electronic structure is elucidated using *in-operando* Raman and UV/Vis/NIR spectroscopy. The RuPBA devices exhibit excellent linearity, symmetry, and consistency during pulsed voltage programming, as well as long term retention of conductance state.

11:15 AM SB04.08.03
Modeling and Measurement of Non-Linear Electrical Properties of Self-Assembled Ag_2S Nanowire Resistive Switching Networks for Neuromorphic Applications Mahshid Hosseini, Nikolay Frick, Damien Guilbaud, Ming Gao and Thomas LaBean; North Carolina State University, United States

Among the outstanding capabilities of biological brains is their ability to visualize, memorize, and recognize objects in erratic and unstable environments. The strength, versatility, and fault-tolerance of brains result from the sheer number of synaptic connections between neurons that is estimated to be ~10^{14}-10^{15} in a human brain. Reactivation of specific groups of neurons and the strength of connections between them play important roles in memorization and information processing. In the age of new information and communications technologies, these traits, among others, serve as motivation for design choices in development of bio-inspired computing technologies. Neuromorphic computing and artificial neural networks today represent an example of the most successful bio-inspired technologies that excel in a broad range of classification and regression tasks.
A large portion of current efforts to reach the goal of neuromorphic systems focuses on the use of ordered nanodevice structures, most notably the memristor crossbar array. Lithographic fabrication of such ordered structures inherently limits neuromorphic systems' complexity and scale and cannot mimic the sheer scale of complex interconnections of biological neural networks. In this study, two-dimensional, stochastic, self-assembled, bio-inspired, highly interconnected silver sulfide (Ag_2S) nanowire networks are studied experimentally and through simulation to investigate their usefulness for neuromorphic hardware applications, potentially for use in Reservoir computers. Resistive switching behaviors resulting from the electromigration interaction between memristive nanowires are explored. Single memristive Ag_2S nanowire, as well as small, randomly assembled networks of NWs with countable numbers of components, are also studied. We further compare experimental measurements with predictions from a novel simulation model, the "stochastic drift R_{ON} memristor model". This computational model suggests that R_{ON}, the resistance observed in the memristors' ON state, is not a constant but rather a function of the volume fraction of reduced silver ions in the Ag_2S matrix. In the experimental memristive systems described, several crucial synaptic functions are demonstrated, such as learning, forgetting, paired-pulse facilitation, and short-term plasticity. Some aspects of the physical mechanisms of the devices are also inferred from the observed behaviors. The self-assembled nanodevices and device networks described in this research

are first steps toward three-dimensional randomly self-assembled nanocomposite memristor networks for neuromorphic computing applications. Such materials represent promising candidates for next-generation biomimetic hardware. A critical issue yet to be resolved involves interfacing such memristive device networks with multi-electrode arrays such that finer-grained substates of the networks' electrical behaviors can be simultaneously and continuously read and routed for biologic-like computational tasks. This work aims to provide a convenient, low cost and low-power physical implementation for Reservoir Computing research with potential applications in communications, signal processing, and control.

11:30 AM SB04.08.04
Closed-Loop Biomimetic Synapse for Neuromorphic Network Design Ugo Bruno, Daniela Rana and Francesca Santoro; Italian Institute of Technology, Italy

As conventional silicon based computing techniques are reaching their limits in terms of energy consumption and density[1], neuromorphic platforms are emerging as new computational paradigm[2], with the ultimate goal of replicating the efficiency of the brain in terms of parallel computation. Among the plethora of the available materials and structures, organic electrochemical transistors (OECTs) have emerged for their natural ionic-to-electronic signal transduction, biocompatibility and possibility of operating in aqueous environment[3]. In particular, PEDOT:PSS based OECTs have been exploited to recapitulate neurotransmitter-mediated synaptic plasticity[4], in which the oxidation of a neurotransmitter modulates the doping state of the transistor, resulting in a change in device conductivity, de facto emulating the synaptic conditioning naturally occurring in biological synapses.
While successfully recapitulating spike-dependent plasticity, this approach still lacks the self-regulation mechanisms naturally found in neuronal networks: when the post-synaptic neuron is engaged in the neurotransmitter-mediated communication, receptor recycling occurs[5], while astrocytes provide a feedback onto the presynaptic terminal, to reduce or increase the release of such neurotransmitter[6]. Moreover, the PEDOT:PSS-based neuromorphic transistor, if used as a building block of an artificial network, would lead to a continuous de-doping of the devices, ultimately leading to the exhaustion of the network dynamics, because of the unidirectional modulation of the synaptic weight.
Taking inspiration from the nigrostriatal DA pathway, in which the endogenously generated H2O2 activates K+ channels, inhibiting DA neuron firing[7], a closed-loop synapse is proposed, in which the bidirectional modulation of the synaptic weight is shown. In particular, the output current of the device closes a feedback loop, allowing for a controller to drive a microfluidic system. As a result, an influx of dopamine (DA), and its subsequent oxidation, is used to cause the de-doping of both OECT gate and channel, while the inverse reaction can be induced by the introduction of hydrogen peroxide (H2O2). The presence of the control system proposed here introduces the astrocytes-like effect of presynaptic input regulation, naturally found in neural networks. This enables for synaptic weight control while avoiding the uncontrolled doping/de-doping of the PEDOT:PSS.
Ultimately, this platform paves the way for the creation of biomimetic complex systems. A network of artificial neurons can be designed in which the output depends on the presence of a neurotransmitter while each node can still be individually controlled, to induce and study topology-dependent dynamics propagation across the network.

11:45 AM SB04.08.05
Oxygen Composition Dependence of Forming Characteristics in Analog Resistive Switching Cells with Pt/TaO_x/Ta_2O_5/Pt Stack Structure Toshiki Miyatani[1], Tsunenobu Kimoto[1] and Yusuke Nishi[1,2]; [1]Kyoto University, Japan; [2]NIT Maizuru College, Japan

Resistive switching (RS) cells are promising as synaptic devices owing to analog controllability of the cell resistance. However, most transition metal oxide-based RS cells often show an abrupt decrease in the cell resistance (set process), resulting in the difficulty of the analog control of the cell resistance by the applied voltage [1]. Moreover, although some studies have reported gradual set processes, the mechanism of the gradual set processes is not clear [2]. Therefore, no design rules exist to improve the analog RS characteristics. In our previous study, we reported that analog RS characteristics can be obtained by adjusting the applied voltage after the unique forming process (semi-forming) in Pt/TaO_x/Ta_2O_5/Pt cells [3]. In this study, we mainly investigated the impacts of oxygen composition of the TaO_x layer on the semi-forming characteristics for the purpose of clarifying the mechanism of the semi-forming and subsequent analog RS phenomena.
We fabricated platinum (Pt)/tantalum sub-oxide (TaO_x)/tantalum oxide (Ta_2O_5)/Pt stack cells on a SiO_2/Si substrate. A 60-nm-thick Pt bottom electrode (BE) was deposited by DC sputtering. Then, a 10-nm-thick Ta_2O_5 and a 20-nm-thick TaO_x layer were deposited by reactive RF sputtering with different oxygen gas flow rates. The oxygen composition of the TaO_x layer was controlled by appropriately adjusting the oxygen gas flow rate between 0.8 sccm and 1.2 sccm. Finally, 25-nm-thick Pt top electrodes (TE) with various diameters (100–300 μm) were formed by electron beam evaporation. We evaluated forming characteristics by performing a current sweep on the Pt/TaO_x/Ta_2O_5/Pt cells with the BE grounded at room temperature.
Two types of initial transition processes occur in the Pt/TaO_x/Ta_2O_5/Pt cells. One is the transition process to a low resistance state (LRS) less than 100 Ω, which is conventionally called a forming phenomenon. The other is the transition process to a higher resistance state than the LRS, which is defined as a semi-forming phenomenon. Next, we examined dependences of the oxygen composition (x), initial resistance (R_{ini}), and occurrence frequency of the semi-forming phenomenon (F_{semi}) on the oxygen flow rate during deposition of a TaO_x layer (f_{Ox}). First, x is proportional to f_{Ox}, and the f_{Ox} range of 0.8–1.2 sccm corresponds to the x range of 1.3–2.0. Second, as x linearly increases, R_{ini} exponentially increases and F_{semi} tends to decrease. Here, we have reported that R_{ini} is mainly dominated by the hopping conduction through oxygen vacancies (V_Os) in the Ta_2O_5 layer [4]. The density of localized states corresponding to the V_O density was estimated from the temperature dependence of R_{ini} in each Pt/TaO_x/Ta_2O_5/Pt cell, resulting in that the density of localized states exponentially decreased from roughly 10^{22} $cm^{-3}eV^{-1}$ to 10^{19} $cm^{-3}eV^{-1}$ as x linearly increased from 1.3 to 1.7. In other words, the density of V_Os supplied from the TaO_x layer to the Ta_2O_5 layer decreases with increasing x.
From the above results, although the semi-forming phenomenon is more likely to occur as more V_Os are supplied to the Ta_2O_5 layer, the more supplied V_O causes the decrease in R_{ini}, bringing about a decrease in the resistance range of RS operation. To obtain the semi-forming and subsequent analog RS characteristics in the high-resistance range for reduction of power consumption, it is necessary to appropriately control the oxygen composition of the TaO_x layer.

Phase change memory (PCM) is a promising candidate for non-von Neumann based analog in-memory computing – particularly for inference of previously-trained Deep Neural Networks [1,2], as well as Neuromorphic computing [3,4]. Many factors including resistance values, memory window, resistance drift, read noise, and programming accuracy impact the performance of PCM in analog neuromorphic computing applications. We previously showed that resistance drift and noise of a mushroom-type PCM device can be reduced by introducing an additional projection liner [5]. The projection liner comprised of a non-phase change material could decouple the read operation from the write operation and help mitigate the non-ideal attributes such as drift and noise.

Here, we perform a systematic study of the electrical properties of these PCM devices—including resistance values, drift, noise, and endurance—and discuss the implications for in-memory computing. We optimize the PCM and projection liner materials to have effective drift mitigation while retaining a large enough memory window. We also examine how endurance cycling affects the phase change materials and the electrical characteristics of the devices. The results show that the liner is helping to maintain a rather constant reset resistance throughout the endurance cycles. With a widened memory window, no degradation in the drift mitigation through the cycling, and reduced read noise, these cycled PCM devices are shown to deliver excellent balance of performance for analog AI applications. Finally, the performance of these PCM devices for neural network inference is analyzed for state-of-the-art image processing and natural language processing tasks.

Artificial Intelligence with Radio-Frequency Spintronic Synapses Nathan Leoux[1], Alice Mizrahi[1], Danijela Marković[1], Dédalo Sanz-Hernández[1], Juan Trastoy[1], Paolo Bortolotti[1], Leandro Martins[2], Alex Jenkins[2], Ricardo Ferreira[2] and Julie Grollier[1]; [1]Université Paris-Saclay, France; [2]International Iberian Nanotechnology (INL), Portugal

For numerous Radio-Frequency applications such as medicine, RF fingerprinting or radar classification, it is important to be able to apply Artificial Neural Network on RF signals. In this work we show that it is possible to apply directly Multiply-And-Accumulate operations on RF signals without digitalization, thanks to Magnetic Tunnel Junctions (MTJs). These devices are similar to the magnetic memories already industrialized and compatible with CMOS. These devices are promising RF emitters. Like biological neurons, MTJs are non-linear oscillators, and it was already proven that they can efficiently emulate neurons in the framework of reservoir computing. These junctions can also be used as detectors and rectify RF signals.
We show experimentally that a chain of these MTJs between 250 and 400 nm of diameters can rectify simultaneously different RF signals, and that the synaptic weight encoded by each junction can be tune with their resonance frequency. Our architecture benefits both from frequency-multiplexing of the RF inputs and from the frequency selectivity of MTJs to route the information with a compact architecture.
Through simulations we train a layer of these junctions to solve the dataset “digits” with an accuracy as good as software neural networks (99.96 %). Finally, we show that our system can scale to multi-layer neural networks using MTJs to emulate neurons. In the future these MTJs could be scaled down to 10 nm.
Our proposition is a parallel and compact system that allows to receive and process RF signals in situ and at the nanoscale.
This work was supported by the European Research Council ERC under Grant bioSPINspired 682955, the French ANR project SPIN-IA (ANR-18-ASTR-0015) and the French Ministry of Defense (DGA).

Memristor-Based Neuromorphic Design for Temporal Pattern Processing and Learning Hai Li, Ziru Li and Brady Taylor; Duke University, United States

Memristor technology provides a more efficient solution to emulating the behaviors of synapses and neurons in neuromorphic systems compared to conventional CMOS technology. Memristive resistances can store synaptic weights, while memristive nonlinearity can be exploited for neuron circuits. Achieving the advanced learning capabilities and adaptability of the brain requires further circuitry to leverage the characteristics of these memristive devices. Basic spike-based learning algorithms such as spike-timing-dependent plasticity (STDP) have previously been demonstrated. In addition, circuits for exploiting novel device dynamics for flexible and powerful training rules will promote computationally efficient intelligence that approaches that of the human brain.
Spike-based encoding methods enable more efficient data processing when applied to memristor-based hardware for artificial deep (DNNs) and spiking neural networks (SNNs). In these designs, the memristor-based synapses take in binary spike trains rather than analog voltages, avoiding power-hungry analog-to-digital conversions and thus elevating energy efficiency. Encoding data as a binary spike train has historically involved generating proportional

spike rates. However, an increase in data value corresponds to an increase in the number of spikes. Temporal coding encodes data as discrete timings of voltage spikes for a much more efficient and precise method of representing data. For example, time-to-first-spike (TTFS) encodes data as the arrival time of the first spike during a predefined time period [1]. It minimizes spike numbers by using only one spike to carry data.
In realizing such neuromorphic systems, new ideas and approaches must be advocated. Architectures consisting of simple crossbar synapses and integrate-and-fire neurons should be adapted in favor of more biologically derived but often oversimplified models. Each component of a neural system incorporates its own unique dynamics and offers opportunities for a behaviorally parallel circuit to be developed and incorporated into a sophisticated neuromorphic design. Furthermore, the fast-shrinking factor size of novel devices promotes the potential for computationally dense neuromorphic building blocks. Following these methodologies, we proposed a memristor-based single-spiking processing engine with a set of circuitry designs for supporting DNN inference with the TTFS scheme, leading to faster computations and lower energy consumption [2]. Compared to conventional memristor-based dot product engines that encode data as the amplitude of voltages or currents, this design leverages the advanced spike-based encoding to shorten the computational period and pursue high efficiency. Furthermore, we demonstrated in-situ learning in a memristor crossbar using a methodology for single-spike-encoded STDP that could be incorporated into a TTFS system [3].
In our future exploration, we will investigate techniques for building large-scale memristor-based neuromorphic systems with online learning capabilities. The targeted system should support both the inference of input data and the update of neural network parameters. Circuit/architecture-level designs are required to implement either supervised or unsupervised learning rules with memristors while ensuring the forward and backward data paths do not interfere with each other.

2:00 PM *SB04.09.03
Robust RRAM-Based In-Memory Computing in Light of Model Stability Gokul Krishnan[1], Li Yang[1], Jingbo Sun[1], Jubin Hazra[2], Xiaocong Du[1], Maximilian Liehr[2], Karsten Bechmann[2], Rajiv Joshi[3], Nathaniel C. Cady[2], Deliang Fan[1] and Yu Cao[1]; [1]Arizona State University, United States; [2]SUNY Polytechnic Institute, United States; [3]IBM T.J. Watson Research Center, United States

Artificial intelligence (AI) today outperforms humans for a variety of applications, such as computer vision and natural language processing. Higher accuracy comes at the cost of increased computational complexity and model size, stressing already limited memory access.
RRAM-based in-memory computing (IMC) provides a dense and parallel structure to achieve high performance and energy efficiency in AI computing. The increased energy-efficiency is attributed to a full-custom design following the assumption that all weights are stored on-chip. However, such an assumption results in a significant area overhead, especially when the AI model size is rapidly increasing. Hence, model compression (e.g. pruning and quantization) is necessary for RRAM-based in-memory acceleration.
When an AI model is mapped to realistic RRAM devices, it will suffer from various non-idealities, such as statistical variations, quantization error, stuck-at-faults, and limited resistance ratio. These issues pose a significant challenge to designing robust RRAM-based IMC architectures. For instance, statistical variations in RRAM cause deviations in the programmed resistance, leading to a significant loss in post-mapping accuracy (i.e., accuracy in the presence of RRAM variations) for AI models. To mitigate the post-mapping accuracy loss, variation-aware training (VAT) is employed. VAT exploits the inherent redundancy in the AI model by embedding the device variations, based on a log-normal or normal distribution model, into the training process to achieve a variation-tolerant model, with no need of re-training for each individual RRAM chip.
Under model pruning and quantization, the efficacy of conventional VAT methods is reduced due to increased model sensitivity to variations, although a lower precision may help improve the tolerance. These algorithmic and device issues interact with each, affecting the optimal design choice of RRAM-based IMC. Hence, there is a need for a more systematic solution for robust RRAM-based in-memory computing with sparse and quantized AI models.
In this work, we propose a model stability-based VAT approach to recover the post-mapping accuracy with model compression. The proposed method utilizes VAT to train the compressed model with different scales of device variations and search for the most stable model to improve post- mapping accuracy. For a given model, higher model stability implies better tolerance of variations and thus, higher post-mapping accuracy. The model stability is visualized by the loss landscape and evaluated by the roughness score. A lower roughness score indicates a smoother loss landscape and a more stable model. We utilize a structured pruning method and model quantization to compress the AI model. The pruning method considers the mapping of the model on to the RRAM crossbar for best IMC performance. We illustrate that pruning results in a less stable model, while quantization improves the model stability.
For accurate modeling, we measured statistical variations from a 65nm CMOS/RRAM 1T1R chip and developed a cross-layer benchmarking tool. This tool incorporates RRAM device models, IMC architecture, pruning and quantization, and evaluation of model stability and outputs post-mapping accuracy, hardware performance, and model stability.
The major contributions of this work are as follows: (1) Based on the roughness score and loss landscape, we present that quantization (low-precision) improves the model stability, but pruning reduces the stability; (2) We propose a model stability-based VAT method, which searches the most stable model under variations to achieve the best post-mapping accuracy, without knowing the exact amount of RRAM testing variations upfront; and (3) We demonstrate that the proposed method achieves up to 19%, 21%, and 11% improvement in post-mapping accuracy on CIFAR-10, CIFAR-100, and SVHN datasets, respectively.

2:30 PM SB04.09.04
Electric Mott Transition and Neuromorphic Applications of Mott Insulators Laurent Cario, Julien Tranchant, Marie-Paule Besland, Benoit Corraze and Etienne Janod; CNRS-Université de Nantes, France

A great challenge in the field of neurocomputing is to mimic the brain behaviour by implementing artificial synapses and neurons directly in hardware. So far, many works were devoted to the realisation of artificial synapses but the realisation of artificial neurons in hardware is still scarce. This work shows that Mott insulators are interesting inorganic materials to consider in order to achieve this goal.
Mott Insulators experience resistive switching above a threshold electric field [1-4]. This resistive switching is related to the creation of hot carriers leading to an electronic avalanche breakdown and a burst of current in the electronic circuit (Firing event) [2]. Moreover, under a train of electric field pulses, narrow gap Mott insulators behave as a leaky integrators of hot carriers and this phenomenon could be modelled assuming the creation of a metallic phase at the local scale [3,4]. Narrow-gap Mott insulators subjected to electric pulsing can therefore implement the three basic functions Leaky Integrate and Fire (LIF) of artificial neurons [5]. A simple two terminal device made of Mott insulator thin film can therefore be considered as a promising LIF artificial neuron. This work shows the realisation and tests of such downscalable artificial neurons made with Mott insulators. [6]

Beyond-CMOS Vanadium Dioxide Devices and Oscillators for Brain-Like Information Processing Stefania Carapezzi[1], Gabriele Boschetto[1], Siegfried Karg[2] and Aida Todri-Sanial[1]; [1]LIRMM, University of Montpellier, CNRS, France; [2]IBM Research Europe - Zurich, Switzerland

In recent years, the improvement of traditional computing machines has been assisted by the Moore's law. However, nowadays, further shrinking of device dimensions is currently impeded by the reaching of physical limits. Additionally, the separation between storage and processing of data in von Neumann classical machines is power consuming, in contrast with the trend of reduction of energy intake for greener electronics. The human brain is an example of how sophisticated tasks may be accomplished by a computing engine with reduced power consumption. Then, neuromorphic computing can provide new precious insights, ready for being hardware-translated. In this respect, oscillatory neural networks (ONNs) are appealing ultra-low-power neuromorphic architectures able to perform intelligent tasks, such as pattern recognition [A]. In the present contribution, we propose the innovative concept of implementing ONN by Beyond Complementary-Metal-Oxide-Semiconductor (CMOS) devices. In particular, we show experimental and simulation results of oscillators based on vanadium dioxide (VO2). VO2 is a transition metal oxide (TMO) that undergoes a phase transition from a high-resistive monoclinic (M1) crystal structure to a low-resistive tetragonal rutile-like (R) one. This phase transition takes the name of insulator-to-metal transition (IMT) and it is triggered by temperature. The IMT brings a resistive switching in VO2, where the resistivity change may be up to several orders of magnitude. It has been observed that the switch in resistance occurs as well in VO2 two-terminal devices, where self-heating is thought to play the main role. This occurrence is a key factor in implementing highly compact and scalable oscillators. We will investigate devices fabricated on Si-compatible technology on SiO2 substrate [B]. The lattice mismatch between the VO2 layer and the SiO2 substrate gives rise to a typical granular texture. We will use dedicated technology computer-aided design (TCAD) 3D electrothermal simulations of VO2 devices [C] and of the associated VO2 oscillators to assess the impact of this grainy structure over the device performances with a multi-scale approach that considers material properties and device architectures. Our findings will help shed light on the entangled thermal and electrical behavior of VO2 oscillators and can help provide guidelines for the successful implementation of ONN technology.

Organic Nervetronics for Artificial Afferent/Efferent Nerves Yeongjun Lee[1], Jin Young Oh[2], Yeongin Kim[3], Alex Chortos[4], Wentao Xu[5], Dae-Gyo Seo[6], Gyeong-Tak Go[6], Zhenan Bao[7] and Tae-Woo Lee[6]; [1]Samsung Advanced Institute of Technology, Korea (the Republic of); [2]Kyung Hee University, Korea (the Republic of); [3]Massachusetts Institute of Technology, United States; [4]Purdue University, United States; [5]Nankai University, China; [6]Seoul National University, Korea (the Republic of); [7]Stanford University, United States

Biological nerves can efficiently process complex information in real-time. To implement biological event-driven and parallel operation artificially, organic nervetronics have been upsurged. The artificial synapses can be combined with sensors and actuators to emulate the functions of biological sensory and motor neurons with a simple circuit structure. Furthermore, compared to CMOS-based von Neumann computing systems, they consume 10^{-6} times less energy to operate. This organic nervetronics can be a new strategy for soft robotics and neuroprosthetics by emulating biological neuroplasticity events that have not been existed nerve before.
Here, we developed an artificial nerve that emulates biological afferent and efferent nerve. The flexible artificial afferent nerve consists of a resistive pressure sensor, organic ring oscillator, and artificial synapse. Sensory signals are converted into spike signals and processed in the artificial synapse, thus movement, simultaneous pressure, and braille characters can be detected through an artificial afferent nerve. The connection of biological organs and artificial afferent nerves shows a hybrid reflex arc that shows future applicability for neural prostheses. The movement of the detached cockroach leg can be controlled by external sensory information. Also, an artificial auditory system was developed by integrating a triboelectric nanogenerator an artificial synapse. The optoelectronic artificial efferent nerve can be constructed by integration of a photodetector, stretchable artificial synapse, and a polymer actuator (role of an artificial muscle). This optoelectronic artificial sensorimotor nerve emulates optogenetically engineered neurons and synapses. The contraction of artificial muscles well imitates biological muscle contraction. Furthermore, the system can distinguish alphabet Morse code for optical wireless communication method. Our flexible organic artificial nervous systems suggest a promising strategy for bioinspired electronics, soft robotics, and neuroprosthetics. Neuroplasticity-based artificial nerves can be used for restoring the biological afferent and efferent nerve response which can pave a new way to technology without using bulky electronic devices.

4:30 PM SB04.10.03
Stress-Based Control of Ferroelectric Memristors Youri Popoff[1,2], Laura Bégon-Lours[1], Mattia Halter[1,2], Heinz Siegwart[1] and Bert Offrein[1]; [1]IBM Research GmbH - Zurich Research Laboratory, Switzerland; [2]ETH Zürich, Switzerland

The impact of stress on the properties of thin film materials plays a crucial role in the performance of integrated devices. Indeed, in the last decades, stress engineering has been purposefully used to enhance the conduction of CMOS transistors thanks to increased carrier mobility under stress [1, 2]. Drawing inspiration from this successful use of stress in integrated devices, we turn our focus to integrated analog synapses used in Artificial Neural Networks which are key to bridging the computing bottleneck in Von-Neumann architectures [3]. In particular, the stress-based control of memristors is of interest.

Not only is static stress targeted, but an external pressure source e.g. from an actuator or from a sound wave can be used as an additional input to the individual synapses in the learning process [4].
In this work we investigate the change in electrical conductivity caused by varying the pressure applied to integrated Ferroelectric Memristor devices. In these devices fabricated on Si with a CMOS compatible process, the switching of the polarization of the 3.5 nm $Hf_xZr_{1-x}O_2$ ferroelectric thin film layer in the stack has an influence on the electrical conduction. The state of the memristor is written by applying an electric field and it is read out with the measured current [5].
For this study, we show the development of a custom indenter setup which uses a flat sapphire tip 100 um in diameter to apply pressure (forces potentially up to 20 N). A calibrated load cell and motorized stage allow for a PID-controlled tuning of the applied force and thus exerted pressure on the device under test.
Increase of the Low Resistive State (2 MOhm LRS) up to 10% per 0.7 N applied force (0.56 GPa) on devices of 40 um diameter can be shown. On the other hand, the High Resistive State (HRS) is much less impacted by the pressure. By releasing the pressure and electrically cycling the device, the change in resistive state is reversible and the device operation is preserved after the pressure cycling. Changes up to 60% can be measured, however at the cost of a non-reversible state behavior or loss of the device after too much cycling. Variation in device dimensions and application of stress is used to investigate the physical mechanism behind the change in resistance.
Moreover, we propose a novel device concept where integrated piezoelectric actuators at the low micrometer and nanometer scale can be used to apply stress on the Ferroelectric Memristors [6]. When used as a synapse, the 2-port device gains through the actuator an additional input to control its state, thus mimicking the control of biological synapses by neuromodulators.
This study validates the use of stress as a new way of controlling analog memristors and this stress-based approach opens up a multitude of new opportunities for the operation of synaptic networks.

Supported Lipid Bilayers as Biomimetic Approach to Tune Neuromorphic Plasticity Claudia Lubrano, Chiara Ausilio, Ugo Bruno and Francesca Santoro; Istituto Italiano di Tecnologia, Italy

Neurodegenerative diseases and brain damage require the constant development of new technologies able to replicate synaptic functionalities and replace damaged connections. As widely reported in literature, synaptic communication is based on electrochemical mechanisms: certain stimuli might induce the release of neurotransmitters from the pre-synaptic site and the consequent recognition of these molecules at the post-synaptic receptors, thus causing the propagation of an action potential from one cell to another.[1] In this scenario, neuromorphic devices represent a powerful platform to recreate artificial neural networks, which will offer the chance to improve implantable devices towards the replacement and repair of injured brain areas. In particular, organic neuromorphic devices, such as PEDOT:PSS organic electrochemical transistor (OECT), offer a unique approach: in addition to the well-known biocompatibility of PEDOT:PSS, owing to its ionic-to-electronic current transduction, the conductance of these devices can be modulated through external stimuli (*i.e.* ionic flow) and the altered conductance state is retained over long time, replicating to some extent the physiological synaptic plasticity.[2] Recently we have successfully established a direct coupling between PC12 neuron-like cells, able to secrete dopamine (DA)[3], and an organic neuromorphic device, thereby recreating an *in vitro* model of the synaptic system which simulate both long and short-term plasticity through the oxidation of DA.[4]
Here, we aim to recapitulate not only the same functionalities of neurons (*i.e.* synaptic plasticity) using an organic neuromorphic device, but also to have a biomimetic platform replicating the physiological neuronal membrane by means of supported lipid bilayers (SLBs), simplified in-vitro models of cell membranes with potential bio-technological applications [5]. We evaluated the role of SLB composition on the OECT plasticity, analyzing how the bilayer fluidity affects the ions flow towards the neuromorphic channel, thus modulating the de-doping level of the PEDOT:PSS. Furthermore, we explored SLBs with neuronal composition in order to resemble the functioning of biological synapses. We expect that such platform thanks to its learning capabilities and biomimetic properties, could really interact with biological neurons, monitoring their activities and providing feedback accordingly, thus creating an artificial biohybrid functional network. This biohybrid platform might be further exploited to engineer future implantable devices able to replace damaged connections either in pathological networks in neurodegenerative diseases, or in case of amputations to create adaptive prosthetics able to reduce the mismatch between these artificial parts and the human body.

5:00 PM SB04.06.04
A Novel Approach for the Analysis of Multivariate Impedance Data—Making Possible the Development of Calibrated Sensor Arrays Lucas Fugikawa-Santos[1], João P. Braga[2], Vinicius M. Oliveira[3] and Vitor B. Leite[2]; [1]São Paulo State University - UNESP, Brazil; [2]University of São Paulo State–UNESP, Brazil; [3]University of Maryland, United States

Functionalized sensor arrays are commonly used in the detection and sensing of chemical compounds in electronic tongue/nose systems. The analysis of the multivariate complex impedance data from sensor arrays is based on the global selectivity principle, which allows the qualitative discrimination of substances and their corresponding concentrations. However, frequently used analytic methods such as principal component analysis (PCA) and interactive document map (IDMAP) are non-quantitative methods and do not allow the development of calibratable devices. We propose a novel approach for the analysis of multivariate impedance data from sensor arrays used as electronic tongue devices. The method allows the representation of the data in a quantitative 2-D space where devices produced using similar fabrication parameters yields similar values when exposed to the same compound, at the same concentration. To prove the concept of the method, an extensive set of experiments was carried out, comprising the impedance (capacitance) vs. frequency spectra from 8 different types of electrodes (functionalized with organic semiconducting films), and 5 types of analytes, at different concentrations.

Triplicated devices were also tested to confirm the reproducibility of the electrical impedance response. The result was a large, multivariate dataset, which required innovative computational aid to be analyzed. Although unspecific electrodes for the detection of substances were used in the experiments, several combinations of electrode arrays were possible to discriminate the analytes, with good reproducibility of the response. The concentration dependence of the electrode array response also permitted the determination of the detection limit for each compound, as well as each detection calibration curve. The method can be easily extended to smart sensing applications, including biosensors, which demand reliable and quantitative analysis.

Neuromorphic Device Based on Non-Volatile Organic Electrochemical Transistors Yuyang Yin, Shaocong Wang, Zhongrui Wang and Paddy K. L. Chan; The University of Hong Kong, China

Neuromorphic computing systems mimicking biological neural network show significant advantages in the efficiency for processing complex data. As a major building block of the new-generation computing hardware, artificial synapses such as those based on novel memory devices are capable to store and process information on the same device, mitigating the von Neuman bottleneck of digital systems featuring physical separation of memory and processing units and thus large time and energy overheads in running AI tasks. To harvest the advantage of in-memory computing, synapses are required to update their weights in a linear and repeatable way, and the operation is supposed to be fast and low power-consumption for in situ training, which remains one of the biggest challenges to various in-memory computing based neuromorphic systems. Besides, the long-term non-volatile memory property of the artificial synapse for retaining the weight value is critical to the learning performance. Here, we demonstrate a neuromorphic device by employing non-volatile organic electrochemical transistors (OECTs) as artificial synapses, which can provide analog weight updates with decent linearity while costing low power supply. The non-volatility of the synapse endows the possibility to emulate long-term synaptic plasticity, augmented by linear and repeatable weight modulation, provides a promising scheme to physically implement mainstream machine learning techniques such as gradient descent. This would significantly benefit the neuromorphic hardware in terms of power consumption, speed, form factors and cost. To verify this, we performed ANN simulations based on the weight update data of the transistors for the learning and recognition of the MNIST handwrite digits dataset. The results indicate the potential of this non-volatile OECT device for further moving towards smart and efficient edge neuromorphic computing hardware.

Electrode Material Dependence of Electrical Characteristics in Double Ta_2O_5-Based Resistive Switching Cells Tomoaki Ohno and Yusuke Nishi; National Institute of Technology Maizuryu College, Japan

Resistive switching cells as one of the next-generation nonvolatile memories to replace the Flash have been extensively studied because of their potential use for neuromorphic devices. However, the mechanism of resistive switching and the origin of conductive filaments in resistance change materials remain controversial. At present, many combinations of electrode metals and resistance change materials have been reported. In particular, conductive filaments in conductive-bridge random access memories are formed by electrode metal such as silver (Ag) extending from the counter electrode instead of oxygen vacancies, and in several cases quantization phenomenon appears upon a voltage pulse application to the cell [1]. In this study, we focus on the effect of electrode materials on the forming and resistive switching characteristics in double tantalum oxide (Ta_2O_5)-based resistive switching cells to clarify the origin of the conductive filament created by the forming.
The resistive switching cells were fabricated as described below. A platinum (Pt) bottom electrode was prepared by dc sputtering. A 10-nm-thick Ta_2O_5 resistance change layer and a subsequent 10-nm-thick TaO_x (x=1.6) oxygen-vacancy reservoir layer were deposited by reactive rf sputtering with different oxygen gas flow rates [2]. Next, top electrodes (TEs), such as Pt, Ag, and gold (Au), were deposited through a metal mask by resistive heating (Ag and Au) or electron beam (Pt) evaporation. We examined the differences in initial resistance, forming voltage, and resistive switching characteristics of three types of cells, Ag, Au, and Pt-TE cells. The bottom electrode was grounded, and voltages were applied to the top electrodes with a diameter of 100 μm using a semiconductor parameter analyzer Keithley 2450. Current or voltage sweeps were applied to the top electrodes to investigate electrode material dependence of initial resistance and forming characteristics, or resistive switching characteristics, respectively.
The results of initial resistance were 5 k~300 kΩ for the Ag-TE cells, 10 k~200 kΩ for the Au-TE cells, and 2 k~3 kΩ for the Pt-TE cells. Besides, the variations of forming voltage at which a cell resistance reaches sub-kΩ were 6~8 V, 7~10 V, and 5 V for the Ag, Au, and Pt-TE cells, respectively, indicating that the Pt-TE cells were more stable with less variation. These results remain unchanged even after a few months except for Ag-TE cells, which show a clear reduction in the forming voltage and the initial resistance. Although the reason for the reduction is unclear at present, Ag ions may be gradually dissolved from the Ag-TE layer to the Ta_2O_5 layer over time, owing not to the oxidation of metal-TE leading to an increase in the cell resistance. Note that the three types of cells after the specific forming show analog resistive switching characteristics upon bipolar voltage sweeps irrespective of the reduction above. These results reveal that an initial state in every cell does not involve the analog resistive switching.
Moreover, Ag and Au-TE cells exhibit discrete conductance fluctuation before the forming, while Pt-TE cells show continuous conductance increase [3]. The appearance frequency of the cell conductance based on quantized conductance is apparently high in Ag-TE cells. From viewpoint of the large variation of initial conductance and forming voltage, Ag ions can pass through the TaO_x layer with random ion collisions and form conductive filaments composed of Ag atoms during the conductance fluctuation and the forming, instead of oxygen vacancy rows supplied from the reservoir layer. Furthermore, in contrast, Pt-TE cells show possibly gradual diffusion of oxygen vacancies from the reservoir layer at the forming.

Keynote: Designing New Materials for Neural Interfacing Molly Stevens; Imperial College London, United Kingdom

This talk will provide an overview of our recent developments in polymer materials with unique electrochemical properties for use in neural bio-interfacing. We design, synthesise and fabricate conjugated polymer-based scaffolds presenting complex electrical and topographical cues that support neural stem cell adhesion, growth and differentiation [1]. I will discuss the applications of our facile strategy for controlled functionalisation and post-polymerisation of the aromatic backbone of conjugated polymers for selective cell stimulation [2]. Our recent developments in the context of bioelectronic nanostructured surfaces for biosensing and interfacing will be discussed [3,4].

Enhanced Bio-Interfacing and Sensing Based on Spatiotemporal Dynamics and Ionic-Electronic Signal Amplification Fabrizio Torricelli; University of Brescia, Italy

The seamless integration of biology with electronics demands for new bio-inspired approaches able to detect, process and amplify both ionic and electronic information. Ions are the ubiquitous biological and physiological regulators, being involved in most of the fundamental processes of every living organism. Ions enable the communication between cells and the metabolic and bioenergetic processes, playing a key role in hydration, pH regulation, and osmotic balance across cell membranes. Biological systems, including animals and plants, communicate and process information using as carriers ions, small molecules, and electronic charges. In the nervous system, stimuli are collected from distributed sensory receptors, computation then takes place locally or centrally, and when necessary, feedback signals drive sensorimotor processes. The technological potential of co-integration between electronics and biology stems from the ability of electronics to bi-directionally interact with biological systems, and even more importantly to emulate biological functions.[1,2]
Using state of art organic electrochemical materials and devices, we show the design and validation of unconventional iontronic circuit and system approaches for (i) integrated ion-sensing amplifier and (ii) spatiotemporal dynamic multiplexing of ionic signals in a shared liquid medium of communication. The ion-sensing amplifier integrates both selective ion-to-electron transduction and local signal amplification demonstrating a sensitivity larger than 2300 mV V^{-1} dec^{-1}, which overcomes the fundamental limit.[3] It provides both ion detection over a range of five orders of magnitude and real-time monitoring of variations two orders of magnitude lower than the detected concentration, viz. multiscale ion detection. The iontronic multiplexing system discriminates locally random-access events with no need of peripheral circuitry or address assignment, thus deceasing significantly the integration complexity.[4] The form factors allow for intimate bio-interfacing communication in shared medium. The ion-sensing amplifier and the spatiotemporal dynamic iontronic multiplexer are fundamental building blocks for multifunctional bio-interfacing and sensing in the emerging fields of bioelectronics, wearables, and neuromorphic computing or sensing.

2:00 PM SB04.12/SB08.16.05
Capacitive Coupling Phenomenon in Multi–Conductive Layer Bioelectronic Devices Remy Cornuejols[1,2], Sofia Drakopoulou[2], Gerwin Dijk[2], Rodney O'Connor[2], Christophe Bernard[1] and Shahab Rezaei-Mazinani[2]; [1]Aix-Marseille Université, France; [2]École des Mines de Saint-Étienne, France

Increasing number of electrodes in neural recording and stimulation devices is a key aspect to improve the spatial resolution. To keep appropriate dimensions for clinical applications, utilization of multiple layers of superimposed conductive leads helps to maximize the number of electrodes in a limited available space. However, close conductive lines with different electrical charges can lead to a crosstalk effect between channels due to capacitive coupling. To understand and quantify this phenomenon on devices made of gold leads with Parylene C encapsulation, we present a study on the influence of the thickness of inter-conductive insulation layer on capacitive coupling and Parylene C permeability. Subsequently, *in vitro* experiments were conducted on a multielectrode array, consisting of spatially distributed multi conductive-layer electrode clusters. This helped to quantify capacitive coupling. Furthermore, *in vivo* experiments were carried out to measure crosstalk in multi conductive layer electrocorticography probes, interfacing the brain. Finally, by shedding light on the optimal insulation-layer thickness between conductive layers, this study will help to optimize organic-bioelectronic sensor's structure, to increase number of electrodes, thus spatial resolution of devices. Therefore, this will lead to an efficient detection of biological events and facilitate interfacing of these devices with small anatomical structures.

SESSION SB04.13: Materials and Devices for Neuromorphic Computing II

Employing the Non-Linear Response of Synaptic Polymer Networks for Reservoir Computing Hans Kleemann, Matteo Cucchi, Lautaro N. Petrauskas and Karl Leo; Technische Universität Dresden iAPP, Germany

The emerging field of organic electrochemical neuromorphic devices is gaining enormous interest as such devices show distinct synaptic properties, operate at a low voltage, and enable biocompatible, intelligent sensor units which might be used, e.g., for real-time classification of bio-signals. So far the focus of research is mainly on the synaptic properties of single organic electrochemical transistors and related devices with the emphasis to control the strength and time constants of synaptic plasticity. However, to do computation, e.g., in a feedforward neural network, a very large number of identical synaptic devices is required with very strict definitions in terms of their synaptic properties to enable efficient learning. Due to these challenges, organic electrochemical synaptic networks have not been used for complex classification tasks.
In this contribution, I discuss how networks of synaptic organic electrochemical devices can be employed to solve complex classification tasks by utilizing a brain-inspired approach of computation denoted as echo-state or reservoir computing. Reservoir computing, a kind of recurrent neural network, is an approach where a low-dimensional input signal is mapped onto a high-dimensional output through a non-linear transformation which exponentially increases the probability to classify the input data according to the features being selected. The reservoir itself does not require training which makes this technique very fast and power-efficient compared to other machine learning approaches.
We create such a reservoir by growing dendritic networks of the benchmark material PEDOT:PF6 in an array of electrodes using field-directed electropolymerization. This method enables us to grow random networks of conductive polymer fibers with a diameter down to 1µm. As these fibers, each operating as an organic electrochemical transistor, are connected through the liquid electrolyte, a situation of complex resistive and capacitive coupling is created in the network. Hence, if an input signal is applied to the reservoir, the signal is distorted in a highly non-linear and transmitted to the output. The degree of non-linearity of the polymer reservoir depends on the balance between inhibitory and excitatory fibers and the strength of capacitive coupling. Implementing a delayed feedback loop connecting input and output of the reservoir (so-called single-node reservoir), the complexity of the system at hand is proven by chaotic oscillations. Ultimately, the single-node reservoir is utilized to demonstrate standardized classification tasks such as heartbeat classification, classification of flowers, time-series prediction, and others.

Enhanced Performance of Ag/HfO_2/Pt-Based Diffusive Threshold Switches for Energy-Efficient Neuromorphic Computing Solomon Amsalu Chekol[1], Rainer Waser[1,2] and Susanne Hoffmann-Eifert[1]; [1]Forschungszentrum Jülich GmbH, Germany; [2]RWTH Aachen University, Germany

Brain-inspired neural networks are emerging as potential alternatives to the traditional von-Neumann architectures, mainly due to their unique structure of combining the memory and processor, giving them the ability to learn more efficiently [1]. Such neural architectures are composed of computing and memory elements, representing the neuron and synapse functions, respectively. Neurons are used to execute current summation, integration, and firing. As frequent integrating and firing events are involved, the power consumption needs to be low enough to ensure an energy-efficient computing element. Currently, neuronal functionality is often performed using a conventional CMOS-based neuron. However, a CMOS neuron, made of several transistors and a capacitor, is area- and energy-inefficient [2]. Hence, there has been a great interest in searching for an alternative neuron device by deploying new concepts, designs, and materials. Recently, a compact neuron design has been exploited utilizing two-terminal threshold switching (TS)-based elements, owing unique features such as thresholding and self-relaxation behaviors.
In our previous work, we developed Ag/HfO_2/Pt-based volatile electrochemical metallization (v-ECM) devices [3]. The stack was built from atomic layer deposited (ALD) 3 nm HfO_2 sandwiched between an Ag top electrode and a Pt bottom electrode. The thin HfO_2 layer serves as electrolyte matrix for the formation/rupture of an Ag filament. The fabricated device exhibits an extremely low-leakage current (I_{off}) of < 100 fA and ultra-low threshold voltage (V_{th}) of < 0.2 V, guaranteeing a low power consumption. In most threshold switching devices such as ovonic threshold switches (OTS) and insulator-to-metal transition (IMT) devices, the I_{off} and V_{th} show a tradeoff, meaning that the improvement in leakage current comes with increased V_{th} and vice versa. In this regard, v-ECMs have a unique advantage of providing low I_{off} and low V_{th} values simultaneously.
Some of the main concerns in such devices are the volatility range (stuck-at-ON) and the switching variability. The morphology of the conductive filament ultimately defines how fast the device relaxes back to the initial state. Excessive Ag in the filament could lead to a non-volatile state. Often, this happens during the initial forming stage, since a relatively higher voltage is required to initiate the switching. Therefore, controlling the amount of Ag constituting the filament is important. The formation/rupture of conductive filaments in v-ECM is closely related to the electrochemical dynamics of the active metal, such as Ag, which could determine the switching speed and the morphology of the filament. In addition to the material's property, the electrochemical dynamics can be modulated by external factors like the electric field, bias duration, and temperature.
In this presentation, we will discuss the advantages of Ag/HfO_2/Pt based TS for artificial neuron applications, and potential improvements to enhance performance such as variability, volatility, and switching speed. For this purpose, different approaches to control the Ag concentration in the matrix - such as hot forming and annealing - will be discussed. Finally, a proof of concept artificial spiking neuron functionality of our device will be shown.

4:45 PM SB04.13.03
Neuromorphic Learning with NiO Sandip Mondal, Zhen Zhang and Shriram Ramanathan; Purdue University, United States

Non-associative learning represents fundamental mechanisms by which organisms interact with their environment. Early studies in neuroscience using sea slugs as model systems demonstrated the synaptic origins of habituation and sensitization. In this presentation, we will discuss non-associative learning mechanisms in NiO, a canonical Mott insulator. By varying the Ni:O stoichiometry, it is possible to obtain a range of transport gaps as well as p-type conduction. Using different stimuli such as oxygen chemical potential and UV light, we have been able to obtain current-voltage characteristics (resistance evolution) that emulate cellular learning in two-terminal NiO devices. Spectroscopic evidence on representative samples indicates that modulation of oxygen vacancy concentration through the film thickness is responsible for such non-associative learning. A set of samples carefully prepared under different oxygen partial pressures (by varying Ar-O_2 ratio) have been studied for resistive switching and learning under electric field pulsing. We find that samples with near-stoichiometric composition do not show switching behavior. However, interestingly, we are able to control the memory formation dynamics in oxygen-deficient samples by training under similar electric field strengths. We have studied such samples in-depth using X-ray scattering techniques and performed drift-diffusion modeling of current-voltage curves to understand the mechanisms behind learning and glass-like relaxation; and will be discussed in this presentation. Mott materials with carefully chosen defect structures possess highly tunable electronic structures and appear to be promising candidates for neuromorphic computation.

8:00 AM SB04.06.03
Flexible Neuromorphic-Neurotransmitter Biohybrid Interface Setareh Kazemzadeh and Yoeri van de Burgt; Eindhoven University of Technology, Netherlands

Neuromorphic devices represent a powerful platform to create artificial neural networks, which will offer the chance to improve implantable devices towards the replacement of brain injuries. As widely reported in literature, the dominant synaptic communication is based on electrochemical mechanisms by releasing neurotransmitters [1]. However most of the existing implantable prosthetics are designed to operate mainly through intrinsic potentials of the brain, overlooking the chemical aspect. In this scenario, neuromorphic devices offer a unique new perspective: these devices can "learn" by receiving stimuli, changing their plasticity similar to physiological synaptic plasticity [2]. Recently we demonstrated a biohybrid synapse that formed a bidirectional coupling between PC12 neuron-like cells and an organic neuromorphic device. Applying a positive bias at the gate leads to oxidation of dopamine secreted from cells and the release positive ions in the electrolyte solution as well as electrons donated to the PEDOT:PSS channel. These processes de-dope the material resulting in a permanent change of resistance of the channel. Additionally, this device shows a high state retention after the pulses are stopped resembling long-term plasticity [3]. This work opens the pathway towards combining artificial neuromorphic systems with biological neural networks for future brain implants. Here we show a further expansion of these biohybrid synapses towards highly reliable prosthetics. Oxidized dopamine gradually forms a layer of polydopamine on the interface of cells and the device, which may result in blockage and limit the device sensitivity. Moreover, in case of prosthetic implants the device must be highly biocompatible and flexible. To tackle these challenges, we introduce a new technique of fabricating flexible organic electrochemical devices on highly biocompatible flexible substrates. These devices use polydopamine as a solid state electrolyte and simultaneously act as a de-doping agent for the PEDOT:PSS layer to increase the resistance of the channel for neuromorphic memory. A more resistive channel avoids excessive current through the device which decreases the energy consumption. The presence of amine in the PEDOT:PSS channel also reduces the diffusion of amines into the electrolyte leading to more stability and higher state retention. Furthermore, using polydopamine as the solid electrolyte significantly increases the energy barrier for ion/proton diffusion which eliminates the need for an access device or resistor. This will significantly increase the ease of design, fabrication and integration of these neuromorphic devices in biological environments. Polydopamine as a biomaterial melanin is inherently biocompatible, which is essential for viable bioelectronic material [4]. We expect these new flexible biocompatible ENODes can be used to bridge hybrid synaptic connections and could further be utilized in an array fashion for integration of future brain-machine interfaces.

Continuously Self-Disinfecting and Broad-Spectrum Polymers—Next Steps Toward Preventing the Spread of Highly Contagious Microbes Reza Ghiladi, Frank Scholle and Richard Spontak; North Carolina State University, United States

Some of the pathogenic challenges currently facing the global community are becoming increasingly life-threatening. For instance, infectious microbes such as SARS-CoV-2 and MRSA constitute major healthcare concerns as invisible predators primarily, but not restricted to, stalking the elderly and immune-compromised. In response, various materials-related methods involving nanoparticles or surface functionalization have been proposed to combat this menace, but many are either limited to specific microbes or promote environmental contamination. In this work, we introduce two promising antimicrobial strategies in which several polymer films and coatings serve as exemplars to demonstrate their potential. The first focuses on embedding photosensitive dye molecules capable of generating singlet oxygen, a strong oxidizing agent, into polymer matrices as films, as well as coatings on polymer fibers and other substrates. In the presence of molecular oxygen and incoherent visible light, this system inactivates at least 99.9999% of two Gram-positive bacterial strains, as well as at least 99.9% of three Gram-negative bacterial strains (belonging to the ESKAPE family of bacteria primarily responsible for nosocomial infections) and three virus strains, in *ca*. 1 h under the conditions employed. Moreover, these materials retain their antimicrobial efficacy even after a month of exposure to light. Alternatively, a vastly different method employs anionic polymer surfaces that are inherently capable of promoting a dramatic pH reduction, resulting in a hostile acidic environment that rapidly kills at least 99.99% of the pathogens tested (including 3 drug-resistant bacteria such as MRSA, as well as *C. difficile* and the SARS-CoV-2 and HCoV229E viral strains) in less than 5 min. These materials afford highly effective and largely unexplored pathways to rapid, scalable and broad-spectrum microbial inactivation.

11:05 AM SB05.01.02
Superhydrophobic and Self-Sterilizing Surgical Mask with Spray-Coated Carbon Nanotubes Ritesh Soni, Shalik Ram Joshi, Mamata Karmacharya, Hyegi Min, Shin Kwan Kim, Sumit Kumar, Gun H. Kim, Yoon K. Cho and Chang Y. Lee; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Coronavirus has affected the entire global community owing to its transmission through respiratory droplets. This has led to the mandatory usage of surgical masks for protection against this lethal virus in many countries. However, the currently available disposable surgical masks have limitations in terms of their hydrophobicity and reusability. Here, we report a single-step spray-coating technique for the formation of a superhydrophobic layer of single-walled carbon nanotubes (SWCNTs) on melt-blown polypropylene (PP) surgical mask. The sprayed SWCNTs form nanospike-like architecture on the PP surface, increasing the static contact angle for water from 113.6° ± 3.0° to 156.2° ± 1.8° and showing superhydrophobicity for various body fluids such as urine, tear, blood, sweat, and saliva. The CNT-coated surgical masks also display an outstanding photothermal response with an increase in their surface temperature to more than 90 °C within 30 s of 1 sun solar illumination, confirming its self-sterilization ability. Owing to the cumulative effect of the superhydrophobicity and photothermal performance of the SWCNTs, the CNT-coated masks show 99.99% higher bactericidal performance towards Escherichia coli than pristine masks. Further, the virucidal ability of the SWCNT-coated mask, tested by using virus-like particles, was found to be almost 99% under solar illumination. As the spray-coating method is easily scalable, the nanotube-coated mask provides cost-effective personal protection against respiratory diseases.

Understanding and Tuning the Visible-Light Induced Photodynamic Properties of TiO_2 Elizabeth C. Dickey; Carnegie Mellon University, United States

In recent years, the rise in antibiotic-resistant bacteria and other nosocomial pathogens has highlighted the need for passive, self-cleaning surfaces and personal protective equipment. The motivation to develop such materials has been emphasized in the past year with the outbreak of the coronavirus pandemic. Numerous classes of materials have been explored for such applications, including metal oxides, organic photosensitizers, and other compounds. Our interdisciplinary team is currently working with titania (TiO_2), a common photocatalytic agent known for its production of reactive oxygen species (ROS), in an attempt to lower the band-gap and increase light absorption in the visible region (>400 nm) and test for antimicrobial ability.
We reduce the bandgap into the visible spectrum via the introduction of mid-gap states using various doping techniques. In particular, we pursue cationic and self-doping methods with readily available components and develop a facile synthesis method. The procedure rapidly reaches completion under mild reaction conditions (ambient temperature, 1 atm) to produce visible-light absorbing TiO_2. Multiple characterization techniques are utilized to investigate the properties of the formed particles and determine the effect of the doping on the band-gap and the subsequent pathogen inactivation. Crystallographic structure, UV-Vis absorption properties, particle morphology, the cationic valence state and other properties are investigated to assess the materials' viability for self-cleaning surfaces.
Materials are exposed to a variety of pathogens: methicillin resistant *Staphylococcus aureus* (MRSA), multi-drug resistant *Acinetobacter baumannii* (MDRAB), and human coronavirus 229E (HCoV-229E) to determine their overall antimicrobial efficacy through antimicrobial photodynamic inactivation (aPDI). Various concentrations of particles (5 and 10 mg/mL), light intensities (65 +/- 5 and 85 +/- 5 mW/cm^2), and illumination times (30, 60, and 90 minutes) are tested. The particles exhibit promising antimicrobial properties with inactivation up to the limit of detection (6 log units, 99.9999%). Further investigations utilizing ROS scavengers and probes are performed to determine the primary mechanism of inactivation. Long term viability and

photobleaching studies are also explored, demonstrating the particles' ability to be exposed to intense illumination for extended periods with no effect on overall antimicrobial properties. Inductively coupled plasma optical emission spectroscopy is utilized to confirm dopants were not leaching from particles and acting as cytotoxic agents.
Several coating methods (slot-die and spray coating) are employed to test particle compatibility with surface application and reuse. This is done by slot-die and spray coating a UV-curable polymer matrix, containing photoactive TiO_2 particles onto glass slides and woven materials. Slot-die coating is chosen because it gives a uniform film across a variety of length scales and translates well to industrial surface coating applications. Similarly, spray coating can aid in applying these particles to personal protective equipment such as N-95 masks as well as other woven materials like curtains and upholstery commonly found in hospitals and other public areas. Further aPDI tests are being performed on coated materials to ascertain how well antimicrobial behavior can be transferred and utilized in the public sector.

2:05 PM SB05.02.02
Grain Size Effects and Mechanisms for Increased Antimicrobial Efficiency in Ultrafine-Grained Bulk Copper Evander Ramos[1], Isabella Bagdasarian[1], Yaqiong Li[1], Masuda Takahiro[2], Y. Takizawa[2], Justin Chartron[1], Alex Greaney[1], Zenji Horita[2], Joshua Morgan[1] and Suveen N. Mathaudhu[1]; [1]University of California, Riverside, United States; [2]Kyushu University, Japan

Copper and it's alloys have long been known for their antiviral and antibacterial properties, and in the course of the global pandemic, research on ways to accelerate their effectiveness have come to the forefront. Recent studies have reported that when the crystal size of bulk copper reduces towards the nanoscale, the anti-viral and anti-microbial efficiency increases non-linearly. The mechanisms for this are diverse, and include the increase in volume fraction of ionic pathways to the surface, oxidation-reduction, topological features and others. In this study, we investigate the antibacterial characteristics of nanocrystalline pure copper produced by severe plastic deformation (SPD), and based on a literature review and our own emerging data, attempt to unravel the mechanisms that promote bacteria or cell destruction as a function of grain size. The versatility of SPD methods allows for the fabrication of bulk components that, unlike thin-film coating approaches, may enable scalability of medical applications.

2:20 PM *SB05.02.03
Laser-Induced Surface Modification to Improve Antimicrobial Properties of Metal Surfaces Rahim Rahimi; Purdue University, United States

Currently, over a million people die each year due to some form of antibiotic-resistant infection. At the same time, the fast mutation of other pathogenic organisms – fungi, viruses and parasites – are also developing resistance to the drugs that are used to tackle them almost as quickly as new ones can be made. A devastating example is the recent outbreak of SARS-CoV-2 virus that began in December 2019 in China, and by March 15, 2021, the global case rate reached 120 million and 2.65 million people died around the world. This pandemic can be explained by the fact that today's world is a global village, with many shared areas and surfaces (e.g., door handles, airplanes, and hospitals) that can serve as routes by which infectious diseases can easily spread around the world within hours. For instance, the SARS-CoV-2 virus has been shown to remain active for up to three days on plastic and stainless-steel door handles and up to 24 hours on cardboard. Some bacteria – including E. Coli and MRSA – can survive for several months on inanimate surfaces. Consequently, special attention has been devoted to the development of new material and surfaces with antimicrobial and antiviral properties that are less susceptible to resistance and can minimize the spread of pathogens at bay. Among different materials, copper (Cu) and silver (Ag) have been recognized as most widely used and well-documented materials that can effectively inactivate different microbes upon direct contact. However, these metals require a few hours of direct contact with the bacteria or virus that lands on its surface to completely inactivate them. Furthermore, it is impractical to make all high-risk surfaces in public places (e.g., buttons and door handles) and medical instruments out of Ag or Cu due to several limiting factors such as cost, weight and mechanical properties.
In this presentation, we will discuss two novel use of laser surface nano texturing and immobilization technologies to enhance the bacterial rate of killing of such metal surfaces (Cu and Ag) as well as effectively immobilize them onto other biologically inert metallic surface. This presentation is divided into two main sections, each showcasing one of these technologies and their applications. In the first section, we will describe a one-step laser nanotexturing process to enhance the bactericidal properties of Cu surfaces via concurrent selective modification of surface topography and chemistry of laser nanotextured copper. This process provides a unique and facile approach for creating robust Hierarchical Micro/Mesoporous structures directly onto metal surfaces in ambient conditions, eliminating complexities of chemical etching as well as metal nanoparticles synthesis and coating processes. In this section we will look at the surface chemistry and morphology that changes with the laser processing conditions and how these surface properties enhance the overall antibacterial properties of the Cu surface against a range of gram positive and negative antibiotic resistant bacteria.
In the second part of this talk, we will showcase the use of a combination of laser nanotexturing and laser immobilization to selectively reduce Ag ionic compounds directly onto the surface of biologically inert titanium metal implants. We will discuss the systematic experimental studies (e.g., elemental and surface morphology analysis) that were conducted with different laser processing condition and silver coating compositions which resulted in both improved cellular integration and antibacterial properties while having minimal change in the bulk mechanical properties of the titanium substrate. We will conclude this presentation by briefly commenting on our efforts to translate some of these technologies into clinical practice and the future directions.

Dual-Dyed Photodynamic Antimicrobial Polyethylene Terephthalate/Cotton Blended Fabrics with Variable Color Expression Chenyu Jiang[1], Wangbingfei Chen[2], Reza Ghiladi[1], Qingqing Wang[2] and Qufu Wei[2]; [1]North Carolina State University, United States; [2]Jiangnan University, China

Aiming to develop scalable, potent, color variable, and comfortable antimicrobial textiles that can help reducing infection transmission in healthcare facilities, we explored photodynamic antimicrobial polyethylene terephthalate (PET) /cotton blended fabric (TC) comprising of photosensitizer-conjugated cotton fibers and disperse dye dyed PET fibers. A small library of TC blended fabrics was constructed wherein the PET fibers dyed with different traditional disperse dyes dominated the color of the fabrics and thereby enables variable color expression, while cotton fibers were covalently coupled with thionine acetate as photosensitizer generating photobiocidal under illumination. Physical (SEM, CLSM, TGA and mechanical strength), colorimetric (K/S and *CIELab* values) characterizations were employed to investigate the resultant fabrics and the photooxidation studies with DPBF demonstrated the ability

of these materials to generate reactive oxygen species (i.e., singlet oxygen) upon visible light illumination. The best results of these materials demonstrated the 99.985% (~3.82 log unit reduction, $P = 0.00208$) photodynamic inactivation of Gram-positive *S. Aureus*, and achieved detection limit 99.99% inactivation (4 log unit reduction, $P \leq 0.0001$) against Gram-negative *E. coli* upon illumination with visible light (60 min; ~300 mW/cm^2; $\lambda \geq 420$ nm). Different disperse dyes on the fabric were observed no photophysical competition relation, leading to lower aPDI efficiency, with photosensitizer and furthermore, playing a 'protection' role for photosensitizer during the photobleaching process which ends up improving the photostability of these materials. Taken together, these results suggested the feasibility of low cost, scalable and color variable thionine conjugated TC blended fabrics as potent self-disinfecting textiles.

Safety and Effectiveness Assessments of Gold Nanorods Coated Titanium Surfaces for Near-Infrared Photothermal Treatment Against Biofilms Kanny R. Chang[1], Thilak Mudalige[2], Jiwen Zheng[2], Matthew Silverman[1], Patrick Regan[1] and Jayaleka Amarasinghe[1]; [1]U.S. Food & Drug Administration, Office of Regulatory Affairs, United States; [2]U.S. Food & Drug Administration, United States

Bacterial biofilms are communities of microbes encased within a self-produced slimy extracellular polymeric substance (EPS) attached to a surface. Biofilms can enable bacteria to survive in hostile environments and release fresh bacteria into the environment. Compared to their planktonic counterparts, biofilm bacteria embedded in layers of EPS are highly resistant to antibiotics and conventional disinfection strategies as compared to their planktonic counterparts.. Particularly, medical implant-associated biofilms accounts for significant increase in chronic diseases and mortality worldwide.
To eliminate biofilm colonization on medical implants, various strategies including antibiotics, disinfectants, cationic materials, and anti-biofilm coatings have been attempted so far with some success. Surfaces coated with gold nanorods (GNRs) have been demonstrated to be promising as they are capable of eradicating bacterial biofilm upon exposure to near-infrared (NIR) radiation. When exposed to NIR, GNRs can generate plasmonic photothermal heat that can inhibit microbial biofilms and thereby, reduce implant failures and the need for revision surgeries. However, the performances of these surfaces may differ as the fabrication methods vary. In addition, the biocompatibility and anti-biofilm performances of such functionalized surfaces prepared by various methods are not yet fully investigated.
This study addresses the regulatory knowledge gap in evaluating safety and effectiveness of GNR-coated titanium surfaces with antibiofilm activity. Herein, we have used medical grade titanium as a model material and coated GNRs by different techniques via thiol- or amine-terminated silane. Successful deposition of GNRs was confirmed and quantified by scanning electron microscope and X-Ray spectroscopies. The results showed that the more polar amine-terminated silane achieved a higher amount of deposited nanorods on titanium. Biocompatibility testing was conducted in vitro on human osteoblast, macrophages, and fibroblast cells by following ISO-10993 Part 5: Tests for *in vitro* cytotoxicity. Titanium coated with GNRs solutions up to 200 µg/mL did not show significant cytotoxicity and were favorable to cell attachment and proliferation. In addition, toxicological assessments, such as cytotoxicity and measurement of inflammatory cytokine levels, are conducted on fabricated surfaces exposed to NIR. Anti-biofilm performance of the GNR-coated surfaces in the presence or absence of NIR will be tested against *Staphylococcus aureus* and *Nontuberculous mycobacterial* biofilms. The results of this research will help the FDA assess medical device submissions that use similar nanomaterial-based anti-biofilm technology.

SB05.03.03
Characterizing Hydrodynamic Wear of Superhydrophobic Materials Daniel Braconnier; Northeastern University, United States

Hydrophobic coatings rely on chemical apolarity and hierarchical roughness to achieve high contact angles and low roll-off angles that lead to self-cleaning and antibacterial properties. Current hydrophobic coatings tend to be delicate and lose their properties easily when subjected to water spray. Many of these coatings become impaled (pinned) with water droplets immediately after incremental hydrodynamic wear from water spray. This hydrodynamic wear differs from seemingly more aggressive mechanical wear including scratching with sandpaper - a common approach used to claim both self-similarity of a material and extreme robustness against wear. However, the hydrodynamic wear of these self-similar materials can quickly erode the hydrophobic constituents, exposing more hydrophilic materials that lead to quick wetting out despite the self-similarity of the greater material. In this work, we systematically study several approaches that have claimed robustness against wear and find that most approaches fall short of application requirements for withstanding a simple onslaught of water spray. Through quantifying hydrodynamic wear, we have also been able to demonstrate an advancement on the leading systems through developing a novel superhydrophobic material. We compare a popular off-the-shelf industry solution to these recent academic works, as well as offer an analytical model that nicely predicts the hydrodynamic wear of these systems.

SB05.03.04
Late News: (Garcia High School Student) Repurposing Waste Fabric by Synthesizing Silver Nanoparticles on Deweaved Cotton Fibers Elizabeth Zhang[1], Ivan J. Yuan[2], Jacob T. Zerykier[3], Ayush Agrawal[4], Tianyu Dong[5], Guanchen Zhu[6], Haojun Xu[7], Michael Cuiffo[8], Stephen Walker[8] and Miriam Rafailovich[8]; [1]Phillips Academy, United States; [2]Shanghai High School International Division, China; [3]Rambam Mesivta-Maimonides High School, United States; [4]Canyon Crest Academy, United States; [5]Northview High School, United States; [6]Experimental High School Attached to Beijing Normal University, China; [7]The Madeira School, United States; [8]Stony Brook University, The State University of New York, United States

Silver nanoparticles (Ag NPs) have well-studied antimicrobial properties effective against many types of bacteria and fungi. Fine Ag NPs have also demonstrated antiviral activity against H1N1 (influenza), SARS-CoV-2, and other viruses.[1,2] The antimicrobial properties of Ag NPs are due to the release of silver ions that inhibit respiratory enzymes of bacteria and fungi. In its main antiviral mechanism, Ag NPs bind to and inactivate membrane proteins, thereby preventing the virus from entering the host cell.[1] Applications of Ag NPs in textiles have gained worldwide attention due to the importance of antimicrobial textiles for wound dressings, medical equipment and staff uniforms, bedsheets, and others. Because textiles serve as a medium for microbe growth and cross-contamination, there is a growing demand for antimicrobial textiles. To reduce waste, especially since the textile industry produces over 10 million tons of waste cotton cloth globally each year, this study seeks to synthesize Ag NPs on discarded cotton muslin tailoring cloth.[3] Cotton fabric can be deweaved into cellulose fibers, which act as a stabilizing agent on which silver nanoparticles can be synthesized through the reduction of silver nitrate with trace amounts of sodium borohydride.

Fabric was deweaved by stirring in a 3:1 by volume ratio solution of 0.5 M citric acid and 0.5 M sodium nitrate at 50 °C and 600 rpm for 15 minutes. After drying, the fibers were used for the synthesis of silver nanoparticles in two ways. Both samples were treated with a solution of 20 mL silver nitrate (0.01 M) and 2-5 drops of sodium borohydride (0.01 M) until a color change was observed. The first sample was placed for 20 minutes at room temperature, while the second sample was ultrasonicated for 20 minutes at 40 °C. Both samples were then air-dried. The solution used in the synthesis process, which contained silver nitrate, sodium borohydride, and silver nanoparticles, was then analyzed using UV-Vis spectrometry. Results showed a peak at 325 nm, which is characteristic of silver nanoparticles.[4] The samples were then observed with SEM to visualize the size and features of the nanoparticles, and EDX was simultaneously performed to verify the existence of silver. The fibers heated in the ultrasonicator showed a higher silver signal in EDX than the non-heated samples, and the silver coating was present on more parts of the fibers in the ultrasonicated sample. The size of the nanoparticles was below the resolution of the SEM. X-ray photoelectron spectroscopy showed that the silver in the nanoparticles existed in both elemental and oxidized forms, both of which are antimicrobial.[5]

We then performed an antibacterial test using *S. aureus* and *E. coli*. Deweaved fibers without Ag NPs did not exhibit any antibacterial properties, while both species of bacteria showed zones of exclusion when the Ag NP-containing fibers were used. The zone of exclusion was larger in the culture of *S. aureus*, suggesting that silver nanoparticles may be more effective against Gram-positive bacteria. Experiments are underway in order to determine the antiviral properties of the silver coating against H1N1 influenza. Hence, this technique has the potential to produce antiviral and antibacterial fibers that can be incorporated into textiles.

SESSION SB05.04: Antimicrobial Materials III
Session Chair: Reza Ghiladi
Wednesday Morning, December 1, 2021
Sheraton, 2nd Floor, Liberty C

10:30 AM OPENING COMMENTS

10:35 AM SB05.04.01
Photodynamic and "pH-drop" Antimicrobial Materials for Infection Prevention in Hospital Environments Reza Ghiladi; North Carolina State University, United States

Efforts to control hospital acquired infections (HAIs) have been hampered by the emergence of drug-resistant pathogens, necessitating the pursuit of advanced functional materials that are capable of the self-disinfection of such microbes in hospital environments. To that end, we have explored the feasibility of antimicrobial photodynamic inactivation (aPDI) of bacteria and viruses using photodynamic materials, as well as pathogen inactivation using "pH-drop" based materials. *In vitro* aPDI studies were performed against bacteria and viruses employing photosensitizer-embedded or conjugated nanofibrillated cellulose, polyacrylonitrile or nylon nanofibers, dual-dyed wool/acrylic blended fibers, olefinic block copolymers, and spray coatings. Pathogens were cultured, deposited onto the materials, and subsequently illuminated with visible light (400–700 nm, 65-80 mW/cm^2, 5-60 min), and their survivability was determined via colony counting or plaque assay methods. For natural polymer scaffolds, cellulose-porphyrin conjugates (either as nanocrystals, nanofibers, or paper sheets) were found to be highly effective against a broad spectrum of pathogens: our best results demonstrated that *S. aureus*, *A. baumannii*, *P. aeruginosa* and *K. pneumoniae* all exhibited photodynamic inactivation by 99.99+%, as well as inactivation of dengue-1 virus (>99.995%), influenza A (~99.5%), and human adenovirus-5 (~99%). As an alternative strategy, non-covalent approaches to photodynamic materials using artificial polymers were also explored: i) using electrospinning, cationic porphyrin and BODIPY photosensitizers were embedded into polyacrylonitrile and nylon nanofibers, and the resultant nonwoven materials possessed both antibacterial and antiviral activities; ii) using melt-pressing, we developed a photosensitizer-embedded olefinic block copolymer that exhibited excellent antimicrobial properties against a range of microbes, including Gram-positive and Gram-negative drug-resistant bacteria, as well as against enveloped and non-enveloped viruses. More recently, we have explored photodynamic coatings on polymer microfibers for pathogen inactivation, and have demonstrated population reductions of >99.9999 and 99.6% for *S. aureus* and antibiotic-resistant *E. coli*, respectively, after exposure to visible light for 1 h. In response to the current COVID-19 pandemic, we also confirmed that these coated fibers can inactivate a human common cold coronavirus serving as a surrogate for the SARS-CoV-2 virus. In a non-photodynamic approach, excellent antimicrobial properties were acheived through the use of charged multiblock polymers wherein the midblock was selectively sulfonated: the resultant hydrophilic and water-swellable polymers led to self-sterilizing surfaces that rapidly act (killing more than 99.9999% in just 5 min) against a wide range of Gram-positive and -negative bacteria, as well as enveloped and non-enveloped viruses. Together, these results demonstrate that such materials may have widespread applicability for non-specific pathogen disinfection, and further research may lead to their application in hospitals and healthcare-related industries where novel materials with the capability of reducing the rates of transmission of a wide range of bacteria, viruses, and fungi, particularly of antibiotic resistant strains, are desired.

10:50 AM SB05.04.02
Laser Functionalized Carbon Membranes with Exceptional Antimicrobial Properties Sina Nejati[1], Seyed Ahmad Mirbagheri[2], Jose F. Waimin[1], Marisa Grubb[1], Samuel Peana[1], David M. Warsinger[1] and Rahim Rahimi[1]; [1]Purdue University, United States; [2]K. N. Toosi University of Technology, Iran (the Islamic Republic of)

Biofilms and microbial colonies are ubiquitous on nearly any substrate exposed to water and can easily spread microorganisms causing severe conditions in water filtration systems. To defeat the formation of biofilm, deposition of silver nanoparticles (AgNPs) on water treatment membranes has been widely exploited through various techniques including physical vapor deposition and chemical vapor deposition, however, the deposited AgNPs are not effectively anchored to the surface. In this study, we functionalized the surface of a carbon membrane via a CO_2 laser in order to generate oxygen containing species to aid perfect attachment of AgNPs on the membrane surface while providing a superhydrophilic surface. Various characterizations including SEM, XRD, and EDX displayed the nanotextures, enhanced surface roughness, and significant alteration of surface chemistry caused by laser processing. To validate the strong AgNPs attachment to the surface, vigorous mechanical agitation as well as probe sonication were performed. Finally, direct contact killing along with antibiofouling properties of laser functionalized carbon membrane with immobilized AgNPs was performed and compared to the pristine membrane. The results demonstrated an exceptional antibacterial of the laser functionalized membrane to fully eradicate the pathogenic bacterial strains of *Escherichia coli* and *Pseudomonas aeruginosa*. It is believed that the developed technology opens new opportunities towards a rapid, scalable, and cost-effective preparation technique for fabrication of carbon membranes with outstanding antimicrobial activities suitable for water purification applications.

11:05 AM SB05.04.03
Anti-Biofilm Activity of Chiral Graphene Quantum Dots and Their Effects on Functional Bacterial Amyloid Proteins Misché Hubbard, Christopher Altheim, Scott J. VanEpps and Nicholas Kotov; University of Michigan, United States

The ability of bacteria to form complex structures called biofilms create numerous human health and industrial problems. These 3D architectures are defined by the extracellular polymer substance (EPS) that consists of a protective assembly of biomolecules surrounding encased planktonic bacterial cells. The current strategies for targeting biofilms weaken the EPS layer but are typically organic in nature and are subject to enzymatic degradation.

Nanoparticles are a promising new class of anti-biofilm agents for their highly tunable physical and chemical properties, stability, and ability to interact with biological molecules, namely proteins. Here, we report the anti-biofilm activity of l-cysteine or d-cysteine derived chiral graphene quantum dots (L/D-GQDs) against amyloid rich *staphylococcus aureus* (*S. aureus*) biofilms. Both enantiomers are capable of biofilm disruption. Notably, D-GQDs displayed higher affinity for amyloid fibers causing increased biofilm dispersal compared to L-GQDs. Chiral GQDs mimic peptide binding proteins, interfering with the self-assembly phenol soluble modulins(PSMs) , the monomeric form of amyloid fibers responsible for biofilm structuring and multiple other virulence factors. The effect of chiral GQDs on key PSM functions including cytolysis, neutrophil production, and anti-biofilm properties were also explored. The chiral interactions between GQDs and biofilm components give rise to a highly tunable antibiofilm NP platform.

11:20 AM SB05.04.04
The Effect of Pillar Stiffness on Mechanical Bactericidal Efficacy of UV Nanoimprint Lithography Patterned Polymeric Surfaces Sophie Lohmann, Abinash Tripathy, A. Milionis, Anja Keller, Martin Loessner and Dimos Poulikakos; ETH Zürich, Switzerland

The world is facing a growing challenge of antibiotic resistance, making diseases assumed benign with antibiotic treatment once again a looming threat to all members of society. Surfaces play an important role in the transmission of bacterial pathogens. Not only can bacteria survive on surfaces, but in aqueous surroundings, surfaces allow the formation of biofilms, stable bacterial ecosystems that make it extremely difficult to remove bacterial contamination. Preventing bacterial transmission on surfaces is relevant in a variety of settings such as public transport, sanitary facilities, electronic devices, food production and in particular, health care. Hospitals are fertile breeding grounds for antibiotic resistance, as patients gather there, bringing many different types of pathogens. Compromised immune systems combined with the widespread use of antibiotic agents promote the development of antibiotic resistance.

Therefore, there is a growing push to develop antibacterial and bactericidal surfaces to reduce the transmission of bacterial pathogens. Common approaches towards designing antibacterial surface employ the release of biocidal agents. Though effective in some applications, biocide releasing systems can contribute to antibiotic resistance, as release rates decrease with time. Furthermore, biocide release can result in undesired pollution of its environment. Especially nanoparticles, commonly used as biocide agents, have toxic effects on other organisms even at low concentration.

To kill bacteria while avoiding the use of biocidal agents, nanotopographies can be designed to mechanically kill adhered bacteria by rupturing the cell membrane during the adhesion process. This form of bactericidal action was initially discovered on cicada and dragonfly wings, which inspired the production of nanostructures on black silicon. Further studies have been conducted on graphene, titanium and gold, as well as stiff polymers such as PMMA and polystyrene. However, the mechanism leading to bacteria death is not yet fully understood. Recent literature points to differences in bactericidal effects of extremely sharp nanostructures such as vertical graphene and carbon nanotubes that could cut the bacterial membrane versus wider nanopillars or nanocones. It is speculated that the latter functions by exerting lateral force on the membrane that leads to membrane rupture.

In order to make use of bactericidal properties of nanotopographies in a wide range of applications, it is necessary to fabricate such surfaces on a large variety of materials. Polymers are widely used in food, sanitation and health settings and often times soft or flexible surfaces are required. It is therefore necessary to understand the interplay between pillar geometry and elastic modulus on the bactericidal mechanism. Furthermore, fabrication methods need to permit low-cost upscaling to large surface areas of varying geometries.

We have developed a nanoimprint lithography process for rapid, simple and scalable fabrication of nanopillar arrays using UV-curable polymeric resins, therefore permitting the use of a wide range of polymers with varying material properties. In addition, surface material properties can differ from the bulk material by combining polymer foil as a carrier with UV-curable resin for the surface topography.

Using this process, we have fabricated nanopillar arrays of different pillar diameters, spacings and materials in order to investigate the effect of pillar geometry and elastic modulus on bactericidal efficacy. After incubation of samples in bacteria-PBS suspension, the number of live and dead cells on each array are quantified via fluorescent live/dead staining. High-resolution SEM imaging shows the change in bacterial morphology and degree of pillar-bending.

Our results help to shed light on bactericidal mechanisms of nanopillars and determine pillar diameter, periodicity and stiffness in order to optimize bactericidal action.

11:35 AM SB05.04.05
Fluorous-Cured Protein Films as Anti-Fouling and Drug-Eluting Antimicrobial Coatings for Medical Implants Sanjana Gopalakrishnan, Li-Sheng Wang, Yi-Wei Lee, Jiaxin Zhu, Stephen Nonnenmann and Vincent M. Rotello; University of Massachusetts Amherst, United States

Nosocomial bacterial infections are a major health crisis, often occurring due to bacterial contamination of medical devices or implants. Antimicrobial coatings are promising materials for preventing bacterial contamination of medical devices. Protein-based materials offer a sustainable and biocompatible strategy for combatting bacterial infections, either by harnessing antimicrobial properties of native proteins or through the fabrication of antimicrobial-loaded protein scaffolds. However, the high aqueous solubility of proteins often results in materials with poor aqueous stability and mechanical properties. Therefore, current strategies rely on physical or chemical treatments to enhance the stability of protein-based materials and prevent rapid degradation in biological milieus. Thermal treatment is an additive-free approach for stabilizing protein films, but proteins are prone to denaturation at high temperatures leading to loss of function.

We employed a thermal treatment approach in fluorous media (hereafter referred to as fluorous-cured or FC) to enhance aqueous stability of protein films while minimizing protein denaturation. We hypothesized that the fluorous environment prevents rearrangement of proteins at the interface during heat treatment thereby minimizing denaturation. Through this strategy, we developed anti-fouling protein coatings for medical implants, by harnessing the native properties of BSA (Bovine serum albumin). FC-BSA films retained most of the secondary structure of the native protein but remained stable in aqueous media. FC-BSA films were hydrophilic and had an overall negative charge, similar to native BSA. The negative charge of the film prevents bacterial contamination through electrostatic repulsion. Conformal BSA coatings were generated on dental implants (screws) by dip-coating in BSA solution followed fluorous-curing. FC-BSA coated dental implants successfully resisted contamination from *E. coli*.

Anti-fouling FC-BSA films provided passive protection against bacterial contamination by preventing bacterial adhesion on the surface. However, they cannot actively eliminate bacteria as BSA is not an inherently biocidal protein. We hypothesized that electrostatic interactions may be utilized to load antibiotics into FC-BSA films to impart antibacterial activity. FC-BSA films were loaded with a cationic antibiotic colistin sulfate by incubated the films in antibiotic solution overnight. Release of colistin was modulated by ionic strength of supernatant – high ionic strength results in slow release of colistin while low ionic strength results in a rapid burst-release. The colistin-loaded FC- BSA not only retained their anti-fouling behavior while also eliminated bacteria in the vicinity of the dental implant.

Colistin-loaded FC-BSA films are biocompatible antibacterial coatings for medical implants, offering passive protection in the form of anti-fouling behavior as well as active antimicrobial activity through release of antibacterial agents. Thermal treatment in fluorous media offers an additive-free, sustainable, and biodegradable approach for fabricating protein-based materials while retaining the native properties of protein precursors.

SB05-Virtual

1:00 PM OPENING COMMENTS

1:05 PM *SB05.05.01
Metal Oxide Nanostructures as Antimicrobial Agents Mohammed Kuku[1,2], Ahmad Fallatah[1,3] and Sonal Padalkar[1]; [1]Iowa State University of Science and Technology, United States; [2]1. Department of Mechanical Engineering, Jazan University, Jazan, Saudi Arabia, Saudi Arabia; [3]2. Space and Aeronautics Research Institute, King Abdulaziz City for Science and Technology, Saudi Arabia

The field of nanotechnology has grown immensely in the last couple of decades owing to the unique properties exhibited by nanomaterials. One such class of nanomaterials are the metal oxide nanoparticles or nanostructures ranging in size from 1 to 100 nm and available in several different shapes. These metal oxide nanostructures find applications in many fields including catalysis, drug delivery, sensing, semiconductors etc. Along with these aforementioned applications, metal oxide nanostructures are favorable candidates as antimicrobial agents.
In the present seminar, the synthesis, characterization and testing of metal oxide nanostructures as antimicrobial agents will be discussed. The influence of nanostructure size and shape on their antimicrobial performance will be evaluated. Additionally, the influence of underlying substrates of the nanostructures on antimicrobial performance will also be addressed. Finally, a tentative guideline will be provided to obtain the best performing antimicrobial nanostructures through the above-mentioned investigation.

1:35 PM SB05.05.02
Carbon Nanomaterials for Antimicrobial Surfaces Laure Giraud[1,2], Celine Cougoule[3], Audrey Tourrette[1,2], Etienne Meunier[3] and Emmanuel Flahaut[2,1]; [1]University of Paul Sabatier, France; [2]CNRS / CIRIMAT, France; [3]CNRS / IPBS, France

Carbon Nanomaterials such as carbon nanotubes as well as graphene and related materials, present many exceptional properties, including antimicrobial ones. The transfer of the latter through their incorporation into materials has generated a growing interest especially the last ten years [1]. However, due to their intrinsic toxicity not only for microbes but also potentially for humans and the environment, their potential release in use conditions is a central issue in terms of practical applications.
Our work stands at the interface between materials science / chemistry and biology, thanks to the fruitful collaboration between our two laboratories. It focuses on the comparison of different carbon nanomaterials against 2 kinds of pathogens: bacteria and viruses. After deposition of carbon nanomaterials onto a surface, we measure the antibacterial activity against both gram + (S. aureus) and gram - (P. aeruginosa) bacteria. In the current context of the COVID-19 pandemic, we also investigate the antiviral activity of the same carbon nanomaterials against SARS-CoV-2. This work is especially important in the current context of the worldwide withdrawal from the market of face masks containing "graphene" for safety reasons, while the literature about the actual antiviral activity of such nanomaterials is clearly deficient.
Our most recent results will be presented and discussed considering the many technical challenges associated to such research.

Covalently Attached Liquid-Like Solid Surfaces Prevent Biofilm Formation Yufeng Zhu[1], Glen McHale[2], Jack Dawson[1], Steven Armstrong[2], Gary Wells[2], Hongzhong Liu[3], Waldemar Vollmer[1], Paul Stoodley[4], Nick Jakubovics[1] and Jinju Chen[1]; [1]Newcastle University, United Kingdom; [2]University of Edinburgh, United Kingdom; [3]Xi'an Jiaotong University, China; [4]The Ohio State University, United States

Biofilms are a major issue for industries from global shipping to health underpinning significant markets for antifouling paints and coatings, and antimicrobial surfaces. To combat biofilm growth porous/textured solid surfaces with a lubricant locked-in to the structure by capillary forces have been used to create a stable hemi-solid/hemi-liquid surface or a continuous liquid lubricant coating – a so-called Slippery Liquid Infused Porous Surface (SLIPS). However, performance under flow conditions where there is shear stress at the surface, such as in catheters, remains a concern due to flow-induced depletion of the lubricant. Here, we report an anti-biofilm surface strategy using liquid-like solid surfaces where the risk of lubricant loss is completely removed. Our coating is a Slippery Omniphobic Covalently Attached Liquid-like (SOCAL) surface, developed as an ultra-slippery non-pinning surface for sessile droplets. This surface displays similar wetting properties to SLIPS through its grafted PDMS coating that behaves as a liquid phase approximately 150ºC above its glass transition temperature. However, since it does not flow and is optically transparent, mechanically durable and thermally stable, it offers significant potential for stable anti-biofilm coatings. In this study, SOCAL surface reduced biofilm formation of *Staphylococcus epidermidis* and *Pseudomonas aeruginosa*, two key biofilm forming bacterial pathogens, by 3 to 4 orders of magnitude compared to polydimethylsiloxane (PDMS) in both static and dynamic culture conditions. This liquid-like solid surface approach offers a new strategy for biofilm resistant surfaces under flow conditions and may find application in medical devices, biosensors and many other areas where biofilms are problematic.

2:05 PM SB05.05.04
Understanding the Zwitterionic Hydration from *Ab Initio* Simulations Pranab Sarker, Md Symon Jahan Sajib and Tao Wei; Howard University, United States

Biofouling is a global problem that stemmed from the gradual accumulation of biomolecules and microorganisms, such as barnacles and algae, on a

submerged surface. It causes pitting and crevice corrosion of vessels' metal surfaces and increases the drag on vessels while sailing. An affordable solution in this regard requires developing a non-toxic, eco-friendly, and sustainable-in-all-marine-environments anti-biofouling coating. Trimethylamine-N-oxide (TMAO), a naturally occurring zwitterionic biopolymer found in the deepwater sea fish, is a promising candidate to this end. Its two oppositely charged moieties are directly connected, possessing zero zwitterionic separation. Experimentally, the antibiofouling property of zwitterions increases as the zwitterionic separation decreases. Employing ab initio molecular dynamics, we thus investigate hydration of TMAO and another zwitterion with a larger separation, carboxybetaine (CBAA1). Our simulations show an inhomogeneous water distribution for both TMAO and CBAA1. Due to the strong hydrogen bonding, a condensed layer of water surrounds the negative moieties. In contrast, the positive moieties have less hydration due to the shielding of three methyl groups.
While comparing the hydrogen bond strength between the zwitterionic oxygens and water molecules, TMAO has far stronger bonding than CBAA1, as validated and quantified by the geometric and quantum theory of atoms in molecules analyses, respectively. Moreover, we utilize the symmetry-adapted perturbation theory (SAPT) to investigate the zwitterion-water interactions. Our SAPT analysis demonstrates that the electrostatic interaction is the dominant attractive term in zwitterions' interactions with hydrogen-bonded-water molecules. The charge transfer between zwitterionic oxygen and water hydrogen plays a critical role in hydrogen bonding, although it is not the dominant term. In the case of TMAO, it is larger, indicating the more rigidity of hydrogen bonding in TMAO than in CBAA1. Our analysis elucidates the origin of the solid antibiofouling behavior of TMAO.

2:20 PM SB05.05.05
Highly Durable and Functionalized Polyurethane Coatings for Protection of Infectious Aerosols and Elimination of Bacteria Moonhyun Choi and Jinkee Hong; Yonsei University, Korea (the Republic of)

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) or Coronavirus Disease 2019 (COVID-19), characterized as a pandemic at 2020 march, is affecting 216 countries and territories around the world. The issues of hygiene to defend against germs and viruses have risen significantly. For antiviral and antibacterial, it is important to prevent anti-microbial and anti-fouling on the surface because of transmission of pathogens droplets and surface contact. We thus developed multi-functionalized polyurethane coating materials and techniques to satisfy both strategies. PU has been widely used commercially and can be controlled with a variety of mechanical properties, such as hardness, toughness, elasticity and so on due to chemical bonding and physical interaction.
Firstly, we synthesized perfluoro tert butanol-hexamethylene diisocyanate (PFtB-HDI) containing of an umbrella-like structure for anti-fouling of airborne infectious particles (< 5 μm in diameter). The fluorine-containing PU coatings have highly hydrophobic properties, scratch resistance and durability after laundry with commercial detergent, which means the coating has a potential of reusability and decreasing waste plastic. The PFtB-HDI-PU-coated fabric had an improved aerosol protection performance without changing its air and moisture permeability.
Secondly, we prepared a quaternary ammonium alkyl chain-isocyanate (QAC-NCO) for coating with curing and bacterio cidal effect. The coatings were prepared with reacting polyol (pHEMA or PEG) and QAC-NCO. This coating contains QCA as a killer of bacteria and urethane bond for durability on the outside and inside. After QAC-NCO coating, percent (%) of bacteria killed for Staphylococcus aureus *(S. aureus)* and Pseudomonas aeruginosa *(P. aeruginosa)* were decreased up to 99.8% and 98.4%, respectively. Our coating systems is based on a polyurethane coating. Therefore, it has a high potential of realizing good performance by applying it to many fields where urethane coating is used.

Potentiation Strategies for Photosensitizer Embedded Anti-Microbial Materials Qingqing Wang[1], Huiyiing Shen[1], Reza Ghiladi[2], Qufu Wei[1] and Chenyu Jiang[2]; [1]Jiangnan University, China; [2]North Carolina State University, United States

Photosensitizers immobilized onto various matrixes as self-disinfecting materials has been widely reported in the last few decades. However, the antimicrobial photodynamic inactivation (aPDI) efficiency of those materials was restricted by different factors including the photosensitizer itself, immobilization strategy, light availability, illumination conditions, etc. In view of this, we have focused on the potentiation of photoactive materials in which different photosensitizers have been embedded to either electrospun nanofibers (*Mater. Sci. Eng. C*, **2021**, *111502*), bacterial cellulose (BC) (*Cellulose* **2020**, *27*, 991-1007), or traditional textile fabrics (*ACS Appl. Mater. Interfaces* **2019**, *11*, 29557−29568). The photodynamic antimicrobial membrane comprised of electrospun cellulose acetate (CA) microfibers into which the photosensitizer protoporphyrin IX (PpIX) was *in situ* embedded (abbr. PPIX/CA) achieved a 99.8% reduction in Gram-positive *S. aureus* after illumination (Xe lamp, 500 W, $\lambda \geq 420$ nm; 30 min), with a lower level of reduction (86.6%) for Gram-negative *E. coli*. Potentiation with potassium iodide was found to be an effective way to further enhance the antimicrobial efficacy of the PpIX/CA microfibrous membrane, achieving 99.9999% (6 log units) inactivation of both *S. aureus* and *E. coli* in the presence of 25 and 100 mM KI, respectively. As an alternative strategy, we have embedded another promising photosensitizer molybdenum disulfide (MoS_2) into BC membrane by a facile *in-situ* growth followed by a dip-coating process to coat a chitosan layer on its surface (abbr. BC/MoS_2-CS). When compared with BC/MoS_2 membrane, which showed a 95% reduction of *S. aureus* and 99.9% inactivation of *E. coli*, the addition of chitosan led to a satisfying synergistic effect between chitosan and MoS_2, showing a 99.998% reduction of *S. aureus* and 99.988% inactivation of *E. coli*. More recently, we have developed photosensitizer-luminous powder dual-coated fabrics using silk-screen printing, and demonstrated that this strategy is able to produce antimicrobial materials working not only in light-available area but also in the dark. Our conclusion is that those photosensitizer-embedded materials, that are not so desirable in anti-microbial efficacy, may still have widespread applicability when appropriate potentiation method was employed.

8:35 AM SB05.06.02
Photoactive Carbon Dots as a New Class of Broad Spectrum Antibacterial and Antiviral Agents Liju Yang[1] and Ya-Ping Sun[2]; [1]North Carolina Central University, United States; [2]Clemson University, United States

Infectious diseases caused by pathogenic bacteria and viruses represent a huge global challenge in public health and have prompted the in-demand search for novel and effective alternative antimicrobial agents. We have recently developed carbon dots (CDots) as a new class of effective and efficient visible/natural light-activated antimicrobial agents, with demonstrated ability against a wide range of bacteria and viruses. CDots are surface-functionalized small carbon nanoparticles (CNPs), represent the nanoscale carbon allotrope at zero-dimension. Attributed to the π-plasmon-associated electronic transitions, CDots have remarkable broad optical absorptions in the entire visible spectrum, extending into both near-UV and near-IR, making them excellent visible light-excitable agents. Mechanistically, upon photoexcitation on CDots, there are rapid charge transfers and separation to form electrons and holes redox pairs, followed up the radiative recombinations of the separated redox pairs resulting in emissive excited states, which are responsible for photodynamic production of classical reactive oxygen species (ROS). The combined action of the initially separated redox pairs and the generated classical ROS are responsible for the observed uniquely effective photoinduced antimicrobial function of CDots.
We have demonstrated the highly effective photoactive antimicrobial activities of CDots against various bacteria and viruses, ranging from laboratory model bacteria (*E. coli*, *Bacillus Subtilis*), pathogenic foodborne bacteria (*Listeria*, *Salmonella*), to multi-drug resistant (MDR) nosocomial pathogens (*Enterococcus*), as well as various viruses (model MS2 virus, vesicular stomatitis virus (VSV), and marine norovirus (MNV)). For the bacterial species tested, the treatments with 0.1 mg/mL CDots under 1 h household light illumination achieved up to more than 7 log viable cell reductions, demonstrating the high efficiency of photoinactivation by CDots. For viruses tested, the treatment with 5 mg/mL to viral samples containing 10^6 PFU/mL under 1 h household light illumination inactivated all the viruses, diminishing viral infectivity to their host cells. Bacterial damages by CDots treatments, including elevated levels of lipid peroxidation, increased membrane permeability, and cytoplasmic structural disruptions, are evident. Degradation in viral proteins and genomic RNAs are also observed.
Along with these demonstrated highly effective antimicrobial activities, our studies on property-function correlations have revealed that the optical properties, the surface functional groups and charges, and the passivation layers of CDots are highly correlated with their antimicrobial activities, which make CDots tunable and expandable material platforms for further improvement. With their tunable structures and uniquely advantageous properties together with their non-toxic nature, CDots present new opportunities for effective control and prevention of infectious diseases.

Superhemophobic and Antivirofouling Coating for Mechanically Durable and Wash-Stable Medical Textiles Anthony Galante, Sajad Haghanifar, Eric G. Romanowski, Robert M. Shanks and Paul W. Leu; University of Pittsburgh, United States

Medical textiles have a need for repellency to body fluids such as blood, urine, or sweat that may contain infectious vectors that contaminate surfaces and spread to other individuals. Similarly, viral repellency has yet to be demonstrated and long-term mechanical durability is a major challenge. In this work, we demonstrate a simple, durable, and scalable coating on nonwoven polypropylene textile that is both superhemophobic and antivirofouling. The treatment consists of polytetrafluoroethylene (PTFE) nanoparticles in a solvent thermally sintered to polypropylene (PP) microfibers, which creates a robust, low-surface-energy, multilayer, and multilength scale rough surface. The treated textiles demonstrate a static contact angle of 158.3 ± 2.6° and hysteresis of 4.7 ± 1.7° for fetal bovine serum and reduce serum protein adhesion by 89.7 ± 7.3% (0.99 log). The coated textiles reduce the attachment of adenovirus type 4 and 7a virions by 99.2 ± 0.2% and 97.6 ± 0.1% (2.10 and 1.62 log), respectively, compared to noncoated controls. The treated textiles provide these repellencies by maintaining a Cassie–Baxter state of wetting where the surface area in contact with liquids is reduced by an estimated 350 times (2.54 log) compared to control textiles. Moreover, the treated textiles exhibit unprecedented mechanical durability, maintaining their liquid, protein, and viral repellency after extensive and harsh abrasion and washing. The multilayer, multilength scale roughness provides for mechanical durability through self-similarity, and the samples have high-pressure stability with a breakthrough pressure of about 255 kPa. These properties highlight the potential of durable, repellent coatings for medical gowning, scrubs, or other hygiene textile applications.

9:05 AM SB05.06.05
Polyethylenimine-Functionalized Silver Nanoparticles as Potential Antiviral and Antibacterial Disinfectant Atul K. Tiwari and Prem C. Pandey; Indian Institute of Technology Banaras Hindu University, India

Polyethylenimine in the presence of organic reducing agent allow the formation of functionalized Silver nanoparticles of controlled particle size distribution. The nanoparticles exhibited potent antimicrobial activity against drug resistant bacterial and also to viruses. as a function of size of silver nnoprticles. Fluorescence imaging of Ag-NPs revealed selective transfusion of Ag-NPs across the cell membrane as a function of the polymeric MW; differential interaction of the cytoplasmic proteins during antimicrobial activity was observed and will be discussed during presentation.

9:20 AM SB05.06.06
Late News: (Garcia High School Student) Fogging H1N1 Virus to Quantify the Survival Rate on Various Surfaces Timothy J. Reinholdt, Kuan-Che Feng, Francis H. White, Qianhui Hong and Miriam Rafailovich; Stony Brook University, The State University of New York, United States

The COVID-19 pandemic has made the general public more aware of the threat of viruses. With that comes interest in how long pathogens are able to survive on surfaces, to help minimize potential exposures. Hypochlorous Acid, or HOCL is an endogenous substance found in mammals, and effective against a wide range of microorganisms1. This research will determine the efficacy of Hypochlorous Acid for eliminating the H1N1 Virus, which is responsible for a highly contagious respiratory disease2, and identify the survival rate on various surfaces.
To identify the reduction rate of H1N1, a plaque assay was executed to calculate the PFU of H1N1 plated on PLA (Polylactic Acid), Polystyrene (280K), and Aluminum at different timeframes. The samples were allocated into vials with 0.2% BSA in MEM (minimum essential media) and vortexed to promote uniformity. Subsequently, the new virus solution underwent a ten-fold serial dilution to perform a plaque assay. The virus was then replaced by the gum medium (0.2% BSA, 0.5% TrypLE Select, 1% PenStrep and 25% Tragacanth gum). Lastly, the plates were placed in the incubator for 3 days and later stained with 1% crystal violet, with 4% formaldehyde and 50% methanol dye. The PFU of each well was counted and documented.
In relation to time (in hours), drying in a room temperature environment was significantly more susceptible to viruses surviving than at 4°C and -20°C, despite the variance in surfaces. In a 4°C refrigerator, the penny, an impure copper surface, had the lowest H1N1 survival surface rate (blank) in coin currencies. For the 24 hour series, PLA—at room temperature—achieved the most resistance to the H1N1 virus with a 2-log reduction. Most notably, an Aluminum surface drying for 48 hours produced a 3-log reduction, which resulted in a 99.9% H1N1 elimination.
At room temperature, all tested surfaces reached antiviral capabilities (at least 4-log reduction or 99.99% elimination) between 24 and 50 hours; however, this span significantly increases the likelihood of pathogens to spread via surfaces. Therefore, the addition of Hypochlorous Acid, a common disinfectant, was deemed necessary to increase the log reduction of H1N1 in a shorter time frame.
To observe the disinfecting effect of Hypochlorous Acid, 350 and 510 ppm (low and high) concentrations were used. Firstly, the H1N1 virus was deposited on three different surfaces: Polystyrene (280K), Aluminum, and PLA. The plated virus samples were then fogged with HOCI at 2.5 minutes, 5 minutes, 7.5

minutes, and 10 minutes with a 5 minute interval of rest for the different concentrations. For H1N1 deposited on all surfaces, there was an increasing correlation between log reduction and time (in minutes) for both chlorine concentrations, denoting that longer fogging cycles eliminates more virus particles. Specifically, Aluminum and Polystyrene infected surfaces exposed to high chloride concentration were considered antiviral between 5 and 7.5 minutes. For low chloride concentration, surfaces plated with H1N1 produced a 4-log reduction between 7.5 and 10 minutes. Therefore, these results provide promising evidence that makes hypochlorous acid fogging, a cheap and readily available substance, a potential method of disinfecting with high efficacy.

9:25 AM SB05.06.07
Evaluation of Antifungal Activity of Ca2Fe2O5 against *Candida utilis* with Changing Susceptibility upon Cultivation Svetlana Vihodceva[1], Olga Muter[2] and Andris Sutka[1]; [1]Riga Technical University, Latvia; [2]University of Latvia, Latvia

Candida species are the most common fungi isolated from nosocomial infections (e.g., hospital-acquired infections), and biofilms formed by these organisms are associated with drastically enhanced resistance against most antimicrobial agents. Nowadays, also rare fungal species of low pathogenic potential, or even species never described before as a cause of disease, are being more commonly detected in health-care settings. Thus, an intensive search and development of the novel anti-fungal agents is of current interest. This study reports the impact of $Ca_2Fe_2O_5$ nanoporous powder on yeast *Candida utilis* – as a fungal model - at different phases of growth, i.e., early exponential, mid-log and stationary phases. After 120 min incubation, the fungicidal activity of nanoporous powder was observed, i.e., log reduction of 2.81 and 2.58 for mid-log and stationary culture, respectively, reaching the maximum of 4 log reduction after 7 days. The early exponential culture of *C. utilis* showed an enhanced resistance to $Ca_2Fe_2O_5$ with a log reduction £0.4 during the 7 days exposure. Our results not only showed that $Ca_2Fe_2O_5$ have the potential to effectively decrease the *C. utilis* cell growth, but also indicated the importance of the physiological state of the test culture. Obtained results may contribute to better understanding of the difference in fungicidal efficacy of antimicrobial materials.

Capture-and-Release Filtration of Aerosolized Bacteria Using Liquid Nets Daniel Regan, Chun Ki Fong, Justin Hardcastle and Caitlin Howell; University of Maine, United States

Materials and methods of collecting bioaerosol for performing analysis on potential biological threats is at an all-time high after over a year of battling COVID-19. Currently, filter-based air samplers capture the highest yield and ratio, while liquid impingers offer the best chance to maintain pathogen viability. In this body of work, we present a novel approach to filter-based filtration by fabricating liquid nets. Infusing polytetrafluoroethylene filters with a perfluoropolyether oil resulted in improved rate of release of captured Escherichia coli aerosols onto culture plates. Furthermore, wetting meltblown polypropylene filters with the same perfluoropolyether oil improved the rate of release, as well as the overall colonies transferred and cultured. The efficiency of bioaerosol transfer demonstrated by the liquid-infused filters could provide a better representation of the airborne pathogens within an environment, enabling informed actions by infectious disease experts and medical professionals.

Graphene-Based Electrode for Cortical Maps and Epilepsy Treatment Jong-Hyun Ahn; Yonsei University, Korea (the Republic of)

Cortical maps, which are indicative of cognitive status, are shaped by experience. Previous mapping tools, such as penetrating electrodes and imaging techniques, are limited in assessing high-resolution brain maps largely owing to their invasiveness and poor spatiotemporal resolution, respectively. In this talk, we developed a flexible graphene-based multichannel electrode array for electrocorticography (ECoG) recording, which enables us to assess cortical maps in a time- and labor-efficient manner. The flexible electrode array, formed by chemical vapor deposition (CVD)-grown graphene, provides low impedance and electrical noise because of the creation of a good interface between the graphene and brain tissue, which improves the detectability of neural signals. In addition, we present the results of simultaneous recordings of multiple cortical sites and responsive neurostimulations for epilepsy treatment carried out in free-moving rats. Flexible graphene-based electrode array which stably wraps onto the cortex surface of a living rat's brain, exhibiting a superior signal-to-noise ratio. The graphene multichannel electrode successfully detected brain signals with high-throughput spatiotemporal resolution and substantially suppressed pilocarpine-induced epileptic discharges and behavior. The simultaneous recording and neurostimulation in awake animals can lead to a fundamental change in the approaches used for the treatment of medically intractable epilepsy.

11:00 AM SB06.01.02
Graphene Quantum Dots Synthesized from Reduced Graphene Oxide for Near-Infrared *In Vitro/In Vivo/Ex Vivo* Bioimaging Applications Md Tanvir Hasan[1,2], Bong Han Lee[2], Ching-Wei Lin[3,4], Ainsley McDonald-Boyer[5,2], Roberto Gonzalez-Rodriguez[6,2], Satvik Vasireddy[2], Uyanga Tsedev[4,4], Jeffery Coffer[2], Angela Belcher[4,4,4] and Anton V. Naumov[2]; [1]National Institute of Standards and Technology, United States; [2]Texas Christian University, United States; [3]Academia Sinica, Taiwan; [4]Massachusetts Institute of Technology, United States; [5]Rice University, United States; [6]University of North Texas, United States

Near-infrared (NIR) emissive nanomaterials are desired for bioimaging and drug delivery applications due to the high tissue penetration depth of NIR light, enabling in vitro/ex vivo/in vivo fluorescence tracking. Considering the scarcity of NIR-fluorescing biocompatible nanostructures, we have for the first-time synthesized nanometer-sized reduced graphene oxide-derived graphene quantum dots (RGQDs) with NIR (950 nm) emission highly biocompatible *in vitro* with no preliminary toxic response *in vivo*. RGQDs are obtained in a high-yield (~90%) top-down sodium hypochlorite/UV-driven synthetic process from non-emissive micron-sized reduced graphene oxide (RGO) flakes. This oxidation of RGO yields quantum dots with an average size of 3.54 ± 0.05 nm and a highly crystalline graphitic lattice structure with distinguishable lattice fringes. RGQDs exhibit excitation-independent emission in the visible and NIR-I region with a maximum NIR quantum yield of ~7%, where *in situ* fluorescence measurements of the synthesis also showed an interdependence of evolution for the visible and NIR-I emissions. Unlike their parent material, RGQDs show substantial biocompatibility with ~75-80% cell viability up to high (1 mg/mL) concentrations verified via both MTT and luminescence-based cytotoxicity assays. Tracked *in vitro* via their NIR fluorescence, RGQDs exhibit efficient internalization in HeLa cells maximized at 12 h with further anticipated excretion. *In vivo*, RGQDs introduced intravenously to NCr nude mice allow for fluorescence imaging in live sedated animals without the need in sacrificing those at imaging time points. Their distribution in spleen, kidneys, liver, and intestine assessed from NIR fluorescence in live mice, is further confirmed by excised organ analysis and microscopy of organ tissue slices. This outlines the potential of novel RGQDs as NIR imaging probes suitable for tracking therapeutic delivery in live animal models. A combination of smaller size, water-solubility, bright NIR emission, simple/scalable synthesis, and high biocompatibility gives RGQDs a critical advantage over a number of existing nanomaterials-based imaging platforms.

11:15 AM SB06.01.03
Exfoliated and Stabilized Biological Carbon Nanotube (CNT) Dispersions, Conductive Films, and Biocatalysts for the Bioengineering Applications Ankarao Kalluri[1] and Challa V. Kumar[1,2,2]; [1]University Of Connecticut, United States; [2]University of Connecticut, United States

As carbon nanotubes (CNT) emerging in the healthcare and bioengineering field, it is essential to produce toxic-free, biofriendly, biocompatible, water-soluble, fewer defects, highly concentrated, and stable biological CNT solutions. We report stable and high-quality multi-walled carbon nanotube (MWCNT) dispersions using proteins as a dispersing agent by a simple stirring on the benchtop. Bovine serum albumin (BSA), anionic or cationic BSA, ovalbumin, lysozyme, and hemoglobin are used to disperse MWCNT, and the dispersions and exfoliation efficiency depended on the charge, size, and nature of the protein. We achieved a minimum dispersion limit ~5 mg/ml and a maximum up to ~12 mg/ml and the undispersed CNT is easily removed by centrifugation and washing or precipitation. The BSA-coated CNT showed controllable surface charge, stable dispersions at pH 7 to 14 and stability over a wide temperature (2–50 °C) up to 6 months. Furthermore, the CNT dispersions loaded on the cellulose filter paper to fabricate the metal-free and conductive bio-CNT films. The bio-CNT films showed a resistance of <30 Ω/sq and conductivity >10000 s/m, greater than the electrical conductivity reported for CNT-polymer composites. This general, powerful approach is used to produce environmentally benign, biocompatible CNT dispersions by a simple method that can be adapted under resource-limited conditions.
Keywords: Carbon nanotubes, protein, bio-conductivity films, biocatalysts

11:30 AM SB06.01.04
Biocompatibility of Large Area Electronic-Grade 2D Materials with Stem Cells and Motor Neurons RT Jayanth[1], Nicholas White[2], Dmitry Kireev[1,2], Martha Serna[1,2], Emmanuel Okogbue[3,3], Yeonwoong Jung[3,3,3], Shelly Sakiyama-Elbert[2] and Deji Akinwande[1,2,2]; [1]University of Texas at Austin, United States; [2]The University of Texas at Austin, United States; [3]University of Central Florida, United States

Two-dimensional (2D) materials have the potential to become the functional elements of future bioelectronic interfaces. So far, studies directed towards understanding their biocompatibility have mostly utilized exfoliated flakes and suspensions resulting in large uncertainty and discrepancies in their cytotoxicity measures. In this work, as a first step before incorporating them in bioelectronic interfaces, we have performed a comprehensive experimental study of *in vitro* cell-viability of large-scale sheets of electronics grade 2D materials that include platinum diselenide ($PtSe_2$), platinum ditelluride ($PtTe_2$), molybdenum disulfide (MoS_2), and graphene. These materials were selected because of their superior electronic and mechanical properties, and their atomically thin layered structure which facilitates efficient surface chemical functionalization. We cultured embryonic stem cells (ESCs) and ESC-derived motor neurons (MNs) on the surface of these large-area 2D sheets and quantified cell-viability using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay and the Lactate Dehydrogenase (LDH) assay. Live-dead fluorescence imaging was performed to qualitatively understand the trends in cellular growth and proliferation. The results suggest that $PtSe_2$ displays cell-viability values on par with those of the controls, graphene, and MoS_2. Contrarily, $PtTe_2$ displays the lowest cell-viability value amongst all the 2D materials when observed through the lens of the MTT assay but displays cell-viability similar to that of the controls when observed through the lens of the LDH assay. We provide experimental validations to explain for this discrepancy with $PtTe_2$'s cell-viability and present an overall view on how our study can be further developed to incorporate other 2D materials and cell-viability measurement assays. We believe these results from the *in vitro* biocompatibility experiments can help large-area 2D materials

become an alternative for both future cell-culture scaffolds and bioelectronic implants.

SESSION SB06.02: Fabrication and Characterization of 2D Materials for Bioelectronics and Healthcare II

Graphene Obtained from Renewable Materials—From Biosensors to Supercapacitors Elvira Fortunato, Tomas Pinheiro, Sara Silvestre, Ana Carolina Marques and Rodrigo Martins; NOVA University Lisbon, Portugal

Graphene has emerged as a novel material with enhanced electrical and structural properties that can be used for a multitude of applications from super-capacitors to biosensors.
The use of laser irradiation to induce networks of graphene-based structures towards cost effective, flexible device fabrication has been a highly pursued area, with application of laser engraving in various polymeric substrates.
In this work, we report the application of this approach towards commonly available, eco-friendly and low-cost substrates, namely office paper and cork to be used as a standard glucose biosensor and supercapacitor.
As proof-of-concept amperometric, enzymatic biosensors were developed, exhibiting a good analytical performance in physiologically relevant glucose levels in blood, with linear sensitivity range between 0.5 and 15 mM, with a limit of detection of 130 µM and a sensitivity as high as 27.23 µA/mM. Furthermore, flexible microcapacitor has been also developed on cork exhibiting an outstanding performance with an areal capacitance of 1.39 mF cm-2 (107.26 mF cm-3) at 0.005 mA cm-2.
It was proved that is possible to join sustainable materials and low-cost techniques for laser induced graphene electrodes production, representing a mandatory step for a clean and green future in wearable and self-sustainable electronics.

1:45 PM SB06.02.03
Tuning the Properties of Printed Graphene to Create Electrochemical Sensors and Integrated Open Microfluidics for In-field Environmental and Health Monitoring Systems Zachary Johnson, Nate Garland, Kelli Williams, Bolin Chen, Carmen L. Gomes and Jonathan Claussen; Iowa State University, United States

Printed graphene (PG) has recently shown promise in the fabrication of low-cost, flexible electrical circuits. However, biosensing applications involving PG have been constrained due in part to low resolution printing, destructive post-print annealing steps, low electrochemical reactivity, and/or relatively smooth, planar non-electroactive surfaces.

In this presentation, we demonstrate how low-cost printed and flexible PG circuits can be fabricated and functionalized fluid transport and electrochemical sensing. First, we demonstrate how the utility of PG is expanded through high-resolution patterning, post-print laser annealing, and biorecognition agent functionalization techniques. A new graphene patterning technique [i.e., inkjet maskless lithography (IML)] is used to form high resolution, flexible graphene films (line widths down to 20 µm) that significantly exceeds current graphene inkjet printing resolution (line widths ~ 60 µm). We build upon this technique and add salt porogens into the graphene inks [i.e., salt impregnated inkjet maskless lithography (SIIML)] to increase the micro/nano surface area of the printed graphene to further improve biosensor performance. Next, a rapid pulse laser annealing technique with a continuous CO_2 laser is used to tune the electrical conductivity, surface wettability, surface roughness, and electrochemical reactivity of the IML PG. Finally, we demonstrate how a newer variant of nano/microstructured PG called laser induced graphene (LIG) can be fabricated. This graphene fabrication technique utilizes a scalable direct-write laser fabrication process that converts polyimide into LIG which eliminates the need for chemical synthesis of graphene, ink formulation, masks, stencils, pattern rolls, and post-print annealing commonly associated with other PG sensors.

Finally, we demonstrate how these graphene-based circuits can be biofunctionalized with enzymes [phosphotriesterase (PTE) and acetylcholinesterase (AChE)] for organophosphate sensing or ion selective membranes for ammonium, nitrate, and potassium sensing in river water soil slurry, or urine samples. The PTE and AChE enzymes offer distinct sensing paradigms where PTE is activated by organophosphates and AChE is inhibited. The detection limits of the biosensors so far have achieved approximately 0.6 nM for organophosphate pesticides which well below the concentration limits we would expect for drinking water or soil samples. We also demonstrate how LIG electrodes were capable of monitoring four major neonicotinoids (CLO, IMD, TMX, and DNT) with low detection limits (CLO - 823 nM; IMD - 384 nM; TMX - 338 nM; and DNT - 682 nM) and a rapid response time (~10s) using square wave voltammetry without chemical/biological functionalization. Finally, we demonstrate how the surface wettability of the LIG can be tuned in order to create narrowing, wedge-shaped hydrophilic tracks surrounded by superhydrophobic walls that permit movement of fluid along the tracks by net Laplace pressure (i.e., open microfluidics). Such definitive control over material properties enables the creation of LIG-based integrated open microfluidics and electrochemical sensors that are capable of splitting a single water sample along four multifurcating paths to three ion selective electrodes (ISEs) for potassium (K^+), nitrate (NO_3^-), and ammonium (NH_4^+) monitoring and to an enzymatic pesticide sensor for organophosphate pesticide (parathion) monitoring. The ISEs displayed near-Nernstian sensitivities and low limits of detection (LODs) ($10^{-5.01}$ M, $10^{-5.07}$ M, and $10^{-4.89}$ M for the K^+, NO_3^-, and NH_4^+ ISEs, respectively) while the pesticide sensor exhibited the lowest LOD (15.4 pM) for an electrochemical parathion sensor to date. Hence, this unique and tunable fabrication approach to PG is expected to enable a wide range of real-time, point-of-use health and environmental sensors.

2:00 PM SB06.02.04
***In Situ* Graphene Liquid Cell Scanning Transmission Electron Microscopy Studies Investigating Antibacterial Mechanisms of Multimetallic Nanoparticles** Abhijit H. Phakatkar, Tolou Shokuhfar and Reza Shahbazian-Yassar; University of Illinois at Chicago, United States

Continuously emerging antimicrobial resistance (AMR) in bacteria is a global challenge. Herein, we propose the strategy to utilize bactericidal multimetallic ternary (Fe/Ni/Cu) nanoparticles (NPs) to address the rising AMR challenge. The ternary NPs were synthesized by using aerosol mediated nebulized spray pyrolysis method. The pure metallic FCC crystal structure of NPs was confirmed by using atomic resolution high angle annular dark field (HAADF) scanning transmission electron microscopy (STEM) analysis. Further energy dispersive X-ray spectroscopy (STEM-EDS) technique was used to confirm the elemental composition of synthesized NPs. In-situ graphene liquid cell (GLC) STEM novel approach was utilized to investigate the antibacterial mechanisms of action of these ternary NPs against *Escherichia Coli* (*E. Coli*) bacteria. Cryo-electron microscopy and conventional transmission electron microscopy (TEM) coupled with ultramicrotomy are well-studied and widely utilized approaches to investigate the antibacterial mechanisms of actions of bactericidal nanomaterials. Although these approaches have shown potential to evaluate the nanoscale antibacterial mechanisms,

there exists challenges with lower spatial resolution and the tedious steps involved for the sample preparation. In-situ GLC STEM approach allows faster sample preparation with minimal efforts and can provide insights of dynamic nanoscale events of antibacterial mechanisms of action. Moreover, GLC has unique advantages with higher spatial resolution and capability to reduce the electron beam damage, especially for the soft matter. In the present study, graphene coated TEM gold grids were prepared by transferring chemical vapor deposition (CVD) grown graphene upon etching of the copper substrate. To prepare GLC pockets, 0.3 µL of reaction solution was encapsulated between two graphene coated TEM grids. *E. Coli* bacteria were cultured prior to the experiments in the LB broth culture media for 4 hours under 37ºC incubation. For in-situ GLC experiments, the final concentration of cultured *E. Coli* bacteria was as low as 20 CFU/ml. To acquire better contrast during STEM study and to reduce the organic content in the cell media, cultured bacteria were transferred into the ultrapure water for GLC studies. For investigating the antibacterial mechanisms of ternary NPs, NPs with 25 µg/ml concentration were mixed with cultured *E. Coli* bacteria in water medium. Upon 10 minutes of interaction, the NPs treated bacteria were immediately encapsulated between TEM grids for GLC studies. STEM-imaging and STEM-EDS mapping acquired in GLC clearly indicate the presence of nitrogen (N), oxygen (O), carbon (C), chlorine (Cl) and phosphorus (P) diagnostic ions, mapping the bacterium morphology and cellular integrity. Cl is responsible for the osmotic balance in the bacterium, while N is associated with amino acids. P is present in the phosphorylated proteins and deoxyribonucleic acid, while O and C are present in almost all cellular components. The cellular integrity of control bacterium was disrupted upon treating with ternary NPs for 10 minutes. Fe, Ni, and Cu metal ions were observed inside the bacterium cytoplasm and along the cell wall, confirming the synergistic release of metal ions. Results also confirm that the ions release rate from the ternary NPs follows a trend, as Cu ions > Ni ions > Fe ions. Further organic corona formed around the NPs was investigated to be the bacterium cytoplasmic and cell membrane components. Synergistic and varying rate of (Fe/Ni/Cu) ions release from the ternary NPs can inactivate the bacteria without allowing to develop AMR and can provide prolonged bactericidal efficiency. The present work investigates the real time nanoscale mechanisms of antibacterial activity of multimetallic NPs, encouraging the developments of novel drug delivery strategies.

Towards 2D Heterostructure Nanopore for DNA Characterization and Sequencing Sihan Chen[1], Siyuan Huang[1], Jangyup Son[1], Kenji Watanabe[2], Takashi Taniguchi[2], Arend van der Zande[1] and Rashid Bashir[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]National Institute for Materials Science, Japan

Sequencing the human genome has helped to improve our understanding of disease, inheritance and individuality. Solid-state nanopores could potentially meet the demand for even cheaper and faster genome sequencing, owing to their superior mechanical, chemical and thermal robustness and durability, and potential for integration into high-density electronic arrays.[1] Despite the promise, solid state nanopores have yet to demonstrate DNA sequencing. Two key challenges remain, i.e., achieving few-base spatial resolution and slowing the translocation of the DNA molecule. 2D materials such as graphene[2] and MoS_2[3] have emerged as attractive possibilities, since the thickness of these films is in the range of a few nucleotides. However, atomic membranes alone are not robust in fluid under an electric field.[4] 2D materials sandwiched within dielectrics could provide a stable platform,[5] but the resulting stack thickness limits the spatial resolution. Resolving these challenges requires new sensing mechanisms beyond ionic currents and translocation control.
This work reports a novel solid state nanopore sensor that has the desired spatial resolution of sub nanometer, integrated electrical sensing, and can potentially control the translocation of the DNA molecule. In this architecture, the nanopore is drilled through a vertical 2D heterostructure consisting of n-type MoS_2 and p-type WSe_2. The heterostructure forms an atomically thin out-of-plane p-n diode. The diode is passivated by atomic layer deposition (ALD) of HfO_2 for electrical insulation. We validated the robustness of the 2D heterostructure nanopore architecture with ionic sensing, by acquiring thousands of DNA translocation events under three different ionic biases. Then we demonstrated modulation of ionic current by 2D diode interlayer potential. Ionic current modulation is more effective with smaller pores and lower salt concentrations, and thus is not caused by leakage or edge electrochemistry. Modulation of ionic transport is also more effective under forward bias than under reverse bias, as a larger fraction of in-plane bias drops across the vertical p-n junction under forward bias.[6] Finally, we obtained signatures of DNA translocation in ionic and diode channels simultaneously. DNA translocation in 10 mM KCl resulted in current increase in ionic channel, as well as current increase in diode channel. The diode channel had better signal-to-noise ratio than the ionic channel. To our knowledge, these proof-of-principle experiments are first-of-its-kind demonstration of 1) simultaneous detection of DNA translocation in a 2D diode nanopore device in both ionic and electrical channels, and 2) modulation of ionic current by the interlayer potential of 2D diode.

SESSION SB06.04: 2D Bioelectronic Sensing I
Session Chair: Dmitry Kireev
Wednesday Morning, December 1, 2021
Sheraton, 2nd Floor, Constitution A

10:30 AM *SB06.04.01
Graphene-Based Sensors for Real-Time Monitoring of Physiological Parameters Mantian Xue[1], Anthony Taylor[2], Wei-Hung Weng[1], Jiadi Zhu[1], Yiyue Luo[1], Ang-Yu Lu[1], Elaine McVay[1], Jing Kong[1] and Tomas Palacios[1]; [1]Massachusetts Institute of Technology, United States; [2]Edwards Vacuum, United States

This paper describes the use of graphene-based sensors for the real-time detection of physiologically-relevant ions and volatile organic compounds (VOCs). Specifically, we have developed a robust sensing platform with more than 200 sensing units on a transparent glass substrate connected to a custom hand-held readout circuit. This system is then combined with a novel calibration algorithm and machine learning software to provide excellent reproducibility and accuracy over a wide range of physiologically-relevant analytes. For example, using this system, potassium, sodium and calcium ions

have been detected and their relative concentrations have been identified in complex multi-ion electrolytes. An analytical study of the impact of sensor redundancy on the sensitivity and reproducibility of the sensing platform will be presented. The impact of device calibration and machine learning data analysis on system performance will also be discussed. Finally, the use of the graphene sensing platform for the detection of VOC's in both breath and skin will be described, as well as the potential of this technology for diagnosis of different disease.

11:00 AM SB06.04.02
Graphene and hBN/Graphene Heterostructure Channels for Ultra-Sensitive Field-Effect Transistor Biosensing of SARS-CoV-2 Spike Protein S1 Subunit Nicholas E. Fuhr, Mohamed Azize and David Bishop; Boston University, United States

Stemming the exponential growth of emergent infectious disease (*e.g.*, COVID-19) requires prompt detection of infection followed by isolation and treatment of the afflicted. If unchecked, infectious evolutionary events can upend the fundamental institutions constituting *Homo sapiens'* society and economy. Here, a biosensing platform is realized via surface functionalization of a two-dimensional channel comprised of graphene/hexagonal boron nitride (hBN) heterostructure field-effect transistor with monoclonal immunoglobulin G specific for SARS-CoV-2 antigen protein. Several surface functionalization schemes with real-time monitoring of surface modification and sensation on both G- and hBN/G-FETs have been performed. These low-cost devices have been observed to be ultra-sensitive to ≥200 ag/mL SARS-CoV-2 spike protein S1 subunit in 1X phosphate buffered saline. This is ~1-3 orders of magnitude lower than contemporary molecular diagnostics (*i.e.*, RT-PCR and ELISA, respectively). Graphene and hBN/graphene materials and fabrication process are characterized with Raman spectroscopy, X-ray reflectometry, atomic force microscopy, and biosensor performance evaluated with two- and three-terminal electrical measurements. The G- and hBN/G-FET devices used in this study contribute to the growing body of knowledge regarding graphene applications in biosensing by including a passivating hexagonal boron nitride layer and help pave the path toward lab-on-chip platforms for point-of-care applications.

11:15 AM *SB06.04.04
Graphene-Based Materials for Biosensing Platforms Arben Merkoci[1,2]; [1]Catalan Institute of Nanoscience and Nanotechnology and The Barcelona Institute of Science and Technology, Spain; [2]ICREA - Institucio Catalana de Recerca i Estudis Avançats, Spain

Graphene-related materials (GRM) such as graphene oxide (GO) and graphene quantum dots (GQDs) display advantageous characteristics with interest for building innovative biosensing platforms and even smart devices such as nano/micromotors for a myriad of uses including sensing. Quenching of the fluorescence induced by GO or photoluminescence of GQDs can easily operate in synergy with various other nanomaterials and platforms opening the way to several unprecedented biosensing strategies and unique nanomotor technologies. Taking advantage of GRMs we are developing simple, sensitive, selective and rapid biosensing platforms that include: a) GO – based microarray & laterals flow technologies taking advantages of high quenching efficiency of GO. A "turn ON by a pathogen" device will be shown as a highly sensitive detection system using plastics or paper/nanopaper substrates; b) GQDs–based sensors for contaminants detection based on the use of multifunctional composite materials that enable rapid, simple and sensitive platforms in connection to smartphone; c) electroluminescent-based approaches d) A water activated GO transfer technology using wax printed membranes for fast patterning of a touch sensitive device with interest for electronic devices including sensing as well as for a cost-efficient nanomotor building technology for several applications. This work is supported by EU (Graphene Flagship), CERCA Programme / Generalitat de Catalunya.

SESSION SB06.05: Wearable Bioelectronics with 2D Materials I

Wireless Graphene E-Tattoos for Long-Term Mental Stress Monitoring Nanshu Lu; The University of Texas at Austin, United States

Mental stress negatively impacts more than 77% population in our modern societies. Electrodermal activity (EDA), a.k.a. galvanic skin response (GSR), is an emotion-induced skin conductance change due to sweat gland activity, which has been widely used as a quantitative index of mental stress levels for decades. Palm has the highest density of eccrine sweat glands which are filled up under psychological stimuli, such as mental stress, primarily. However, state-of-the-art EDA monitors suffer from limitations such as obstructiveness, short-term wearability, motion artifacts, etc. My group has previously engineered mechanically and optically imperceptible wearable sensors named graphene e-tattoos (GET).[1-3] Herein, we introduce a wireless, long-term wearable (e.g. 24 hours), high-fidelity palm EDA sensor based on 150-nm-thick GET. The ultrathin GET can fully conform to the finest texture of human skin, resulting in an interface impedance even lower than that of the wet Ag/AgCl gel electrodes. GET is laminated on the palm and needs to extend to the wrist to connect to a wristwatch which provides data acquisition, storage, and wireless transmission. The orders-of-magnitude mismatch of stiffness and thickness between the GET and the wristwatch poses a significant challenge for the electrical connection in between. We propose a simple yet effective solution named "heterogenous serpentine ribbon (HSR)." Compared with contacts between straight GET and metal ribbons, HSR offers a ten-fold strain reduction. We have successfully applied such GET-watch-based wearable EDA sensor for long-term, continuous, and ambulatory EDA sensing during our daily activities as well as during sleep. The HSR could be a generic solution to robustly connect any ultrathin and ultrasoft e-tattoos to smartwatches or rigid PCBs, which could significantly expand the sensing modalities of future smartwatches and other wearable devices.

Van der Waals Semiconductor Enabled Miniaturized Color Sensing Ningxin Li, Aisha A. Okmi, Tara Jabegu, Udagamage K. Wijewarden, Diren Maraba and Sidong Lei; Georgia State University, United States

The miniaturized image sensor has received great attention recently, due to their significances in micro-robotics. Current research mainly focuses on developing curved image sensors to correct the field curvature induced by the small lens. However, the innovations in color image sensors are so far very

rare, because of the two major challenges. First, conventional image sensors typically adopt a Bayer filter to endow the laterally arranged pixel with the function of color sensing, rendering a large device profile. Second, aggravated optical chromatic aberrations due to lens system simplification is another difficulty. In this study, we developed a novel vertical color recognition structure (CRS) by stacking multiple layers of van der Waals semiconductors (vdW-S) including $CuIn_7Se_{11}$, InSe, and GaS as the sensing layers which are sensitive to red, green, and blue light from bottom to top, and the neighboring sensing layers are separated with flexible and transparent insulating materials, such as mica or hexagonal boron nitride to prevent short circuits. Meanwhile, adjusting the thickness of these insulating layers makes it feasible to align each of the sensing layers to their respective focal plan to compensate the chromatic aberration. Experimentally, upon the successful fabrication of the CRS, by carefully selecting the vdW-S and control their thicknesses, each sensing layer obtained the desired spectral responses, as well as excellent photoresponsivity linearly depending on incident light power. In addition, depending on the structural superiority of the vertical stacking design, the simulation of chromatic aberration correction based on this CRS is also achieved. The as-developed CRS can serve as individual pixels and implement miniaturized full color image sensor through a scalable fabrication and integration of them, with incomparable advantages in a compact size, aberration correction function for the utilization in medical care, environmental surveillance, and many other areas.

SESSION SB06.06: Poster Session: 2D Materials for Bioelectronics
Session Chair: Dmitry Kireev
Wednesday Afternoon, December 1, 2021
8:00 PM - 10:00 PM

SB06.06.02
Energetically Preferred Bilayered Coacervation of Oppositely Charged Inorganic Nanoplatelets Minchul Sung[1,2], Jaemin Hwang[1], Bokgi Seo[1], Daeyeon Lee[2] and Jin Woong Kim[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]University of Pennsylvania, United States

Colloidal particles with 2-dimensional geometry exhibit high adhesion energy at the interface so there have been studied to synthesized new types of particles with a tailored platelet structure. Compared to typical spherical particles, high aspect ratio of 2D nanoparticles not only stabilize interface more effective but also enhance the interaction between particles due to their large lateral surface area. A platform is introduced for bilayered coacervation of oppositely charged nanoplatelets (NPLs) at the oil-water interface. To this end, we synthesized two types of zirconium hydrogen phosphate (ZrHP) NPLs, cationically charged NPLs (CNPLs), and anionically charged NPLs (ANPLs) by conducting surface-initiated atom transfer radical polymerization. Taking advantages of the platelet geometry and controlled wettability, we demonstrated that ANPLs and CNPLs coacervate themselves to form a bilayered NPL membrane at the interface, which was directly confirmed by confocal laser scanning microscopy. Via theoretical consideration using the hit-and miss Monte Carlo method, we determined that electrostatic attraction-driven coacervation of ANPLs and CNPLs at the interface shows a minimum attachment energy of ~-10^6 k_bT, which is comparable to the cases where NPLs charged with the same type of ions are attached. This unique and novel interfacial coacervation behavior allowed use to develop a pH-responsive smart Pickering emulsion system. All of these results highlight that platelet-type colloids are indeed effective in inducing controllable interfacial adsorption and desorption at interfaces, as well as interactions between them, and also pave ways to develop various interfacial engineering technologies.

SB06.06.03
Interface of Electrogenic Bacteria and Reduced Grapheneoxide: Energetics and Electron Transport Sheldon Cotts, Bijentimala Keisham, Jay Rawal, Vikas Berry and Roshan Nemade; University of Chicago, United States

A synergistic, nanoscale electrical interface with the membranes of exoelectrogenic microbes will have a transformative impact on biological cell-based electronic devices. Here, we report that a conformal graphenic interface on biocatalytic Geobacter sulfurreducens membrane results in quantum-capacitance induced n-doping in reduced graphene oxide (rGO) that further enhances electron shuttling from the membrane to improve electron harvesting from the electrogenic organism. The quantum coupling of rGO with the connected protein-membrane channels leads to an additional electron density of 3.91 x $10^{12}$$cm^{-2}$ and an increase in the in-plane phonon vibration energies (G) of rGO by ~5 cm^{-1}. This n-doping enhances the electron transfer rate from the cell membrane into the rGO via a net driving potential of 158 meV with a 3-fold increase in the power density. The synergistic electron-harvesting and conformal membrane-interfacing of flexible 2D nanomaterials can lead to an evolution in the design of microbe-circuitry to power stand-alone nanodevices.

SB06.06.04
Fabrication Constraints of Flexographic Printed Graphene Electrodes for Chemical Sensing Rebecca R. Tafoya[1], Bryan Kaehr[1], Michael Gallegos[1] and Ethan B. Secor[2]; [1]Sandia National Laboratories, United States; [2]Iowa State University of Science and Technology, United States

To leverage recent advances in the production of printed graphene electrodes, there exists a need to develop a graphene ink suitable for high-throughput fabrication processes. Herein, we fine-tune previously developed graphene ink, formulated with exfoliated graphene and an ethyl cellulose stabilizing polymer, to be suitable for flexographic printing. Further, the impact of process parameters and ink formulation are investigated by analyzing print quality and electrical properties. Characterization reveals anisotropic electrical properties due to striations caused by viscous fingering. Ambient environmental responses are characterized, which inform the scope of graphene electrode applications and need for functionalization of graphene in complex environments. Overall, this work informs the viability of graphene as an environmental and biological sensor and outlines fabrication constraints of production scale printed graphene electrodes.

SB06.06.05
Dual COVID-19 and Influenza Virus Detection via Antibody-Functionalized Graphene Field-Effect Transistors Neelotpala Kumar, Dalton Towers, Dmitry Kireev, Andy Ellingtion and Deji Akinwande; University of Texas at Austin, United States

The advent of pandemic caused by SARS-CoV-2 (COVID-19) has highlighted the requirement of devices capable of carrying out rapid differential diagnosis of various viruses that may manifest similar physiological symptoms but demand tailored treatment plan. Annually, the world undergoes multiple cycles of seasonal Flu infection which now poses a bigger challenge, exacerbated by the pandemic. In this work, we demonstrate liquid-gated graphene field effect transistor (GFET) based rapid biosensing device capable of making differential diagnosis between Influenza (H3N2) and COVID-19 viruses. The device consists of four onboard GFETs arranged in a quadruple architecture, where each quarter is functionalized with specific antibody to utilize the antibody-antigen reaction on graphene's surface to indicate the presence of either Influenza (H3N2) or COVID-19. The antigen-antibody interaction is

dependent on uniform diffusion of virus delivered in low ionic strength phosphate buffered saline, entailing a facile operating procedure, where the user is only required to pipette in a drop of the viral solution onto the device.
Our devices were sucessfully tested against a range of concentrations of both the viruses (COVID-19 and Influenza), indicating extremely high sensitivity. Unlike the standard polymerase chain reaction-based testing kits which have a turn-around time of at least three hours, our device has a lower response time of a few milliseconds; hence enabling rapid diagnosis. Furthermore, the device is highly specific as confirmed by cross-reactivity tests: the COVID-19 functionalized channels are not reactive to the Influenza virus, and the Influenza-functionalized channels are not reactive to the COVID-19 spike protein. In addition, both the channels are not reactive to the introduction of bovine serum albumin, confirming excellent specificity of the multi-targeted biosensor.

SESSION SB06.07: 2D Neurotechnologies
Session Chair: Dmitry Kireev

SB06-Virtual

4:00 PM *SB06.07.01
Graphene Transistors for Biosensing Applications Amaia Zurutuza; Graphenea, Spain

Over the past two decades, graphene has attracted a great deal of attention due to its extraordinary properties. When these properties are translated into applications graphene could have a large impact in various industries and markets such as telecommunications, healthcare, automotive, etc. However, for this to occur there are many milestones that have to be achieved such as graphene manufacturing (growth and transfer) and device fabrication at relevant wafer scales, before moving to component fabrication and system integration into the final product.

Graphene's electronic and mechanical properties make it an ideal candidate to be applied in various types of sensors. The sensors' market is extremely large since we are dealing with the automotive, electronics and healthcare industries among others. Therefore, it is an excellent starting platform for graphene applications. For example, the current COVID-19 pandemic has demonstrated the urgent need for fast diagnostics in order to minimise and control its effects, here, biosensors based on graphene field effect transistors (GFETs) have shown great potential as a platform for future diagnostics.

During this talk, I will cover the fabrication of graphene at wafer scale and the use of graphene in various types of sensors including MEMS [1,2], ion sensors (ISFETs) [3-5], gas sensors [6] and biosensors. Depending on the type of sensor, the graphene requirements including the transfer and characterisation vary considerably.

4:30 PM *SB06.07.02
Graphene-Based Active Neural Sensors for Brain Monitoring and Mapping Jose A. Garrido; Catalan Institute of Nanoscience and Nanotechnology - ICN2, Spain

Large effort is being dedicated to the integration of novel materials into neural interface devices capable of providing an efficient and consistent activity for the duration of their functional lifetime. Recording capabilities need to be such that they allow the detection of brain activity over large areas and with a high spatial resolution. For stimulation applications, a suitable charge injection capacity is required in order to elicit a response from the tissue being targeted without causing damage. Additionally, these devices must be biocompatible and mechanically compliant with neural tissue. Because its two-dimensional nature, graphene exhibits a rather unique combination of physicochemical properties which make it an attractive platform for neural technologies.
This contribution will focus on the recording capabilities of active sensor technology based on single-layer graphene, highlighting its potential for the development of the next-generation neural prostheses and brain-computer interfaces. Recently, solution-gated field-effect transistors (SGFET) based on graphene are being explored with increasing interest as novel transducers for neural signals. The electrochemical stability of graphene and its facile integration with flexible substrates were among the initial triggers that attracted the interest of the community to develop flexible neural probes for brain interfacing. In addition, other properties such as the high carrier mobility and the field effect associated to single-layer graphene allows for the implementation of an active sensor configuration that will be shown in this contribution to offer significant advantages with respect to the classical passive metallic electrodes. Further, this presentation will discuss how SGFET-type sensors allow us the implementation of multiplexing strategies, time-domain and frequency-domain multiplexing, that reduce the footprint of connectivity, permitting an aggressive scaling up in the number of recording sites. Very interestingly, we will demonstrate that SGFETs also have a distinctive capability to expand the temporal resolution of classical electrocorticography technologies, allowing the recording of the relatively unexplored infra-slow brain activity and, thus, potentially enabling the study of novel biomarkers for monitoring neurological disorders.
Acknowledgements. This work has been partially funded by the EU Horizon 2020 programme under Grant Agreement no. 881603 (GrapheneCore3) and no. 732032 (BrainCom)

5:00 PM *SB06.07.03
Graphene-Based Neural Interfaces for Multimodal Probing Brain Activity Duygu Kuzum; University of California, San Diego, United States

The complexity of neural activities has challenged both neuroscience research and clinical practice for decades. Understanding neuronal dynamics and information processing performed by neural populations requires advanced technologies with high-resolution sensing and stimulation capability. Clinical neuromodulation therapies widely used for neurological disorders also depend on the ability to manipulate the dynamics of neural circuits. Conventional

neural interfaces offering electrical, optical, or chemical signals have greatly advanced our understanding of neural functions, however, most of these technologies are based on a single functionality. Combining multiple functionalities in a single system has recently been pursued as an integrative approach in new neurotechnology development. Graphene has recently emerged as a neural interface material offering several outstanding properties, such as optical transparency, flexibility, high conductivity, functionalization and biocompatibility. The unique combination of these properties in a single material system makes graphene an attractive choice for multi-modal probing of neural activity. In this talk, I will present our recent work on graphene-based neural interfaces, highlight key applications, and finally discuss future directions and potential advances for graphene-based neurotechnologies in both basic neuroscience research and medical applications.

5:30 PM SB06.07.04
Hexagonal Boron Nitride Heat Dissipation Neural Opto-Probe for *In Vivo* Applications-- JuSeung Lee and Tae-il Kim; Sungkyunkwan University, Korea (the Republic of)

Due to the development of various advanced new materials and process technologies, electronic devices are being reduced in size to a microscale and are being integrated with high density in a limited area. Through this, energy is saved and performance and efficiency are greatly improved, but heat generated from components of device concentrated in a narrow area is a new problem that cannot be found in previous conventional devices. In particular, in the case of the micro light emitting diodes (LEDs), the heat problem more stands out as it is used as densely integrated injectable or wearable devices for photodynamic therapy, optogenetics, and various sensors. The heat generated by the LED causes problems such as deterioration of light emitting performance, change of emission wavelength property, and reduction of lifespan, which can be a fatal disadvantage to the device.
Although in order to solve this problem, recent research tried to control the LEDs temperature through various methods such as size reduction, pulsed operation, and high thermal conductivity substrate, these are acceptable in limited applications, and it is difficult to apply on the bio-injectable devices. Here, we present an injectable neural opto-probe using the Boron Nitride (BN) as a heat dissipation layer. BN is a 2D inorganic material with excellent thermal stability, electrical inlsulation property, and high thermal conductivity. Recently, various research using it as a heat dissipation material have been published. We applied the BN to neural opto-probe device as a heat dissipation layer to effectively disperse the heat generated during operation. The temperature of the device is verified through finite element method simulation and actual IR temperature measurement to ensure heat dissipation performance of up to 40°C or higher. This heat dissipation performance increased the thermal stability of the device, thereby increase the emitting efficiency of the LEDs and preventing the red shift of the wavelength of the LEDs by spreading the heat from the heat source. The heat dissipation neural opto-probe has superior emitting performance than general devices, and the penetration depth of light in vivo, especially in the brain, has been greatly increased. Through this, it was possible to develop a device that can effectively deliver light to a wider range in applications such as PDT and optogenetics.

5:45 PM SB06.07.05
Diagnosis and Treatment of Epilepsy Using Hybrid Structured Graphene-Based Multielectrode Array Jejung Kim[1], Jeongsik Lim[1], Sangwon Lee[2], Sunggu Yang[2] and Jong-Hyun Ahn[1]; [1]Yonsei University, Korea (the Republic of); [2]Incheon National University, Korea (the Republic of)

In decades, neural interfacing devices have attracted huge attention because they can provide not only diagnosis of neurodegenerative diseases but also treatment for a patient suffering from them. Recent researches on surface neural electrodes on the cortical surface have suggested that recording ECoG can diagnose neurodegenerative diseases and also treat them with electrical stimulation. In order to achieve the chemically stable, biocompatible, and electrochemically conductive neural interface, various materials have been investigated such as noble metals, conductive polymers, and nanomaterials. However, each of them has still several defects such as non-transparency, unstability in long-term implantation, their mechanically stiff nature, which impede the chronic biomedical use of implantable devices. Graphene is one of the nanoscale forms of carbon materials, which consists of a single-atomic hexagonal lattice of sp^2 hybridized carbon atoms. It is an attractive candidate for implantable biomedical devices due to its excellent electrochemical property, biocompatibility, chemically inert nature, and mechanically flexibility.
Herein, we suggest graphene-based neural electrode arrays for the treatment of epilepsy. We investigated various graphene-based electrodes for improving the neural interface. First is 4-layer doped graphene. The second one is graphene/Au/graphene sandwich structure. The sandwich structure was synthesized with the followed process; (1) conventional CVD growth process of graphene on copper foil (2) deposition of nanoscale thick gold layer on it (3) wet transfer of monolayer graphene coated with PMMA on it. The sandwich structure takes both advantages of electrical conductivity of gold and electrochemical property and a good interface with neural cells of graphene. We electrochemically characterized these graphene-based electrode arrays and long-term stability and biocompatibility after *in-vivo* implantation. Finally, we successfully demonstrated detection of epileptic form neural activity and treatment of epilepsy using electrical stimulation *in-vivo* rat experiments. These graphene-based electrodes showed very high signal-noise-ratio compared with other neural electrodes and the capability to treat brain diseases. We expect that our graphene-based electrode arrays can demonstrate a breakthrough toward the non-invasive medical application of neural devices.

SESSION SB06.08: Wearable Bioelectronics with 2D Materials II

SB06-Virtual

8:00 AM *SB06.08.01
Wellness and Eye Tracking with Graphene-Based Flexible Photodetectors Frank Koppens; ICFO, Spain

Sensors for ubiquitous sensing purposes should be low-cost, invisible and seamlessly integrable with many different surfaces such as bendable plastic, textiles and glass. Graphene based light sensors [1,2] are inherently flexible and transparent and can be integrated with low-cost CMOS technology [3], hence providing a disruptive platform for future wearables and vision devices.
We will show a prototype non-invasive wellness monitor based on hybrid nanoparticle-2D material systems. We leveraged graphene's flexible and transparent properties to create a wearable device that is conformal to the human body so that it can reliably extract vital signs such as heart rate, breathing rate and oxygen saturation [4]. Furthermore, we present a graphene-based UV-sensing patch. It records harmful UV-exposure on the skin. The patch does not need a battery as a smartphone provides energy via wireless power transfer.

Moreover, we present the first transparent camera based on an array of graphene photodetectors. These transparent image sensors can have a far-reaching impact on human-computer interfaces, smart displays, and eye-tracking for augmented and virtual reality. The operation of these devices presents a fundamental shift in how we think about image sensor, as these devices can be hidden in plain sight.

Integration of Graphene Materials with Textiles Fibers and Fabrics for Applications in Wearable Bio-Electronics Monica Craciun; University of Exeter, United Kingdom

Graphene materials are emerging systems for wearable electronics and smart textiles applications due to their exceptional properties such as electrical conductivity, optical transparency and mechanical flexibility. These properties offer opportunities for the seamless incorporation of electronic devices in textiles, unlocking a future where interacting with bio-electronic devices will be as simple as getting dressed. In this invited talk, I will give an overview of our developments in the integration of graphene materials with flexible substrates, including textile fibers and fabrics for various wearable applications. In our earlier studies [Sci. Rep. 5, 9866 (2015) and Sci. Rep.7, 4250 (2017)] we demonstrated a versatile method to coat a wide range of common insulating textile fibres with monolayer and few layer graphene grown by Chemical Vapor Deposition. Fibre materials such as polypropylene, polylactic acid, polyethylene and nylon, of tape and cylindrical shapes, display sheet resistance values as low as 600 Ohm/ sq, demonstrating that the high conductivity of graphene is not lost when transferred to textile fibres. These graphene-based conductive fibres were used as a platform to build integrated electronic devices directly in textiles. For example, we demonstrated graphene electronic textile fibers that function as touch-sensors and light-emitting devices [npj Flexible Electronics 2, 25 (2018)]. We also demonstrated the weaving of such graphene electronic fibres in a fabric which enabled the realization of pixels for displays and position sensitive functions. Finally, we recently demonstrated the use of graphene-coated polypropylene (PP) textile fibers as temperature sensors within a low-operating voltage carbon–graphene e-textile system [ACS Appl. Mater. Interfaces 12, 26, 29861 (2020)].
For the development of fabric-based wearable devices, one of the critical challenges is the seamless incorporation of electronics in textiles that will preserve their softness and comfort. A key feature is the realisation of electrically conductive coatings on textile that conform to the irregular and coarse structures of the textile fabrics. Therefore, a different approach compared to fibers is needed for creating conductive textile fabrics without compromising the properties of the fabric. We recently demonstrated a simple, low-cost, efficient, and highly scalable method of ultrasonic spray coating for coating three types of textile fabrics, meta-aramid, polyester and nylon, with a water based graphene nanoplatelets suspension [J. Phys. Mater. 4 014004 (2021)]. These conductive textile fabric electrodes show a sheet resistance as low as 4.5 kOhm/sq without any intentional doping or required additives for improved adhesion. Such fabric electrodes have applications in sensors or energy-harvesting wearable technologies.
One of the main advantages of 2D materials for various applications is that they can be prepared in form of water-based solutions. The high yield and cost-effectiveness of this method make them of great interest for printed electronics, composites, and bio- and healthcare technologies. In the final part of my talk I will discuss our developments in this area. I will present the integration of high quality graphene films obtained from scalable water processing approaches in emerging energy harvesting devices [Adv. Mater. 30, 1802953 (2018)], opening new possibilities for self-powered electronic skin, flexible and wearable electronics. Building on this work, we developed a method for the fabrication of micrometer-sized well-defined patterns in water-based 2D materials [Adv. Sci. 6, 1802318 (2019)]. This method was used to create humidity sensors with performance comparable to that of commercial ones. These sensor devices are fabricated onto a 4 inch polyethylene terephthalate (PET) wafers to create all-graphene humidity sensors that are flexible, transparent, and compatible with current roll-to-roll workflow.

9:00 AM SB06.08.03
Direct Writing of Highly Crystalline Laser-Induced Graphene on Polydimethylsiloxane for Wearable Devices Shuichiro Hayashi, Fumiya Morosawa, Rikuto Miyakoshi and Mitsuhiro Terakawa; Keio University, Japan

Laser-based modification of polymers has been emerging as a versatile method to simultaneously synthesize and pattern electrically conductive structures on polymer substrates for flexible device applications. By simply irradiating and scanning the polymer substrate with a laser beam, optical and thermal effects are induced near the focal spot, and electrically conductive graphitic carbon (ie., laser-induced graphene, LIG) can be directly patterned onto the substrate. Although laser modification is promising for the fabrication of flexible devices, polymer precursors used in previous studies are limited to inelastic materials, such as polyimide (PI) and biomasses (ie., cellulose). We have been studying the femtosecond laser-induced graphitization of a well-known elastomer, polydimethylsiloxane (PDMS). PDMS-based LIG generally shows comparably lower conductivity than those of structures fabricated from PI, possibly due to the aliphatic structure of PDMS, hindering graphitization. However, fabrication of highly conductive structures, composed of highly-crystalline graphene, was achieved by irradiating femtosecond laser pulses at a high repetition rate onto the surface of native PDMS. The structures fabricated by using our method exhibited an electrical conductivity as high as ~51.6 S m^{-1}, which is, to the best of our knowledge, the highest value achieved (ie., ~300% of highest value previously reported) using the laser modification of PDMS. Raman analyses of the fabricated structures indicated the formation of highly crystalline and few-layered graphene by laser irradiation, which is considered to contribute to the high conductivity of the fabricated structures. Furthermore, when the fabricated structures were excited using UV light (365 nm), photoluminescence was observed for the fabricated structures. The emission spectra obtained from the structures indicated two peaks centered at 400 nm and 720 nm, suggesting the formation of nano-sized carbonaceous (ie., carbon quantum dots, graphene quantum dots) and siliconaceous (ie., silicon carbide, porous silicon) structures, respectively. The structures fabricated with the proposed method exhibited piezoresistive behavior, and by exploiting the elasticity of PDMS, in combination with the high conductivity of the fabricated structures, a soft, small, and sensitive (ie., ~2.2 kPa^{-1}) piezoresistive sensor that could detect pressures as low as approximately 0.1 Pa was realized. When compression cycle tests were performed on the sensors, the relative changes in resistance to applied pressure at the end of compression cycles were comparable to those at the beginning, indicating high stability and repeatability. The high sensitivity indicated by the sensor, regardless of the small size, is attributable to the elasticity of the PDMS substrate. Furthermore, a PDMS-based ring-shaped heartrate (HR) monitor capable of obtaining the pulse wave-form, and resultantly the HR, of the human subject from just the index finger was demonstrated; indicating the potential of the structures fabricated with the proposed method for health monitoring applications.

SESSION SB06.09: 2D Bioelectronic Sensing II

10:30 AM SB06.09.01

Detection of SARS-CoV-2 Receptor-Binding Domain Using Surface-Enhanced Raman Scattering and Machine Learning Kunyan Zhang[1], Ziyang Wang[1], He Liu[1], Néstor Perea-López[1], Allen M. Minns[1], Randall M. Rossi[1], Scott E. Lindner[1], Xiaolei Huang[1], Mauricio Terrones[1,2] and Shengxi Huang[1]; [1]The Pennsylvania State University, United States; [2]Shinshu University, Japan

COVID-19 was one of the leading causes of death in the United States in 2020 and early 2021 and it continues to threaten public health. Thus, it is imperative to understand and identify SARS-CoV-2 including different mutant lineages. Surface-enhanced Raman spectroscopy (SERS) can provide characteristic fingerprints of biomolecules, and with the assistance of machine learning, can become a powerful tool to rapidly identify and understand complicated biosamples. In this work, we developed a platform combining SERS and machine learning to detect the receptor-binding domain (RBD) of SARS-CoV-2 spike protein, a key component related to the infection and transmission. The Raman modes of SARS-CoV-2 RBD were enhanced by gold nanoparticles under a 785 nm laser. To understand the origin of the Raman modes, we analyzed the correlation between the Raman spectra of SARS-CoV-2 RBD and compositing amino acids using our *Frequency Matching* algorithm and achieved high consistency with the genome sequence. In addition, we can classify RBDs of SARS-CoV-2 and MERS-CoV with accuracy, precision, and recall all over 97% using machine learning classifiers. Our SERS-machine learning integrated platform holds promise for rapid detection of SARS-CoV-2 mutants that hinder the immunity efficacy.

10:45 AM SB06.09.02
Transparent, graphene-based Organic Charge-Modulated Field-Effect Transistor for chemical sensing Stefano Lai[1], Ylea Vlamidis[2], Neeraj Mishra[2], Vaidotas Miseikis[2], Pier Carlo Ricci[1], Camilla Coletti[2], Piero Cosseddu[1] and Annalisa Bonfiglio[1]; [1]University of Cagliari, Italy; [2]Istituto Italiano di Tecnologia, Italy

In recent years, graphene and its derivatives have been demonstrated as valuable materials for the development of several kind of biochemical sensors. In particular, its integration in Field-Effect Transistor (FET) structures as active layer has been thoroughly explored in literature. Nonetheless, graphene-based FETs are typically characterized by poor switching properties, which severely limit their actual exploitation in electronic circuits. Moreover, proposed devices typically need a reference electrode in the measurement environment, which is another important limitation for their actual exploitation in a real application scenario.
Here, we report an innovative approach, using graphene as conductive element in a peculiar device structure named Organic Charge-Modulated FET (OCMFET). The OCMFET is a floating gate Organic FET, where a part of the floating gate, namely the sensing area, is exposed to the measurement environment. Through a modification of the sensing area with a proper biochemical receptor, the floating gate can act as a probe for the investigated analytes, which is recognized by means charge variations/modulations induced in the measurement environment and then transduced in a variation of the threshold voltage of the transistor. By decoupling the sensing element by the active layer of the transistor, it is possible to exploit at their best the peculiar properties of graphene as sensing element, while the transistor structure can be optimized to reach electronic performances suitable for the future integration into electronic systems. Moreover, the OCMFET operates in a electrically-floating environment, i.e. the need for a reference electrode in solution is avoided.

It is noteworthy that, although the OCMFET working principle has been already successfully exploited in several kinds of biochemical sensors, conventional materials and fabrication processes have been always employed, as well as chemical functionalization processes of the sensing area. In this new version of the OCMFET, graphene is used for defining the floating gate and the sensing area of the OCMFET, while the other elements in the transistor structure are defined by means of large area, industrial-like techniques such as Chemical Vapor Deposition and inkjet printing. Moreover, we report a straightforward, non-convalent modification of graphene by means of molecules hosting a pyrene moiety, which ensures an highly stable functionalization without affecting the optical and electrical properties of graphene.

As a result, the fabrication process here proposed is suitable for future scale-up to an industrial scale. Taking advantage of the peculiar optical properties of graphene and of the organic materials employed for the fabrication of the transistor structure, highly transparent devices have been fabricated, showing a transmittance higher than 90%.

The actual functionality of this new OCMFET implementation as biochemical sensor has been demonstrated considering pH sensing as a benchmark. Graphene has been non-covalently functionalized with pyrenate peptides hosting chemical groups that can change their charge state with pH. A complete characterization in a wide pH range (3-12) has been carried out using peptides with different net charge profiles. This study paves the way to the development of novel, high-performing sensors integrating graphene and organic semiconductor-based devices.

11:00 AM SB06.09.03
Improving Biosensors Through Understanding the Bonding of Amine Groups on CVD Graphene Elizabeth J. Legge[1,2], Muhammad M. Ali[3], Hina Y. Abbasi[3], Benjamen Reed[1], Barry Brennan[1], Zari Tehrani[3], Vlad Stolojan[2], S Ravi P. Silva[2], Owen J. Guy[3,3] and Andrew J. Pollard[1]; [1]National Physical Laboratory, United Kingdom; [2]University of Surrey, United Kingdom; [3]Swansea University, United Kingdom

Graphene biosensors are a rapidly growing area of research, due to graphene's desirable properties, such as the ease of chemical functionalisation, high electrical conductivity, and high surface area. To achieve the required selectivity for this application area, graphene must be functionalised with an appropriate molecule, which can vary depending on the analyte under investigation. For some sensors, amine groups are required to bind to antibodies then used for the detection of biomarkers. However, there are a range of possible methods to functionalise graphene with amine, and the optimal method is still unclear.

Typically, covalent functionalisation is more durable, due to the greater bond strength, but this can disrupt the sp^2 carbon structure and thus degrade the electrical conductivity. Non-covalent functionalisation is expected to be less durable but maintains the sp^2 lattice and electrical conductivity. In our work we have investigated the differences between a covalent functionalisation, using 4-nitrobenzene diazonium tetrafluoroborate (4-NBD) to bind nitro-phenyl groups and subsequently phenyl amine groups to graphene, and a non-covalent functionalisation, using 1,5-Diaminonaphthalene (DAN) to form poly(1,5-diaminonaphthalene) (pDAN) layers on graphene.

The I_D/I_G ratio from the Raman spectra of graphene can be used as an indication of the level of disorder, and therefore can approximate the level of sp^3 defects due to molecules bound to the graphene. Consequentially, it is typically used to confirm the success of a functionalisation process. However, Bissett, M. A *et al.* and Knirsch, K. C. *et al.* both previously reported unexpected changes in the I_D/I_G, where the I_D/I_G increased with functionalisation, but decreased again after an external force, due to strain and a chemical process respectively. Greenwood, J. *et al.* also reported changes in the Raman spectra after scanning tunnelling microscopy (STM) on functionalised highly oriented pyrolytic graphite (HOPG).

The work presented here on amine functionalised chemical vapor deposition (CVD) graphene shows that while covalent functionalisation is usually the method of choice, it is not necessarily preferable over non-covalent alternatives. Removal of functional groups from CVD graphene with contact-mode

atomic force microscopy (AFM) explains unexpected changes in the Raman spectra, and suggests the durability of covalent functionalisation can be similar or worse than non-covalent functionalisation.

By using a combination of imaging techniques, we demonstrate some imaging challenges that can occur and the importance of using different analytical techniques to investigate the physicochemical properties of biosensors. Our characterisation combines the use of contact-mode AFM, tapping-mode AFM, Raman spectroscopy and time-of-flight secondary ion mass spectrometry (ToF-SIMS). We have also shown how different functionalisation processes affect the operation of a pH sensor, showing a higher sensitivity for the non-covalent process compared to the covalent process.

11:15 AM *SB06.09.04
Ultrasensitive Detection of Crumpled Graphene Biosensors for DNA and Proteins Michael T. Hwang[1,2], Insu Park[2], Mohammad Heiranian[2], Amir Taqieddin[2], Seungyong You[2], Yerim Kim[2], Juyoung Leem[2], Yuhang Jing[2,3], Vahid Faramarzi[2], Angela A. Pak[2], SungWoo Nam[2,2,2], Arend van der Zande[2,2], Narayana Aluru[2,2] and Rashid Bashir[2,2,2]; [1]Gachon University, Korea (the Republic of); [2]University of Illinois at Urbana-Champaign, United States; [3]Harbin Institute of Technology, China

Electrical field effect sensors are an important class of devices that can enable point-of-care sensing by probing the intrinsic charge in the biological entity to be sensed. Use of graphene and especially curved or crumpled graphene for this application is especially promising. We have recently reported the lowest limit of detection (LoD) on electrical label-free field effect-based sensors using single or double stranded DNA molecules on the crumpled graphene FET platform. These devices with even millimeter scale channels show an ultra-high sensitivity detection in buffer and human serum sample down to 600 zM and 20 aM, respectively. Computational simulations reveal that the nanoscale deformations can form ‘electrical hot spots’ in the sensing channel which reduce the charge screening at the concave regions. We have also used the crumpled graphene field effect transistor-based biosensing of important biomarkers including small molecules and proteins. We show that dopamine can be captured by an aptamer and the conformation change of the probe molecule induced electrical signal changes in the sensor. Three different kinds of proteins were captured with specific antibodies including interleukin-6 (IL-6) and two viral proteins. All tested biomarkers were detectable with the highest sensitivity reported on a label-free electrical platform. Significantly, two COVID-19 related proteins, nucleocapsid (N-) and spike (S-) proteins antigens were successfully detected in PBS with extremely low LoDs. This label-free electrical tests can contribute to the challenge of rapid, point of care diagnostics for infectious disease and other important clinical conditions.

11:45 AM SB06.09.06
Highly Sensitive One-Dimensional Material-Based Biosensor for Residual Cancer Cell Detection Sophia Chan[1], Denise Lee[1], Maria P. Meivita[1], Lunna Li[1], Yaw Sing Tan[2], Christine Cheung[3], Natasa Bajalovic[1] and Desmond K. Loke[1,4]; [1]Singapore University of Technology and Design, Singapore; [2]Agency for Science, Technology and Research, Singapore; [3]Nanyang Technological University, Singapore; [4]Changi General Hospital, Singapore

Nanoscale materials present excellent electrical and optical characteristics that can be harnessed for biosensing applications. Moreover, these materials are biocompatible and can be employed for cancer cell-specific detection, making them ideal candidates for bioelectrical sensing. Here, we developed an electrical-based biosensor based on one-dimensional (1D) materials with specific biosensing activity towards breast cancer cells. High sensitivity of the cancer cells were achieved within a hetrogenous population. Atomistic simulations and experimental studies indicate a 1D material-facilitated change in electrical conductivity. Our results provide a promising method of harnessing 1D materials for cell-specific bioelectrical sensing, and has the potential to recognize residual cancer cells within a clinical setting.

SESSION SB06.10: Fabrication and Characterization of 2D Materials for Bioelectronics and Healthcare III

1:00 PM *SB06.10.01
Water-Based and Biocompatible 2D Material Inks for Bioelectronics and Healthcare Cinzia Casiraghi; University of Manchester, United Kingdom

Liquid-phase exfoliation (LPE) [1] allows mass-scalable, cost-effective and versatile production of graphene and other 2-dimensional (2D) material formulations suitable for a wide range of applications. This approach can be also applied to biomedical applications, as LPE can be easily performed in water via non-covalent functionalisation with stabilisers. In particular, pyrene derivatives have shown to be more effective exfoliating agents than traditional surfactants and polymers [2], while providing defect-free 2D materials in water [3-4].

In this talk I will show that non-covalent functionalizion with pyrene derivatives is a simple one-pot approach that allows to make 2D material formulations with strong potential for biomedical applications. In particular, anionic, cationic and amphoteric graphene inks can be easily made by tuning the pyrene derivative used as stabilizer [5-7]. Cationic graphene dispersions show exceptional biocompatibility, intracellular uptake profile and stability in the biological medium, even with protein serum, making them a very attractive material for nanomedicine applications [7].
Finally, I will show that our graphene formulations can be used in combination with other materials to make a viscoelastic surface microelectrode array, which plastically deforms to allow conformation to the complex geometry of soft tissues such as brain [8].

Development of Non-Bonded Interaction Parameters between Molybdenum Disulfide and Water Abhishek T. Sose[1], Esmat Mohammadi[1], Preeya F. Achari[1], Samrendra Singh[2] and Sanket Deshmukh[1]; [1]Virginia Tech, United States; [2]CNH Industrial, United States

Molybdenum Disulfide (MoS2) has shown potential for applications in the field of electronic devices that can be used in the fields of bioelectronics to healthcare. In almost every application MoS2 is exposed to water or humidity, making it important to study the interactions between MoS2 and water. Here to explore the structure of water at the MoS2 surface, we have developed the non-bonded force-field (FF) parameters between the MoS2 surface and three different water models. A single-layered MoS2 surface was represented with Stillinger-Weber (SW) potential and SPC, SPC/E and SPC/Fw water models were used. In order to develop the non-bonded FF parameters, we have employed all-atom (AA) molecular dynamics (MD) simulations integrated with particle swarm optimization (PSO). The new parameters were optimized to reproduce the experimental contact angle of the water droplet on the MoS2 surface as well as the binding energy of a water molecule in four different orientations placed above the MoS2 surface. Using the newly developed parameters, we showed that the binding energies between water molecules and the MoS2 surface is equal to ~ -6.5 kJ/mol, which is in good agreement with the previously reported values in the literature. We have also analyzed the structural properties of water molecules in a droplet on a MoS2 sheet to validate the precision of the developed parameters. The analysis includes z-density profile of oxygen atoms, average hydrogen bond distribution per water molecule, and the angle made by the O-H vector with the normal to the MoS2 sheet.

1:45 PM SB06.10.03
Direct Conversion of PTFE into Reduced Graphene Oxide by Ultraviolet Laser Writing Method Parand R. Riley, Roger Narayan and Jagdish Narayan; North Carolina State University, United States

Reduced graphene oxide has caused a flurry of excitement between researchers for its numerous applications including flexible electronics, biosensing, batteries, supercapacitors, photovoltaics, and optical devices. We report a simple and cost-effective method for the direct writing of reduced graphene oxide (rGO) from polytetrafluoroethylene (PTFE). The ArF excimer laser with a wavelength of 193 nm was utilized for the fast and non-equilibrium transition of PTFE into rGO in ambient conditions with no additional steps for the reduction of graphite. We show that this method has the capability of writing rGO from PTFE on different substrates. The Raman, SEM, and TEM studies indicated that an energy density window of 0.8-1.1 $J.cm^{-2}$ was necessary for providing the appropriate undercooling to form rGO structure. The studies suggested the mechanism of the transformation from PTFE into rGO is the photothermal process in which the chains of PTFE experience unzipping, melting, degassing of volatile components, and restructuring under the ablation threshold.

2:00 PM SB06.10.04
Late News: Next-Generation PPE: Synergistic Antimicrobial Activity and Low-Cytotoxicity of Graphene-Derivative and Nanoparticles on Cotton/Silk Fabrics Shovon Bhattacharjee[1], Rakesh Joshi[2], Muhammad Yasir[2], Anurag Adhikari[1], Abrar Ahmad Chughtai[2], David Heslop[2], Rowena Bull[1], Mark Willcox[2] and C Raina MacIntyre[1]; [1]The Kirby Institute, UNSW Sydney, Australia; [2]UNSW Sydney, Australia

During epidemics or pandemics of emerging infections, personal protective equipment (PPE) is a critical non-pharmaceutical intervention that significantly reduces the spread of pathogens, especially when drugs and vaccines are unavailable. Due to many shortcomings of conventional PPE, there is a need for sustainable, re-usable high-performance PPE with antimicrobial properties. Herein, we report antimicrobial, biocompatible, and multifunctional cotton/silk fabrics coated with reduced graphene oxide (RGO) and silver (Ag)/copper (Cu) nanoparticles (NPs) by using a silane coupling agent followed by chemical reduction and vacuum heat treatment. Results reveal that due to the synergistic impact of NPs and RGO, incorporating a tiny amount of Cu and Ag NPs on top of the RGO boosts the bactericidal activity. All RGO-Ag/Cu NPs coated cotton/silk fabrics showed ~99% inhibition of *Escherichia coli* and *Pseudomonas aeruginosa* (Gram-negative bacterium). RGO−Ag NPs coated cotton/silk fabrics showed inhibition of 78−99% *Staphylococcus aureus* (Gram-positive bacterium). All the developed samples sustained their remarkable antimicrobial activity even after ten times washing. The RGO-Cu NPs cotton/silk demonstrated better inhibition of *Candida albicans* (Fungi), than all other samples. Additionally, developed fabrics exhibited lower cytotoxicity (<30%) than the pure, untreated fabrics, suggest good biocompatibility. These findings indicate that RGO− Cu/Ag NPs coated cotton/silk fabrics have excellent potential to be used in PPE development, such as protective clothing and face masks.

2:15 PM SB06.10.05
Study of Interaction of Polycaprolactone/Graphene Scaffold Using CompuCell3D Kartik S. Menon[1], Aparna K. Menon[1], Praseetha P. Nair[1], Bhushan V. Dharmadhikari[2] and Prabir Patra[3]; [1]Government Engineering College, India; [2]Minnesota State University, United States; [3]University of Bridgeport, United States

Introduction: Polycaprolactone (PCL)/Graphene nanocomposites emerge as promising scaffolds in biomedical applications owing to their unique properties. Understanding molecular level interactions of PCL/Graphene is inevitable to explore its potentials. Here we attempt a computational approach to study the interaction of PCL scaffold and Graphene nanoparticles using the software package, Compucell3D (CC3D). CC3D is a flexible, scriptable modeling environment, which allows the rapid construction of sharable virtual tissue in-silico simulations of a wide variety of multi-scale, multicellular problems.
Materials and Methods: The computational package, CC3D, used in this work is based on the Cellular Potts Model (CPM). CPM is a spatial lattice-based formalism that is extensively applied to understand complex multicellular behaviors in tissue morphogenesis. The technique is based on the free energy minimization using a dynamic Monte Carlo simulation algorithm where the cell behavior depends on a balance of forces described by the Hamiltonian function.
Results and Discussion: The biocompatibility of the PCL scaffold can be improved in the presence of graphene quantum dots due to their high electron mobility and conductivity. Attractive interaction between graphene and PCL is observed in the simulated results, which is primarily due to the natural hydrophobicity of graphene and PCL nanofibers. Van der Waal's interaction also contributes to the same. As the concentration of GQDs increases, the hydrophilicity of the scaffold increases, changing the trend in their interaction. Basic properties of the solvent like viscosity and chain length play an essential role in the scaffold's stability.
Conclusions: Simulation studies for PCL/Graphene interaction using CC3D were conducted. The results obtained indicate improved interaction of PCL and graphene. Reduced cytotoxicity of graphene GQDs is expected as PCL molecules surround it. Moreover, improvement in the diffusional properties of the system is anticipated. The simulation results are to be validated with experimental studies. Further simulation studies are to be conducted using CC3D to find out and optimize the parameters that influence the system and the system's permeability to check the efficiency of the same as a permeable membrane.

Designing a Universal OECT Platform for Sensing at Biological Interfaces and in Wearables Jonathan Harris, Songyan Yu and Erin L. Ratcliff; University of Arizona, United States

This talk will focus on device physics, interface characterizations, and viability of organic electrochemical transistors (OECTs) for chemical sensors. OECTs are printable, biocompatible and exhibit a hybrid electrical-ionic conduction mechanism which gives rise to high levels of gate electrode amplification at low operating voltages.

To develop a “universal” platform that can detect a range of biomarkers, ranging from redox active to not, we take inspiration from a number of different approaches to chemical sensing, including the ultra-high sensitivity of electrochemical-based approaches and the biomarker selectivity of biorecognition elements. Through a number of strategic interface modifications, we show high levels of transconductance at low operating voltages and low detection limits for biomarkers of interest, where the only difference between platforms is the bio-recognition element used for capture. The final architecture is a floating gate OECT. Briefly, an organic semiconductor is used as the channel element and is interfaced with a printable solid state electrolyte. Channel modulation is driven by voltage drops at faradiac floating gate electrodes, one of which is interfaced with complex fluids, such as human sweat, as a demonstration for wearables. A second application considers yeast sensing, with applications to food and beverage industries to biofuels.

Strain-Insensitive Intrinsically Stretchable Transistors and Circuits Weichen Wang; Stanford University, United States

Intrinsically stretchable electronics can form intimate interfaces with the human body, creating devices that could be used to monitor physiological signals without constraining movement due to its tissue-like mechanical properties. The seamless integration between intrinsically stretchable devices and human body will benefit both signal qualities and wearing comfort, which are essential for the future wearable electronics.

However, mechanical strain invariably leads to the degradation of the electronic properties of the devices, which severely limits the applications of quantitative processing of physiological signals. Here we show that strain-insensitive intrinsically stretchable transistor arrays can be created using an all-elastomer strain engineering approach, in which the patterned elastomer layers with tunable stiffnesses are incorporated into the transistor structure. By varying the cross-linking density of the elastomers, areas of increased local stiffness are introduced, reducing strain on the active regions of the devices.

This approach can be readily incorporated into existing fabrication processes, and we use it to create arrays with a device density of 340 transistors cm^{-2} and a strain insensitivity of less than 5% performance variation when stretched to 100% strain. We also show that it can be used to fabricate strain-insensitive circuit elements, including NOR gates, ring oscillators and high-gain amplifiers for the stable monitoring of electrophysiological signals.

A Stretchable and Strain-Unperturbed Pressure Sensor for Motion-Interference-Free Tactile Monitoring on Skins Qi Su[1,2], Qiang Zou[2], Yang Li[1], Yuzhen Chen[3], Lihua Jin[3] and Sihong Wang[1]; [1]The University of Chicago, United States; [2]Tianjin University, China; [3]University of California, Los Angeles, United States

A stretchable pressure sensor is a necessary tool for perceiving and recording physical interactions that take place on soft/deformable skins present in human bodies. However, all existing types of stretchable pressure sensors have an inherent limitation, that is the interference of stretching with pressure

sensing accuracy. This has been a roadblock in providing quantitative pressure sensing under motion-induced stretching, preventing the deployment of pressure sensors in a number of human-integrated applications. Here, we report the design of a novel stretchable pressure sensor that achieves intrinsically strain-unperturbed performance while providing a high pressure sensitivity of 2.2 kPa^{-1}. This is realized through the synergistic creations of electrical double-layer based interfacial-capacitive sensing mechanism and the pyramid microstructure with designed stiffness hierarchy. Specifically, the use of an ionic elastomer for the micro-pyramids renders the sensor's overall capacitance dominated by the electrical double-layer formed at the interface between the tip of the pyramid and the top electrode, which remains almost unchanged under in-plane stretching. This is enabled by the patterned stiffening micro-electrodes underneath each of the pyramids, together with the assist from a pair of soft spacers that keep the two ends of the sensor with the same separation distance between the top and bottom layers. Under different strain states, the sensor can maintain not only a highly stable capacitance value when there is no pressure, but also the same capacitance changing behaviors to normal pressures, exhibiting 98% strain-insensitivity up to 50% strain. Besides the strain-unperturbed performance, our design also provides a low detection limit (0.2 Pa) and a high response speed to pressures (~50ms), as well as repeatable and robust sensing performance. The stretchability and low modulus of our sensor allows it to be attached to the human body with soft embodiments and great conformability. Being the first sensor that can provide all the desired characteristics for quantitative pressure sensing on a deformable surface, it has been demonstrated to realize the accurate sensation of touching information on human skin even in the presence of stretching deformation (under revision).

Soft Multimodal Sensor for Sensing and Distinguishing of Pressure, Strain and Temperature Li-Wei Lo, Haochuan Wan, Junyi Zhao and Chuan Wang; Washington University in St. Louis, United States

Soft wearable sensors are essential components for applications such as motion tracking, human-machine interface and soft robots. However, most of the reported sensor are either specifically designed to target an individual stimulus or capable of responding to multiple stimuli (e.g. pressure and strain) but without the ability to distinguish them. Here we report an elastomeric foam-based three-dimensional sensor that can not only respond to but also distinguish three different kinds of stimuli (pressure, strain and temperature). The sensor utilizes a porous poly(dimethylsiloxane) (PDMS) template coated with a poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) conductive polymer through a low-cost dip-coating process. Responses to different types of stimuli can be differentiated by simultaneously recording resistance and capacitance changes. When pressure is applied normal to the top surface of the sensor, the conductive network of PEDOT:PSS and the air-gap inside the pores are both being compressed, resulting in a decrease in electrical resistance and increase in capacitance. In contrast, when the sensor is being stretched, the PEDOT:PSS network exhibits an increase in electrical resistance and a decrease in capacitance due to the elongation in distance between the two electrodes. Moreover, the sensor can also respond to change in temperature due to the enhancement of charge transport within PEDOT under elevated temperatures. As the temperature increases from 20 °C to 80 °C, the sensor exhibits a decrease in resistance but no noticeable change in capacitance. We have also systematically studied the effect of the pore size on the sensor sensitivity to different stimuli and have found that smaller pore size generally leads to better sensor performance. With its high sensitivity to pressure, strain and temperature stimuli, we have demonstrated the use of the 3D porous sensor on an artificial hand for object detection, gesture recognition and temperature sensing applications.

Sono Healing of Conductive Nanomaterial Network on Polymer Substrate for Reusable Flexible Electronics Bo Li and Thomas Scully; Villanova University, United States

Advanced manufacturing technology to repair and regenerate nanomaterial-on-polymer flexible electronics (NPFEs) will be crucial for their sustainable and affordable applications. Unlike healing strategies for bulk systems, here, we demonstrated an ultra-fast and eco-friendly sono healing method that selectively repairs the ultra-thin nanomaterial network assembled on polymer for NPFEs. The sono healing method highlights a unique energy design of hydrophobic nanomaterial and hydrophobic polymer substrates in water solution such that the nanomaterial will reorganize the network at substrate-water interface energized by sono field (40 kHz and 0.3 W/cm^2). The graphene ultrathin film assembled on polydimethylsiloxane (PDMS) was used as the demonstration system. To mimic the complex deformation in the practical applications of an NPFE device, we used a combined stretch-twist method to initiate the network damage, and the healing process was performed by putting the damaged graphene/PDMS devices back to pure DI water with sonication for 1 min. The damage degree can be defined as R_d/R_0, where R_d is the sample resistance after the damage and R_0 is the initial resistance, while a healing degree is defined as R_r/R_0 where R_r is the regenerated resistance after sono healing. Healing coefficient $R_r/R_0 = 1$ means full regeneration. We have demonstrated that for damage degree less than 10, full regeneration or even enhanced conductive network ($R_r/R_0 < 1$) can be realized. For more severe damage (*e.g.*, $R_d/R_0 = 26.6$), the healing process can recover the resistance close to its original resistance ($R_r/R_0 = 3.2$). The morphology observation suggests that sonication can help rearrange the disturbed graphene network, merging the cracks and reattaching the delaminated graphene flakes, even without a new supply of nanomaterial in the solution. As a proof-of-concept, we have first demonstrated the regeneration of a flexible resistor in a circuit with a lighting diode. The recovered light intensity is the direct evidence of functional recovery. We have also demonstrated the regeneration of a strain sensor where, the gauge factor, the factor describing the strain sensitivity, can be recovered. We have further explored the influence of nanomaterial shape on repairability by studying two other carbon allotropes: 0D carbon black and 1D carbon nanotube and find that 2D graphene presents the best recovery capability. In summary, the selective, ultra-fast, and clean sono healing method will be extremely valuable for eco-repairing flexible devices for biological interfaces and wearables.

SESSION SB07.02: Soft, Healable Materials and Devices for Biological Interfaces and Wearables II
Session Chair: Fabio Cicoira

Stretchable, Degradable and Healable Conducting and Semiconducting Polymers Darren J. Lipomi; University of California, San Diego, United States

Mechanical deformability underpins many of the advantages of organic semiconductors in applications from flexible solar cells to wearable devices for healthcare and virtual touch. The mechanical properties of these materials are, however, diverse, and the molecular characteristics that permit charge transport can render the materials stiff and brittle. In this talk, I describe the ways in which molecular structure and solid-state packing structure govern the mechanical properties of organic semiconductors, especially of π-conjugated polymers. In particular, I describe how low modulus, good adhesion, and absolute extensibility prior to fracture enable robust performance, along with mechanical "imperceptibility" if worn on the skin. The discussion focuses on

the mechanisms by which mechanical energy is either stored (i.e., elastically) or dissipated (i.e., by plastic deformation or fracture). Mechanical energy is mediated at the level of both the molecular structure (determined by synthesis) and solid-state packing structure (determined by processing techniques). Development of metrological methods are critical for the accurate determination of the mechanical properties of thin films of materials for which only small quantities are available from laboratory-scale synthesis. We often find that the interplay between the semiconducting polymer and the substrate influence the mechanical properties and the fracture behavior. Computational molecular dynamics simulations have been particularly helpful in predicting the molecular mechanisms responsible for deformation. The talk concludes with applications of organic semiconductor devices in which every component is intrinsically stretchable or highly flexible.

Ionic Polydimethylsiloxane-Silica Nanocomposites—From Synthesis and Characterization to Self-Healing Property Clément Mugemana[1], Ahmad Moghimikheirabadi[2], Daniel F. Schmidt[1], Martin Kröger[2] and Argyrios Karatrantos[1]; [1]Luxembourg Institute of Science and Technology, Luxembourg; [2]ETH Zurich, Switzerland

Polydimethylsiloxane (PDMS) is the most widely explored and utilized polysiloxane, possessing an extremely low glass transition temperature, excellent thermal stability, high permeability and good biocompatibility.[1] As a liquid at room temperature, most applications require PDMS to be chemically crosslinked and / or combined with nanofillers to realize the requisite mechanical properties. Cross-linking PDMS via reversible dynamic bonds such as hydrogen bonds,[2] ionic interactions,[3] or metal complexes[4] has led to smart self-healable materials. While mechanical reinforcement of PDMS by nanofillers is well-known, the realization of consistently high levels of dispersion of nanofillers in a PDMS matrix remains a challenge. One strategy to control nanoparticle dispersion involves grafting ionic functional groups to the nanoparticle surface (thus creating so-called nanoparticle ionic materials, or NIMs[5]) and combining these charged nanoparticles with a polymer matrix containing functional groups with the opposite charge. Following such an approach, we describe ionic PDMS-silica nanocomposites from (cationic) ammonium-functionalized PDMS and (anionic) sulfonate-functionalized silica nanoparticles, formulated with the aim of influencing the distribution and dispersion of the nanoparticles. The impact of the PDMS molecular weight, charge density and charge location on the distribution, dispersion of ionic silica nanoparticles and on the mechanical reinforcement of the resultant nanocomposites is explored. The potential for self-healing arising from reversible ionic interactions located at the interface between polymer matrix and highly dispersed silica nanoparticles is investigated by studying the impact of ionic nanoparticles loading and the PDMS molecular weight under different healing conditions, *i.e.* temperature and humidity. Finally, coarse-grained molecular dynamics simulations are carried out to calculate the lifetimes of temporary ionic crosslinks between the nanoparticles and the polymer matrix comprising these nanocomposites[6].

Dynamic Metal-Ligand Coordinated PDMS with Tunable Surface Hydrophilicity Xinyue Zhang and Meredith N. Silberstein; Cornell University, United States

Polydimethylsiloxane (PDMS) has been widely used in biomedical, soft lithography, marine antifouling, flexible electronics, and other fields due to its appealing physical and chemical properties. However, the surface energy of PDMS is low and it is highly hydrophobic, which not only yields poor adhesion to substrates but also facilitates undesired adsorption of substances such as protein, biofouler, etc. These drawbacks limit the lifetime and application of PDMS. Moreover, traditional surface modification techniques do not work well on the PDMS surface, because its low glass transition temperature allows the chain to move easily and cover up the modified surface. To overcome this challenge, we investigated a series of dynamically crosslinked PDMS containing metal-ligand coordination, which show tunable surface wettability. The intrinsic hydrophilic functionality is introduced by the metal-ligand coordination, and therefore hydrophilicity of the bulk PDMS can be tailored by the choice of metal cations, counterions, and coordination density in the polymer matrix. The possible mechanisms in the context of metal-ligand bond dynamics are discussed. We show that a properly designed PDMS system with metal-ligand coordination can improve PDMS hydrophilicity as well as control the surface reconstruction speed.

2:30 PM SB07.02.05
Vitrimers and Vitrimer Nanocomposites—Thermomechanical and Self-Healing Properties Amber M. Hubbard[1], Yixin Ren[1], Peter Papaioannou[1], Dominik Konkolewicz[2], Alireza Sarvestani[3], Catalin R. Picu[4], Gary Kedziora[1], Ajit Roy[1], Vikas Varshney[1] and Dhriti Nepal[1]; [1]Air Force Research Laboratory, United States; [2]Miami University, United States; [3]Mercer University, United States; [4]Rensselaer Polytechnic Institute, United States

With sustainability at the forefront of materials research, recyclable polymers, such as vitrimers, have garnered increasing attention since their introduction in 2011. In addition to a traditional glass transition temperature (T_g), vitrimers have a second topology freezing temperature (T_v) above which dynamic covalent bonds allow for rapid stress relaxation, self-healing, and shape reprogramming. Herein, we demonstrate the self-healing, shape memory, and shape reconfigurability properties of this unique material with an aim towards recyclability and increased part lifetime. In addition, a variety of nanofillers (*e.g.*, graphene, clay) are introduced to make vitrimer nanocomposites. We demonstrate an increase in the T_v as a function of nanofiller concentration, while nanofiller composition produces a negligible change in T_v. Furthermore, we establish the addition of nanofillers into the vitrimer matrix increases the mechanical properties but does not hinder the recyclability of these composites as explored via thermomechanical testing. These photothermally activated composites allow for shape memory and shape reconfigurable applications such as actuators and self-healing components.

2:45 PM SB07.02.06
The Mechanical Study of Polyelectrolyte Complexes with Copolymers Hongyi Cai, Yuval Vidavsky and Meredith N. Silberstein; Cornell University, United States

Oppositely charged polyelectrolytes in solution can associate and form polyelectrolyte complexes (PECs), which are widely used in hydrogels, self-

assembly and drug/nucleic acid deliveries. They are versatile materials with morphologies ranging from solid precipitates to liquid-like coacervates to micelles and nanoparticles. People can regulate PECs with both internal factors, like the charged species, and external stimuli, like the environmental ionic strength. Ionic bonds within the materials can break and reform, acting as dynamic crosslinkers to enable self-healing and easy reprocessing while maintaining mechanical strength. One unexplored strategy to modify the mechanical properties of PECs is using copolymers. In this work, we incorporate monomers with different degrees of hydrophilicity into the PEC system. Unlike traditional PECs that are brittle when dried, the resulting materials show elastomeric behavior with high stretchability and self-healing. Further, mechanical strength can still be maintained after equilibration in water. We will present both chemical and mechanical characterization, and demonstrate how the co-monomer type and ionic component ratio affects bulk PEC behavior. This can be an inspiration for future development of soft ionotronics used in biological wearable devices.

3:00 PM *SB07.02.07
Organic Mixed Conductors for Bioelectronics—Understanding the Fundamentals and Putting Them to Good Use Alberto Salleo; Stanford University, United States

Conjugated mixed conductors have attracted much attention lately as soft materials with applications in bioelectronics, energy storage and brain-like computing. In addition to the well-known PEDOT:PSS blend, new families of polymers with glycolated side-chains have been recently developed with promising performance. Interestingly, details of how charge transport occurs and how it's related to ionic transport are still not well understood in both PEDOT:PSS blends and newer materials. This lack of understanding hinders the rational design of the next generation of high-performance materials. In this talk I will show the result of experiments that suggest that while its role in ion transport is well understood, the insulating PSS phase also plays an unexpected role in electronic transport in PEDOT:PSS blends, suggesting new design rules to control electronic transport in these materials. Furthermore, I will show how the microstructure of glycolated polymers must exhibit a balance between aggregates and disordered regions in order to ensure optimal electrochemical performance such as low turn-on voltage and lack of hysteresis. Hence, these important operational parameters do not depend only on energy levels but also on microstructure, making materials more challenging and introducing the importance of processing. Finally, I will show how understanding these materials properties is useful towards using them in high-performance devices such as biosensors.
