Silicon heterojunction (SHJ) solar cells have exhibited efficiencies well above 25% [1]. To further boost the efficiencies of c-Si-based solar cells, high-bandgap perovskite cells are stacked on top, achieving a world record efficiency of 29.52% [2]. However, as most of the high-quality perovskite films are solution-processed [3], the front surface of the bottom device should be flat. Therefore, in this work, we optimized SHJ bottom c-Si cells featuring front-side-flat and read-side-textured morphology, which delivers high V_{OC} [4] together with excellent near-infrared response [5].

We firstly optimized plasma-enhanced chemical-vapor-deposition (PECVD) deposition conditions of (*i*)a-Si:H for both symmetrical flat <100> and textured <111> *n*-type c-Si surfaces. We observed that the optimized (*i*)a-Si:H monolayer (~ 10-nm-thick) on flat <100> surface using pure SiH_4 plasma results in limited performances (τ_{eff} = 1.2 ms, i-V_{OC} = 701 mV). While an optimized hydrogen dilution ratio (DR = *f*[H2]/*f*[SiH4]) of 3 was found for textured <111> surface (τ_{eff} = 4.3 ms, i-V_{OC} = 730 mV). This may be ascribed to an easier defective epitaxial growth for <100> as compared to <111> as reported previously [6]. To understand better the relations between passivation qualities and the microstructure properties (*i*)a-Si:H on flat <100> surface, we characterized layers via Fourier-transform infrared spectroscopy (FTIR) and spectroscopic ellipsometry (SE). We conclude that the monolayer that contains more H, a higher fraction of monohydrides and fewer defects (high refractive index) is beneficial for achieving a better passivation quality.
To improve further the passivation quality of monolayer (*i*)a-Si:H on flat <100> surface, we investigate approaches aiming at incorporating more H without promoting detrimental epitaxial growth. Firstly, we tested hydrogen plasma treatment (HPT) [7]. With HPT, we could only slightly improve the i-V_{OC} from 701 mV to 705 mV. While with a bilayer approach [8] that features firstly a less H-containing (*i*)a-Si:H to prevent epitaxial growth and then covered by a H-rich (*i*)a-Si:H, we could double the τ_{eff} to 2.4 ms with an i-V_{OC} of 720 mV. Eventually, by combining the bilayer approach with an intermediate HPT, the best sample showed a τ_{eff} up to 8.3 ms and an i-V_{OC} of 734 mV for a total thickness of 10-nm (*i*)a-Si:H on the flat <100> surface.
For the two-terminal tandem solar cells, bottom cells with (*n*)-contact on top are preferred due to the optical advantage of the perovskite top cells with the *p-i-n* configuration. Therefore, we symmetrically deposited (*n*)-type hydrogenated nanocrystalline silicon oxide (nc-SiO_x:H) on (*i*)a-Si:H coated flat <100> surface. Surprisingly, a drop of i-V_{OC} to 689 mV was observed after depositing (*n*)nc-SiO_x:H on (*i*)a-Si:H obtained via bilayer + HPT approach. We ascribe the deteriorated passivation qualities to possible excessive H incorporation during the (*n*)nc-SiO_x:H depositions. Therefore, we chose bilayer (*i*)a-Si:H, which has lower H-content as compared to the combined approach, and we obtained improved τ_{eff} (5.8 ms) and *i*-V_{OC} (724 mV) in combination with doped layers.
With this method, we successfully implemented various (*n*)-contacts with either (*n*)a-Si:H, (*n*)nc-Si:H, (*n*)nc-SiO_x:H or (*n*)nc-Si:H/(*p*)nc-SiO_x:H/(*p*)nc-Si:H into solar cells, which delivered V_{OC}s range from 703 to 710 mV and *FF*s range from 78.8% to 81.0%. Therefore, we have building blocks ready for tandem cell fabrications. Besides, advanced optical simulations aiming at improving the matched tandem current are also being conducted.

Loss Analysis for Perovskite/Si Tandem Solar Cells Masafumi Yamaguchi, Kan-Hua Lee, Ryo Ozaki, Kyotaro Nakamura, Nobuaki Kojima and Yoshio Ohshita; Toyota Tech. Inst., Japan

PV-powered vehicle application are very attractive for reducing CO_2 emission and creation of new market. Development of high-efficiency (> 30%) and low-cost solar cell modules is necessary [1]. According to our analysis [2], the 2-junction and 3-junction tandem solar cells have potential efficiencies of more than 36% and 42%, respectively. The perovskite/Si tandem solar cells are thought to be one of the most promising PV devices because of high-efficiency and low-cost potential. However, efficiencies of perovkite/Si tandem solar cells with an efficiency of 29.15% are lower compared to 37.9% with III-V 3-junction tandem solar cells and 35.9% with III-V/Si 3-junction tandem solar cells. Therefore, it is necessary to clarify and reduce several losses of perovskite/Si tandem solar cells. This paper presents high efficiency potential of perovskite/Si tandem solar cells analyzed by using our analytical procedure [3] and discusses about non-radiative recombination, optical and resistance losses in those tandem solar cells.
One of problems to attain the higher efficiency perovskite/Si tandem solar cells is to reduce non-radiative recombination loss. The open-circuit voltage V_{oc} drop compared to bandgap energy (E_g/q - V_{oc}) is dependent upon non-radiative voltage loss ($V_{oc, nrad}$) that is expressed by external radiative efficiency (ERE). Open-circuit voltage is expressed by
$V_{oc} = V_{oc, rad} + (kT/q)\log(ERE)$, (1)
where the second term shows non-radiative voltage loss, is radiative open-circuit voltage and 0.28V was used as $\triangle V_{oc, rad}$ (= E_g/q - $V_{oc, rad}$) for perovskite and III-V compounds and 0.26V was used for Si in this study. The practical limiting efficiencies of perovskite/Si tandem solar cells were calculated by assuming ERE = 30%, optical loss of 5% and resistance loss of 2%.
The perovskite/Si 2-junction tandem solar cells is shown to have efficiency potential of 37.4% as a result of non-radiative recombination loss of 2.3%, optical loss of 2.7% and resistance loss of 3.1%. The perovskite/Si 3-junction tandem solar cells are thought to be very attractive because the III-V and III-V/Si 3-junction tandem solar cells have potential efficiencies of 45.9% and 42.9%, respectively. Although they still have non-radiative recombination loss of 1.9% and 1.5%, optical loss of 2.9% and 2.3% and resistance loss of 3.2% and 2.7%, respectively.
Several non-radiative recombination losses such as bulk recombination, interface recombination, resistance loss including inter-connection and so forth in tandem solar cells are discussed in this paper. In addition, practical limiting efficiency (29.4%) and several losses of crystalline Si single-junction solar cells are discussed in order to compare with those of tandem solar cells in this study.

Role of Amorphous Silica Interlayer in Enhancing the Performance of Perovskite/Silicon Tandem Solar Cells Gekko P. Budiutama, Sergei Manzhos and Manabu Ihara; Tokyo Institute of Technology, Japan

Tandem solar cells with perovskite top cell and Si bottom cell have attracted a lot of attention for their potential to achieve energy conversion efficiency beyond the Shockley-Queisser limit. In the n-i-p perovskite/c-Si variant of this tandem solar cell, recombination at the interface of c-Si and the electron transporting layer of perovskite top cell greatly affect the performance of the device. In this study, we propose the utilization of Scanning Zone Annealing (SZA), a selective heat treatment with high degree of control, to control carrier recombination at Si/TiO_2 interface for perovskite/Si tandem solar cell application. Here, we found that recombination velocity at Si/TiO_2 interface can be reduced down to 40 cm/s using SZA. We also found that the amorphous silica interlayer affected the recombination dynamics at Si/TiO_2 greatly. To understand this phenomenon, theoretical approaches to model triple layer interfaces of $Si/SiO_x/TiO_2$ were utilized. A combination of molecular dynamics and density functional theory calculations was employed to study the effect of amorphous silica stoichiometry and layer thickness on the electronic properties of the interfaces including band alignment, charge transport, and carrier lifetime.

Micrometer-Thick Solution Processed Perovskite Solar Cells on Industrial-Like Textured Si Substrates for Efficient Light Harvesting Ahmed Farag[1,2], Raphael Schmager[1], Paul Fassl[1,2], Bianca Wattenberg[3], Torsten Dippell[3] and Ulrich W. Paetzold[1,2]; [1]Institute of Microstructure Technology, Karlsruhe Institute of Technology (KIT), Germany; [2]Light Technology Institute, Karlsruhe Institute of Technology (KIT), Germany; [3]SINGULUS Technologies AG, Germany

In the past few years, perovskite/silicon (Si) tandem solar cells have emerged as one of the most promising candidates for next generation photovoltaics with the potential to beat the theoretical efficiency limit of single junction solar cells (~33%). Lately, a record power conversion efficiency (PCE) > 29 % has been demonstrated for two-terminal (2T) perovskite/Si tandem solar cells, which already surpasses the record PCE of single junction Si solar cells.

Yet the vast majority of high efficiency 2T perovskite/Si tandem solar cells reported to date, have been demonstrated using front-side polished Si wafers. While this approach is compatible with laboratory scale processes, it is not practical as industrial standard for Si photovoltaics due to the high costs. Industrial textured Si wafers are essential to achieve efficient light incoupling (i.e., to reduce the reflection losses) and light trapping near the band gap and typically exhibit pyramids that partly exceed 3 µm in size. However, such large textures are not compatible with the fabrication of conventional solution-processed perovskite thin films (thickness ~500 nm) on top.

In response to this challenge, we report on industrial-like textured Si wafers with a reduced pyramid size of ~1-2 µm that demonstrates (1) very low reflectance, similar to the conventional industrial textured Si wafers and (2) compatibility with thick solution-processed perovskite solar cells (PSCs) on top. To investigate the light management in PSCs fabricated over textured surfaces in depth, we replicate the Si texture by nanoimprint lithography on glass substrates and fabricate highly efficient *p-i-n* PSCs over the replicated texture.

A thick PSC absorber layer is necessary to cover all pyramid tips and prevent shunting paths. Therefore, we first developed highly-efficient *p-i-n* PSCs on a planar surface (PCE > 19 %) with a 1 µm thick double cation perovskite absorber layer ($Cs_{0.17}FA_{0.83}PbI_{2.75}Br_{0.25}$). Efficient charge carrier extraction is achieved by using urea additive to enhance the charge carrier diffusion length. Then, we optimized the spin-coating parameters for perovskite thin films processed over the replicated textures such that all pyramids are fully covered. In comparison to the planar PSCs, the PSCs processed over the textured substrates exhibit a voltage loss of ~50 mV. To explain the underlying reasons of the voltage loss, we investigated the perovskite crystallization dynamics over the industrial-like textured substrates by performing a full characterization scheme using XRD, EDX, EBIC, cross sectional SEM as well as the standard electrical and optical characterization means. Thereby, we present a guideline on how to minimize these voltage losses [1].

Finally, to demonstrate the optical gains that can be obtained by processing PSCs over textured surfaces, we study in detail the optical properties of the optimized thick PSCs processed over the replicated texture as well as the planar surface. While the textured stack exhibits a considerable broadband antireflection behavior, the planar stack suffers from higher reflection losses due to the thin film interference pattern (2.5 times higher reflection than the textured stack at around 570 nm). The textured stack also exhibits very efficient light incoupling even up to 70° angle of incidence as compared to the planar reference. The efficient light harvesting in our devices results in a remarkable improvement in the broadband spectral response, which leads to efficient J_{sc} amplification with one of the highest reported J_{sc}/J_{SQ} ratios [2,3].

In summary, our contribution shows that, by means of optimized pyramidal surface textures and adapted thick solution-processed PSC, we can solve a key hurdle in the fabrication of textured perovskite/Si tandem photovoltaics.

Implementation and Analysis of Tunnel Junction Based on Transition Metal Oxides on Carrier Selective Contact Architecture Shikha Marwaha and Kunal Ghosh; Indian Institute of Technology Mandi, India

Till date, the photovoltaic industry is dominated by crystalline silicon (c-Si) solar cells because of their reliability, rapid cost reduction and improved efficiency. However, the thermalization losses occurring in the device limits its performance. Most common approach to surpass this limit is to use solar cells in tandem configuration with the top sub-cell having wide band gap absorber and bottom sub-cell possessing silicon as the absorber layer. Perovskite solar cells have proven to be a promising candidate to be used as a top sub-cell in tandem configuration because of their band gap tuning. Monolithic integration of silicon/perovskite devices reduces the wiring complexity and the additional fabrication steps. Most of the monolithic silicon/perovskite solar cells have been obtained either by homojunction or heterojunction silicon bottom cells. However, a tremendous amount of work shows an improved efficiency of transparent metal oxide (TMO) based carrier selective contact (CSC) silicon solar cells. The doped a-Si:H layers in the conventional SHJ solar cells are replaced by TMOs such as V_2O_5, MoO_x, TiO_2, and NiO_x . MoO_x has been proven to be an efficient substitute for p-doped aSi:H layer. The high work function (about 6.7eV) in MoO_x and higher band gap (about 3.2 eV) increases the fraction of light reaching the CSC device. The larger work function also causes an inversion in the c-Si thereby facilitating the transfer of holes from c-Si to the front end electrode. The CSC solar cell incorporating MoO_x as a hole transport layer has obtained an experimental efficiency of 22.5%. The rear side p-doped a-Si:H is also being substituted by TiO_x which introduces higher conductivity for electrons and lower conductivity for holes in CSC configuration. The highest efficiency reported for TiO_x based CSC devices is 21.6%. The monolithic tandem configuration requires optical coupling and minimized electrical losses which is obtained by adding a tunnel layer in between the top and bottom solar cells.
In this work, the performance parameters of tunnel junction (TJ) formed by TMO layers are investigated on the top of a carrier selective contact (CSC) based silicon solar cell in Sentaurus. We have employed a tunnel junction by adding TiO_x on the top of a hole transport layer, MoO_x from the silicon bottom sub-cell. The band alignment between TiO_x and MoO_x would allow transport of charge carriers by tunneling thus substituting the conventional tunnel layers. The simulations give a profound picture of the transport mechanism occurring in the device. The variations in electron affinity values and defect density of tunneling layers shows their effect on the hole collection ability of MoO_x.

Superacid-Based Passivation of Silicon—New Insights into Bulk and Surface Recombination and a Route to Stability John D. Murphy[1], Sophie L. Pain[1], Marc Walker[1], Pietro Altermatt[2] and Nicholas E. Grant[1]; [1]University of Warwick, United Kingdom; [2]Trina Solar Limited, China

High quality stable surface passivation is an essential requirement for high efficiency silicon solar cells, and there are many ways of achieving this (*e.g.* Al_2O_3, SiN_x, their stacks and more recently TOPCON). Good surface passivation is also required for the accurate diagnosis of defect-related degradation phenomena in cells and wafers, although the stability requirement is less critical in this context. Established passivation strategies for solar cells and test structures often complicate material and degradation studies, as they can modify the bulk properties of the sample under investigation. This is because they include elevated temperature (>300 °C) steps during which recombination-active defects can form, be annihilated or even be gettered. Changes in the hydrogenation state of the material also need to be considered.

Over the past five years, we have developed a range of temporary surface passivation schemes for measuring very long carrier lifetimes in silicon. Thin films are formed on wafer surfaces by treatment with bis(trifluoromethanesulfonyl)-based solutions, including superacidic and non-acidic chemicals, at room temperature. The films provide excellent surface passivation (surface recombination velocity < 1 cm/s), without modifying the bulk lifetime under investigation. Effective lifetimes in excess of 75 ms have been measured, and bulk lifetimes exceeding the currently accepted Auger limit have been extracted in some cases. As part of the talk's introduction, the latest developments in our passivation methods will be presented, building on studies we have published previously [1-4].

The main part of the talk will include new insights gained from using these temporary passivation schemes on the latest silicon materials and photovoltaic cells. One key feature of the superacid-derived approach is that it can be applied after samples have been stripped of dielectric passivation, diffusions or even metallisation. We can therefore use it to measure the true impact of a process on the material's lifetime without the modification that occurs in other passivation processes. New results to be presented will show how the activation annealing widely used for Al_2O_3 surface passivation can modify bulk lifetime, as well as chemical and field effect passivation. Our data show that the optimal activation temperature of around 460 °C occurs because recombination centres form in the bulk at higher processing temperatures. Our approach is also valuable in the study of light and elevated temperature induced degradation (LeTID), and data for some of the latest commercial Ga doped passivated emitter and rear cell (PERC) devices will be presented.

The final part of the talk will focus on the stability of superacid-derived passivation. Our standard approach is stable on the timescale of hours, which is sufficient for diagnostics but not for devices. Our standard approach involves an HF treatment to remove any native oxide layer on the sample surface, as native oxides provide very little surface passivation. Importantly, we have found that treating a thin (<1 nm) native oxide layer on the sample's surface with a superacid-based solution at room temperature can however give rise to good levels of surface passivation (surface recombination velocity < 20 cm/s), which can last for several months. Using X-ray photoelectron spectroscopy (XPS) we show that fragments of the superacid molecule (particularly fluorine) become incorporated into the treated native oxide layer. Room temperature chemically enhanced thin oxides could therefore be a promising concept for silicon-based solar cell devices.

Graphene Oxide Films As Passivation Material For Silicon Solar Cells Michelle Vaqueiro-Conteras; University of New South Wales, Australia

Reduction of the surface and interface recombination losses on crystalline silicon (c-Si) solar cells is at present a crucial need for the fabrication of high efficiency devices. At an industrial level, these losses account for at least 0.5%abs efficiency decrease on passivated emitter and rear cells (PERC). In recent years many efforts have been made to reduce these recombination currents for which the concept of a passivated contact cell has aroused and gained a lot of attention. This more advanced concept of a cell, which is often referred to as carrier-selective contact cell, is meant to supply a carrier collection channel that will be able to reduce metal-semiconductor interface recombination while allowing free flow of selected charge carriers. Several approaches for the formation of selective contacts in silicon solar cells have been proposed. Amongst them there is: 1) the application of heavily doped regions under the contacts which reduce minority carrier conductivity as the result of a chemical potential introduction and low minority carrier mobility, 2) reduction of the minority carrier concentration at the surface by the application of external potential sources from materials with large fixed charges (Qf) or a low (/high) work-functions, or 3) the formation of a heterojunction with a wide-bandgap material with the desired conductivity type (*n* or *p*). At present, the highest achieved power conversion efficiencies (PCE) on silicon devices have been achieved by the application of amorphous silicon (a-Si) passivated contact and heterojunction technology. This technology benefits from carrier selectivity provided by the combined cases 2 and 3 given by the a-Si properties, and has led to the remarkable PCE = 26.3%, with the potential to reach >27% efficiencies.
A graphite oxide monolayer, also known as graphene oxide (GO), is a carbon-based material
whose properties have been investigated since its discovery and first-time fabrication over a
hundred years ago. This material exhibits some remarkable properties such as high transmittance and fixed surface negative charge which makes it very appealing for optoelectronic applications. Further to this, graphene oxide optical absorption can be tuned by the degree of oxidation of the material. Thorough studies of this process have been shown experimentally, resulting in optical bandgap tuneability from 1.15 eV and up to 3.06 eV. Similar to the a-Si case, these two properties of graphene oxide are likely to provide the carrier selectivity required for a high-quality passivating contact on PV devices, with the advantage of very low temperature and low-cost fabrication.
It has already been shown that graphene oxide films on silicon can act as passivation layers achieving surface recombination velocities as low as 17.4 cm/s. In this work, we study the application of multilayered graphene oxide films as passivating contacts on passivated emitter and rear locally diffused cells (PERL). It is found that graphene oxide interlayers aid carrier collection and reduce rear recombination leading to an increase of open-circuit voltages in the excess of 5mV and short-circuit currents greater than 3.5mA. A discussion of the cell performance and recombination parameters will be discussed during the presentation.

7:30 PM EN04.07.03
Method for Extraction of Spatial External Luminescence Efficiency in Solar Cells Using Photoluminescence Measurements and Optical Modeling Tamir Yeshurun, Mor Fiegenbaum-Raz and Gideon Segev; Tel Aviv University, Israel

Continuous effort is being put towards device optimization for high efficiency solar energy conversion systems. As these devices are greatly affected by the various loss mechanisms and charge transport properties of the structures and materials, in-depth mapping of loss and charge transport mechanisms can be

key for rapid device optimization.
By combining wavelength dependent photoluminescence quantum yield (PLQY) measurements with optical modeling, we extract the depth dependent spatial external luminescence efficiency (SELE), which is defined as the probability of an electron-hole pair that is photo-generated at a certain depth to contribute to photoluminescence from the device. Since the external luminescence efficiency is related to the obtainable photovoltage from the device, extraction of the SELE profile could be used to map the contribution of different regions in the device to the photovoltage. In this contribution, we will discuss the SELE extraction method and analyze the SELE profiles of Silicon and GaAs wafers, serving as model systems.
In addition, the use of finite elements simulations of the measured structures while accounting for charge transport and photon recycling effects, allows computing of the SELE profile and attributing features in the profile to important physical quantities such as the surface recombination velocity, internal luminescence yield and the optical coupling between the device and its ambient. Analysis of SELE profiles for advanced solar cells could assist in mapping loss mechanisms and further promote high efficiency solar energy conversion devices optimization.

7:45 PM EN04.07.04
Study of Terbium-Doped AlNxOy: H / c-Si (p) Interfaces by Transient Surface Photovoltage Spectroscopy Jorge A. Dulanto Carbajal[1], Miguel Á. Sevillano-Bendezú[1], Rolf Grieseler[1,2], Jorge A. Guerra[1], Steffen Fengler[3], Jan A. Töfflinger[1] and Thomas Dittrich[4]; [1]Pontificia Universidad Catolica del Peru, Peru; [2]Technische Universität Ilmenau, Germany; [3]Helmholtz-Zentrum HEREON GmbH, Germany; [4]Helmholtz-Zentrum Berlin für Materialien und Energie GmbH, Germany

Aluminum nitride (AlN) is a versatile material for chemical and field-effect passivation of silicon since fixed charges can be positive or negative, enabling to passivate n-type and p-type c-Si [1]. In this study, hydrogenated AlN layers (AlN:H) were deposited onto p-type c-Si by sputtering at hydrogen fluxes of 1 sccm, 3 sccm and 5 sccm and negative charges were activated on AlN through rapid thermal annealing (RTA) at 850ºC. AlN also can work as a converter layer as it is suitable as a host for rare earth ions such as Terbium Ions for spectral downshift in solar cells [2].
Transient surface photovoltage (SPV) spectroscopy allows to investigate transport, generation and recombination processes as well as their relaxation times. In addition, due to its non-contact characteristic of transient SPV spectroscopy, it is possible to perform measurements where other techniques are not capable.
SPV signals associated with the transfer of electrons and holes at the AlNxOy: H / c-Si (p) interfaces were separated from those related to reducing the surface band bending. The distribution of negative fixed charges was high so that an accumulation regime near the silicon surface was established. At high hydrogen flux, the band bending was low due to an increase in the interface defects that compensate for the negative fixed charge. Complementary measurements with modulated SPV give additional information on defect and tail energies [3].
By measuring SPV spectra at different times, one can obtain information about the charge transfer [4], the tail energies and offset deep defects [3]. Comparing the results obtained from the tail energies and offsets, we found that charge transfer to defects was dominated by a disordered layer at the AlNxOy:H / c-Si interface and by deep defect states for the samples deposited at 1 and 5 sccm of hydrogen flow, respectively.
The three-variable measurements (time, photon energy/wavelength, SPV) allows for a deeper study of dominating charge separation mechanisms.

Understanding Light and Elevated Temperature Induced Degradation in Fielded Arrays Ingrid Repins, Dirk Jordan, Michael Woodhouse, Joseph Karas, Alexandria McPherson and Christopher Deline; National Renewable Energy Laboratory, United States

A levelized cost of electricity (LCOE) of 3¢/w, for U.S. locations with average solar resource, has been identified as a critical threshold for wide-spread adoption of photovoltaics without subsidies. Achieving this cost goal requires improvements in all facets of the technology, from cell efficiency increases, to component cost decreases, to lower soft costs associated with installation, to reduced system performance degradation, and so forth. Maintaining long-term high performance in modules is often an under-recognized opportunity in this cost reduction because it is not fully quantified at the time of manufacture. While certain standardized tests minimize risk of early failure, information on long-term performance for new modules is largely unknown and thus does not appear in datasheets or quotes.

In this work, we explore several aspects of how light and elevated temperature degradation (LeTID) impacts long-term module performance and thus LCOE. First, we document the behavior of two commercial module types fdeployed at NREL starting in 2016 and 2018. ~7 kW of each module type was installed on-site at NREL, and both exhibited degradation hypothesized to be LeTID. In cooperation with the international testing and standards community, an accelerated test for LeTID was developed. This accelerated test was performed on unfielded spare modules from the degrading NREL arrays, and the presence of LeTID was confirmed. An approach for predicting long-term performance loss due to LeTID, utilizing the accelerated test results and observed defect behavior, is presented. The predictions from this approach are compared with yearly flash test data on fielded modules from the two degrading 7 kW arrays at NREL and other published results. Cost models based on the predictions indicate that LeTID has a significant and climate-dependent impact on LCOE. Areas where predictions could benefit from a deeper understanding of LeTID are identified.

Although there are significant uncertainties in the predictions, the general process demonstrated in this work is the same as that needed to develop reliability predictions more widely. The process starts with observation of degradation in the field or in accelerated tests. Next a physical model – a mathematical relationship between the stresses and the degradation - is hypothesized, and accelerated tests to probe the kinetics are performed. Long-term predictions are compared with fielded behavior and extended experiments with modest acceleration. As more information about the physical mechanism and how to measure it become available, the model may be refined. This iterative approach can supply some information for stakeholders to estimate costs associated with new products, while successively decreasing uncertainty of predictions and addressing apparent disagreement between data sets.

Research Challenges in Silicon Photovoltaics Susan Huang; U.S. Department of Energy Solar Energy Technologies Office, United States

The Department of Energy's Solar Energy Technologies Office (SETO) supports applied research related to photovoltaics, concentrating solar power, and systems integration with the goal of making solar energy more affordable and facilitating solar energy deployment. Over the past decade, commercial silicon cell developments have targeted efficiency losses under standard test conditions due to surface and bulk defects. The silicon photovoltaic cell industry continues to move towards new architectures to reduce losses from defects and increase efficiency. In the future, addressing performance challenges at the module-level, controlling field performance through better understanding of degradation pathways, such as potential and carrier induced degradation, and improving sustainability will become increasingly important. This talk will highlight the research funded by the SETO in silicon-based photovoltaics, how research areas have evolved as industrial capabilities and technologies change, and a few of the materials-level research problems in silicon photovoltaics that will promote future solar deployment.

11:30 AM *EN04.09.03
Photovoltatronics—Intelligent PV-Based Devices for Energy and Information Applications Patrizio Manganiello, Hesan Ziar, Miro Zeman and Olindo Isabella; Delft University of Technology, Netherlands

Two of the major trends in nowadays energy sector are electrification and digitalization. Large-scale introduction of variable renewable energy sources, energy storage and power-electronics components, all based on direct current (DC), is fundamentally changing the electrical energy system of today, based on alternating current (AC). This trend leads to a complex hybrid AC/DC power system with the extensive deployment of information and communication technologies (ICT) to keep the system stable and reliable. Furthermore, the expanding urban areas are increasingly so energy intensive that the demand for local and optimal generation of clean electricity is growing as well. In this scenario, photovoltaics (PV) technology will play an essential role. However, to take full advantage of PV in the urban environment, PV technology must become intelligent and PV devices must become multi-functional.

Recently, we identified, described, and labelled a new research field that deals with intelligent PV and its application in components with multiple functionalities. We denoted this field **photovoltatronics** [1]. Photovoltatronics aims at facilitating the large-scale implementation of photovoltaic technology in urban areas by combining it with electronic and photonic devices as well as digital technologies. As a result, photovoltatronics will deliver intelligent devices that we refer to as multi-functional *PV-based intelligent energy agents* (PV-IEA), by bringing together disciplines of energy and informatics. Since photons and electrons are carriers of both energy and information, photovoltatronics is the field that designs and delivers autonomous devices for electricity generation and information communication. It introduces a pathway from harvesting energy of photons (hν) to creating bits of information (01) through the energy of photo-generated electrons (eV). Photovoltatronics will deliver solutions for electricity generation and information communication in applications such as building environment, e-mobility, sensing, and domotics. This aim is realized by combining different research areas. Five major research areas that lay the foundations for the photovoltatronics research field are: (1) modelling and multi-layer mapping for maximizing energy harvesting from ambient energy sources at a particular location; (2) design of PV-IEAs for delivering optimum electrical energy including reconfigurable electrical topologies of PV generators, (passive) cooling elements, electronics, sensor systems, and control; (3) security and flexibility of electrical energy supply by integrated storage (4) wireless transmission of electricity through a novel design of PV module electrode, and (5) light-based communication (e.g. LiFi) by integrating and controlling embedded light-generating elements such as light-emitting diodes (LEDs) and by leveraging the inherent ability of PV devices to work as receiver in light-based communication systems while still being able to generate energy from the received natural or artificial light.

Soon, these devices can become building blocks for energy and information flows in cities, as every surface in urban areas can play an important role in providing useful energy from solar radiation to urban dwellers. Multi-functional PV-IEAs will thus represent the backbone of the combined energy/information system of the future.

We review photovoltatronics research areas and introduce new directions for each area. In this process, we show that ~10 keV energy is at least needed for transceiving one bit of information in the energy-information chain of the photovoltatronics, while the ultimate efficiency of the chain can reach up to 33.4%. We show that the number of publications related to photovoltatronics is exponentially increasing and the publication rate of combined research areas has been doubled in the present decade and reached 3.4% as a clear sign of its emergence.

Late News: In-Space Research and Manufacturing of Semiconductor Materials Divya Panchanathan; Axiom Space, United States

Over the past several decades, the semiconductor materials landscape has expanded from silicon-group elements to binary compounds, ternary alloys, perovskites, and 2D materials. However, each one of these materials has been created under the constraints of Earth's gravitational field. What if this force could be negated? Microgravity offers a unique environment to achieve materials innovation in ways that cannot be accomplished on Earth. Changes in fluid behavior such as the lack of buoyancy-driven convection and sedimentation in microgravity lead to beneficial characteristics in materials like semiconductor crystals, 2D materials, and photonic materials. Some demonstrated benefits of the microgravity environment include the ability to isolate and study non-gravitational phenomena, preparing defect-free crystals, diffusion dominated processing, and containerless processing of materials.

While early focus of experiments in space was on fundamental research to enable and improve space exploration, the advent of the new space age has made it possible to bring the benefits of space closer to home. The emergence of commercial space stations like Axiom Station opens new opportunities for academic and industry researchers to perform focused applied research that leads to manufacturing of advanced materials in space for electronics and energy applications. This talk will highlight: (1) the fundamental ways in which microgravity affects materials processes; (2) the use of microgravity environment an innovation platform; and (3) potential future in-space manufacturing applications.

Improving the Rear Side of High Efficiency Rear Junction Silicon Heterojunction Solar Cells Andres Lambertz, Weiyuan Duan, Karsten Bittkau, Depeng Qiu and Kaining Ding; Forschungszentrum Juelich GmbH, Germany

The main objective of crystalline silicon photovoltaic (PV) technology development is to increase the power conversion efficiency and further reduce the production costs, aiming to reduce the levelized cost of electricity (LCOE). As one of the technologies with passivating contacts, silicon heterojunction (SHJ) solar cell technology is considered to expand its share in the PV industry in the coming years due to the high-power conversion efficiency, lean fabrication process and low temperature coefficient.
In this work, we show how to improve the rear side of silicon heterojunction (SHJ) solar cells. The improved rear side increases the cell certified efficiency of 23.55% to 24.51% on a full-size n-type wafer (total area, 244.53 cm^2). The route towards the higher efficiency SHJ solar cell is proposed through a combination of experimental work accompanied by device simulation. In this study the gain in in efficiency was achieved primarily by (i) adjusting the properties of the hydrogenated intrinsic amorphous silicon (a-Si:H) i-layer on the rear side of the solar cell and (ii) improving the optical properties of the back reflector of the solar cell.
All SHJ solar cells were fabricated using M2-size n-type Czochralski (CZ) crystalline silicon as-cut wafers from LONGi company textured in alkaline solution and cleaned via an ozone cleaning process. The plasma enhanced chemical vapor deposition (PECVD) process was performed in an AK 1000 system from Meyer Burger for intrinsic and doped a-Si:H layers. Afterwards, indium tin oxide (ITO) layers were sputtered from an 3% Sn-doped In_2O_3 target. Silver grids with a busbar-less design were screen printed and subsequently cured at 170 $^{\circ}C$ for 40 min. The MgF_2 and Ag layers were evaporated. For material characterization we used an ellipsometer (J. A. Woollam M-2000) and the structural characterization was performed by Fourier Transform Infrared Spectroscopy (FTIR) in a Nicolet 5700 system. To evaluate the solar cells performance, current-voltage characteristics, the external quantum efficiency, and reflectance were measured by the integrated solar cell characterization system called LOANA from pv-tools with a Wavelabs Sinus 220 light source.
The properties of the a-Si:H i-layers play multiple roles in SHJ solar cells not only as a surface passivation layer but also as a carrier transport to the electrode. To improve both, intrinsic a-Si:H bi-layers with a porous first layer (i_1) and a dense second layer (i_2) are a viable route. The silane (SiH_4)/hydrogen (H_2) flow ratio and thickness of the second intrinsic a-Si:H (i_2), were specially optimized here to reduce the vertical charge carrier transport loss but still achieving an excellent passivation quality. By using a denser and thinner second part of the intrinsic a-Si:H layer, a reduced vertical rear resistance loss was achieved. This favored vertical carrier transport and led to a higher *FF*.
To improve the optical properties of the back reflector we reduced the plasmonic absorption at the back reflector by inserting a low-refractive-index magnesium fluoride (MgF_2) before the Ag layer resulting in an increased short circuit current density (J_{sc}). In total, together with MgF_2 double antireflection coating and other small optimizations during cell fabrication process, ~1% absolute efficiency enhancement is finally obtained. Finally, we were able to improve the efficiency from certified 23.55% mainly due to an improvement in *FF* and J_{sc} improvement to 24.51%, with an J_{sc} of 39.52 mA/cm^2, an open circuit voltage (V_{oc}) of 741.8 mV and a *FF* of 83.61%.

1:30 PM *EN04.10.02
Selectivity and Extraction Efficiency of Solar Cell Contacts—Comparing Different Definitions and Their Experimental Quantification Michael Rienäcker[1], V. Titova[1,2], J. Schmidt[1,3], R. Peibst[1,3] and R. Brendel[1,3]; [1]Institute for Solar Energy Research in Hamelin (ISFH), Germany; [2]Hamburg University of Applied Sciences, Germany; [3]Leibniz Universität Hannover, Germany

Although carrier-selective contacts are crucial for the operation of any photovoltaic energy converter, it was only the increasing interest in non-traditional contact schemes in c-Si PV that has sparked a debate of how a metric for the ability of a contact to extract desired charge carriers versus blocking undesired ones should be defined and measured.
In the last years, several authors defined metrics for the quantification of the selectivity of contacts to solar cells. They can be classified in two categories: the first one compares the internal versus external voltage of the solar cell at open-circuit operation and the second one compares the transport coefficients for electron and hole transport through the contact. The different approaches are not identical in terms of defining the spatial boundaries of the selective contact and the processes involved in the charge carrier extraction at the contact. In the following, we present the carrier-selective contact from a thermodynamic and kinetic point of view, and compare different figures of merit for carrier-selective contacts. We present experimental investigations to access the different figures of merit by means of a three-terminal photovoltaic device.
First, we briefly summarize the thermodynamic interpretation of a solar cell in terms of a two-step conversion process with two respective conversion efficiencies: After converting sun's heat radiation into an excited electron-hole gas in the absorber, the contacts convert the chemical energy of the electron-hole gas into electrical energy. The (carrier) extraction efficiency corresponds to the efficiency of the latter and measures the contact's ability to extract charge carriers selectively. For the kinetic considerations, we discuss the spatial boundaries of the absorber, the carrier-selective membranes and the electrodes of a photovoltaic energy converter and pay special attention to the charge carrier processes occurring in the selective membrane and the electrode. We review the existing definitions of the contact selectivity metric and its measurement from the literature.
In order to examine the selectivity and the extraction efficiency, we use a three-terminal photovoltaic device with almost perfectly electron-selective and hole-selective reference contacts and a TiO_x-based electron-selective contact as model system. The perfectly selective reference contacts allow to measure the electron and hole current densities at the TiO_x-based contact separately. Therefore, it enables us to study the two different categories of selectivity metrics in the literature on a single test device by using two different methods.
For the first method – the three-terminal Suns-V_{OC} method – our device operates without an external current flow and provides access to the internal and external open-circuit voltage of the device as often used by several author in c-Si, organic and perovskite PV. From a TiO_x-based-contact-limited test device, we determine the extraction efficiency and selectivity coefficient of the TiO_x-based contact as function of the illumination intensity.
For the second method, we use the transport coefficients of electron and hole transport through the TiO_x-based contact to quantify the selectivity coefficient. For this purpose, we estimate the transport coefficient for holes – the recombination pre-factor $J_{0,C}$ – from J_{SC}-V_{OC} characteristic between the electron-selective TiO_x-based contact and the perfectly hole-selective reference contacts. From dark *J-V* characteristic between the electron-selective TiO_x-based contact and the perfectly electron-selective reference contact of the three-terminal device, we determine the transport coefficient for electrons in the TiO_x-based contact – the contact resistivity. Finally, we compare the results of both methods.

The Critical Role of TCO Deposition on Solar Cell Performance Monica Morales-Masis; University of Twente, Netherlands

Transparent Conducting Oxides (TCOs) are widely accepted transparent electrodes in a variety of solar cells employing passivating and selective contacts, such as silicon heterojunction (SHJ) solar cells and thin film technologies such as CIGS and perovskite solar cells[1]. Among all possible ways to deposit TCOs, sputter deposition is the most employed technology, both in academia and industry. However, the high kinetic energies of the arriving species during sputtering may damage sensitive functional layers beneath, affecting interface formation, passivation and ultimately device performance. This has motivated the search for alternative sputter system designs or deposition techniques, allowing low damage growth of TCOs on the sensitive layers. Here we explore pulsed laser deposition (PLD) as an alternative low-damage physical vapor deposition technique. PLD is operated at high deposition pressures, promoting thermalization of particles, and therefore reducing the kinetic energy of ablated species. Broadband transparent and high mobility TCOs were developed using wafer-scale (4-inch) PLD with deposition rates on par with lab-scale RF sputtering[2]. To investigate the effects of the deposition pressure,

we developed ITO with identical sheet resistance (50 Ohm/sq) at deposition pressures three orders of magnitude apart, and applied them as a front TCO in SHJ cells and as rear-contact in semitransparent perovskite cells. The role of the deposition pressure on TCO properties, absorber carrier lifetime and its link to SHJ and perovskite solar cell parameters such as series resistance and fill factor (FF) will be discussed. Strategies to mitigate damage, for each type of cell will be furthermore discussed.

The Application of Ultra-Thin MoO_x in Silicon Heterojunction Solar Cells Liqi Cao, Yifeng Zhao, Can Han, Guangtao Yang, Miro Zeman, Luana Mazzarella and Olindo Isabella; Delft University of Technology, Netherlands

Since the first inception of silicon heterojunction (SHJ) solar cells, prominent developments have been realized in both front/back-contacted (FBC) [1] and interdigitated back-contacted (IBC) [2] (world record efficiency of 26.7%) architectures. However, the conventional silicon-based doped layers, which work as carrier-selective transport layers, are not optimally transparent especially when used as window layers.

To circumvent this fundamental limitation, several transition metal oxide (TMO) layers have been investigated because of their good transparency in the wavelength range of interest and appealing electronic properties to efficiently extract charge carriers from the device [3]. MoO_x as the most promising for hole-selective transport layer (HTL) has been applied in SHJ solar cells to replace the conventional doped layer in SHJ FBC devices. Normally, the thickness of HTL is between 6 and10 nm, while a power conversion efficiency (PCE) of 23.5% SHJ solar cell with 4-nm thick MoO_x was recently demonstrated by J. Dreon *et al*. [4]. The thinner the layer is, the less the optical loss is. However, still 0.5 mA/cm^2 was found to be lost in MoO_x [5]. According to the work by L. Mazzarella et al. [6], who applied a plasma treatment (PT) on the interface of i-a-Si:H and MoO_x to improve the electric performance, thinner MoO_x layer could be possible for application in solar cells. This is the focus of our contribution.

We used 4-in wide double-side textured n-type FZ wafers as substrate. A layer of i-a-Si:H was deposited on both sides and n-a-Si:H film was deposited on the rear side by plasma-enhanced chemical vapor deposition (PECVD). A PT was applied on the front surface before the deposition of MoO_x. A thickness series of MoO_x HTL was thermally evaporated at the pressure of 5×10^{-6} mbar. Tested thickness of MoO_x were 0 nm, 1 nm, 1.7 nm, 2 nm, 2.9 nm, and 4 nm. After that, indium tin oxide (ITO) was sputtered though a mask on the front and rear side with the thickness of 70 nm and 150 nm, respectively, forming five 2×2-cm^2 wide cells per wafer. From the light facing side, the stack of the layer is therefore ITO/MoO_x/i-a-Si:H/n-Si/(i+n)-a-Si:H/ITO. Initially, front grid and rear contact were screen printed with Ag paste followed by curing (30 min at 170 °C) and two standard SHJ solar cells [7] were fabricated as reference. After measuring our devices, we found that screen printing was rather aggressive on MoO_x-based cells with V_{oc} dropping by more than 20 mV with respect to the implied V_{oc} prior metallization. So, to isolate the performance of the thin MoO_x HTL, we used a thin Ag layer as seed for room temperature Cu-plating at the front side (~1.6% metallization fraction) and sputtered a full-cell wide 500-nm thick Ag at the rear side. Overall, thanks to our PT, thinner-than-4nm MoO_x layers in Cu-plated SHJ FBC cells delivered excellent transport (FF > 81%) in combination with good passivation (Voc > 720 mV). So far, the best device was endowed with 2.9-nm thick MoO_x and exhibited η_{active} = 22.92% (V_{oc} = 722 mV, J_{sc_EQE} = 39.04 mA/cm^2, FF = 81.3%). The realization of other thicknesses of MoO_x in SHJ FBC solar cells is ongoing and will be presented at the conference. From preliminary passivation tests up until front/rear sputtered ITO, we expect even higher performance for thickness of MoO_x < 2 nm, which would positively translate into larger cell J_{sc}.

Towards TCO-Less Bifacial Cu-Plated SHJ Solar Cells Can Han, Rudi Santbergen, Yifeng Zhao, Daragh O'Connor, Guangtao Yang, Paul Procel, Miro Zeman, Luana Mazzarella and Olindo Isabella; Delft University of Technology, Netherlands

Silicon heterojunction (SHJ) solar cells have exhibited high efficiencies in both academia and industry [1,2]. Key challenges to be addressed in the upscaling process are the cost of materials and the abundance of the utilized elements. Therefore, consumption of Ag and In, widely used in the electrodes of SHJ devices, must be reduced [3]. Cu has proven to be a good candidate for replacing Ag electrode; however, complexity in the metallization process remains to be tackled [4]. For the widely used electrochemical Cu-plating technique, separate control is generally needed for processing both sides of the wafer, which means that one side of the wafer is protected when plating the other side [5]. This step further increases the cell production costs. On the other hand, to reduce the In consumption, basic strategies include: (i) use of In-free TCOs, such as AZO; (ii) reduction of the TCO thickness (*TCO-less* option); (iii) development of TCO-free SHJ devices. For (i), challenges may lie in low carrier mobility, interface/material stability issues [6]; For (iii), proof-of-concept TCO-free SHJ cells have been demonstrated recently [7], but efforts have been partially frustrated from the passivation deterioration, and contact problems [8]. Also, it is still an open question whether TCO-free design could give optimal device performance. Moreover, a TCO layer is practically needed to act as a Cu diffusion barrier layer in Cu-plating processes. To circumvent these limitations, we focus on the *TCO-less* solution in combination with Cu-plating metallization approach.

We developed TCOs with different opto-electrical properties, which are tin-, fluorine-, and tungsten-doped indium oxides, namely, ITO, IFO, and IWO [9][10]. By utilizing a double layer anti-reflection coating formed by TCO/SiO_x layer stacks on both sides of our SHJ device structure, we performed optical simulations with varied front and back TCO/SiO_x thicknesses. Results show that bifacial solar cell architecture provides the most effective way to reduce the TCO use, and the optimal optical response appears at the point where a thin TCO layer is applied, due to a low free carrier absorption and a favorable refractive index enabling light in-coupling. Thus, we applied 25 nm-thick of different TCOs on both sides of the cell precursors fabricated using plasma-enhanced chemical vapor deposition technique. Finally, we developed single step Cu-plating process on lithography patterned openings, which could well control the metal finger growth on both sides of the wafer and largely simplify the simultaneous metallization on both sides. Champions bifacial cell was observed in the devices with IWO use on front and ITO use on the rear side of the device. After applying an additional 110 nm-thick SiO_x layers on both sides of the complete cell, the device parameters were measured to be: V_{OC} = 721 mV, J_{SC} = 39.20 mA/cm^2, *FF* = 79.57%, η = 22.50% (*n* side illumination); V_{OC} = 717 mV, J_{SC} = 38.72 mA/cm^2, *FF* = 79.91%, η = 22.19% (*p* side illumination). The bifaciality factor is 0.99. Compared to the standard

TCO utilization of 75 nm and 150 nm on front and rear side of the monofacial SHJ device, respectively, we achieved comparable cell performance with a 78% reduction in TCO use. TCO thickness-dependent contact properties for both *n*-contact and *p*-contact are still under investigation.

3:00 PM EN04.10.06
Late News: Impact of Process Steps on the Performance of Heterostructure Solar Cells Sergey M. Karabanov and Mikhail Reginecich; Ryazan State Radio Engineering University, Russian Federation

The high open circuit voltage (up to 750 mV) of heterojunction solar cellsis provided by the excellent ability of a layer of hydrogenated amorphous silicon to passivate the surface of the silicon wafer. A number of methods for the deposition of a-Si:H layers are well known. To obtain solar cells with high parameters, it is necessary not only to get good passivation of the crystalline silicon surface, but also to create conditions for efficient charge transfer. One of the widely used methods of deposition of a-SiH is the method of PECVD; during the formation of a-Si:H layer, various types of defects arise. Various process steps, including annealing, lead to a decrease in the number of defects.
In this work, we investigated the formation of defects and the properties of the a-Si:H layer after two-stage deposition with intermediate hydrogen plasma treatment, followed by deposition of a transparent conducting oxide, annealing of defects, and the influence of these factors on the characteristics of solar cells.
For the study, we usedn-type monocrystalline silicon wafer with a resistivity of 1-5 Ohm * cm, with a size of 156.75 * 156.75 mm, and 180 microns thick. After the damaged layer removal, texturing and appropriate cleaning a-Si:H layers were applied to the surface of silicon wafer with the goal to obtain a p-i-i-n structure on one side and n-i-i- n^+ on the other side. An ITO layer about 75 nm thick was deposited by magnetron sputtering of an In-Sn target in an argon-oxygen atmosphere. Metallization was formed as a final step and the parameters of solar cells were measured.
As a result of the studies carried out, it was found that the use of an intermediate hydrogen plasma treatment of the first layer of amorphous silicon leads to the passivation of defects with hydrogen; an increase in the number of silicon-hydrogen bonds and, as a consequence, an increase in the microstructure factor R from 0.4 to 0.55.This additional step in the PECVD process results in an increase in the lifetime of minority charge carriers from 2 to 5 milliseconds and an increase in the efficiency of the solar cell.

Gettering and Hydrogenation of Defects and Impurities in High Efficiency Silicon Solar Cells Daniel Macdonald, AnYao Liu, Hang Cheong Sio, Sieu Pheng Phang, Rabin Basnet and Chang Sun; Australian National University, Australia

Impurities and defects continue to play an important role in limiting the efficiency of both laboratory and industrial silicon solar cells. In this work, we review recent progress in reducing the impact of some of the most important of these limiting defects through impurity gettering and hydrogenation steps, which occur coincidentally during device fabrication. Since the dominant defects in a material depend very strongly on the crystal growth conditions, we categorise them by the three common silicon crystal growth techniques – Czochralski-grown mono-crystalline silicon, Cast-grown silicon (including both multicrystalline and cast-mono silicon), and Float-Zone silicon.

Czochralski-grown monocrystalline silicon (Cz-Si)
The primary defects in Cz-si, whether p- or n-type, are oxygen-related. In boron-doped p-type silicon, the very well-known Light-Induced Degradation (LID) caused by boron-oxygen defects dominates. Although in principle it is not affected by gettering, hydrogen is widely thought to play a key role in the permanent regeneration of this defect, which is a crucial step in stabilising the high efficiency p-type PERC cells that now dominate the PV industry.
In n-type Cz-Si, which is the preferred substrate for IBC, SHJ and poly-silicon passivating contact solar cells, an important class of defects that sometimes occur during high-temperature processing are the oxygen-related ring defects. These consist of oxygen precipitates, and sometimes their associated dislocations and decorating metallic impurities. Under certain conditions, they can be partially mitigated by impurity gettering and hydrogenation steps. These ring defects can also occur in p-type Cz-Si wafers.
Industrial Cz-Si wafers often also contain traces of dissolved metals such as Fe, which can significantly affect the carrier lifetime, if not removed during processing by gettering. Such gettering can be achieved by phosphorus or boron diffusion, aluminium alloying, doped-poly-silicon layers, and even deposited dielectric films such as silicon nitride and aluminium oxide.

Cast-grown silicon (HP mc-Si and cast-mono Si)
Cast high-performance multicrystalline silicon (HP mc-Si), by design, contains many grain boundaries. Fortunately the recombination activity of these grain boundaries can be significantly reduced after hydrogenation, such as via fired silicon nitride films during cell metallisation. Cast-monocrystalline silicon (cast-mono Si), on the other hand, tends to be dominated by dislocation clusters. These are much more difficult to negate through hydrogenation, which reduces the achievable efficiency and yield for devices made on such wafers. Both HP mc-Si and cast-mono wafers also contain significant quantities of metallic impurities, some of which are precipitated at structural defects, whilst others remain dissolved. Under the right conditions, they can be gettered to a significant extent during phosphorus or boron diffusions, or by deposited films. This provides a convenient method to identify the metallic species present in these materials.

Float-Zone silicon (FZ-Si)

Although not used in industrial solar cells, Float-Zone silicon (FZ-Si) is often used in research laboratories, partly due to its immunity to oxygen-related LID and ring defects, and very low metallic impurity concentrations. However, due to the addition of nitrogen during crystal growth to control dislocations, they are subject to the formation of nitrogen-vacancy complexes. Once formed, these defects are highly recombination active. However they can be partly mitigated by hydrogenation.

Finally, although hydrogen is helpful in passivating some defects in silicon, it can also cause recombination-active defects when present in excess, such as the widely-researched Light and elevated-Temperature Induced Degradation (LeTID). Since these defects are caused by firing hydrogen-containing dielectric films, they can be found in all three types silicon wafer described above, whether n- or p-type.

4:30 PM *EN04.11.02
Light Induced Degradation in Silicon—A Comparison of Defects Detected in Boron-Doped Material and in Si with Other Group III Dopants Matthew P. Halsall[1], Joyce A. De Guzman[1], Vladimir Markevich[1], Ian Hawkins[1], Jose Couthino[2], Jeff Binns[3], Nikolay V. Abrosimov[4], Iain F. Crowe[1] and Anthony Peaker[1]; [1]The University of Manchester, United Kingdom; [2]University of Alveiro, Portugal; [3]GCL Solar Materials, United States; [4]Leibniz Institute for Crystal Growth, Germany

It has been known for decades that solar cells fabricated from Czochralski-grown silicon (Cz-Si) using Boron as p-dopant display a loss of efficiency in their first few hours of operation. In order for the effect to be observed both Oxygen and Boron need to be present, giving the effects its usual name of Boron Oxygen light induced degradation or BOLID. It has been recently argued that a complex consisting of a substitutional boron atom and two oxygen atoms (B_sO_2) is a center with negative-U properties, and it is responsible for minority carrier trapping effects, persistent photoconductivity and light induced degradation of lifetime (and hence BOLID) in these materials. Depending on the position of the Fermi level, the B_sO_2 defect is either a deep donor or it can be in a few configurations with a shallow acceptor level. The E(-/+) occupancy level of the defect has been found to be at E_v + 0.32 eV using deep level transient spectroscopy (DLTS). Transitions between the different states associated with hole/electron emission or capture by the defect have been monitored with the use of junction capacitance techniques. The presenter will review the evidence that this defect is responsible for this energy loss process in commercial cells from a combination of technqiues, DLTS and optical spectroscopy.
The ability to detect the defect electrically gives scientists a vital tool to detect the presence of this defect, for Boron and, potentially, other alternative p-type dopants. The presenter will review recent work at Manchester on alternative dopants. We have detected a hole emission signal similar to that due to the B_sO_2 defect in Schottky diodes on p-type Si crystals doped with either Al, Ga, or In impurities. It appears that nearly identical hole emission signals with their maxima at about 391-392 K occur in all the DLTS spectra. The hole emission rates have been measured in these diodes in the temperature range from 360 K to 420 K with the use of the high-resolution Laplace DLTS technique. Arrhenius plots of the measured hole emission rates in Si samples doped with either B, Al, Ga, or In impurity atoms show that the emission rates and the derived values of activation energy for hole emission are very close for the differently doped samples. Finally we have carried out measurements of temperature dependencies of equilibrium occupancy and hole capture kinetics for the detected traps in samples doped with the different acceptor impurities. It is found from the analysis of the changes in magnitude of the DLTS signals with temperature that in all the samples the equilibrium occupancy function of the traps are characteristic for a defect with negative-U properties. Further, it is revealed that positions of the E(+/-) occupancy level are very close in different samples, E(+/-) » E_v + 0.32 eV. We suggest that the observed negative-U defects in Cz-Si samples doped with different acceptor impurities are associated with the complexes incorporating a substitutional group-III impurity atom and two oxygen atoms (A_sO_2, where A can be B, Al, Ga, or In). According to the model proposed transformations between the deep donor and shallow acceptor configurations of the B_sO_2 center are related to a transformation of the oxygen dimer in the vicinity of a B_s atom from a “square” to a staggered configuration. It appears that the presence of different group-III atoms in the A_sO_2 complex does not result in significant changes of the O_2 transformation processes. However, the (B_sO_2) to $(B_sO_2)^+$ reaction is enhanced compared to that for other Group III atoms probably because of local tensile strain induced in the lattice by a relatively small substitutional boron atom. It is argued that this enhancement is one of possible reasons of much more effective formation of recombination active defects, which are responsible for LID, in p-type material doped with boron compared to that in Si crystals doped with other group-III impurity atoms.

Excess Carrier Concentration in Silicon Device and Wafers: How Material Properties are Expected to Accelerate Light and Elevated Temperature Degradation Alexandria N. McPherson, Joseph Karas, David L. Young and Ingrid Repins; National Renewable Energy Laboratory, United States

Predicting degradation rates under fielded conditions is important for understanding energy yield, project return on investment, and how to assign higher value to products where the degradation has been eradicated. Some processes, such as light and elevated temperature induced degradation (LeTID), and the regeneration portion of boron-oxygen light induced degradation (BO LID), are accelerated by the presence of excess carriers. It is therefore important to understand how excess carrier concentration changes as a function of conditions and materials properties both in operating solar cells, and in wafers, where these processes are often studied. In this investigation, we simulate excess carrier concentration as a function of wafer thickness and minority carrier lifetime in solar cells and wafers using SCAPS and Quokka. The same results are obtained whether one uses simulation software or analytic expressions based on the physics of p-n junctions. For wafers, there is a simple nearly linear relationship between excess carrier concentration, lifetime, and thickness. For solar cells, as lifetime increases or thickness decreases, excess carrier concentration becomes limited by rear surface recombination. Thus, LeTID may appear to progress more quickly in wafers than in cells, and the degradation rate will have a stronger dependence on minority carrier lifetime in wafers than in cells.

Overview and State-of-the-Art of Degradation Phenomena in c-Si Solar Cells Giso Hahn; Univ of Konstanz, Germany

Over the last years, tremendous progress could be observed in improving the efficiency of industrial crystalline Si solar cells. The race towards higher efficiencies brings degradation phenomena occurring under working conditions of the solar cell more and more into the focus as the bulk material quality and surface passivation both play a crucial role for obtaining high efficiencies. In this presentation an overview of the known degradation phenomena on solar cell level will be given. This includes degradation of the bulk quality like the well-known boron-oxygen(BO)-related degradation under injection of charge carriers and the more recently detected LeTID (light and elevated temperature induced degradation) phenomenon as well as degradation of surface passivation quality under injection conditions in conjunction with elevated temperatures.
For BO-related degradation, the presence of H in the Si bulk allows for a regeneration of bulk material quality after degradation, which is stable under further illumination. The LeTID phenomenon seems to be triggered by the presence of H in the Si bulk, too, but here H seems to be the (direct or indirect) cause for degradation. As for BO-related degradation, a regeneration process for LeTID can be observed for longer treatment times, making it harder to cope with in cell processing. For longer treatment times, often changes in the surface passivation quality can be observed as well, at least for some dielectric layer systems. While the detailed microscopic picture of the defect formation is still unclear at least for LeTID and most surface passivation degradation phenomena, H seems to be involved for all of them in a direct or catalytic way.
For BO-related degradation a recently developed generalized model including the interactions of the BO-related defect and H in the c-Si wafer will be

discussed. For LeTID, some key findings and experiments will be presented to highlight the state-of -the-art of understanding. For degradation of surface passivation selected examples will be given and discussed. In the last decades, B-doped c-Si had highest PV market share. Currently a trend towards Ga-doped c-Si wafer material can be observed which eliminated the BO-related degradation. But LeTID seems to be observed in Ga-doped c-Si wafers, too, although with a different kinetics. Some recent findings in this field will be presented and discussed.

Reactive Silver Inks as Front Electrodes for Next-Generation Silicon Solar Cells Michael W. Martinez-Szewczyk[1], April Jeffries[1], Steven DiGregorio[2], Owen Hildreth[2] and Mariana Bertoni[1]; [1]Arizona State University, United States; [2]Colorado School of Mines, United States

Fabrication of low-resistivity, robust front contacts for solar cell electrodes typically requires temperatures exceeding 200 ºC to evaporate high-resistivity organic additives and sinter the suspended silver particles that form screen printing pastes. Novel technologies such as passivating contact, perovskite, and silicon heterojunction solar cells, along with their tandems, stand to benefit greatly from high performance metallization formed at temperatures that are compatible with each solar cell architecture [1,2,3].
Passivating contact technologies like silicon heterojunction (SHJ) cells have shown record power conversion efficiencies of 25.11% on full-size M2 monocrystalline wafers and continue to show promise as the platform for ever higher efficiencies (e.g. tandem) [4,5]. One of the main drivers of the SHJ solar cell's high efficiency is the passivating layers of a-Si that offer extremely low surface recombination velocity, <5 cm/s at room temperature [6]. The efficiencies of these cells are typically limited by their series resistance, which arises from the low conductivity of the low temperature silver paste used for front-grid metallization. While higher processing temperatures would enable lower metallization-related losses it would inevitably degrade the surface passivation quality of the SHJ cells. Therefore, metallization technologies that can offer silver-like resistivity and low contact resistance at temperatures below 150 ºC have the potential to further propel passivating contact technologies.
In this presentation we will present the use of reactive silver ink (RSI) and dispense printing to fabricate solar cell front-grids that result in a low-resistivity, low-temperature metallization. When used to metallize a front-grid, the RSI results in media resistivities of 2.4-6 μΩ-cm and a cell series resistance of 0.76 Ω-cm^2, which is lower than commercially available screen-printed low-temperature silver paste with a media resistivity of 10 μΩ-cm and series resistance of 0.79 Ω-cm^2. This RSI metallization can be deposited at temperatures between 60-115 ºC depending on the ink composition with a much lower silver loading than low temperature screen-printing pastes. These inks composition offer also the added benefit of being more corrosion resistant that the screen-printing paste counterparts. Using RSI allows a 55% decrease in silver consumption with improved cell efficiency when compared to the standard low-temperature silver paste metallized cell. This results in a substantial decrease in the cell metallization cost, which accounts for 30% of cell production costs [7]. Herein we will show the electrical performance of cells and modules prepared with RSI metallization, optical modeling of the dispensed RSI fingers as well as aging results under damp heat conditions.

Towards Industrialization of Perovskite/Silicon Tandem Solar Cells—Advances in Metallization, Large-Area Perovskite Deposition, and Encapsulation Brett A. Kamino[1], Ton Offermans[2], Soo-Jin Moon[1], Arnaud Walter[1], Christophe Allebé[1], Gabriel Christmann[1], Ludovic Lauber[1], Patrick Wyss[1], Adriana Paracchino[1], Bertrand Paviet-Salomon[1], Quentin Jeangros[1], Christophe Ballif[1] and Sylvain Nicolay[1]; [1]CSEM, Switzerland; [2]CSEM Muttenz, Switzerland

While crystalline silicon solar cells (cSi) continue their steady march towards ever higher efficiencies, the practical physical efficiency limit for these devices looms on the horizon. In order to continue to increase module efficiency and lower overall system costs, new technologies which can surpass this limit must be realized. A tandem solar cell approach which pairs cSi with a Perovskite solar cell is the most promising current possibility to achieving this. Such an approach promises the potential of minimal additional production costs over existing cSi with a significantly higher efficiency limit. Indeed, with efficiencies of over 29% having been reported by several laboratories it is clear that this technology has great potential. However, significant work still must be done in order to assess the compatibility of this technology with industrialization and to challenge the assumption that the processing steps will incur a minimal cost increase. One central question in this vein is can we adapt existing industrial solutions for the large-scale production of Silicon/Perovskite tandems? Towards answering this question, three critical areas are examined: 1) Metallization, 2) Large-area perovskite deposition, and 3) Encapsulation.
Screen-printed Ag metallization is a standard process for commercial solar cells. However, the heat sensitive nature of perovskite solar cells makes this step challenging to adapt in tandem solar cells. Specifically, the requirement to have high conductivity and low contact resistance between the Ag fingers and the TCO appears difficult to achieve with most commercial pastes. Using optimized Ag pastes and standard screen-printing processes we demonstrate 4 cm^2 devices with a flat or textured front surface can be produced achieving efficiencies of 27.7% and 26.2%, respectively.
While these results are very promising, they were accomplished using spin coated layers on non-standard PV wafers. Moving towards a normal PV wafer requires a process with a very high throughput, good process control, and ultimately result in good semiconductor properties. However, the design parameters of this process are convoluted with the surface topology of the silicon wafer. As mechanically polished wafers are not realistic for commercial production, the question of surface preparation on commercial wafers becomes very important. To this end, we demonstrate a strategy of using meniscus deposited perovskite layers on top of chemically polished silicon M2 CZ bottom cells to achieve efficiencies over 22% on an area of 100cm^2. Such an approach should be compatible with existing industry standard wet-chemical preparation of silicon wafers. Additionally, meniscus coating of perovskite layers promises extremely high throughput potential using a technique that is already widespread commercially (albeit not in the PV world).
Finally, encapsulation of these devices is a critical step to ensuring good stability and reliability in the field. To enable adoption of this technology into existing production lines, demonstration of glass-glass encapsulation using a membrane laminator appears to be essential. It is demonstrated that by

optimizing the encapsulant materials and lamination process for lower temperature conditions allows for good encapsulation of tandem solar cells. However, a significant performance drop related to degradation of the cell during the process is observed. Through process optimization and optical refinement of the tandem stack we can minimize this performance loss and demonstrate a 4cm^2 device with printed metallization and glass-glass encapsulation with a stabilized efficiency of 24.8% (representing a 0.3% drop in efficiency over the unencapsulated cell).

2:30 PM EQ17.08/EN04.02.04
Detailed-Balance Efficiency Limits of Two-Terminal Perovskite/Silicon Tandem Solar Cells with Planar and Lambertian Spectral Splitters Verena Neder, Stefan Tabernig and Albert Polman; AMOLF, Netherlands

The photovoltaic conversion efficiency of two-terminal (2T) perovskite/Si tandem solar cells is strongly dependent on the degree of current matching that can be achieved between the top and bottom cell. In conventional cell designs, the distribution of light that is absorbed in the top and bottom cells is simply determined by the single or double-pass absorption in the planar sub-cells. For high-bandgap perovskites this will always lead to a current mismatch, as too small an amount of light is absorbed in the top cell. Here we show how a spectrum-splitting metasurface, placed at the perovskite/Si interface can help optimize the absorption distribution between the subcells for certain tandem cell geometries.

As a starting point we use detailed-balance calculations of the tandem cell efficiency for ideal subcells. For a 500 nm thick perovskite top cell the optimum perovskite bandgap is 1.57 eV for single-pass absorption (1.66 eV for double-pass absorption), in order to achieve optimal current matching. We then add a Lambertian-scattering metasurface at the perovskite/Si interface that reflects light in a narrow spectral band above the perovskite bandgap. This shifts the bandgap for which current matching is achieved to 1.70 eV and yields a higher efficiency, as the bandgap is closer to the ideal bandgap for perovskite/Si tandems (1.73 eV).

For wider perovskite bandgaps >1.73 eV, a spectrum splitter shows a major improvement as it strongly enhances the current in the (current-limiting) top-cell. For an idealized geometry we predict an absolute efficiency enhancement of more than 5% absolute for a top cell bandgap of 1.77 eV. Using experimental external quantum efficiency data for perovskite and Si cells this would translate to a practical efficiency gain of 2.7% (absolute) for this perovskite bandgap.

In practice, spectrum splitter metasurfaces may have small parasitic absorption. We include this in our model and find that for a top cell bandgap of 1.70 eV, a Lambertian spectral splitter with 15% parasitic loss and a reflectivity of 0.5 would still yield an efficiency gain of 2% absolute. Hydrogenated amorphous Si scatterers are ideal candidates to achieve this experimentally, as we have experimentally shown in four-terminal perovskite/Si tandem solar cells.

A subtlety in our analysis is the fact that the optimum energy at which the spectral splitter reflects light back into the top cell does not necessarily coincide with the top cell bandgap. This energy depends on which cell is current limiting, and for bandgaps around the ideal bandgap, like 1.70 eV, an onset of 20 meV above the bandgap yields the highest efficiency.

Our calculations show that a planar or Lambertian spectral splitter could be of significant benefit for two-terminal perovskite/Si tandems, especially around and above the ideal perovskite bandgap of 1.73 eV. Furthermore, we find that for non-ideal reflectivities and considering parasitic loss, significant efficiency gains can be achieved in these tandem solar cells.

Low-Temperature Passivated Contacts for Silicon Solar Cells Mathieu Boccard, Luca Antognini, Julie Dréon, Davi Febba, Julien Hurni, Vincent Paratte, Corentin Sthioul, Jonathan Thomet and Deniz Türkay; EPFL - PVlab, Switzerland

We review here the recent trends in silicon heterojunction solar cells using low-temperature passivated contacts. Beyond the archetypal amorphous silicon and indium tin oxide (ITO), several novel materials have recently demonstrated excellent performances when integrated in devices. Nanocrystalline silicon and silicon oxide alloys relax in part the trade-off between optical and electrical performances. Both n- and p-type contacts can be made with such material, with different strategies being necessary to enable excellent performance while maintaining surface passivation. Beyond silicon, several materials are investigated as more transparent alternative, including metal-oxides or nitrides. We will discuss what makes such materials attractive and what is still limiting the performance of devices incorporating them.

8:30 AM *EQ17.12/EN04.08.02
Titanium Oxide Carrier Selective Contacts for High Efficiency Crystalline Silicon Solar Cells Jesús Ibarra, Di Yan and James Bullock; The University of Melbourne, Australia

Titanium oxide (TiO_x, $x\approx2$) has been shown to be an effective passivating contact interlayer in a range of high efficiency crystalline silicon (c-Si) solar cells. It has been incorporated in a broad range of configurations; with and without passivating interlayers (i.e. silicon oxide SiO_x, and amorphous silicon *a*-Si:H); with and without overlaying low work function electrodes (i.e. calcium, lithium fluoride / aluminium stacks LiF/Al); and in partial area and full area contact architectures. Passivating contacts incorporating TiO_x have enabled <10 fA/cm^2 scale recombination currents and <10 mΩcm^2 contact resistivities which are no inhibitor to cell efficiencies above 24%, with efficiencies above 23% already demonstrated in the laboratory. Though most of these high-efficiency structures employ TiO_x at the electron side of the cells, some studies have shown its potential tunability, which has enabled its use in hole contacts on c-Si as well, simply by varying deposition conditions and consequently changing its material properties. This talk explores the tunability of TiO_x thin films and their incorporation into passivated contacts. Interface properties, doping, thermal stability and post-metallisation stability will all be covered. Finally, remaining challenges for the incorporation of TiO_x in industrial c-Si cells will be discussed.

9:00 AM *EQ17.12/EN04.08.03
Atomic Layer Deposition of Passivating, Carrier-Selective Oxides for Silicon Photovoltaics Kristopher O. Davis, Jannatul Ferdous Mousumi, Geoffrey

Gregory, Chien-Hsuan Chen, Parag Banerjee and Titel Jurca; University of Central Florida, United States

Metal oxides offer a diverse range of physical properties and can serve various roles in photovoltaic (PV) cells. The wide band gap of these materials allows them to be used on the front side of devices without adding parasitic optical absorption. There is a long track record of depositing metal oxides with atomic layer deposition (ALD), a manufacturing friendly process that results in highly conformal film growth and excellent film thickness control. This presentation will review how ALD metal oxides can be used as passivating, carrier-selective contacts for crystalline silicon (c-Si) PV cells. This begins with a breakdown of desirable characteristics for passivating contact materials, including transparency, interface defect passivation, carrier-selectivity, and carrier transport, as well as thermal stability and compatibility with high-volume manufacturing processes. Next, the performance of the more common metal oxides are surveyed and their process-structure-property relationships discussed, including how chemical interactions between layers can impact performance for better or worse. Much of this discussion will focus on aluminum oxide as a tunneling passivation layer, molybdenum oxide as a hole-selective material, and titanium oxide as an electron-selective material. Finally, remaining challenges and areas of opportunity for future research are covered.

9:30 AM EQ17.12/EN04.08.04
Polymer-Embedded Silver Microgrids by Particle-Free Reactive Inks for Flexible High-Performance Transparent Conducting Electrodes Ziyu Zhou and Paul W. Leu; University of Pittsburgh, United States

Metal microgrid-based transparent conductors enable the acceleration of wearable electronic applications development by constructing the high transparency, low sheet resistance and mechanically stable metal grid within flexible substrates. In this study, we demonstrate polymer-embedded silver microgrid structures with low porosity using a particle-free silver ink for flexible transparent electrodes. The conductive grids indicate a high transparency of 91.8% and a low sheet resistance of 0.88 Ω/sq, corresponding to a figure of merit value σ_{dc}/σ_{op} of nearly 4500 with gridlines of 10 μm width. The optimized gridline width may be fabricated down to 3.5 μm. Furthermore, the embedded structure of Ag microgrids shows 3 times lower surface roughness compared to particle-based conductive Ag inks and better mechanical as indicated by bending, folding and tape peeling test. The results demonstrate (1) a scalable approach for microgrid manufacturing, (2) microgrids with nearly the best transparent electrode performance properties, and (3) the benefit of reactive silver inks as opposed to particle-based ones. Metal microgrids may address technical and economical limitations with indium tin oxide (ITO) as well as enable the development of a various flexible and wearable optoelectronic applications.

9:45 AM EQ17.12/EN04.08.05
Selective Passivation of TiO_2 Defects via Targeted Dehydration Jessica C. Jones and Alex Martinson; Argonne National Laboratory, United States

Heterostructure interfaces are of critical importance for next generation device architectures. Defects at these interfaces significantly impact the resulting properties and ultimately device performance. Many studies focus on the growth of thin films by Atomic Layer Deposition (ALD) but neglect the unique surface chemistry and atomic structures formed at the resulting interface. This limits the device applications of heterostructures made with these types of thin films due to the limitations in crystallinity and lattice match. In an ALD-based approach we call selective interface reactions (SIRs) we target specific undesirable defect sites on a surface to achieve uniform behavior at interfaces formed on these surfaces. TiO_2 is considered the prototypical oxide surface and has been intensely studied due to its photocatalytic and optoelectronic properties. It is well established that the defects on the TiO_2 surface affect the optical and electronic properties, interfaces, and performance of resulting devices. DFT calculations are used to predict the difference in reactivity of "perfect" TiO_2 and minority atomic configurations such as step edges. We translate these differences in site reactivity to differences in thermal dehydration which is confirmed by STM. SIR is ultimately used to exploit these differences in thermal dehydration to selectively deposit material specifically on defect sites to prevent defect formation.

8:00 AM *EN05.01.01
The Role of Crystallographic Orientation and Heterostructures on Charge Carrier Transport in Halide Perovskite Solar Cells Juan Pablo Correa Baena; Georgia Institute of Technology, United States

Electronic defect passivation has been used as a strategy to achieve high performance perovskite solar cells. This strategy relies on interlayers that hinder carrier transfer through the bulk and across interfaces. I will discuss how different crystallographic phases of the halide perovskite affect charge carrier transport in the bulk. Charge carrier transport across interfaces will be further studied to understand whether crystalline structures or amorphous phases are able to efficiently allow transport out the device. Synchrotron-based characterization techniques, such as grazing incidence x-ray spectroscopy and x-ray fluorescence will be used to understand the structural and chemical composition of the films, whereas intensity-modulated photocurrent spectroscopy will be used to understand transport processes in the devices. As a result of these contributions, we aim at further understanding the role of interfacial layers and texture on carrier transport for efficient optoelectronic devices.

8:30 AM EN05.01.02
Quantitative Imaging of Structural Dynamics and Emerging Ferroelectricity in Inorganic Halide Perovskites Ye Zhang and Peidong Yang; University of California, Berkeley, United States

Halide perovskites are a class of semiconductor materials holding great promise for various energy conversion applications such as photovoltaics, light-emitting diodes and even electromechanical devices. Their advantages including the ease of processing, bandgap tunability, phase modification and defect tolerance are largely due to the soft and dynamical ionic lattice of halide perovskite structure. In particular, all-inorganic halide perovskites, with better thermal stability and a rich diagram of chemical/phase transformations, provide ideal platforms for the fundamental understanding of their structural dynamics as well as studying the emerging properties. A facile anion exchange chemistry is one of the examples of their dynamical lattice behaviors, which has been utilized in tuning the electronic bandgaps while the host perovskite structure still remains. In this presentation, I will first focus on a quantitative study of the anion exchange kinetics by directly visualizing the transformation process on single-particle level with spatial, temporal and spectroscopic information, enabled by the confocal photoluminescence imaging microscopy and a design of vapor-phase chemical treatment. We identified the two-step transformation for $CsPbBr_3$ to $CsPbI_3$ as: 1) initial surface reaction; 2) subsequent lattice anion diffusion. The quantitative imaging of anion exchange also revealed a diffusion-limited reaction mechanism. Another example of structural dynamics is the phase transition in $CsPbI_3$ between a metastable perovskite phase and a non-perovskite phase that is reversible and responsive to external stimulus such as temperature, moisture and light. The optical microscopic imaging method is also applied to study a moisture-induced phase transition kinetics where the nucleation and the propagation steps can be decoupled on individual single crystals.

I will later focus on discussing a different structural phase transition in $CsGeX_3$ (X=Cl, Br, I) where Ge (II) cation displacement leads to a rhombohedral distortion that introduces an inversion symmetry breaking and the emergence of ferroelectricity. Through a combination of *ab initio* theory and experiments from structural characterizations to multiscale material behaviors, we identified the role of lone pair stereochemical activity of Ge (II) in determining the ferroelectric origin and found out their spontaneous polarizations. Furthermore, characteristic ferroelectric domain patterns are imaged with both piezo-response force microscopy and nonlinear optical microscopic method. We anticipate that our discovery of this new semiconducting ferroelectric system will expand the understanding of physical phenomena related to ferroelectrics and introduce new possibilities to halide perovskites as well.

8:45 AM EN05.01.03
Defect Quantification in Lead Halide Perovskites—The Shortcut to Stability Michel De Keersmaecker, Neal R. Armstrong and Erin L. Ratcliff; The University of Arizona, United States

Since the late 1970s, operando electrochemical approaches have allowed a direct connection to the defect chemistry in semiconductor materials and the quantification of their energy levels with unprecedented limits of detection. However, the applicability of these solution-based electrochemical methods for defect quantification in metal halide perovskites has been rather limited and restricted to a few non-solvents.
Here, we demonstrate a straightforward three-electrode configuration with a "peel and stick" electrolyte for the electrochemical and spectroscopic investigation of metal halide perovskites. Our ability to effectively characterize defect energetics and densities is illustrated by controlling hole and electron injection in methylammonium lead triiodide and triple cation perovskite films using a systematic modulation of the potential. Introducing redox active probes facilitates operando mapping of the electronic structure, including probing the density of states, elucidation of surface defect reactivity, and assessment of defect passivation strategies, as electron transfer events represent charge injection and charge extraction events in operational optoelectronic platforms. Additional advantages include the ability to make chemical-electronic-physical connections, translate from macro-to nanometer length scales, and study the effect of photon flux, heat, humidity, and/or electrical bias. Finally, we illustrate the electrolyte film is optically transparent to visible and X-ray photons for simultaneous characterization of band gap and physical structure, and can be easily removed for characterization of the near-surface composition and energetics using photoelectron spectroscopies.
Overall, we establish an electrochemical approach that overcomes challenges in characterizing defects in printable electronic materials and provides opportunities for the operando characterization of thin film perovskites, organic semiconductors, quantum dots, conventional semiconductor materials, material blends and device stacks, where the removable solid electrolyte functions as the "top contact". These advanced electrochemical characterization platforms are crucial towards the search for low cost, improved and stable (opto)electronic materials to realize industry-scalable technologies in the field of photovoltaics, charge storage systems, photoelectrochemical cells, etc.

9:00 AM EN05.01.04
Manganese Doping for Enhanced Magnetic Brightening and Circular Polarization Control of Dark Excitons in Paramagnetic Layered Hybrid Metal-Halide Perovskites Timo Neumann[1], Sascha Feldmann[1] and Felix Deschler[2]; [1]University of Cambridge, United Kingdom; [2]Technical University of Munich, Germany

Materials combining semiconductor functionalities with spin control are desired for the advancement of quantum technologies. Here, we study the magneto-optical properties of novel paramagnetic Ruddlesden-Popper hybrid perovskites $Mn:(PEA)_2PbI_4$ (PEA = phenethylammonium) and report magnetically brightened excitonic luminescence with strong circular polarization from the interaction with isolated Mn^{2+} ions. Using a combination of superconducting quantum interference device (SQUID) magnetometry, magneto-absorption and transient optical spectroscopy, we find that a dark exciton population is brightened by state mixing with the bright excitons in the presence of a magnetic field. Unexpectedly, the circular polarization of the dark exciton luminescence follows the Brillouin-shaped magnetization with a saturation polarization of 13% at 4 K and 6 T. From high-field transient magneto-luminescence we attribute our observations to spin-dependent exciton dynamics at early times after excitation, with first indications for a Mn-mediated

spin-flip process. Our findings demonstrate manganese doping as a powerful approach to control excitonic spin physics in Ruddlesden-Popper perovskites, which will stimulate research on this highly tuneable material platform with promise for tailored interactions between magnetic moments and excitonic states.

9:15 AM EN05.01.05
Multiple Exciton Series in Two-Dimensional Metal Halide Perovskites Arise from Lattice Deformations Giulia Folpini[1], Maurizia Palummo[2], Daniele Cortecchia[1], Luca Moretti[3], Giacomo Giorgi[4], Giulio Cerullo[3], Annamaria Petrozza[1] and Ajay Ram Srimath Kandada[5]; [1]Istituto Italiano di Tecnologia, Italy; [2]Università degli Studi di Roma Tor Vergata, Italy; [3]Politecnico di Milano, Italy; [4]Università di Perugia, Italy; [5]Wake Forest University, United States

In recent years, two-dimensional metal-halide perovskites (2D MHPs) have emerged as a promising class of due to their desirable characteristics, with bright and color pure emission at room temperature stemming from their high excitonic binding energy. The study of excitonic properties in 2D MHPs is not only relevant for light emitting and photovoltaic applications [1], but has garnered interest also for the unique physics of exciton-polarons in these materials, where the coexistence of multiple bright and dark states has been revealed [2-4]. Optical and electronic properties of lead-based 2D MHPs are conventionally tuned by changing halides or organic cations, but the effect of substituting the metal cation is also crucial to the development of more environmentally friendly alternatives based on tin [5-6].
Here we investigate the excitonic energetic landscape of the prototypical 2D MHP phenethylammonium tin iodide ($(PEA)_2SnI_4$), and compare it with its lead counterpart to clarify the role of the metal cation [7], demonstrating that the role of the organic-inorganic interactions can also be effectively manipulated by the metal cation, especially moving from the heavier lead to lighter tin. We elaborate on the origin of multiple excitonic resonances uniquely observed in the linear absorption spectrum of $(PEA)_2SnI_4$ at energies about 200-300 meV above the primary exciton. We investigate their origin through calculations based on density functional theory and many-body perturbation theory, which suggest that the excitonic series at these higher energies are composed of electronic transitions from a lower lying valence band. Importantly, the valence band splitting does not stem from changes in spin-orbit coupling, but it is driven by the octahedral conformations that follow small variations in the organic-inorganic interactions within the crystal lattice.
We then discuss transient absorption spectroscopy results upon resonant and non-resonant exciton generation conditions to investigate the interaction between the multiple excitonic resonances: we experimentally show that the presence of the higher energy states results in a relatively slow nanosecond component in the formation dynamics of the primary exciton, in addition to the ultrafast phonon-driven hot carrier thermalization. While the presence of such slow relaxation channel for the excitons might be beneficial to many optoelectronic applications, our work suggests its possible control via systematic design of the organic cation. Moreover, our observations indicate that spin-orbit coupling does not play a primary role in the intricate yet crucial change as in the excitonic characteristics imparted by the tin substitution.

Late News: The Atomic-Scale Microstructure of Metal Halide Perovskites Elucidated via Low-Dose Scanning Transmission Electron Microscopy Mathias U. Rothmann[1,1], Judy S. Kim[1,2,3], Juliane Borchert[4,1], Kilian B. Lohmann[1], Colum M. O'Leary[5,1], Alex A. Sheader[1], Laura Clark[1], Henry Snaith[1], Michael B. Johnston[1], Peter D. Nellist[1] and Laura Herz[1]; [1]University of Oxford, United Kingdom; [2]Diamond Light Source, United Kingdom; [3]Rosalind Franklin Institute, United Kingdom; [4]University of Cambridge, United Kingdom; [5]University of California, Los Angeles, United States

Understanding the atomic-scale crystallographic properties of photovoltaic semiconductor materials such as silicon, GaAs, and CdTe, has been essential in their development from interesting materials to large-scale energy conversion industries. However, studying photoactive hybrid perovskites by transmission electron microscopy (TEM) has proved particularly challenging due to the large electron energies typically employed in these studies.[1] In particular, the very close structural relationship between a number of crystallographic orientations of the pristine perovskite and lead iodide has resulted in severe ambiguity in the interpretation of EM-derived information, severely impeding the advance of atomic resolution understanding of the materials.

Here, we successfully image the archetypal $CH(NH_2)_2PbI_3$ ($FAPbI_3$) and $CH_3NH_3PbI_3$ ($MAPbI_3$) hybrid perovskites in their thin-film form with atomic resolution using a carefully developed protocol of low-dose STEM.[2] Our images enable a wide range of previously undescribed phenomena to be observed, including a remarkably highly ordered atomic arrangement of sharp grain boundaries and coherent perovskite/PbI_2 interfaces, with a striking absence of long-range disorder in the crystal. These findings explain why inter-grain interfaces are not necessarily detrimental to perovskite solar cell performance, in contrast to what is commonly observed for other polycrystalline semiconductors. Additionally, we observe aligned point defects and dislocations that we identify to be climb-dissociated, and confirm the room-temperature phase of $CH(NH_2)_2PbI_3$ to be cubic. We further demonstrate that degradation of the perovskite under electron irradiation leads to an initial loss of $CH(NH_2)^{2+}$ ions, leaving behind a partially unoccupied, but structurally intact, perovskite lattice, explaining the unusual regenerative properties of partly degraded perovskite films. Our findings thus provide a significant shift in our atomic-level understanding of this technologically important class of lead-halide perovskites.

Observation of Spatially-Resolved Rashba States on the Surface of $CH_3NH_3PbBr_3$ Single Crystals Zhengjie Huang[1], Shai Vardeny[2], Tonghui Wang[3], Zeeshan Ahmad[4], Ashish Chanana[5], Eric Vetter[1,3], Shijia Yang[1], Xiaojie Liu[5], Giulia Galli[4,6,7], Aram Amassian[3], Z. Valy Vardeny[5] and Dali Sun[1,1]; [1]North Carolina State University, United States; [2]Los Alamos National Laboratory, United States; [3]North Carolina Central University, United States; [4]The University of Chicago, United States; [5]University of Utah, United States; [6]University of Chicago, United States; [7]Argonne National Laboratory, United States

Hybrid organic-inorganic perovskites (HOIPs) are prime candidates for studying Rashba effects due to the heavy metal and halogen atoms in their crystal structure coupled with predicted inversion symmetry breaking. Nevertheless, the observation of Rashba effect in cubic

$CH_3NH_3PbBr_3$ single crystals that possess bulk inversion symmetry is the subject of extensive debate due to the lack of conclusive experiments and theoretical explanations. Here we provide experimental evidence that *Rashba state* in cubic $CH_3NH_3PbBr_3$ single crystal at room temperature occurs exclusively on the crystal surface and depends on specific surface termination that results in local symmetry breaking. We demonstrate this using a suite of spatially-resolved and depth-sensitive techniques, including circular photogalvanic effect, inverse spin Hall effect and multi-photon microscopy; and is supported by first-principle calculations. Our work resolves the existing controversy of Rashba states in three-dimensional HOIPs, and suggests using surface Rashba states in these materials for spintronic applications.

10:30 AM EN05.01.09
Structural Origins of Stability in Cubic Photoactive Metal Halide Perovskites Tiarnan A. Doherty[1], Satyawan D. Nagane[1], Dominik Kubicki[1], Young-Kwang Jung[2], Duncan Johnstone[1], Kyle Frohna[1], Miguel Anaya[1], Stuart Macpherson[1], Sean Collins[3], Aron Walsh[4], Paul Midgley[1] and Samuel D. Stranks[1]; [1]University of Cambridge, United Kingdom; [2]Yonsei University, Korea (the Republic of); [3]University of Leeds, United Kingdom; [4]Imperial College London, United Kingdom

Halide perovskite materials exhibit promising performance characteristics for low-cost optoelectronic applications. Photovoltaic devices fabricated from perovskite absorbers have reached power conversion efficiencies above 25.5 % in single-junction devices and 29.5% in tandem devices. Formamadinium (FA) lead iodide ($FAPbI_3$) and FA-rich perovskites are preferred for photovoltaic applications, but their widespread adoption is hindered by the rapid degradation of the desirable corner-sharing cubic (3C) phase to an undesirable wide bandgap, face-sharing, hexagonal (2H) phase under ambient conditions. Alloying FA with small amounts of Cs^+ and methylammonium (MA) on the A site cation of the ABX_3 perovskite structure has proven a promising strategy for stabilizing photoactive perovskite phases. For example, photovoltaic devices fabricated with compositions such as $Cs_{0.05}FA_{0.78}MA_{0.17}Pb(I_{0.83}Br_{0.17})_3$ (triple cation) perovskites have achieved high device efficiencies with greatly enhanced reproducibility and ambient stability [1]. Recently, there has also been renewed interest in methods to stabilize pure $FAPbI_3$ through strategies such as the incorporation of MA via treatment with methylammonium thiocyanate vapour [2], addition of formamidinium formate [3] or methylammonium formate [4].
The mechanism of improved stability obtained from these approaches is generally explained as either originating from a tuning of the Goldschmidt tolerance factor towards the perfect cubic perovskite structure via cation mixing in the case of Triple Cation perovskites [1,5], by templating growth of the corner-sharing cubic structure in stabilized-$FAPbI_3$ perovskites[2,4], or by reducing intrinsic defect density [3]. A key tenet in all these explanations is that the final photoactive perovskite material, regardless of stabilization approach, is a cubic perovskite structure and that this is the structure that should be pursued for optimal stability and performance. Here, we reveal that contrary to conventional wisdom, this is not the case. In this talk using scanning electron diffraction (SED) we reveal the nanoscale structural origins of improved material stability in $(Cs_{0.05}FA_{0.78}MA_{0.17})Pb(I_{0.83}Br_{0.17})_3$ and stabilized thin films of a- $FAPbI_3$, two of the most promising candidates for commercial PV applications. Further, we will describe how these nanoscale stability mechanisms are related to our recent reports of performance limiting trap clusters in high-performing perovskite films[6]. Together, our talk will help answer questions such as *"What are the nanoscale origins of instability in perovskite materials and devices?", "how important is phase purity for performance?"*

Effects of Anion-Cation Composition on the Urbach Energy and V_{OC} Deficit of Perovskite Solar Cells Biwas Subedi, Chongwen Li, Zhaoning Song, Maxwell M. Junda, Yanfa Yan and Nikolas J. Podraza; University of Toledo, United States

Power conversion efficiency of organic-inorganic metal halide ABX_3 (*A*: methylammonium-MA, formamidinium-FA, cesium-Cs; *B*: lead-Pb, tin-Sn; *X*: iodine-I, bromine-Br, chlorine-Cl) perovskite-based solar cells highly depends upon the structural and optoelectronic quality of the absorber layer. For polycrystalline perovskite films, higher material quality generally implies larger grain size, continuity of grains with reduced grain boundaries, increased carrier lifetimes and diffusion lengths, and reduced recombination, thereby increasing both the current and voltage generation in solar cells. Variation in the anion-cation composition affects the bandgap energies, absorption coefficient, and material structural quality such as crystal structure, phase stability, and grain size. In semiconductors like these perovskites, a wider exponentially decaying tailing effect in the absorption coefficient spectra below the bandgaps is indicative of the presence of lattice vibrations, defects, and impurities. The Urbach energy is the width of this exponentially decaying tail, and its value is reported for more than 60 unique perovskite compositions with bandgaps ranging from 1.2 – 2.3 eV. Urbach energies for pristine perovskite films are measured using the combination of photothermal deflection spectroscopy and spectroscopic ellipsometry. In mixed Sn + Pb perovskites, films with < 50% Sn increase the Urbach energy, whereas intermediate or higher Sn contents lower it. Doping small amounts of Cl and Br (< 30%) with I slightly decreases the Urbach energy, whereas Cl or Br content > 30% increases it. More importantly, a correlation between the Urbach energy of perovskite absorber and corresponding device performance, in terms of the open-circuit voltage (V_{OC}) deficit here, has been studied. V_{OC} deficit is defined as the difference between the absorber bandgap normalized to the electron charge and the measured device V_{OC}, and largely refers to the existence of imperfections in the absorber layer. Most perovskite solar cells fabricated with low Urbach energy absorbers also exhibit low V_{OC} deficit and vice versa. However, those with Cs-based inorganic or mixed Sn + Pb perovskites with very high Sn content show a large V_{OC} deficit even though the corresponding pristine absorber layers show low Urbach energy. In these cases, the absorber layers inside these solar cells degrade or transition to non-perovskite phases due to atmospheric exposure, and no longer reflect the pristine film conditions at which their Urbach energies were measured.

"Hollow" Iodide and Bromide Perovskites—Between 2D and 3D Mercouri G. Kanatzidis; Northwestern University, United States

Hybrid halide perovskites consisting of corner-sharing metal halide octahedra and small cuboctahedral cages filled with counter cations have proven to be

prominent candidates for many high-performance optoelectronic devices. The stability limits of their three-dimensional perovskite framework are defined by the size range of the cations present in the cages of the structure. In some cases, the stability of the perovskite-type structure can be extended even when the counterions violate the size and shape requirements, as is the case in the so-called "hollow" perovskites. We can take advantage of their defect tolerance to engineer a new family of 3D highly defective "hollow" iodide and bromide perovskites with general formula $(FA)_{1-x}(en)_x(Pb)_{1-0.7x}(X)_{3-0.4x}$ (FA = formamidinium, *en* = ethylenediammonium, x = 0-0.44, X=Br, I). The corresponding materials were characterized by a battery of techniques, including single crystal X-ray diffraction (XRD), high resolution powder X-ray diffraction (PXRD), and solid state nuclear magnetic resonance (NMR) measurements. Pair distribution function (PDF) analysis shed light on the local structural coherence, revealing a wide distribution of Pb-Pb distances in the crystal structure, validating further that the corresponding materials are lead deficient and that *en* inclusion has the same structural effect as in the case of the "hollow" iodide analogs. By manipulating the number of defects, we finely tuned the optical properties of the pristine $FAPbBr_3$, by blue shifting the band gap from 2.20 eV to 2.60 eV for the 42% *en* sample. A most unexpected outcome was the fact that above 40% *en* incorporation the material exhibits strong broad light emission with 1% photoluminescence quantum yield that is maintained after exposure in air for more than a year. This is the first example of strong broad light emission from a 3D hybrid halide perovskite and is a clear demonstration that defect engineering can be utilized in our favour to add unusual, exotic optoelectronic properties to this versatile class of materials.

2:00 PM *EN05.02.02
Multi-Functional Conjugated Ligand Engineering for Perovskite Solar Cells and LEDs Letian Dou; Purdue University, United States

Surface passivation is an effective way to boost the efficiency and stability of perovskite devices. However, a key challenge faced by most of the passivation strategies is reducing the interface charge recombination without imposing energy barriers to charge extraction. In this talk, I will present a novel multi-functional semiconducting organic ammonium cationic interface modifier inserted between the light-harvesting perovskite film and the hole transporting layer. We show that the conjugated cations can directly extract holes from perovskite efficiently, and simultaneously reduce interface non-radiative recombination. Together with improved energy level alignment and stabilized interface in device, we demonstrate a triple-cation mixed-halide medium-bandgap perovskite solar cell with an excellent power conversion efficiency of 22.06% (improved from 19.94%), and the suppressed ion migration and halide phase segregation, which lead to a long-term operational stability over 1000 hours. Using a similar concept, we achieved high performance red LEDs with external quantum efficiency over 20%. Our strategy provides a new practical method of interface engineering in perovskite solar cells and LEDs towards improved efficiency and stability.

2:30 PM EN05.02.03
Characterization and Modeling of Solid-Vapor Reactions for $MAPbI_3$ Perovskite Solar Cell Processing Alexander Harding, Austin Kuba, Kevin Dobson, Ujjwal Das, Babatunde Ogunnaike and William Shafarman; University of Delaware, United States

As the stability and efficiency of perovskite solar cells improve, efforts toward developing a manufacturing process have expanded. One promising candidate for high-speed perovskite producition is vapor transport deposition (VTD). A vairant of this process is used by First Solar LLC for the deposition of CdTe solar modules and has assisted CdTe in becoming the market leader in thin film photovoltaics. While VTD presents a viable fabriation route for single-step or two-step perovskite deposition, an understanding of the processing fundamentals is required to design functional equipment. This information is acquired from the precursor technology: close space vapor transport (CSVT).
Previously, we presented a two-step, all-vapor, CSVT deposition process to fabricate methylammonium lead iodide ($MAPbI_3$) thin films.[1] The two steps of this process are 1) the deposition of a PbI_2 thin film, followed by 2) a reaction in methylammonium iodide (MAI) vapor.[1] While the PbI_2 deposition process is well-understood,[2,3] the MAI reaction remains uncharacterized. Our preliminary work found that the consumption of PbI_2 to form $MAPbI_3$ could be approximated using a first-order reaction rate law, though deviations between model and experiment were notable.[1] Here, we expand upon our understanding of the MAI reaction process using controlled experimentation and mathematical modeling.
Experiments were carried out by depositing thick films of PbI_2 (600-800 nm) onto C_{60}/ITO/glass substrates. Isothermal reactions in MAI vapor were then carried out at a fixed pressure of 9 Torr for three temperatures: 110°C, 120°C, and 130°C. Reaction times were varied at each condition, and replicates were carried out to assess process reproducibility. This allowed the intermediate reaction states to be studied using variable-angle glancing incidence x-ray diffraction (GIXRD) and cross-sectional scanning electron microscopy (SEM).
GIXRD measurements were carried out on reacted samples from an incident angle of 0.3° to 3.0° in 0.1° increments and were used to determine the structure of the sample at different x-ray penetration depths. These scans showed that the principal tetragonal $MAPbI_3$ peak (110)/(002) at $2\theta = 14.0°$ was present at every incident angle, while the principal PbI_2 (001) peak at $2\theta = 12.6°$ appeared at different angles of incidence depending on the reaction temperature and time. The onset angle was measured for each sample and used to calculate an x-ray penetration depth to determine the $MAPbI_3$ film thickness.
Cross-sectional SEM measurements were performed on each partially-reacted sample to determine the structure as a function of film thickness. It was observed that a distinct layered structure formed during the reaction. There was good agreement between the calculated x-ray penetration depth through $MAPbI_3$ and the thickness of the top layer, which confirmed the layers were $MAPbI_3$ on top of unreacted PbI_2.
The MAI reaction was found to be consistent with a non-catalytic, heterogeneous, solid-fluid reaction model.[4] A mathematical model will be developed based on these experimental data, and a reaction rate law will be presented at the conference. Using the three reaction temperatures, the temperature dependence of the reaction will also be presented and will account for the concentration of MAI taking part in the reaction[5] and the temperature dependence of the Thiele modulus.[4]
The information to be presented at the conference will serve as a critical stepping-stone for the development of high-throughput, two-step perovskite vapor processes.

Compositional Tailoring and Photophysical Features of Thick-Layers in 2D Hybrid Lead Halide Perovskites: Structure, Luminescent Properties and Stability Eugenia S. Vasileiadou[1], Xinyi Jiang[1], Ido Hadar[1], Mikael Kepenekian[2], Jacky Even[2], Bin Wang[3], Qing Tu[4], Christos Malliakas[1], Daniel Friedrich[1], Ioannis Spanopoulos[1], Justin Hoffman[1], Vinayak Dravid[1], Alexandra Navrotsky[5] and Mercouri G. Kanatzidis[1]; [1]Northwestern University, United States; [2]Univ Rennes, France; [3]University of California, Davis, United States; [4]Texas A&M University, United States; [5]Arizona State University, United States

2D hybrid lead halide perovskites are light-harvesting semiconductors with tailorable structural and photophysical features that provide a vast

compositional space to engineer new and environmental stable materials for optoelectronic applications. Herein, we actuate a comprehensive exploration of the structure-property relationships in several, newly reported series of 2D halide perovskites with thick layers (n≥2) in bulk crystal and film form. Firstly, thermochemical evaluation of the representative 2D structure types of Ruddlesden-Popper (RP) and Dion-Jacobson (DJ) perovskites is presented based on calorimetric measurements that reveal that the enthalpy of formation for the studied RP perovskites is negative while for the DJ perovskites is positive.[1] Film stability tests demonstrate consistent observations with the thermochemical findings, where RP lead iodide perovskites are both thermodynamically and environmentally stable candidates for optoelectronic applications. Synthesis and characterization of the second known example of a *n*=6 perovskite compound: $(PA)_2MA_5Pb_6I_{19}$ (where PA= pentylammonium) is reported with a favorable enthalpy of formation.[1] Secondly, the methodical tailoring of the 2D perovskite structure's composition (organic and inorganic component), unveils trends in the comparison of thick-layered lead iodide and lead bromide perovskites, for the acquisition of halide perovskites with enhanced stability.[2] New members of n=2 lead bromide perovskites that belong to the Ruddlesden-Popper structure type are presented with formula: $(C_mH_{2m+1}NH_3)_2(CH_3NH_3)Pb_2Br_7$ (m = 6−8) incorporating long chain alkyl-monoammonium cations ($C_mH_{2m+1}NH_3$) of hexylammonium (m=6), heptylammonium (m=7) and octylammonium (m=8). 2D thick-layer lead bromide perovskites reveals pronounced differences with their lead iodide congeners, in terms of lattice match between the inorganic $[PbX_6]^{4-}$ perovskite layer and organic layer, carrier lifetime and film stability behavior.[2] Lastly, we examine the crystal chemistry of thick-layer perovskites consisting of organic molecules with bifunctional groups and investigate thoroughly the excited-state dynamics by transient absorption (TA) spectroscopy. Our work highlights the importance of the optimal synthetic design and engineering of environmentally robust, 2D lead halide perovskite materials for next-generation optoelectronic devices.

Double Perovskite Single-Crystals of $Cs_2AgBiBr_6$—The Role of Cu Doping on the Photophysics and Crystal Structure Ana F. Nogueira; University of Campinas (UNICAMP), Brazil

The use of lead-based perovskites in photovoltaic applications has demonstrated to be a successful alternative for future energy generation, but still lead toxicity is a concern and a limitation in some countries. Lead-free double perovskites have attracted attention of the research community due to the ability of tuning their bandgap, structure and stability by selectively choosing the combination of metals. $Cs_2AgBiBr_6$ presents great ambient stability, a relatively easy synthesis route, and consists of cheap and abundant materials. However, the large and indirect band gap of this composition hinders its potential as an efficient light-harvesting material. Doping is a promising strategy to improve the optical and electronic properties of this material, even though only few works studied in details the chemistry and physics involved in $Cs_2AgBiBr_6$ doping. In this work, we work on some modifications of $Cs_2AgBiBr_6$ single crystals with various cations and realize structural investigations combined with photophysical tests to elucidate the mechanism involved in the doping. The understanding of doping allows the comprehension of $Cs_2AgBiBr_6$ chemistry, opening opportunities to obtain other promising double perovskites.

4:00 PM EN05.02.07

AI-Driven Design of High Entropy Halide Perovskite Alloys Arun Kumar Mannodi Kanakkithodi[1], Maria K. Chan[2], Rishi Kumar[3] and David P. Fenning[3]; [1]Purdue University, United States; [2]Argonne National Laboratory, United States; [3]University of California, San Diego, United States

Halide perovskites with desirable stability, electronic band structure, and optical absorption are sought for solar cells, electronic devices, infrared sensors and quantum computing. Compositional manipulation via alloying at cation or anion sites, or via incorporation of point defects and impurities, can help tune their properties. In this work, we develop AI-based frameworks for the on-demand prediction and multi-objective optimization of the phase stability, band gap, optical absorption spectra, photovoltaic efficiency, and defect formation energies for a chemical space of ABX_3 halide perovskites with several choices for A, B and X, mixing allowed at each site, and several possible crystal structures. These frameworks are powered by high-throughput density functional theory (DFT) computations, dimensionality reduction techniques applied upon unique encodings of the atom-composition-structure (ACS) information, and rigorous training of advanced neural network (NN)-based predictive and optimization models. In the current work, we restrict the atom choices to the following: A Î {FA, MA, Cs, Rb, K}, B Î {Pb, Sn, Ge, Ba, Sr, Ca}, and X Î {I, Br, Cl}; we also note that the design frameworks can easily be extended to other atom choices with the infusion of fresh data.

DFT-based geometry optimization and property estimation is performed for hundreds of perovskite alloys simulated using special quasi-random structures (SQS), with new data points sequentially selected using Bayesian active learning approaches to comprehensively traverse the compositional chemical space and iteratively improve prediction accuracies. NN regression models trained upon the DFT data enable the simultaneous prediction of all properties of any ACS combination in the perovskite chemical space, with a special focus on high entropy alloys containing fractions of 5 or 6 elements at the A or B sites. We find that with all end-point and selected mixed compositions included in the training dataset, the predictive models are successfully able to reproduce known formation energy and band gap bowing behavior in perovskite alloy compositions. Further, multi-fidelity learning helps to bridge the gap between (high quantities of) low accuracy calculations and (lower quantities of) high-fidelity data, constituted of either accurate, expensive computations or experimental measurements collected from the published literature. The best predictive models are combined with two different multi-objective optimization techniques, namely, state-of-the-art genetic algorithms and variational autoencoders, to determine optimal high entropy alloy perovskite compositions with desired stability, optoelectronic, and defect properties. Finally, AI-based recommendations are synergistically coupled with targeted synthesis and characterization, leading to successful validation and discovery of novel halide perovskite compositions for improved performance in solar cells.

Exploration of Hybrid Perovskite Superlattice for Efficient and Structurally Stable Stand-Alone Hybrid Solar PV Material Tsz Hin Edmund Chan and Steven Hepplestone; University of Exeter, United Kingdom

Hybrid perovskite solar cells (with chemical formula ABX_3) are of great interest due to the recently measured power conversion efficiency of greater than 25% (but theoretically, 33.7%). Perovskite structures are easily customisable, with a range of options for A, B and X. This enables us to both tune the electronic band gap and the stability by varying the composition. Two promising perovskites are the $CH_3NH_3PbI_3$ (MAPI) and $CH(NH_2)_2PbBr_3$ (FAPB) structures. By varying the ratio of FA and MA and doping with Br, we can potentially tune the band gap and effective masses (and hence electronic transport).

In order to compromise for a more desirable bandgap for stand-alone PV and better structural stability, the hybrid perovskite constituents are then strategically layered into superlattice form. We explore the bulk properties and interfacial engineering to improve the material's electronic transport.

We present a theoretical investigation of the structural and electronic properties of MAPI(x)/FAPB(y) superlattice, performed using first–principles density functional theory and temperature dependent vibrational entropy correction. Our results show that dominating number of layers of FAPB over MAPI will decrease the band gap. We discuss why the formation energies of superlattice in hexagonal and cubic phases differ across temperature and contradicts from the ones of its ground-state constituents. The solutions will be suggested for experimental validation.

No Need for Tin—Perovskite/Organic Tandem Solar Cells Approaching 24% Kai O. Brinkmann[1], Tim Becker[1], Florian Zimmermann[1], Cedric Kreusel[1], Tobias Gahlmann[1], Manuel Theisen[1], Tobias Haeger[1], Selina Olthof[2], Manuel Günster[1], Timo Maschwitz[1], Fabian Göbelsmann[1], Christine Koch[2], Dirk Hertel[2], Piedro Caprioglio[3,4], Lorena Perdigon[4], Lena Merten[5], Alexander Hinderhofer[5], Amran Al-Ashouri[6], Leonie Gomell[7], Steve Albrecht[6], Frank Schreiber[5], Klaus Meerholz[2], Dieter Neher[4], Martin Stolterfoht[4] and Thomas Riedl[1]; [1]University of Wuppertal, Germany; [2]University of Cologne, Germany; [3]University of Oxford, United Kingdom; [4]University of Potsdam, Germany; [5]University of Tuebingen, Germany; [6]Helmholtz-Zentrum Berlin, Germany; [7]Max-Planck-Institute Duesseldorf, Germany

Perovskite solar cells saw a phenomenal development over the past years and for some time dwarfed all progress in the field of organic solar cells. Meanwhile, the introduction of non-fullerene acceptors unlocked skyrocketing efficiencies of up to >18% in organic solar cells recently, with an absorption spectrum extending well into the infrared.[1] Therefore, new opportunities open up, to implement them for high efficiency tandem architectures. As perovskites and organic semiconductors share similar processing technologies they are attractive partners for the monolithic tandem integration. On top of that, low gap perovskite materials are almost exclusively based on Sn^{2+} containing structures, which still give rise to fundamental stability concerns, as the 2+ state is easily oxidized resulting in deterioration by parasitic self-doping of the active material.[2]

Likewise, serious concerns currently exist about photo instability of most non-fullerene organic systems. Now, in surprising contrast to these almost paradigmatic concerns, we evidenced an outstanding operation stability of an organic single junction (~ 100% PCE remaining after >1000 h continuous operation) that is based on the PM6:Y6 active system (>17% efficiency), if excitons are exclusively generated on the acceptor material Y6 (which is the case in a tandem application). Hence, in stark contrast to perovskite-perovskite tandem approaches, the sub-cell limiting operation stability shifted from the low gap (Sn-) perovskite to the wide gap (1.85 eV) Br-rich perovskite cell. To this end we were also able to show, that the effect of detrimental halide segregation in high (50%) Br content perovskite solar cells strongly depends on the choice of hole transporting material, providing a possible pathway towards how those concerns might be further addressed in the future.

Despite of high promise, as of yet the efficiency of perovskite/organic tandem cells remain underwhelming at approximately 20% due to severe optical and electronic losses.[3] By a combination of interface optimization at the wide-gap perovskite cell, a lossless and almost perfectly shunt resilient ALD grown indium oxide interconnect and the highly robust gas quenching technique utilizing n-methyl-2-pyrrolidon (NMP) as co-solvent, we are now able to demonstrate perovskite / organic tandems with efficiencies approaching 24%. As all three utilized sub processes for the building blocks are extremely reproducible, we were at the same time able to achieve an extremely narrow process variation.
Based on a realistic simulation, we foresee efficiencies of perovskite/organic tandem cells exceeding 31% in the future.

Origin of High Photoresponse in Anisotropic Strain-Engineered $CsPbBr_3$ Photodetectors Da Bin Kim and Yong S. Cho; Yonsei University, Korea (the Republic of)

Lattice-strain has been recognized as a critical attribute in determining electronic and optoelectronic properties of halide materials, on the basis of experiment and theoretical estimation. Herein, we propose a unique experimental approach to induce extra lattice-strain in flexible cesium lead bromide ($CsPbBr_3$) thin films by modulating the level of bending curvature of the plastic substrate to produce different magnitudes of tensile or compressive strain during the two-step solution deposition. The $CsPbBr_3$ thin films processed with the in situ strain of −0.83% to +0.83% were used to fabricate a self-

powered photodetector of Ag:LiF/ Phenyl-C61-butyric acid methyl ester (PCBM)/$CsPbBr_3$/ poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS)/ITO/PEN structure. As a result, the maximum responsivity of 121.5 mAW^{-1} and detectivity of $2.28x10^{10}$ $cmHz^{0.5}W^{-1}$ were achieved at a light intensity of 0.47 $mWcm^{-2}$ for the maximum tensile strain of +0.83% without applying a bias, which were the increases by ~61 and ~55%, respectively, relative to the unstrained reference case. These improvements were attributed to the weakened orbital coupling between Pb 6s and Br 4p with longer Pb−Br bonds in the case of tensile strain, causing the down-shifts in the valence band minimum and conduction band minimum, with the promoted drift of photogenerated carriers.

11:00 AM EN05.03.06
Non Corrosive Halide Exchange to Form $CsPb(Br_{1-x}Cl_x)_3$ from $CsPbBr_3$ for Light Emission and Lasing Cedric Kreusel[1,2], Kai O. Brinkmann[1,2], Manuel Runkel[1,2], Manuel Theisen[1,2], Detlef Rogalla[3], Selina Olthof[4], Frederic van gen Hassend[1], Lena Merten[5], Alexander Hinderhofer[5], Frank Schreiber[5], Arne Röttger[1] and Thomas Riedl[1,2]; [1]University of Wuppertal, Germany; [2]Wuppertal Center for Smart Materials & Systems, Germany; [3]Ruhr-Universität Bochum, Germany; [4]University of Cologne, Germany; [5]University of Tübingen, Germany

All-inorganic perovskites are particularly attractive for optoelectronic applications such as light emitting diodes and lasers, due to their excitonic properties and benefits of thermal and environmental stability in comparison to some hybrid analogues.[1] Especially for lasers all-inorganic perovskites, such as $CsPbCl_3$, with emission in the blue/violet wavelength region are desirable. Unfortunately, as of yet, the solution-based preparation of $CsPbCl_3$ is strongly complicated by the poor concomitant solubility of the two precursor salts $PbCl_2$ and CsCl.

Recent reports have shown the conversion of $CsPbBr_3$ by exposure to hydrochloric acid (HCl) as a chlorine source.[2] While the resulting $CsPbCl_3$ layers showed some blue emission, the HCl simultaneously caused significant etching of the exposed perovskite layers.

Here, we propose a non-corrosive and highly controllable halide exchange process for $CsPbBr_3$ via pulsed exposure to metal halide precursors (e.g. $SnCl_4$ or $TiCl_4$) inside an Atomic Layer Deposition (ALD) reactor. The successive conversion from $CsPbBr_3$ to $CsPb(Br_{1-x}Cl_x)_3$ (up to $x = 1$) with an increasing number of ALD pulses is confirmed by optical absorption and emission spectroscopy, X-ray diffraction (XRD), as well as Rutherford-Backscattering Spectrometry (RBS) and X-ray photoelectron spectroscopy (XPS). Grazing-incidence wide-angle X-ray scattering (GIWAXS) evidenced that the layers are homogeneously converted. We demonstrate that the converted films do not show any signs of etching due to the conversion process. We furthermore demonstrate that our concept can be likewise applied for $CsPbBr_3$ layers that have been imprinted by thermal nanoimprint, which is particularly important with regard to photonic nanostructures. In first orienting studies, optically pumped amplified spontaneous emission (ASE) at $\lambda = 426$ nm with a threshold of 1.2 mJ/cm^2 at room temperature could be achieved in these converted layers. This is a significant step towards all-inorganic perovskite lasers emitting in the violet/blue spectral region.

SESSION EN05.04: Perovskite Properties
Session Chairs: Davide Ceratti and Maria Antonietta Loi
Tuesday Afternoon, November 30, 2021
Hynes, Level 3, Ballroom B

1:30 PM *EN05.04.08
Light-Soaking, Photo-Damage and Self-Healing in Halide Perovskites Gary Hodes[1], David Cahen[1], Philip Schulz[2], Jean-François Guillemoles[2] and Davide R. Ceratti[2]; [1]Weizmann Institute of Science, France; [2]Centre National de la Recherche Scientifique, France

Light-soaking, photo-damage and self-healing are intriguing phenomena widely reported in halide perovskites. Yet, their origin is still not understood even if they strongly influence the stability of the material. We discussed recently which could be the chemical origin of various phenomena connected to these effects [1] revealing how the stability of the interstitial Br defects (associated with photodamage) in $MAPbBr_3$, $FAPbBr_3$, $CsPbBr_3$ is inversely related to the kinetic of self-healing of photodamage after intense illumination.
In this talk, I will extend the description of the effects of intense illumination to $MAPbI_3$ showing how this material can also self-heal from photodamage with kinetics in the order of (several) minutes. I will reveal the presence of multiple (chemical) pathways activated by intense illumination some of which cause an increase of the photoluminescence (light soaking) and some of which decreasing it (photodamage). All of these are, at least partially, reversible and proceed from what can be called the “high entropy” of the halide perovskites.
I will also show how water, even in conditions that do not cause the degradation of the material, strongly influences all the mentioned processes actually “protecting” $MAPbI_3$ from photodamage but also substantially impeding light-soaking. This causes the measurements performed over a short time in an inert atmosphere to provide better results because of transient light-soaking effects which, eventually, disappear over time in both humid and inert atmospheres.
The talk will conclude with a panoramic over the literature of the reported effect trying to identify any other critical experimental condition inducing variations on the photodamage and light soaking effect or the kinetics and extent of self-healing. I will also provide additional information on the activation energies involved in the mentioned processes as obtained studying the temperature dependence of these in $MAPbBr_3$, $FAPbBr_3$ and $CsPbBr_3$

2:00 PM EN05.04.02
Process Engineering-Based Modification for Optimal Performance of Organometallic Halide Planner Perovskite Solar Cells Vikas Sharma[1], Neha Sepat[2], Suraj Prasad[3] and Dinesh Kabra[1]; [1]Indian Institute of Technology Bombay, India; [2]Linköping University, Sweden; [3]Karlstad University, Sweden

Halide perovskite semiconductors are emerging candidates for new age Photovoltaics with high power conversion efficiency in single-junction cell and tandem geometry.[1] Researcher are exploring the structural, photo-physics, and optoelectronic properties of these semiconductors.2,3 In this quest, we investigate the different layers of cells from the electron transport layer to the oxide protection layer, the active layer, and the hole transport layer in terms of thickness, molar concentration of precursors, doping concentration for optimal performance. The photoluminescence study of ETL-perovskite reveals that electrons extracted efficiently without quenching due to the high conductivity of tin oxide and better interface alignment with the perovskite layer. A significant change of near about 21 ‰ between the highest and lowest power conversion efficiency was observed by a simple variation of process parameters.

Time-Series Prediction of Perovskite Film Photoluminescence Using Machine Learning Meghna Srivastava[1], Tao Gong[1,1], John Howard[2,2] and Marina Leite[1]; [1]University of California, Davis, United States; [2]University of Maryland, United States

The commercialization of perovskite solar cells (PSC) for next-generation photovoltaic technology hinges on improvements to their long-term stability. Several environmental stressors (light, humidity, temperature, bias, and oxygen) are known to trigger degradation in PSC, which limits device lifetimes to far below those of state-of-the-art Si cells. For effective commercialization, the large parameter space of perovskite compositions and synthesis conditions must be traversed to design optimal devices. Such devices must also undergo lengthy stability testing to prove their viability. With this development process in mind, taking a standard trial-and-error materials research approach to PSC design, fabrication, and stability testing becomes untenably time consuming while demanding significant human labor costs. The field of machine learning (ML) presents an alternate strategy that can contribute to a new research paradigm: one with greater pace, rationality, and reproducibility than trial-and-error methods. Here, we first present ML as a toolkit to accelerate PSC commercialization and demonstrate a general framework for projects to follow. We establish a roadmap to guide researchers through all steps of ML model development, which include collecting the initial training data, data cleaning and pre-processing, feature engineering, model selection, and model optimization and testing.

Next, we showcase this framework in action by using ML to forecast the optical performance of perovskite thin films under dynamic environmental conditions. We track the photoluminescence (PL) signal from the films over time while controlling the relative humidity (rH) and temperature in a sealed, nitrogen-filled chamber, then use ML to predict the PL response for each film composition using rH and temperature data alone. For this time-series prediction task, we implement recurrent neural networks (RNN), a class of neural networks with a historical state or "memory." The network forecasts dynamic PL responses using the environmental state (rH and temp) at a specific time point along with the historical state, which represents physical changes that have occurred within the film. Our optimized model generates PL forecasts over 4 hours for methylammonium lead triiodide ($MAPbI_3$) and triple-cation (formamidinium-methylammonium-cesium) perovskite thin films with normalized root mean square error (NRMSE) of 18% and 14%, respectively. Our network can be driven by weather forecast data, predicting future PL output with high time resolution (one point every 15 seconds) and providing insight into the optical response and stability of perovskite materials under various weather conditions. This work illustrates the potential of ML for PSC development through the example of time-series prediction of optical properties. We envision extensions of this concept to other perovskite compositional families and to other combinations of environmental stressors, including full devices under standard operating conditions and International Summit on Organic Photovoltaic Stability (ISOS) stability testing protocols.

2:30 PM EN05.04.05
Late News: Ultrafast Excited-State Localization and Charge-Carrier Mobility in Cs2AgBiBr6 and Cu2AgBiI6 Adam D. Wright[1,2]; [1]Princeton University, United States; [2]University of Oxford, United Kingdom

Building upon the success of lead halide perovskites, lead-free silver−bismuth semiconductors have become increasingly popular materials for optoelectronic applications. Of these materials, perhaps the most prominent is $Cs_2AgBiBr_6$, which has demonstrated a better thermodynamic stability than $MAPbI_3$ but whose photovoltaic power conversion efficiency lags behind [1]. One reason for this is the strong electron-phonon coupling in $Cs_2AgBiBr_6$, which sets a fundamental limit on the charge-carrier mobilities and hence critically affects device performance. Understanding the nature of the charge-lattice coupling in $Cs_2AgBiBr_6$, and its influence on charge-carrier dynamics, is thus crucial for the optimization of these materials in a variety of optoelectronic applications and to further the understanding of a wide range of related silver− bismuth−halide semiconducting materials. Of these, one particularly promising contender is Cu_2AgBiI_6, which was first reported earlier this year [2] and is notable for its direct bandgap.

In this study, I report on the evolution of photoexcited charge carriers in $Cs_2AgBiBr_6$ [3] and Cu_2AgBiI_6 [4]. In both materials, I observe rapid decays in terahertz photoconductivity transients that reveal an ultrafast, barrier-free localization of free carriers on the time scale of a few picoseconds to an intrinsic small polaronic state. I attribute this to the strong charge-lattice coupling in these bismuth-silver materials, while the temperature-independence of the self-trapping is indicative of low electronic dimensionality due to the electronic isolation of the distinct Ag^+ and Bi^{3+} sites. Through a combination of temperature-dependent photoluminescence and absorption spectroscopy, I identify the electronic states occupied before and after localization, directly tracing the localization of the charge carriers with time and interpreting its influence on the charge-carrier mobility in terms of a quantitative model. Since the small polaron motion is temperature-activated, I find that their mobility still exceeds 1 $cm^2 V^{-1}s^{-1}$ in both materials, leaving open the prospect of their application in efficient photovoltaic devices.

2:45 PM EN05.04.06
Late News: Understanding the Effects of Grain Size and Indentation Size on the Mechanical Properties of Hybrid Organic-Inorganic Perovskite Materials Omolara V. Oyelade[1,2,3], Oluwaseun K. Oyewole[2], Yusuf A. Olanrewaju[1], Richard Koech[1], Sarafadeen Adeniji[1], Dairu Sanni[1], Kingsley Orisekeh[1], Vitalis Anye[1] and Winston W. Soboyejo[2,4]; [1]African University of Science and Technology, Nigeria; [2]Worcester Polytechnic Institute, worcester, MA 01609., United States; [3]Bingham University, Nigeria; [4]Worcester Polytechnic Institute, United States

This paper examines the effects of grain size on the mechanical properties of hybrid organic-inorganic perovskites (HOIPs). Nanoindentation measurements and statistical deconvolution techniques are used to study the Young's moduli and hardness or strengths of perovskite layers in HOIPs. The

size dependence of indentation hardness is discussed within the context of Mechanism-based Strain Gradient (MSG) plasticity theories. These are also used to obtain information on the underlying geometrically necessary and statistically stored dislocation densities. The grain size effects associated with the different annealing temperatures (between 80 and 170ºC) are also characterized using Hall-Petch approaches. The implications of the results are then discussed for the microstructural design of robust perovskite solar cells on rigid and flexible substrates.

3:00 PM EN05.04.09
High Quality 2D Perovskite Thin Films Obtained Through a Simple Blade-Coating Approach Herman Duim[1], Sampson Adjokatse[1], Gert H. Ten Brink[1], René De Kloe[2], Simon Kahmann[1,3], Bart J. Kooi[1], Giuseppe Portale[1] and Maria Antonietta Loi[1]; [1]University of Groningen, Netherlands; [2]Ametek BV, Netherlands; [3]University of Cambridge, United Kingdom

Layered metal halide perovskites are attractive semiconductors for a range of different optoelectronic applications owing to their large structural versatility and rich photophysics. As is the case for the more conventional 3D perovskites, thin films of these materials can be deposited directly from solution, thereby holding the promise of procuring flexible and cost-effective films through large-scale fabrication techniques. However, such solution-based deposition techniques often induce large degrees of heterogeneity due to poorly controlled crystallization. While much attention is focused on the optimization of thin film microstructure and its relation to device performance in the case of 3D perovskites, the microstructure of layered perovskite thin films remains markedly underexplored.

In this talk, I will present a detailed characterization of the optical properties and microstructure of the archetypal 2D perovskite phenylethylammonium lead iodide ($(PEA)_2PbI_4$). Using a combination of structural characterization techniques, we demonstrate that thin films with large grains and strong texture are readily obtained through a simple and scalable blade-coating process. Moreover, we highlight the large impact that the stoichiometry of the precursor solution has on the crystallinity, morphology, and optical properties of the resulting thin films.

All in all, we illustrate the large potential for scalable fabrication of 2D perovskite films and underline some of the major hurdles to be overcome for the further development of devices based on large area layered perovskite film.

3:15 PM EN05.04.10
Thermal Properties of Large Crystalline $CsPbBr_3$ Perovskite Thin Films—Remarkable Behavior at Phase Transitions Tobias Haeger[1,2], Moritz Ketterer[1], Ralf Heiderhoff[1,2] and Thomas Riedl[1,2]; [1]University of Wuppertal, Germany; [2]Wuppertal Center for Smart Materials & Systems, Germany

Thermal management in LEDs and lasers is important for both efficiency and lifetime. Thermal management is especially challenging in perovskite-based devices [1], due to their exceptional thermal properties, such as ultra-low thermal conductivity λ, low thermal diffusivity *a*, and small volumetric heat capacity $c_{vol.}$ at room-temperature [2]. These thermal properties strongly depend on temperature and structural phase transitions, which in some perovskites even occur at moderate temperatures. In this context it should be noted that for inorganic cesium-based perovskites there are only a few reports on the thermal properties at their respective phase transitions [3].

Here the thermal properties of perovskites are studied using a Scanning Thermal Microscope, which takes advantage of the 3ω-method in the frequency domain without the need of elaborate sample preparation. Furthermore, it allows the simultaneous acquisition of the thermal properties λ(T), a(T), and c_{vol}(T) [4]. The thermal properties of nano crystalline and large crystalline $CsPbBr_3$ perovskite thin films were examined from room-temperature to 150°C, in which orthorhombic to tetragonal to cubic phase transitions occur [5]. The thermal properties of large crystalline films with layer thicknesses 110 nm, 150 nm, and 200 nm were investigated.

It could be confirmed from the λ(T), a(T), and $c_{vol.}$(T) characteristics that $CsPbBr_3$ thin films with small crystallites (200nm) show a second order phase transition at 88°C from orthorhombic to tetragonal and a first order transition at 132°C from tetragonal to cubic, as described in earlier works [6]. In stark contrast, for thin films with large crystals (5-10µm), instead of abrupt changes in l(T) at the tetragonal to cubic phase transition temperature, a continuous increase was found. The onset of the increase of the thermal conductivity shifts slightly to lower temperatures with decreasing the layer thickness from 200 nm to 110 nm. In addition, we also find that the thermal diffusivity *a(T)* significantly decreases already in the tetragonal phase in comparison to the orthorhombic phase. On the other hand, only the thin films with a thickness of 110 nm a typical signature of latent heat (pointing to a first order transition) is found in the transition from tetragonal to the cubic phase, basically associated with the freedom of rotational modes of $PbBr_6$ octahedra around the three principal axes, while c_{vol}*(T)* of the thicker films (150 nm and 200 nm) indicate a 2nd order phase transition. It should be noted that the 1st order phase transition of the 110 nm thick $CsPbBr_3$ perovskite film was found at a lower temperature 115°C than that reported for polycrystalline films and large single crystals at 132°C.

These temperature dependent thermal properties of large crystalline $CsPbBr_3$ perovskite thin films are similar to that of a material that exhibits phase transitions causing the material to contract upon increasing the temperature due to either a redistribution or ordering effects. This remarkable behavior at phase transitions requires particular attention because it will significantly influence the thermal management in perovskite-based LEDs and lasers.

3:30 PM EN05.04.11
Bromine in Triple Mesoscopic Hole-Conductor-Free Perovskite Solar Cells Hindia Nahdi[1,2], Sarah Cherif[3], Frédéric Oswald[4], Stephanie Narbey[5], Olivier Plantevin[3], Bernard Geffroy[4,1], Denis Tondelier[1], Yvan Bonnassieux[1] and Madjid Haddad[2]; [1]LPICM, CNRS, Ecole polytechnique, France; [2]SEGULA Technologies, France; [3]Université Paris-Saclay, France; [4]CEA, CNRS, France; [5]Solaronix, Switzerland

Within the challenging race for alternative energy sources, hybrid metal halide perovskite solar cells (PSCs) have undergone unprecedented progress with efficiencies reaching now 25.5% [1-3]. These remarkable performances result from the exceptional optoelectrical properties of hybrid perovskite materials. Coupled with their potential for low fabrication cost, perovskite solar cell technology is very promising. However, since hybrid halide perovskites have a highly ionic character, they can decompose under external stresses such as moisture, solvents and heating cycles [4-6]. Reducing environmental stresses imposed by moisture or oxygen for example, in order to improve the long-term stability of perovskite solar cells, is critical to the deployment of this technology.

In 2017, Grancini *et al* [7] published a structure proven to be stable for more than 10,000 hrs, measured uned controlled standard conditions, by engineering an ultra-stable 2D/3D $(HOOC(CH_2)_4NH_3)_2PbI_4/CH_3NH_3PbI_3$ perovskite junction. This structure is based on a fully printable architecture made of three mesoporous layers in which the perovskite is embed.

In this communication, we investigate the effects of changing the perovskite composition in this architecture by adding and/or replacing iodine with bromine into its chemical composition to tune device, increasing the band gap of the material [8], opening the gate to potential application in water splitting (V_{OC} > 1.23 V at pH = 0 [9]). After characterization of their photovoltaic properties, the cells, reaching V_{OC} ~1.3 V are studied by SEM coupled to EDX, XRD, Raman, absorption and photoluminescence spectroscopies.

SESSION EN05.05: Perovskite Interfaces
Session Chairs: Letian Dou and Maria Antonietta Loi
Wednesday Morning, December 1, 2021
Hynes, Level 3, Ballroom B

10:30 AM *EN05.05.01
Instability at Interfaces—How Metal-Oxides Interact with Perovskites and Their Precursors Selina Olthof; University of Cologne, Germany

In optoelectronic devices, the function and performance depends crucially on the proper alignment of the energy level landscape throughout the device, allowing for efficient charge transport across the various interfaces. For applications containing halide perovskites as active layer it turned out that such interfaces can show rather complex behavior. Not only the energetic alignment of transport levels play a role - more importantly, the perovskite composition and formation can be significantly influenced by chemical reactions taking place at these interfaces. In order to prepare highly efficient and stable devices, it is crucial to understand and control these interactions.
In this talk, I will summarize our work on a variety of metal-oxides such as SnO_2, MoO_3, ZnO, TiO_2 etc. where we use photoelectron spectroscopy to analyze which components are responsible for the strong interface chemistry. For this, we investigated a variety of different perovskites (i.e. organic vs. inorganic ones, I vs. Br, etc.) as well as the individual perovskite precursors. We find that the reactivity strongly depends on the individual material combination and that different metal oxides show fundamentally different reaction/degradation pathways. Furthermore, we found that by changing the defect density of the surface we can affect the degree of thin film degradation significantly.
Overall, I will show how photoelectron spectroscopy measurements can help to probe and understand the processes going on at these various bottom contact materials which should ultimately help to improve the stability of perovskite related devices.

Probing the Chemistry of Perovskite Systems by XPS and GD-OES Depth-Profiling—Potentials and Limitations Pia Dally[1,2], Stefania Cacovich[3,1], Davina Messou[1,2], Armelle Yaiche[4,1], Jean Rousset[4,1], Arnaud Etcheberry[2] and Muriel Bouttemy[2]; [1]IPVF, France; [2]ILV, France; [3]CNRS, France; [4]EDF, France

Despite the outstanding rapid evolution of Perovskite based solar cells efficiencies, the main drawbacks of this technology remain their intrinsic and extrinsic stabilities. Researches nowadays are focusing on enhancing the device architecture where interfaces properties play a crucial role on the final performances and durability. In particular, it is crucial to understand the physical and chemical phenomena occurring at those interfaces, site of defects accumulation and carrier recombination, band mis-alignment or even chemical drift.
This approach is particularly challenging on perovskite solar cells because of the alternating of organic / inorganic layers, requiring a fine optimization of the analysis conditions. The present study addresses the question of the reliability of the chemical information when profiling perovskite layers by X-ray Photoelectron Spectroscopy (XPS) and Glow Discharge Optical Emission Spectroscopy (GD-OES).
XPS and GD-OES are first performed separately on a half-cell constituted of glass/FTO/c-TiO_2/m-TiO_2/triple cation Perovskites ($Cs_{0.05}(MA_{0.14}$, $FA_{0.86})_{0.95}$ Pb ($I_{0.84}$, $Br_{0.16})_3$). The high sensibility of perovskite layers requires to first evaluate the stability of those layers during the transfer from the glove box where they are elaborated to the spectrometers and during analyses themselves (X-Ray, UHV and ion bombardment) to find optimal operating conditions. Especially, the perturbation generated by ion beam and plasma etching has to be accurately studied to infer possible artefacts likely leading to misinterpretation and to determine the best parameters for the abrasion sequences.
In the case of GD-OES, not only the Radio Frequency power and the plasma gas pressure are changed, but also the nature of this gas (Ar, Ar/O, Ne). Concerning XPS, both monoatomic (Ar^+) and cluster (Ar_n^+) projectiles are tested, varying their energies and the cluster size. Finally, GD-OES and XPS show similar trends for the composition profiles. However, we observe that all the conditions employed for XPS profiling lead to a systematic reduction of lead as well as the degradation of the organic part and iodine loss, more or less pronounced. This raises the question of the bombardment effect on the perovskite surface, influencing the integrity of the collected chemical information. Craters obtained with the ion gun of the XPS spectrometer have been accurately characterized to have a better understanding on the bombardment impact on the perovskite surface and also beyond. First, AFM (Atomic Force Microscopy) and SEM (Secondary Electron Imaging) clearly evidence a remarkable change in the surface morphology between a bombarded surface by Ar^+ and Ar_n^+, and thus a proof that analyzed surfaces during XPS sequential sputtering differ. Secondly, the perturbed depth is evaluated in the case of Ar^+ by means of PL (Photoluminescence) and optical measurements. Obtained spectra inside craters resulting from different sputtering duration (i.e. different residual perovskite thicknesses) show no peak shift nor phase segregation. This demonstrates that there is no cumulative effect of sputtering nor drastic chemical modifications.

Finally, a strategy for studying the complete device by an innovative coupling between GD-OES and XPS, very complementary, is discussed. The GD-OES, semi-quantitative technique, assures a fast depth profiling to quickly reach specific areas of interest, which makes it interesting to perform profiling on complete cells and quickly reach the perovskite layer. On the other hand, XPS allows to precisely probe the composition of the extreme surface and to have access to the atomic composition and the chemical environments. This strategy has already been satisfactorily implemented on CIGS, Si and III-V materials. Results of this coupling will be presented and discussed in the case of a perovskite absorber, showing the potential as well as the remaining obstacles that still need to be addressed.

11:15 AM EN05.05.03
Mobile Interfaces Encourage Degradation of MAPbI3 Rhiannon M. Kennard[1], Clayton Dahlman[1], Ryan DeCrescent[1], Jon Schuller[1], Kunal Mukherjee[2], Ram Seshadri[1] and Michael L. Chabinyc[1]; [1]University of California, Santa Barbara, United States; [2]Stanford University, United States

Hybrid perovskites are being commercialized using roll-to-roll processing and are attractive for flexible optoelectronics. This raises questions about how bending impacts the structure and stability of thin films. Here, we examine how mobile interfaces respond to bending in MAPbI3, the prototypical halide perovskite. MAPbI3 is a ferroelastic, which means that it forms domains that are contained within the features seen via SEM. We will first review distinctions between ferroelastics and ferroelectrics, and explain conditions necessary for ferroelasticity: briefly, ferroelastics have spontaneous strain, while ferroelectrics have spontaneous electric polarization. Ferroelastic domains have identical crystal structure and different crystallographic orientations, and are separated by interfaces called twin walls. Bending MAPbI3 moves the twin walls, which changes the proportions of the ferroelastic domains. We mapped the stresses needed to move the twin walls onto the stress-strain curve of MAPbI3. Bending MAPbI3 films outwards causes faster degradation to the undesired PbI2 phase: this degradation is correlated with nucleation of new ferroelastic domains that form to accommodate the applied strain, and consequently, formation of new twin walls. The enhanced degradation is attributed to twin walls containing higher concentrations of point defects, which is a well-known phenomenon in oxide ferroelastics. To prevent twin wall movement or nucleation, and thus reduce degradation, one must keep mechanical or thermal stresses below 50 MPa. The roles played by twin walls in influencing ion migration, carrier trapping, and degradation are discussed. [1]

11:30 AM EN05.05.04
Improvement of the Thermal Stability of the Inverted (p-i-n) Perovskite Solar Cell Devices Using Alumina as a Passivation Layer Tamanna Mariam, Ramez H. Ahangharnejhad, Zhaoning Song, Abdul Quader, Zahrah S. Almutawah, Suman Rijal, Kamala K. Subedi, Adam J. Phillips, Yanfa Yan, Randy J. Ellingson and Michael J. Heben; Wright Center for Photovoltaics Innovation and Commercialization, United States

One of the main challenges for perovskite solar cells is the lack of stability in hot and/or humid environments. In this research, we intend to improve the thermal stability of inverted(p-i-n) structured perovskite solar cell devices by depositing alumina (Al_2O_3) as a passivation layer at charge transporting layer (CTL)/absorbing layer interfaces using atomic layer deposition (ALD) technique. To do this, we use fully solution processed Poly[bis(4-phenyl) (2,5,6-trimethylphenyl) amine (PTAA) hole transport layer (HTL) and (6,6)-phenyl C61 butyric acid methyl ester (PCBM)/Bathocuproine (BCP) electron transport layer (ETL). For the absorber perovskite material, we use a triple cation and mixed halide material with composition $Cs_{0.05}(FA_{0.83}MA_{0.17})_{0.95}PbI_{0.83}Br_{0.17}$ and 1.62 eV bandgap. We fabricated devices with and without alumina at the HTL/perovskite, perovskite/ETL and both CTL/perovskite interfaces. To investigate how the alumina affects the thermal stability, compare the device performance of the samples with the passivation layer at various interface as a function of time on a 55 °C hotplate. To avoid other potential degradation pathways, the samples are heated inside an N2-filled glovebox. The performance was tracked by measuring the open circuit stability of the samples for 960 hours. The device with alumina at the HTL/absorber layer maintained 75% of the initial value, while the sample with the alumina at the absorber/ETL maintained 56% of the initial value. Both of these were higher than the control sample, which held 44% of the initial value. These results clearly indicate that incorporating alumina at the interfaces of the inverted perovskite solar cell can increase the thermal stability of the devices. In addition to the open circuit stability tests, we completed maximum power point (MPP) tracking on the devices held at 50 °C in a moisture-free, N_2 environment for 85 hours. The MPP tracking data also shows the improved stability of the devices with alumina compared to the control device. These measurements clearly exhibit the improved stability of the alumina passivated inverted perovskite solar cell devices in comparison with the non-passivated inverted structured devices.

11:45 AM EN05.05.05
Study of Degradation Mechanism in Halide Perovskite Solar Cells Using Impedance and Modulus Spectroscopy Haeyeon Jun[1,2], Denis Tondelier[1], Bernard Geffroy[1,3], Jean-Eric Bourée[1], Sufal Swaraj[2] and Yvan Bonnassieux[1]; [1]LPICM-CNRS (UMR7647), Ecole Polytechnique, IP Paris, France; [2]Synchrotron SOLEIL, France; [3]Université Paris-Saclay, CEA, CNRS, NIMBE, LICSEN, France

Organic inorganic hybrid halide perovskites have emerged as an innovative material with excellent optoelectronic properties, in bulk or as single crystals with low defect density with specific morphologies [1]–[3]. Perovskite solar cells (PSCs) have become a trending technology in photovoltaic research due to a rapid increase in efficiency in recent years. [4].
However, they show a degradation of their performance under operational conditions (light, bias, environmental stress, etc.). To increase their long-term stability is one of the biggest challenges for market applications. The presence of strong internal electric fields, the existence of ferroelectric domains, or the diffusion of ions/defects are suggested as possible causes for the degradation processes. Several authors suggest the existence of native vacancy defects in these materials and attribute to those defects a major role in the control of the optoelectronic properties, such as hysteresis in the photo-induced current-voltage curve, as well as in device degradation and lifetime. [5], [6]
Among various degradation mechanism in PSCs, it's important to understand the mechanism in both bulk perovskite and at the interfaces between perovskite layer and transport layers.
Electrochemical impedance spectroscopy (EIS) is a powerful technique to examine the charge carrier dynamics in perovskite solar cells. It gives insight about internal electrical processes in PSCs and distinguishes between bulk and interfacial processes [7]–[9]. Each physical parameter can be extracted in the form of resistance (R), capacitance (C) and Warburg capacitance (W) using an equivalent electrical circuit model. In addition, dielectric modulus is applied for studying the microscopic mechanism of charge transport, contribution of grains (crystals) and grain boundaries and recombination dynamics [10].
In this study, we focus on the degradation of inverted planar structure perovskite solar cells through impedance and modulus spectroscopy. Two samples with the same structure are prepared and stored in air and under dark for 30 days. EIS is measured periodically, on the first sample, without J-V measurement to prevent EIS results from being affected by electrical field that occurs during J-V measurements, while J-V characteristic is measured periodically on the second sample. From combined impedance and modulus data, we confirmed that grains and grain boundaries can be distinguished. The results of modulus spectroscopy imply that the grain size decreases and grain boundaries increases which accelerates ionic accumulation and electronic polarization at interfaces. The results of J-V measurement confirms this hypothesis. Furthermore, we prepared two types of PSCs with electron transport layer based on wet- and dry- processes in order to investigate the effect of solvent on degradation mechanism.

Addressing the Stability and Reliability Challenges in Perovskite Solar Cells via Microstructural and Interfacial Tailoring Nitin P. Padture; Brown University, United States

Most commercial devices, including photovoltaics (PVs), have gone through a familiar research and development trajectory — increasing performance, upscaling, improving stability, and enhancing mechanical reliability — before making it to the marketplace successfully. In this context, perovskite solar cells (PSCs) are likely to be no exception, but little attention has been paid to the latter issue of mechanical reliability. In fact, enhancing the mechanical reliability of PSCs is particularly important and challenging because the low formation energies of MHPs that makes them easy to solution-process renders them inherently poor in mechanical properties: they are compliant (low Young's modulus), soft (low hardness), and brittle (low toughness). To address this perhaps final hurdle in the path towards PSCs commercialization, several rationally designed microstructural- and interfacial-tailoring approaches are used. These include grain-coarsening, grain-boundary functionalization, and interfacial engineering. Most importantly, these approaches are designed such that they not only enhance the PSCs mechanical reliability but also increase performance and improve stability. The scientific rationales for these approaches are discussed, together with the presentation of the current results.

2:00 PM EN05.06.02
Perovskite's Additives—A General Assessment Strategy Towards Stable p-i-n Devices Luigi Angelo Castriotta[1], Francesco Di Giacomo[1], Emanuele Calabrò[1], Reddy Sathy Harshavardhan[1], Daimiota Takhellambam[1] and Aldo Di Carlo[1,2]; [1]CHOSE Centre for Hybrid and Organic Solar Energy, Italy; [2]CNR-ISM, Italy

During the last few years research community has been interested in studying hybrid (organic-inorganic) metals halide Perovskite materials, a brilliant semiconductor as an active layer in new generation photovoltaics, due to its large absorption coefficient, excellent charge mobilities, and the capability of tuning the bandgap. An additional value to this technology is the possibility to be fabricated by low temperature (below 100°C) and solution-processable techniques, lowering the actual production cost of its Silicon counterpart. Perovskite also widens its potential application as from standard Perovskite Solar Farm to Tandem thin film application, Building Integrated Photovoltaics (BIPV), Building Applied Photovoltaics (BAPV), e-Mobility and Internet of Things (IoT). Perovskite solar technology has become a trending topic in the last decade, reaching promising efficiencies up to 25.5%. In the first decade from its photovoltaic application, researchers mainly focused on obtaining high results instead of caring about stability measurements over time using standard stress test conditions, such as thermal and light soaking stressing tests. Only in 2020, an interlaboratory effort among more than 50 researchers agreed on standardizing stability measurements for Perovskite Solar Cells, recognizing its importance to address the research in this topic in order to grab the attention of the investors, stakeholders and the rest of the population, with the final aim of lowering the CO_2 consumption as stated in the Sustainable Development Goals of the United Nations by 2030. For this reason, we conducted our work taking into account the integrated lifetime energy yield (LEY), a fundamental parameter to check the performances of a device over time. We started by studying a standard triple cation perovskite, with the presence of Methylammonium (MA), Formamidinium (FA) and Cesium (Cs) as cations, Iodide (I) and Bromide (Br) as anions, in a combination to form a narrow bandgap active material (~1.55eV) suitable for single-junction device. We then move towards wider bandgap materials (~1.63eV) more suitable for tandem application with the scope of finding a common strategy to build a robust device stable over time irrespective of the perovskite used. In order to improve the intrinsic stability of the perovskite layer, we focused on the addition of perovskite precursors first, such as the use of PbI_2 excess, the addition of FACl (both materials known for increasing the device performances), and the removal of MA cation, the most volatile material which easily degrades and it is mainly known for accelerating intrinsic degradation. We finally combine all these engineering approaches and have arrived to a stage of inserting ionic liquids, such as 1-Butyl-3-methylimidazolium tetrafluoroborate (BMIM-BF4), and alkylamine ligands, such as Oleylamine (Oam), studying their effects at different trace amounts separately and together. Our work reveals that the excess of PbI_2, more than 4%, and the presence of FACl shows lower LEY with respect to their references, whereas the removal of MA in the perovskite crystal indeed improves LEY values, also with the presence of BMIM-BF4 and OAm. As a final remark of our study, we upscaled the best combination of additives in the perovskite film, giving us the better LEY, for the fabrication of high efficient Perovskite Solar Module (PSM), showing exciting ISOS-T1 and ISOS-L1 test results.

2:15 PM EN05.06.03
Efficiency Enhancement Due to Nonreciprocal Photonic Management of Materials with High Radiative Efficiency Andrei Sergeev[1] and Kimberly Sablon[2]; [1]Army Research Laboratory, United States; [2]AFC, United States

Recent progress in photovoltaic materials with high radiative efficiency, such as halide perovskites, raises a set of principle questions about optimal photonic management, limiting efficiencies of photovoltaic (PV) converters with advanced photonic management, and design of such converters. Here we propose a practical design of the single cell converter with nonreciprocal photonic management, generalize the finite time thermodynamics to electron distributions with the photon-induced chemical potential, calculate the limiting efficiency of the nonreciprocal converter with a single junction cell, and evaluate efficiency of such converters with available GaAs and halide perovskite cells.
Advanced photonic nanostructures with broken time-reversal symmetries demonstrate a strong potential to revolutionize numerous applications ranging from optical quantum-information technologies to solar energy conversion. Nonreciprocal optical structures can provide high absorptivity, $\alpha(\omega, n) \approx 1$, together with near-zero emissivity, $e(\omega, \mathbf{n}) \approx 0$, in some narrow absorption cone with the axis direction $\mathbf{n}$ and high emissivity, $e(\omega, \mathbf{n}') \approx 1$, together with

near-zero absorptivity, $\alpha(\omega, \mathbf{n}') \approx 0$, in the strongly different direction $\mathbf{n}'$. Due to separation of emission and absorption, nonreciprocal optical structures can drastically reduce emission from a PV converter without reduction in the light absorption. In our design, we split the absorption cone into two parts. The first part will be used for absorption of solar light. The second part of the cone is employed for re-absorption of the emission by the same PV cell. Alternatively, we can employ the design with high quality mirror doom, which reflects the emitted light back to the cell. In this design, the nonreciprocal high absorption - low emission electrodynamics should be realized just in the narrow angle directed to the narrow hole for incoming solar light.
By using of cells with large number of junctions, we can also suppress the losses related to the relaxation of photocarriers and approach the Carnot efficiency with ideal PV material with negligible nonradiative recombination. Operating of the proposed PV converter with multi-junction cell at the Carnot limit requires an infinite number of external recycling processes. So, any small dissipation in the non- reciprocal photonic system significantly affects this limiting solution. This result provides straightforward resolution of the thermodynamics paradox related to optical diode.
We generalize the finite time thermodynamics to nonequilibrium electron distribution functions specific for PV conversion and derive the limiting efficiency of a single-junction non-reciprocal PV converter. Nonreciprocal photonic management of PV cells with high radiative efficiency may substantially increase the photovoltaic performance. We evaluate performance of the nonreciprocal converter with high quality GaAs and halide perovskite solar cells. Our results show that the nonreciprocal management increases the conversion efficiency of these cells by ~ 5%.
For solar light conversion, the nonreciprocal high absorption-low emission should be realized just in very narrow angle range ($9.3 \times 10{-}3$ radians) and the narrow photon energy range of 5 - 7 kB T above the bandgap. The light emitted from the cell may be reflected back by high quality mirror doom. Development of such PV converters may be expected in the nearest future.

2:30 PM EN05.06.04
Controlling Stress and Strain in Perovskite Solar Cells to Enhance Efficiency and Stability Gabriel McAndrews[1,2], Boyu Guo[3], Aram Amassian[3] and Michael McGehee[1,2]; [1]University of Colorado Boulder, United States; [2]National Renewable Energy Laboratory, United States; [3]North Carolina State University, United States

Despite promising initial efficiencies of metal halide perovskite solar cells, their operational stability is hindered by degradation which limits commercial viability. Mechanical strain has recently been identified as a significant factor influencing perovskite degradation. Specifically, tensile strain in perovskites has been shown to accelerate undesirable PbI_2 formation (1, 2). Therefore, it is crucial to identify and reduce sources of residual tensile strain to enhance the stability of metal halide perovskites. Thermal annealing promotes crystallization and removes excess solvent from solution processed perovskites. High temperature crystallite attachment combined with a coefficient of thermal expansion (CTE) mismatch between the perovskite and rigid substrate, such as glass, results in in-plane biaxial tensile stress (2).

Despite the demonstrated origin of residual tensile strain and its influence on perovskite stability only a few studies have addressed potential solutions (3,4). Here, we evaluate several strategies to reduce or avoid tensile strain on their ability to enhance stability of perovskites without sacrificing optimal initial optoelectronic properties and efficiencies. First, room temperature crystallization and mechanical attachment of perovskite crystallites to the substrate avoids tensile stress from the CTE mismatch during the cooldown from the elevated anneal temperature. In fact, perovskites attached to the substrate at room temperature are under compression at operating conditions (i.e. 65C) which is hypothesized to enhance stability (1, 2). The film formation kinetics can be influenced by several factors to induce room temperature perovskite attachment. For example, certain antisolvents and quench methods rapidly remove excess solvent, decomplex solvate phases, and induce a chain reaction perovskite crystallization at room temperature. Furthermore, extended times between the quench and subsequent anneal allows for adequate time for perovskite crystallites to form and mechanically attach to the substrate.

Using room temperature perovskite attachment to avoid tensile strain from the CTE mismatch has several advantages over alternative strain mitigation strategies. Using substrates with CTEs matched with perovskites or manipulating strain post crystallization introduce additional costs and can sacrifice optimal photovoltaic performance. We present a solution to reduce tensile strain in metal halide perovskites: room temperature attachment using typical processing methods.

Efficient and Stable Pb-Based All-Perovskite Tandem Solar Cells Chongwen Li, Zhaoning Song and Yanfa Yan; University of Toledo, United States

Bandgap-tunability of metal halide perovskites endows them with a wide selection for assembling all-perovskite tandem solar cells to break the efficiency limit for single-junction solar cells. $FAPbI_3$ showing outstanding optical and electronic properties has been exclusively employed to pursue record efficiencies for single-junction perovskite solar cells, yet it has not been exploited in the fabrication of all-perovskite tandem solar cells. Here, to pair with high-quality $FAPbI_3$, all-inorganic $CsPbI_xBr_{3-x}$ with superior thermal stability is introduced as the top subcell. By finely tuning the bandgap of $CsPbI_xBr_{3-x}$, we achieved an excellent current match of the two subcells. Moreover, a self-assembled polyelectrolyte was used as the surface modifier for NiO_x to reduce the non-radiative recombination at the $CsPbI_xBr_{3-x}/NiO_x$ interface, which contributes to improved hole extraction and overall device performance. More importantly, this new tandem combination based on Pb-perovskites significantly advances the operational stability, one such a tandem cell delivered an initial efficiency of >23% and remained 80% of the efficiency after >1000 hours operation under continuous one sun (AM 1.5G) illumination at 65 °C. Our strategy provides an alternative pathway for realizing practical application of all-perovskite tandem solar cells.

4:00 PM *EN05.06.06
Chemical (In)Stability in MA-Free Halide Perovskites – Thin Films versus Quantum Dots Qiuming Yu; Cornell University, United States

Methylammonium lead triiodide ($MAPbI_3$) perovskite is one of the most studied perovskites, and a power conversion efficiency (PCE) over 20% has been demonstrated for single junction solar cells. However, $MAPbI_3$ perovskite is not an ideal option to fabricate high performance and stable single junction perovskite solar cells mainly due to its intrinsic moisture and thermal instability. Formamidinium (FA) as another organic cation has been applied as a replacement for MA to solve the instability issues. However, $FAPbI_3$ suffers from phase instability under room temperature. It spontaneously transfers

from a black photoactive α-phase to a yellow photoinactive δ-phase at room temperature in a few days. To solve the phase instability problem, alkaline cation such as Cs^+ and Rb^+ cations are introduced to partially replace the large FA cation to adjust the Goldschmidt tolerance factor. We investigate the phase and device stability of $FAPbI_3$ perovskites by introducing both Cs^+ and Rb^+ cations in compared to Cs^+-only with the perovskite thin films fabricated via one-step plus anti-solvent solution process. We also investigate the stability of phase and device made by spin-coating plus solid-state ligand exchange of $FAPbI_3$ colloid quantum dots. We find that even with incomplete incorporation, Rb^+ cation can significantly improve the device performance. We reveal the defect-mediated cation and anion migration under electric field using cross-sectional secondary electron microscopy, X-ray photoelectron spectroscopy, and time-of-flight secondary ion mass spectrometry, and identify that Rb^+ is more vulnerable compared to Cs^+. By simply mixing the precursor solution before spin coating, we significantly reduce the defect states in both types of perovskites and improve the device stability against an electric field. The modified precursor solution provides the devices with $Rb_{0.05}Cs_{0.1}FA_{0.85}PbI_3$ and $Cs_{0.15}FA_{0.85}PbI_3$ active layers that retain 68% and 92% of their initial PCE, respectively, over 30 days under N_2 protection. Surprisingly, solar cells made with spin-coating plus solid-state ligand exchange of $FAPbI_3$ quantum dots display long-time stability with no device performance degradation over 30 days under N_2 protection. We conduct systematically structural, chemical, electronic, and photophysical studies to reveal that cations and anion, used in solid-state ligand exchange, can selectively passivate surface defects and suppress ion migration. The rationally controlled ligand exchange of colloid perovskite quantum dots could open a new avenue to manipulate the chemical stability of halide perovskites.

4:30 PM EN05.06.08
To Be or Not to Be? Methylammonium in Hybrid Lead Halide Perovskites for Tandem Solar Cells Moses Kodur[1], Deniz N. Cakan[1], Rishi Kumar[1], Connor Dolan[1], Yanqi Luo[2], Barry Lai[2] and David P. Fenning[1]; [1]University of California, San Diego, United States; [2]Argonne National Laboratory, United States

Whether methylammonium is beneficial or detrimental, necessary or superfluous for high-performing wide-bandgap perovskite compositions suitable for tandem photovoltaics has remained a contested enigma. Borrowing from advances in single-junction perovskite design, mixed cation and halide chemistries have shown improvements to both the open-circuit voltage and stability of top-cell devices, but also suffer from compositional complexity and the risk of phase separation under the wide range of operating conditions a PV cell experiences. Here, we investigate the role of methylammonium (MA) on the formation, halide incorporation, optoelectronic properties, and photovoltaic performance of perovskite thin films designed for perovskite-silicon tandems devices, exploring the >1.6 eV triple-halide compositional space (A-site: Cs/MA/FA).

We use synchrotron X-ray microscopy combined with correlative mapping of optoelectronic performance to assess the role of MA-incorporation on the microscopic chemical distribution and device performance. We see little distinction in performance between MA and MA-free triple halide perovskite compositions. In contrast, whether MA is present or not, Cl incorporation to create triple halide compositions shows distinct benefits, and we gain insights into the limits of Cl incorporation before phase segregation manifests and how MA modulates those limits. Our results suggests that MA is not critical to the high-quality wide bandgap, chlorine-incorporated perovskites and that its removal may facilitate the development of more stable perovskite solar cells.

4:45 PM EN05.06.10
Reducing Roughness and Improving Efficiency of $MAPbI_3$ Perovskite Solar Cells Made by High-Throughput Photonic Curing Weijie Xu and Julia Hsu; The University of Texas at Dallas, United States

For perovskite solar cells (PSCs) to be commercially viable, the slow and energy-insufficient thermal annealing step must be eliminated. Among the photo-irradiation methods proposed to replace thermal annealing, photonic curing is the fastest conversion method. Photonic curing delivers short (20 μs to 100 ms) but intense light pulses from a broadband (200-1500 nm) xenon flash lamp, making it the only method to convert perovskite under 20 ms. This processing time can be extrapolated to a roll-to-roll web speed of 40 m/min based on laboratory processing conditions.[1] However, most reported PSCs made by photonic curing under 1 second have inferior performance (~10% PCE). Although SEM images show dense and pinhole-free perovskite films, AFM images indicate secondary wavy features of 500 nm-wide ridge and 80 nm-deep trenches on photonically cured perovskite films, the existence of which correlates with poor device performance. We suggest that this morphology feature is produced by volatile solvent evaporation during the fast photonic curing process. Two approaches have been made to remedy this issue: (1) adding CH_2I_2 as the third solvent in the conventional DMF-DMSO system and (2) applying a controlled air-blowing step before photonic curing to remove excess solvent further. Combining these two approaches produces photonically-cured perovskite films with a comparable film roughness and device performance. Alkyl halide additives have been reported to enhance PSC performance by modulated solvent-solute interactions and C-X (X = Cl, Br, and I) cleavage. Photonic curing can cleave CH_2I_2, producing disassociated iodide ions to replenish iodine loss induced by photonic curing, which is confirmed by EDX. As a co-solvent, the high boiling point of CH_2I_2 can also make the solvent less volatile, reducing surface roughness in photonically cured perovskite films. Additionally, photonically-cured perovskite films have longer PL lifetimes and a higher recombination resistance compared to thermally-annealed counterparts. As a result, we demonstrate that photonic curing is a suitable method to replace thermal annealing in high-throughput PSC fabrication.

Polysalt Ligands Achieve Higher Quantum Yield and Improved Colloidal Stability for CsPbBr3 Quantum Dots Sisi Wang, Selin E. Donmez and Hedi M. Mattoussi; Florida State University, United States

Recently, Colloidal all inorganic lead halide perovskite quantum dots (PQDs) have generated much interest and activity, due to the great promise they offer for use in optoelectronic applications. However, their poor colloidal stability, which can be traced to the ionic nature of the crystal cores and the high desorption rates of the native ligands, has impeded progress in fundamental research and slowed integration of such materials in devices. Developing novel surface ligands with strong coordination to passivate surface traps and enhance fluorescence, while improving colloidal stability is needed.
Here, we detail the synthesis of a new family of multifunctional polymer ligands and their use for surface engineering of the $CsPbBr_3$ nanocrystals. The ligand synthesis relies on the nucleophilic addition reaction between poly(isobutylene-alt-maleic anhydride), PIMA, and distinct nucleophiles. The modular

ligand stoichiometrically displays multiple ammonium and/or imidazolium salt groups for coordination onto the PQD surfaces, along with several alky chains with different length to promote affinity to various organic solvents. The results show that the PQDs coated with those polysalts exhibit great colloidal stability and significantly enhanced photoluminescence. The coating also allows the resulting colloids to be dispersed a wide range of solvent conditions, including ethanol and methanol, while maintaining strong fluorescence and preserving the nanocrystal integrity after ligand substitution.

Late News: Mechanical Reliability of Perovskite Solar Cells Reisya Ichwani, Oluwaseun K. Oyewole and Winston W. Soboyejo; Worcester Polytechnic Institute, United States

Highly efficient organic-inorganic perovskite solar cells (PSCs) consisting of multiple layers of functional materials are needed to be mechanically stable for the development of perovskite solar cells that can be deposited on rigid or flexible perovskite solar cells. In this study, we explore the possible effects of interfacial robustness on the performance of organic-inorganic PSCs. The interfacial fracture energies are determined for the interfaces in model perovskite solar cell structures. These are obtained using Brazil disk specimens that are used to study the mode-mixity dependence of the interfacial fracture toughness in bi-material interfaces. The underlying crack/microstructure interactions are investigated along with the crack-tip shielding mechanisms associated with crack growth under monotonic loading. These are elucidated via scanning electron microscopy and energy-dispersive X-ray spectroscopy studies of the crack profiles and fracture surfaces. These reveal the kinking in-and-out of interfaces that can occur between layers in PSCs. The observed crack-tip shielding models are also modeled with zone shielding fracture mechanics models. The measured interfacial toughening/fracture toughness levels are then correlated with the performance characteristics (power conversion efficiencies, short circuit currents, and open circuit voltages) of PSCs with perovskite layers that are produced using spin coating and vapor deposition techniques. The implications of the results are then used to rank the robustness of interfaces in multilayered PSCs.

SESSION EN05.08: Perovskite Stability

Feature Engineering to Capture Effects of Uncertainty in Machine Learning Models Forecasting the Decay of Halide Perovskite Optoelectronic Properties Wiley A. Dunlap-Shohl, Timothy Siegler, Andrew Tischhauser, Chang-En Tsai, Yuhuan Meng, Preetham Sunkari, Yu-Chia Chen, David Beck, Marina Meila and Hugh W. Hillhouse; University of Washington, United States

A promising application of machine learning in materials science is service lifetime forecasting[1] of halide perovskites, a potentially disruptive photovoltaic technology limited by degradation in ambient environments due to the action of heat, light, moisture, and oxygen. It is imperative for prospective manufacturers to know how long their products are likely to survive to provide warranties and develop sound business plans. In prior work, we have developed predictive machine learning models that can accurately forecast the service lifetime of the archetypal halide perovskite, methylammonium lead iodide ($MAPbI_3$), in a variety of different environmental conditions, using data available from a unique characterization tool that simultaneously measures transmittance, photoluminescence, and photoconductivity in situ. Early modeling efforts indicated that the material decomposition rate, detected by using the optical transmittance of perovskite films, is strongly predictive of decay in the perovskite's carrier diffusion length. The importance of environmental factors on halide perovskite degradation is well, if incompletely, understood. However, the degree to which sample-to-sample variation can affect lifetime forecasts has not been studied. It is well-known that the manner and environment in which a perovskite film is prepared can have large impacts on its photovoltaic performance, but these links are often opaque and may involve factors that are hard or impossible to measure. To understand how best to handle this inherent uncertainty, we employ a dataset consisting of over 60 perovskite degradation runs in which environmental conditions are held constant, and identify features that capture the influence of this variation on service lifetime. We observe that T80-LD, the time it takes for the diffusion length to decay to 80% of its starting value, can vary by over an order of magnitude in the same ambient conditions, making the ability to capture this variation extremely important for forecasting. In assigning decomposition rate-related features high importance, machine learning algorithms that forecast T80-L_D thus uncover key links between the extent of a perovskite film's degradation and the evolution of its electronic properties: T80-LD possesses a strong inverse relation to the material decomposition rate, as calculated from in-situ transmittance measurements. This relationship is quite similar to the T80-LD-decomposition rate relationship observed over a dataset in which environmental conditions are deliberately varied, showing that these relatively simple models can nevertheless uncover the general patterns underlying degradation. We have recently developed a first-principles kinetic model to predict the initial degradation rate of $MAPbI_3$ from the ambient environmental conditions,[2] and we explore the performance of hybrid models that incorporate both *a priori* information about the expected degradation rate in a given environment using physics-inspired features derived from the kinetic model, and *in situ* optical and optoelectronic measurements made on each specific sample in the dataset. This approach maximizes the predictive potential of the models by encoding both contextual and sample-specific information.

Insights into the Carrier-Induced Degradation of Halide Perovskites Through Correlated Structure-Property Measurements Rebecca A. Belisle; Wellesley College, United States

The mixed-conducting nature of halide perovskites has a variety of impacts on their optoelectronic properties and device performance. Current-voltage hysteresis, reverse-bias breakdown, photo-brightening, carrier-induced degradation, and thermal stability are all examples of behaviors that have been linked to the appreciable ionic conductivity in these materials. However, despite the significance of ionic defects on perovskite performance, there remain many open questions as to the number of ionic defects in perovskite semiconductors and their effects on device performance. In this work I will present recent advances in our understanding of one phenomenon linked to ionic defects in perovskite semiconductors: carrier-induced degradation. Using correlated structure, optoelectronic property, and transport measurements we monitor the chemistry and performance of $MAPbI_xBr_{(1-x)3}$ perovskites over extended illumination and document both reversible and irreversible changes in performance in halide perovskites. Using complimentary XRD,

photothermal deflection spectroscopy, photoluminescence, and mixed-conductivity measurements we document changes in crystal structure, bandgap, and Urbach energy, and connect those changes to variations in ionic conductivity and optoelectronic performance. In the case of mixed halides, we see a non-reversible increase in bromine concentration and corresponding increase in the photoluminescence stability with prolonged illumination, suggesting that the loss of iodine leaves behind a higher-quality and more photostable film. Overall, these advances shed light on the relationship between perovskite chemistry, ionic defect density, and photostability in this increasingly important class of semiconductors and suggest pathways towards increased device performance and stability.

Late News: Defect States Transformation in Perovskite During Photo-Aging and Their Passivation by Fluorinated Interface Modifier Seong Ho Cho[1], Junseop Byeon[1], Kiwan Jeong[2], Jiseon Hwang[3], Hyunjoon Lee[1], Jihun Jang[2], Jieun Lee[1], Taehoon Kim[1], Kihwan Kim[3], Mansoo Choi[1,2] and Yun Seog Lee[1,2]; [1]Seoul National University, Korea (the Republic of); [2]Global Frontier Center for Multiscale Energy Systems, Korea (the Republic of); [3]Korea Institute of Energy Research (KIER), Korea (the Republic of)

Stability of perovskite solar cells has advanced significantly by removing extrinsic degradation factors such as moisture and oxygen through encapsulation techniques. However, encapsulated devices often show irreversible degradation during photo-stability test. In this contribution, we investigated photo-aging mechanism by observing changes in intrinsic defects excluding extrinsic degradation factors. We fabricated perovskite solar cells with similar power conversion efficiencies of 21% but different Pb to I ratio at interface, which exhibited completely different photo-aging trend. We investigated the shift in their intrinsic properties during photo-aging in nitrogen-filled chamber. Evolutions in opto-electronic properties and elemental constituents during photo-aging were traced by various measurement, including photoluminescence spectra, UV-visible absorption spectra, X-ray fluorescence measurements, and time-of-flight secondary-ion mass spectroscopy. Relatively Pb-rich interface presented halide sublimation and strain relaxation, implying formation of new defects states near grain boundaries and interfaces. We investigated changes in Fermi level and intrinsic defect properties and energetic distribution by X-ray photoelectron spectroscopy measurements, space charge limited current measurement, and thermal admittance spectroscopy. Formation of donor-type deep-traps were shown in the perovskite after irreversible degradation.[1] We suggest balanced stoichiometry at the interface and passivation of Pb-I related defects are crucial for enhancing photo-stability.[1] We studied interfacial defect passivation using novel fluorinated organic spacers by synthesizing fluorine groups with different anchoring positions on organic spacers and compared their properties. We report an enhanced efficiency by effective defect passivation retaining over 90% of their initial power conversion efficiency during 500 hours of continuous 1-Sun illumination and outstanding hydrophobic nature without encapsulation.

Late News: Temperature-Induced Degradation of Triple-Cation Mixed Halide Perovskite Solar Cells Yusuf A. Olanrewaju[1,2], Omolara V. Oyelade[3,2], Richard Koech[1,2], Oluwaseun K. Oyewole[2,4] and Winston W. Soboyejo[2,5,4]; [1]African University of Science and Technology, Abuja (AUST). Km 10 Airport Road, Abuja, Nigeria, Nigeria; [2]Worcester Polytechnic Institute, 100 Institute Road, Worcester, MA 01609, USA., Nigeria; [3]African University of Science and Technology,(AUST) Km 10 Airport Road, Abuja, Nigeria, Nigeria; [4]Worcester Polytechnic Institute, 100 Institute Road, Worcester, MA 01609, USA, United States; [5]Worcester Polytechnic Institute, 60 Prescott Street, Gateway Park Life Sciences and Bioengineering Center, Worcester, MA 01609, USA., United States

The triple-cation mixed halide perovskite $Cs_{0.05}(MA_{0.17}FA_{0.83})_{0.95}Pb(I_{0.83}Br_{0.17})_3$ is one of the most promising photon absorbers that is being considered for emerging photovoltaic applications. This is due to its outstanding optoelectronic properties. However, the limited thermal stability of mixed halide perovskites is still a major challenge that may limit their applications over a wide range of temperatures that may be encountered in service. Hence, in this work, we study the temperature-dependence of the degradation of solution processed triple-cation mixed halide perovskite solar cells. These are subjected to temperatures that simulate potential service conditions. Our results show that the reductions in device power conversion efficiency originate from decreasing charge mobility and the formation of charge recombination sites at the ETL/perovskite layer interface. This is shown (using scanning electron microscopy) to be associated with the thermal-induced delamination of the layered structure. The underlying degradation of the solar cell characteristics is also shown to be associated with the formation of defects during the controlled heating of mixed halide perovskite cells. The implications of the results are then discussed for the development of perovskite solar cells with improved thermal stability.

2:30 PM EN05.08.05
Vapor-Phase Tuning of Ruddlesden-Popper Perovskites via Deliquescence/Efflorescence Lorenzo Y. Serafin; University of North Carolina at Chapel Hill, United States

Hybrid perovskites (HPs) have created intense excitement in the chemistry and materials community for a variety of reasons, not the least of which is their remarkable capacity for facile tuning of optoelectronic properties. Specifically, regarding the layered Ruddlesden-Popper perovskites this is accomplished by tuning the stoichiometric ratio of the small intercalating ion (e.g. methylammonium) to the larger organic spacer cation (usually an alkyl ammonium such as *n*-butylammonium). The inclusion of the bulkier alkylammonium cation has the effect of breaking up the regular packing of the lead halide octahedra, creating “slabs” of the traditional perovskite structure, separated from each other by the dielectric environment created by the layers of the bulky spacer cations. The size of these slabs is dictated by the stoichiometry between the two varieties of cations, and synthesis of pure single crystals of these various layered perovskites has been accomplished via solution-grown methods. Attempts to create a phase-pure thin film, containing only slabs of a certain thickness have yielded mixed results. The deliquescent properties of HPs (the uptake of vapor phase amine molecules by HPs leading to the liquefaction of the HP) have been thought of as a way to improve crystallinity of HP thin films. We show herein that this deliquescent behavior of HPs can be used as a way to exert control over the stoichiometry of HP thin films by carefully controlling the vapor-phase stoichiometry of an amine atmosphere during deliquescence. This approach may even be a way to realize the elusive goal of creating a phase-pure Ruddlesden-Popper thin film, something that has not been accomplished as yet through conventional solution processing methods.

2:45 PM EN05.08.06
Photooxidative Healing of Lead Halide Perovskite Solar Cells Katelyn P. Goetz[1,2], Qingzhi An[1], Yvonne J. Hofstetter[1], Tim Schramm[1], Fabian Thome[3], Aymen Yangui[4], Ivan Scheblikyn[4], Nir Tessler[5] and Yana Vaynzof[5]; [1]Technische Universität Dresden, Germany; [2]National Institute of Standards and Technologies, United States; [3]Universität Heidelberg, Germany; [4]Lund University, Sweden; [5]Technion–Israel Institute of Technology, Israel

Lead halide perovskites have attracted enormous interest from both the scientific and industrial communities due to their unprecedented success in optoelectronic devices. Particularly impressive is their performance as active layers in solar cells, where certified power conversion efficiencies (PCE) surpassing 25% have been demonstrated. Despite this tremendous success, several key challenges prevent their large-scale deployment and require further research. Among these challenges, the presence of hysteresis in perovskite solar cells has triggered significant efforts in developing strategies for its suppression. The fundamental origins of hysteresis, however, remain under debate. Moreover, the interplay between the presence of specific ionic defects

in the perovskite layer and the appearance of hysteresis remains largely unexplored.
Focusing on methylammonium lead triiodide ($MAPbI_3$) as a model system, we purposefully introduce defects into the perovskite layer by fractionally modifying the solution precursor stoichiometry.[1] We find that only overstoichiometric devices – those with excess of iodine – show significant hysteresis, as well as a greatly reduced short-circuit current (J_{SC}), thus resulting in low PCEs. While exposure to O_2 under illumination is typically associated with causing the degradation of perovskite thin films,[2] surprisingly, for the overstoichiometric perovskite layers such exposure leads to the elimination of hysteresis and the recovery of the short-current density to the expected value for high-performance perovskite solar cells.
To investigate the origin of this effect, we characterized the composition of the overstoichiometric films before and after exposure to O_2 under illumination. As expected, we find that the I/Pb ratio in the overstoichiometric films, measured by X-ray photoemission spectroscopy, is rather high (4.08±0.15) due to the excess iodine introduced during processing. After the exposure to oxygen, this ratio is reduced to 3.86±0.19, suggesting that a photooxidative process leds to the expulsion of excess iodine from the surface of the perovskite film. 2D photoluminescence mapping in the fluence and frequency domains [3] revealed that the overstoichiometric samples exhibit a large density of traps, which, upon photooxidation, are eliminated from the film, bringing it to the same electronic quality as a perfectly stoichiometric $MAPbI_3$ film. A similar, albeit less pronounced effect, was also observed for overstoichiometric triple cation and MA-free perovskite solar cells, suggesting that photooxidative healing can be applied to various perovskite compositions.

3:00 PM EN05.08.07
Late News: Residual Stress/Strain by Phase Transition Govern Optoelectronic Properties of Halide Perovskites Muhammad N. Lintangpradipto and Osman M. Bakr; King Abdullah University of Science and Technology, Saudi Arabia

Methylammonium lead iodide has become a holy-grail of perovskite material since its inception owing to the facile fabrication (e.g., one/two-step film process, Inverse temperature crystallization) and versatile semiconductor applications (e.g., Light Emitting Diode, photovoltaic) with its superior absorption coefficient, charge mobility, and diffusion length properties. Despite extensive studies of MAPbI3 in optoelectronic application, it possesses a significant challenge that may prove counter-productive as in seemingly inconsistent results of TDPL (Temperature-Dependent Photoluminescence) properties, particularly during phase transition. Unification explanation is essential since TDPL properties have emerged as standard to elucidate the optoelectronic's defect, charge carrier dynamics, and device performance.

In this study, we investigate three archetypical MAPbI3 crystals (Single-crystal, Polycrystalline, Highly oriented Crystal) representing different crystal states based on optoelectronic device variation. We illustrated considerable numbers of diffraction peak trends over the temperature range and observed onset phase transition from certain orientations of crystal states and the co-existence phase of orthorhombic-tetragonal phase of MAPbI3 at PC and HOC using TD-XRD (Temperature Dependent X-ray Diffractometer). We calculated the FWHM value based on the Gaussian model to illustrate the peak broadening trend that occurred strongly on PC and HOC states throughout the temperature range as evident of inter-domain stress by domain boundaries. We showed stress accumulation on MAPI SC and PC with (TDRS) Temperature-Dependent Raman Spectroscopy. Accessing low wavenumber of octahedral twist (SC) and C-N torsion (PC), we realized abrupt lattice rearrangement and smooth transition Raman vibration between SC and PC during temperature change.
In conclusion, we found that domain-size and density of domain boundaries from MAPbI3 crystal states determine the degree of residual stress/strain for thermal lattice expansion and reconstruction lattice to define the phase transition of crystal. We observed that the phase transition characteristics agree with TDPL properties as the origin of MAPbI3 distinctive characteristics as optoelectronic devices. We consider crystal states of being an essential factor to control in order to obtain consistent device properties.

3:15 PM EN05.08.08
The Importance of Proton Chemistry in Halide Perovskites Davide R. Ceratti[1], Gary Hodes[2], David Cahen[2], Philip Schulz[1] and Jean-François Guillemoles[1]; [1]Centre National de la Recherche Scientifique, France; [2]Weizmann Institute of Science, Israel

The widely used Methylammonium (MA+) and Formamidinium (FA+) cations are relatively acidic compounds, with the potential to dissociate in the halide perovskites, giving a proton (H+) and the corresponding ammine. Despite the fact that they were considered not to do so, I will bring new evidence that the dissociation does happen and that H+ can migrate, associate with eventual water molecules internalized in the perovskite, be absorbed by basic hole transporting layers and other related phenomena. I will also comment on the chemistry of H+ in solution and show how it influences the final state of a perovskite layer after the coating.

As it happens in general, in the perovskites the chemistry of protons is reversible and is characterized by chemical equilibria, which are modified by a large number of factors. I will provide indications on how temperature, illumination intensity, electronic doping of the perovskite material and the presence of other molecules pushes the acid-base equilibrium towards the dissociation or the association. The complexity of these equilibria is at the base of a series of phenomena that have been observed in halide perovskites like fast ion-migration, light-soaking and reversible damage repair (self-healing).

In this talk, I will provide proof of the migration of protons in the perovskites as obtained by exchange of H+ with deutons (D+) and discuss their diffusion coefficient in halide perovskite single crystals. Through optical microscopy (confocal, hyperspectral, fluorescence lifetime imaging spectroscopy), I will also provide proof on how the proton chemistry influences the photoluminescence of the perovskites showing how proton deficient perovskites have better optoelectronic properties. In particular, I will analyze how the positive effects of methylamine treatment in the perovskites can be related to proton chemistry and how light might locally originate methylamine causing the effect of light soaking in the perovskites. I will also show that H+ acts as an oxidizer when the perovskite is put into contact with metals and its influence should be considered when depositing contacts directly on the perovskite material.

I will also analyze the chemistry of protons in the perovskite precursor solutions showing how their presence influences which particular lead complexes are actually in solution during crystallization. I will show how the electrochemical potential of the precursor solution (and therefore of the perovskite material) is partially determined by the presence of protons with consequences on the quality and quantity of defects in the perovskite materials.

To conclude, the aim of this talk is to provide the listener a wide view on proton chemistry in halide perovskites providing the theoretical tools to understand the influences that proton chemistry has on the optoelectronic properties and the stability of the perovskites. This talk will be rich in chemical knowledge but it will be adapted to an audience working on halide perovskite devices with more engineering or physics background.

3:30 PM BREAK

4:00 PM EN05.08.09
Late News: Nanostructure Strategies for Improved Perovskite Solar Cells Zhelu Hu[1], Lionel Aigouy[1], Jose Miguel Garcia-Martin[2], Maria Ujue González[2], Hung-Ju Lin[1], Mathilde SCHOENAUER[1], Laurent Billot[1], Patrick Gredin[3], Michel MORTIER[3], Zhuoying Chen[1] and Antonio Garcia-Martin[2]; [1]LPEM, ESPCI Paris, PSL Research University, CNRS, Sorbonne Universités, France; [2]Instituto de Micro y Nanotecnologia -CSIC, Spain; [3]Chimie ParisTech, PSL Research University, CNRS, Institut de Recherche de Chimie Paris, France

Organic-inorganic hybrid perovskite solar cells have attracted much attention due to their high power conversion efficiency (＞23%) and low-cost fabrication. Directions to further improve these solar cells include strategies to enhance their stability and their efficiency by modifying either the perovskite absorber layer or the electron/hole transport layer. For example, the transparent electron transport layer (ETL) can be an important tuning knob influencing the charge extraction, [1] light harvesting, [2] and stability [3] in these solar cells, or the use of up-conversion nanoparticles to get better performance in the near IR part of the visible spectrum. [4] Here we present two strategies based on nanostructuration, first a fundamental study of upconversion fluorescence enhancement effects near Au nanodisks by scanning near-field optical microscopy and second the effects of a nanocolumnar TiO2 layer on the performance and the stability of Cs0.05(FA0.83MA0.17)0.95Pb(I0.83Br0.17)3 perovskite solar cells. For the first case, the enhancement and localization of light near the metallic structures are directly visualized by using a single Er/Yb-codoped fluorescent nanocrystal glued at the end of a sharp scanning tip. [5] For the second we find that, compared to devices with planar TiO2 ETLs, the TiO2 nanocolumns can significantly enhance the power conversion efficiency of the perovskite solar cells by 17 % and prolong their shelf life. By analyzing the optical properties, solar cells characteristics, as well as transport/recombination properties by impedance spectroscopy, we observed light-trapping and reduced carrier recombination in solar cells associated with the use of TiO2 nanocolumn arrays. [6]

***Ab Initio* Material Design of Low-Band Gap Double and Vacancy Ordered Perovskites** George Volonakis[1], Bruno Cucco[1], Pedesseau Laurent[2] and Mikael Kepenekian[1]; [1]Université de Rennes 1, France; [2]INSA Rennes, France

Lead-based halide perovskites have emerged as a most prominent candidate for emerging opto-electronic applications. In this talk we will briefly showcase recent efforts towards designing new Pb-free semiconductors that are alternatives to traditional halide perovskites, for which computational approaches from first-principles have been extensively successful and revealed a series of new compounds within the so-called halide double perovskites family and vacancy ordered perovskites. Among these, $Cs_2BiAgBr_6$ has the narrower indirect band gap of 1.9 eV, [1] and $Cs_2InAgCl_6$ is the only direct band gap semiconductor, yet with a large gap of 3.3 eV. [2] All of them exhibit low carrier effective masses and consequently, are prominent candidates for a range of opto-electronic applications such as photovoltaics, light-emitting devices, sensors, and photo-catalysts. [3] We will specifically outline the computational ab initio design strategy that led to the synthesis of these compounds, and particularly focus on the insights we can get from first-principles calculations in order to facilitate the synthesis, improve their opto-electronic properties and the in-silico identification of compounds with properties that are similar to the lead-halide perovskites. The newly developed concept of analogs will lead us to identify a new oxide double perovskite semiconductor, Ba_2AgIO_6, which exhibits an electronic band structure remarkably similar to that of our recently discovered halide double perovskite $Cs_2AgInCl_6$, but with a band gap in the visible range at 1.9 eV. [4] In the final part of our talk, we will employ this strategy to explore the phase space of vacancy-ordered double perovskite and discuss the case of Zr-based compounds as stable alternates to Cs2TiX6 with X=Br,I, which exhibit lighter charge carrier effective masses.[5]

4:30 PM EN05.08.12
Material Stability Assessment of Low Band Gap Pb-Sn Perovskites Christina Kamaraki[1,2], Matthew T. Klug[1] and Laura Miranda[1]; [1]Oxford Photovoltaics Ltd, United Kingdom; [2]University of Bath, United Kingdom

Mixed lead-tin (Pb-Sn) perovskites have excelled as leading candidates for low band gap absorber materials demonstrating efficiencies up to 21% for single junctions[1,2]and 24.8% for all-perovskite tandem solar cells[3]. Although various ionic species and ratios can be combined to form low band gap perovskites, the propensity of Sn^{2+} to oxidize comprises the Achilles' heel of all of these compositions resulting in undesirable p-type doping of the material and poor optoelectronic quality[4–7]. A deep understanding of the intrinsic degradation mechanisms is imperative in order to successfully integrate these materials into perovskite multi-junctions and even though the deleterious effects of Sn oxidation have been widely explored, the composition's influence on degradation mechanisms has captured less attention.

Herein, the impact of the intrinsic stability of various low band gap compositions is investigated by monitoring changes in their structural and optoelectronic properties during either thermal or humidity stressing over time. As expected, the vulnerability of the material under humidity exposure scales with increased Sn content, while the degradation is governed by the A-cation choice under thermal stressing and absence of oxygen, with the compositions including volatile species proving to be more susceptible. Interestingly, even under humidity exposure different degradation response was observed for compositions with the same Sn content and different A-cation combination, indicating that ambient stability depends not only in Sn content but on A-site as well. Moreover, practical characterization methods which best capture this degradation at the time scales meaningful for device operation are identified. Our side-by-side degradation assessment highlights how materials composition can alter the degradation footprint and particularly how ion choice influences the speed and the mechanism of degradation, which can inform compositional selection for the practical development of all-perovskite tandems.

Nonpareil Electrical Performance of Rb-Based Halide Perovskite at the Nanoscale Richa Lahoti[1,2,1], John Howard[1,1], MD Arafat Mahmud[3], Thomas White[3] and Marina Leite[2]; [1]University of Maryland, United States; [2]University of California, Davis, United States; [3]The Australian National University, Australia

A-site cation management in metal halide perovskites (MHPs) has shown to appreciably impact the stability and optoelectrical properties of the material. There has been notable investigation on MHPs at the nanoscale using atomic force microscopy (AFM) – based techniques. [1, 2] The incorporation of a small cation such as Rb^+ cation to the A-site of the traditional perovskite has considerably alleviated shortcomings in device performance. Though these advancements are well-realized at the macroscopic level, a comprehensive study on the electrical characteristics at the nanoscale remains incomplete. At the macroscopic level, quad-cation ($Cs_{0.07}Rb_{0.03}FA_{0.76}MA_{0.14}Pb(I_{0.85}Br_{0.15})_3$) solar cells show reduced J-V hysteresis (90%) in comparison to dual-cation ($Cs_{0.17}FA_{0.83}Pb(I_{0.83}Br_{0.17})_3$) devices. We resolve their electrical performance through photovoltage [3] and photocurrent with nanoscale spatial resolution using Kelvin probe force microscopy (KPFM) and photoconductive-AFM (pc-AFM), respectively. At the nanoscale, our dark KPFM results indicate upward band bending at grain boundaries (GBs) for both chemical compositions. We note increased voltage homogeneity (34%) in quad-cation perovskite largely due to improved halide homogeneity by Rb^+ cations. We observe a 55% faster post-illumination residual voltage decay in quad-cation perovskite. For the pc-AFM experiments, a Schottky contact is formed between the metal probe and the perovskite, which leads to the collection of holes at the probe end. From the upward band bending indicated by the KPFM results, we expect to see the presence of holes at GBs due to an electron barrier formation. We find that the photocurrent maps for quad-cation perovskite are in agreement with the expected outcome with most GBs reading a photocurrent value higher than their adjacent grains. Surprisingly, the majority of the GBs in dual-cation perovskites display photocurrent response comparable to dark current values. We conclude defect-assisted recombination at GBs in dual-cation perovskite and defect-passivation at GBs in quad-cation perovskite due to the addition of Rb^+ cations. Further, we uncover that the defect-passivated GBs in quad-cation perovskite form a highly conductive GB network that enhances the overall photocurrent response of the material by ~50%. In addition, the photocurrent is independent of topography for both chemical compositions. Our analytical approach, which uses the combined knowledge of band bending and photocurrent response at GBs from KPFM and pc-AFM, respectively, can be used as a universal method to probe the presence and passivation of defects at GBs for any optoelectronic material. Our results underscore the beneficious characteristics, such as improved efficiency, reduced J-V hysteresis, and increased uniformity in photovoltage/current response present in quad-cation perovskite, imparted by the addition of Rb^+ cation.[4]

Fracture Behavior of Organic-Inorganic Halide Perovskite Thin Films for Solar Cells Zhenghong Dai and Nitin P. Padture; Brown University, United States

Organic-inorganic halide perovskites (OIHPs) has emerged as the most promising light-absorber materials in the photovoltaic community due to their near-ideal bandgaps. However, the low formation energies of OIHPs render them unstable. While significant progress has been made in improving the stability of OIHPs, perovskite solar cells (PSCs) will also need to be mechanically reliable if they are to service satisfactorily for decades. In this context, we study the fracture behavior of PSCs by measuring their cohesion energies (Gc) using double cantilever beam method and report a novel approach to strategically enhance the interfacial adhesion and performance of PSCs using self-assembled monolayers (SAMs), where we find that the perovskite solar cell stability is closely intertwined with its mechanical reliability. This work points to a new route for designing mechanically robust PSCs with long-term durability.

EN05.09.04
Doule-Layered Porous Planar Electron Transport Layer for Flexible Perovksite Solar Cell and Modules Jaehoon Chung[1,2], Seong Sik Shin[2], Yanfa Yan[1] and Jangwon Seo[3,2]; [1]The University of Toledo, United States; [2]Korea Research Institute of Chemical Technology, Korea (the Republic of); [3]Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Planar perovskite solar cells(PSCs) using low temperature process is a promising candidate for high throughput production such as roll-to-roll process using a flexible substrate. However, the performance of the planar PSCs is still lower than that of the mesoscopic PSCs using high temperature process. Here, we report a new concept on low temperature processed porous planar electron transport layer (ETL) inspired by mesoporous structure for improving

the performance of flexible devices. The structurally and energetically designed porous planar ETL has induced the formation of high quality perovskite and a preferred band alignment, resulting in the improved charge collection efficiency in device. Through the porous planar ETL, we have achieved an efficiency of 20.7% with a certified efficiency of 19.9 % on a flexible substrate, which is the highest power conversion efficiency ever reported. In addition, for the first time, we succeed to fabricate a large area flexible module with porous planar ETL, demonstrating an efficiency of 15.5% and 12.9% on 100 cm^2 and 225 cm^2, respectively. We believe that this strategy shad a new light on the overcoming a limit of flexible devices.

EN05.09.05
Refractory Plasmonics Enabling 20% Efficient Lead-Free Perovskite Solar Cells Nageh K. Allam; American University in Cairo, Egypt

Core-shell refractory plasmonic nanoparticles are used as excellent nanoantennas to improve the efficiency of lead-free perovskite solar cells (PSCs). SiO_2 is used as the shell coating due to its high refractive index and low extinction coefficient, enabling the control over the sunlight directivity. An optoelectronic model is developed using 3D finite element method (FEM) as implemented in COMSOL Multiphysics to calculate the optical and electrical parameters of plain and ZrN/SiO_2-modified PSCs. For a fair comparison, ZrN-decorated PSCs are also simulated. While the decoration with ZrN nanoparticles boosts the power conversion efficiency (PCE) of the PSC from 12.9% to 17%, the use of ZrN/SiO_2 core/shell nanoparticles shows an unprecedented enhancement in the PCE to reach 20%. The enhancement in the PCE is discussed in details.

EN05.09.07
Evaporation Properties of Formamidinium Iodide During the Preparation of Perovskite Solar Cells Martin Kroll, Zongbao Zhang, Ran Ji, Marcus Papmeyer, Yana Vaynzof and Karl Leo; TU Dresden IAPP, Germany

The fast development of metal halide perovskite solar cells over the last years has reached a level where application in commercial devices is becoming very realistic. This requires scalable deposition techniques like vacuum deposition. It is widely known that during the processing of perovskite, many factors influence the quality of the absorber layer. For solution processed perovskite layers, the research on this topic is growing, but in the case vacuum deposition, the influencing factors are still not fully known. One important factor is the quality of the vacuum in the deposition chamber. Because of material changes of the precursors, residual water, and the vacuum system power, the background pressure changes from deposition to deposition, or even over the course of the processing of a single absorber layer. Due to the different deposition properties of the organic and inorganic precursor salts, the materials are influenced differently. To ensure high reproducibility and high film quality, an increase in the control over all processing parameters is important. In this work, we investigate the influence of the background pressure during the deposition process on important factors like the material tooling and with it the stoichiometry, the crystal structure and finally the device performance. By varying the background pressure about ~ 2 orders of magnitude ($\sim 2*10^{-6}$mbar à $1*10^{-4}$mbar) a bandgap change of the produced perovskite of 60 meV was observed. Besides the stoichiometry the layer thickness is strongly influenced by the background pressure. This results in a decrease in device performance from 15.6 % to 12.6 %.

EN05.09.08
Characterizing Organic Cation Dynamics in Hybrid Halide Perovskites with Neutron Scattering Eve Mozur[1] and James R. Neilson[2]; [1]University of California, Santa Barbara, United States; [2]Colorado State University, United States

Hybrid halide perovskites have many exciting optoelectronic properties that make them suitable for photovoltaic and lighting applications. Unlike conventional inorganic semiconductors, including silicon, cadmium telluride, and gallium arsenide, hybrid halide perovskites posess many dynamical degrees of freedom. These dynamics underly many of their optoelectonic properties, suggesting a new paradigm of dynamics-based structure property relationships. Neutron scattering and spectroscopies are ideal tools to better understand the dynamics of these materials. Here, we present several case studies that demonstrate how neutron scattering enriches our understanding of the phase behavior and functional properties of hybrid halide perovskites. We propose that these insights provide targets for engineering perovskite functional properties.

EN05.09.10
Two-Phased but Not Two-Faced—Superior Performance of Two-Phase Triple Halide Inorganic Perovskites Deniz N. Cakan[1], Moses Kodur[1], Rishi Kumar[1], Connor Dolan[1], Yanqi Luo[2], Tao Zhou[2], Zhonghou Cai[2], Barry Lai[2], Martin Holt[2] and David P. Fenning[1]; [1]University of California, San Diego, United States; [2]Argonne National Laboratory, United States

Inorganic halide perovskites are attractive for achieving the wide bandgap optimal for a high-efficiency perovskite-perovskite tandem based on today's Pb-Sn low bandgap compositions. However, they have suffered from lower photoluminescent quantum yield relative to hybrid compositions and phase instability. To improve upon metastable CsPbI3, we explore triple-halide alloying of minor amounts of Br and Cl with I. In agreement with previous reports for hybrid analogues, we observe a chlorine solubility limit in the majority iodine-bromine all-inorganic perovskite lattice. Past this solubility limit we observe the perovskite forming a split phase of iodine-bromine-rich and bromine-chlorine-rich clusters. Interestingly, these dual-phase thin-films show superior performance, which hints at possible *synergistic* effects of this chemical heterogeneity. We leverage multi-modal synchrotron microscopy and correlative spectroscopic micro-photoluminescence (µPL) on all-inorganic triple halide perovskites CsPbX3 (X-site: I/Br/Cl) films to elucidate mechanisms for superior performance in the face of phase segregation. The results suggest that a greater focus on harnessing the flexibility of the inorganic perovskite material system holds promise to retrace the outstanding performance and stability gains made in hybrid analogues.

EN05.09.11
Late News: What is the Origin of Optical Emission in Cs2TiBr6? Emma J. Pellerin, Emma Burton, Caroline Jaeger, Maranda Allen, Ronald L. Grimm and Lyubov Titova; Worcester Polytechnic Institute, United States Minor Outlying Islands

Thin-film perovskite solar cells (PSCs) now rival established Si photovoltaics inefficiencies and could be less expensive with fewer resources required for processing. A major drawback of the leading PSCs is the presence of Pb in their structure, raising concerns about toxicity. Cs2TiBr6 is one leading candidate among Pb-free perovskites. It has a suitable bandgap to be the top absorber in tandem-junction photovoltaics at ~1.8 eV, and Cs2TiBr6-based PSCs have demonstrated efficiencies up to 3.3%. However, a complete view of the optical properties, carrier dynamics, and environmental stability remains incomplete.

Herein, we use time-resolved photoluminescence spectroscopy to investigate optical emission and carrier lifetime in both large-grain and thin-film Cs2TiBr6 under different environmental conditions. Cs2TiBr6 demonstrates high stability in an N2 with photoexcited radiative lifetimes on the order of 0.5 ns, sufficient for photovoltaic consideration. We investigate the origins of several prominent emission features and their dependence on sample morphology as well as on environmental conditions.

EN05.09.12
Maximizing the Global PLQY Through Local Bandgap Variation in Mixed-Halide Perovskites Sascha Feldmann[1], Henning Sirringhaus[1], Michael

Saliba[2], David Beljonne[3], Samuel D. Stranks[1], Achim Hartschuh[4] and Felix Deschler[5]; [1]University of Cambridge, United Kingdom; [2]Universität Stuttgart, Germany; [3]Universite de Mons, Belgium; [4]Ludwig-Maximilians-Universität München, Germany; [5]Technische Universität München, Germany

Halide perovskites have emerged as high-performance semiconductors for efficient optoelectronic devices, not least because of their bandgap tunability using mixtures of different halide ions. This makes them particularly attractive as candidates for tandem solar cells or spectrally tailored lighting.
We demonstrate that spatially varying energetic disorder in the electronic states of such mixed-halide films causes local charge accumulation, creating photodoped regions, which unearths a strategy for efficient energy conversion in solar cells and light-emitting diodes at low charge densities. We combine temperature-dependent photoluminescence microscopy with computational modelling to quantify the impact of local bandgap variations from disordered halide distributions on the global photoluminescence yield in mixed-halide perovskite films. We find that fabrication temperature, surface energy, and charge recombination constants are key for describing local bandgap variations and charge carrier funneling processes that control the photoluminescence quantum efficiency. We report that further luminescence efficiency gains are possible through tailored bandgap modulation, even for materials that have already demonstrated high luminescence yields.

EN05.09.14
Synthesis, Properties and Prospects for Photovoltaics of Chalcogenide Perovskite Thin Films Ida Sadeghi, Kevin Ye and Rafael Jaramillo; Massachusetts Institute of Technology, United States

Sulfides and selenides in the perovskite and related crystal structures - chalcogenide perovskites - are an exciting family of semiconductors for solar energy conversion and optoelectronics [1]. Here, we explore materials in the Ba-Zr-S system to determine their potential for thin-film photovoltaics (PV).
We demonstrate making $BaZrS_3$ thin films by gas-source molecular beam epitaxy (MBE) [2]. $BaZrS_3$ forms in the orthorhombic distorted-perovskite structure with corner-sharing ZrS_6 octahedra (space group Pnma, no. 62), and has a direct band gap of E_g = 1.85 eV. We present a wealth of data reporting film processing and properties, including reflection high-energy electron diffraction (RHEED), atomic-force microscopy (AFM), X-ray reflectivity and diffraction (XRR and XRD), scanning transmission electron microscopy (STEM), spectroscopic ellipsometry, Hall transport, and photoconductivity. Our single-step MBE growth process produces films that are atomically smooth, single phase, chemically homogeneous, and oxygen free. The films are brightly colored even at 20 nm thick, due to the strong optical absorption typical of chalcogenide perovskites. Films grow via two, competing epitaxial growth modes: (1) buffered epitaxy, with a self-assembled interface layer that relieves the epitaxial strain, and (2) direct epitaxy, with rotated-cube-on-cube growth that accommodates the large lattice constant mismatch between the oxide and the sulfide. The propensity for these two modes can be tuned by adjusting the H2S gas delivery rate. We further show results making thin films of $BaZr(S,Se)_3$ alloys (achieved by co-flowing H_2S and H_2Se), which provide a path towards tuning the direct band gap in the range 1.3 – 1.9 eV.

We also report on time-resolved photoluminescence (TRPL) and photoconductivity (TRPC) studies of excited-state transport in $BaZrS_3$ and the related, Ruddlesden-Popper phase $Ba_3Zr_2S_7$ (E_g = 1.25 eV). We model the data using semiconductor physics simulations, to enable more direct determination of parameters key for photovoltaic performance (e.g. surface recombination velocity, Shockley-Read-Hall lifetime, diffusivity) than is possible with empirical data modeling. We find that chalcogenide perovskites have SRH lifetime exceeding 100 ns and ambipolar diffusion length on the order of 10 m. If time allows, we will present further results of advanced characterization including impedance spectroscopy and X-ray absorption spectroscopy.

Our high-quality thin-film synthesis and excited-state transport measurements suggest a bright future for chalcogenide perovskites thin-film PV. We will end by briefly summarizing the state of the field, and highlighting key challenges on the road to device demonstrations and commercialization.

EN05.09.16
Optical Origin of External Quantum Efficiencies near Unity in Perovskite Solar Cells Kai O. Brinkmann, Tim Becker, Florian Zimmermann, Cedric Kreusel, Tobias Gahlmann, Tobias Haeger and Thomas Riedl; University of Wuppertal, Germany

Hand in hand with the outstanding progress of perovskite photovoltaics, reports of very high values of external quantum efficiency (EQE) appeared. Values of EQE up to 98 % were reported, typically peaked in the range between 400 and 500 nm. Even considering a very high internal quantum efficiencies of the perovskite close to 100%,[1] this observation strikes as a contradiction at a first glance, as the transmittance of ITO/glass substrates typically does not exceed 90% in this wavelength range. Therefore reports of high EQE numbers (EQE is one of the standard characterization procedures for solar cells to exclude or correct spectral mismatch of light sources used for solar cell fabrication[2]) frequently give rise to doubts or concerns about potentially erroneous EQE measurements.
Here, we discuss and explain the root cause of the high EQE by a combination of experimental data and optical simulations. We show, how the transmittance into the active material is significantly governed by its refractive index, enabling very high portions of light being coupled into the high refractive perovskite material at the given wavelength region. At the same time transmission into a low refractive material like air, gives rise to a significant reflectance.[3]
These effects can be nicely seen in optical simulation, experimentally acquired EQE spectra, and optical absorption/reflection measurements. Finally we are able to unravel, that the maximum of the transmittance spectrum is mainly shifted by the thickness of the underlying transparent conductive oxide (TCO) layer. As an example, for our wide gap $FA_{0.8}Cs_{0.2}Pb(I_{0.5}Br_{0.5})_3$ cells (1.85 eV) we found that an increasing ITO thickness would even increase the maximal reachable current and therefore being beneficial in a twofold purpose: reducing the sheet resistance of the bottom electrode while simultaneously increasing the in-coupling of light into the active layer.

Late News: Light Intensity Analysis of Photovoltaic Parameters for Perovskite Solar Cells Damian Glowienka[1,2] and Yulia Galagan[2]; [1]Gdansk University of Technology, Poland; [2]National Taiwan University, Taiwan

The number of publications on perovskite solar cells (PSC) continues to grow exponentially. Although the efficiency of PSC is exceeded 25.5%, not every research laboratory can reproduce this result or even pass the border of 20%. Unfortunately, it is not always clear which dominating mechanism is responsible for the performance drop. Here, we develop a simple method of light intensity analysis of JV parameters allowing the understanding what are

the mechanisms appearing in the solar cell and limiting device performance. The developed method is supported by the drift-diffusion model and aimed to help in the explanation of the parasitic losses from the interface or bulk recombination, series, or shunt resistance in the perovskite solar cell. This method can help not only point on the dominating of bulk or interface recombination in the devices but also determine which interface is more defective. The detailed and stepwise guidance for such a type of light intensity analysis of JV parameters is provided. The proposed method and the conclusions of this study are supported by a series of case studies, showing the effectiveness of the proposed method on real examples.

SESSION EN05.10: Advancing Perovskite Devices I

8:00 AM *EN05.10.01
Engineering Long Lived Perovskite Solar Cells—The Role of Cation Induced Temperature Destabilization Christoph J. Brabec[1,2] and Yicheng Zhao[2]; [1]FAU Erlangen-Nuremberg, Germany; [2]Research Center Julich, Germany

Perovskite photovoltaics based on metal halide perovskites is a most promising photovoltaic technology, but further advance demands improved device stability. Here we show the importance of perovskite composition engineering by demonstrating long-term stable perovskite solar cells. A high-throughput robotic approach is used to screen 160 mixed-cation mixed-halide perovskites based on several optical characterizations, such as UV-vis absorption and photoluminescence spectra. Such automated big data approaches allow to uniquely identify the most photo-thermal-stable perovskites under elevated temperature and 1-Sun illumination. Most interestingly, while several perovksite compositions are found to be stable against high temperatures of up to 85 C, the situation is more complex in working devices, as a stable device requires both - a stable semiconducotr layer and stable interfaces. A p-tyüer interface consisting of polymeric mulitlayers with variable dopign is introduced as a robust anode interface. By integrating the most stable perovskite into this structure, we achieve stable devices without encapsulation that attain nearly 100% of their initial efficiency and 98% of their peak efficiency, after 1000 hrs of continuous mpp operation at temperatures of 60-65 degrees Celsius. Nevertheless, degradation is still observable when the operation temperature is further raised towards 85 C and above, which highlights that the microscopic degradation mechanisms in perovskite devices are still not fully understood. This work introduces into the fundamentals how to accelerate the screening for stable perovskites layer and devices for operation at elevated temperatures.

8:30 AM *EN05.10.02
Efficient Perovskite Solar Cells and Light-Emitting Diodes Jingbi You; Chinese Academy of Sciences, China

The champion efficiency of perovskite solar cells (PSCs) is over than 25%, and the external quantum efficiency of perovskite light-emitting diodes (PeLEDs) in green and red is over than 20%, which is great potential for practical application. In this report, I will talk about our recent progresses in PSCs and PeLEDs. 1) By rational design the composition of perovskite, we got over than 25% efficiency while using nearly pure $FAPbI_3$, 2) For the perovskite light-emitting diodes with blue emission, we modulated the hole transport layer to reduce the injection barrier, and got over than 16% external quantum efficiency of PeLEDs in blue.

9:00 AM EN05.10.03
Late News: Nanostructured Metal Halide Perovskite Materials for Novel Optoelectronic Devices Zhiyong Fan; Hong Kong University of Science and Technology, China

Metal halide perovskite materials are regarded as highly promising materials for high performance optoelectronics due to excellent optical absorption, long carrier diffusion length, tunable composition, etc., thus have triggered broad attention for applications including solar cells, photodetectors and light-emitting diodes. Conventionally, solution processes have been utilized to fabricate perovskite materials. In our work, in order to achieve high material quality and device scalability, we have developed chemical vapor deposition process to grow ordered high density perovskite nanowire (NW) arrays in nanoengineering templates with materials including $MAPbI_3$, $MASnI_3$, $CsPbI_3$ and $FAPbI_3$. The geometrical factors of NWs, namely, periodicity, diameter and length can be precisely nanoengineered. Intriguingly, we have discovered that the chemically and mechanically robust template can effectively protect perovskite NWs against water and oxygen invasion thus the material chemical stability and phase stability are significantly better than planar perovskite films. To explore device applications of perovskite NW arrays, they have been fabricated into novel optoelectronic devices such as photodetectors and bionic eye. Meanwhile, we have also fabricated high efficiency thin film Pero LEDs on self-organized nanophotonic templates and achieved much improved external quantum efficiency (EQE) as compared to planar control device. These results will be demonstrated in this presentation. And they suggest that in addition to material optimization, device structure innovation, particularly utilization of various types of nanostructures can lead to high performance optoelectronics.

9:30 AM *EN05.10.04
Thermally Co-Evaporated Perovskites for Mini-Modules, Tandem Solar Cells Annalisa Bruno, Nripan Mathews and Subodh Mhaisalkar; Nanyang Technological University, Singapore

Although perovskite solar cells (PSC's) with efficiencies of 25.5% [1] have been reported, the best-performing perovskite solar cells rely primarily on lab-scale solution-processed techniques that typically yield small-scale (~0.1 cm^2) devices. Besides scaling up of these devices, demonstration of stability of these devices are also essential. [2-5]

Deposition of perovskite absorber layers by thermal co-evaporation have gathered considerable interest for silicon-perovskite tandem solar cells. The main advantages for thermal evaporation include potential compatibility with silicon solar cell processing, conformal coatings, control of deposited layer thicknesses, and possibility of multi-layer processing. We have recently demonstrated highly eficient, large area, planar PSCs with uniform $MAPbI_3$ perovskite active layer deposited by thermal co-evaporation of PbI_2 and MAI. The high-quality co-evaporated perovskite thin films are pinhole-free and uniform over several centimetres, showing large grain sizes, low surface roughness, and a long carrier lifetime. The high-quality perovskite thin films translates to small area PSCs (0.16 cm^2) with PCE above 20% and high reproducibility. Large area PSCs with area up to 4 cm^2 did not show a significant drop in the PCE. Furthermore, the first thermally evaporated mini-modules with an active area larger than 20 cm^2 achieved the record PCE of 18.13%. [6]

Thermal stability is a critical criterion for assessing the long-term stability of perovskite solar cells. Thermally evaporated perovskites also deliver remarkable thermal stability compared with solution processed solar cells. The improved stability may be attributed to the perovskite growth process leading to a compact and almost strain-free films. This work represents an important step towards the development of high quality, stable, and reproducible large-area perovskite solar cells and mini-modules, the main requirements for the industrialization of this technology.

Defects Activity in Wide and Narrow Bandgap Metal Halide Perovskite Semiconductors Annamaria Petrozza; Istituto Italiano di Tecnologia, Italy

Metal halide perovskites (MHPs) have demonstrated huge potential to build a rich library of materials for a new disruptive optoelectronic technology. The main strength comes from the possibility of easily tune the semiconductor bandgap in order to integrate it in devices with different functionalities – in principle. In reality, this cannot be achieved yet. In fact, while defect tolerance is claimed for MHPs with a bandgap of about 1.6 eV, the model system object of intense investigations, MHPs with lower and higher bandgaps are far from this claim. They show various forms of instabilities which are mainly driven by a strong defect activity.

Here I will discuss our studies on the nature of defects and their photo-chemistry as a function of the semiconductor bandgap and chemical composition in order to identify their role in defining the semiconductor electronic properties and stability.

1:30 PM EN05.12.01
Local Structural Correlations and Low-Temperature Anharmonicity in Methylammonium Lead Tribromide Nicholas J. Weadock[1], Cameron MacKeen[2], Louis Waquier[3], Julian Vigil[4], Yevgeny Rakita[5,6], Hemamala Karunadasa[4], Frank Bridges[2] and Michael Toney[1]; [1]University of Colorado Boulder, United States; [2]University of California, Santa Cruz, United States; [3]SLAC National Accelerator Laboratory, United States; [4]Stanford University, United States; [5]Columbia University, United States; [6]Weizmann Institute of Science, Israel

The hybrid metal halide perovskite (MHP) family exhibits large structural fluctuations which are believed to contribute to, or perhaps cause, their remarkable optoelectronic properties. Additionally, experimental studies including Raman spectroscopy and X-ray total scattering demonstrate that these fluctuations cause local deviations from the **average** bulk structure in the three-dimensional MHPs, such as $CH_3NH_3PbBr_3$ (herein MAPB). [1–3] MAPB has three well defined crystal structures; orthorhombic, tetragonal, and cubic, with phase transitions identified at 141 K and 235 K. An additional incommensurate phase bridges the orthogonal and tetragonal phases. These phase transitions proceed as an unlocking of the organic cation and rotational modes of the $PbBr_6$ octahedra. Several studies have characterized the dynamics of the organic cation, the $PbBr_6$ octahedra, and their interactions, however the dynamics of the Pb-Br bond have received less attention. [4–7]
We investigate the temperature dependence of correlated motions and anharmonicity of the Pb-Br bond with a combined extended X-ray absorption fine structure (EXAFS) and single crystal X-ray diffraction (XRD) study of MAPB. EXAFS provides a snapshot of the local environment around the probe atom, rather than the time- and space-averaged structure obtained from XRD. Fitting the EXAFS spectra to a cumulant expansion reveals that the Pb-Br bond exhibits anharmonicity even in the low-temperature orthorhombic phase. We also examine the correlated motion of the Pb and Br atoms by comparing the mean squared displacement obtained from XRD with the mean squared *relative* displacement obtained from EXAFS. [8,9] In this picture, we find that Pb and Br motions are strongly correlated along the bond direction and somewhat correlated perpendicular to the bond direction. Interestingly, the effective Pb-Br spring constant and correlation coefficients increase through the orthorhombic-tetragonal transition, a highly unusual effect likely resulting from a charge rearrangement on the Pb atom which increases the Pb-Br orbital overlap. Finally, we compare the various asymmetric Pb-Br pair distribution functions which can arise from an anharmonic potential. An in-depth understanding of anharmonicity and the phase transitions will allow designs of structurally robust MHP devices.

Late News: Shallow Dopants and Deep Defects in Halide Perovskites John L. Lyons[1] and Michael W. Swift[2]; [1]U.S. Naval Research Laboratory, United States; [2]ASEE Fellow residing at the Naval Research Laboratory, United States

Chemical doping of lead halide perovskites remains challenging. One major issue is that commonly considered dopants (such as bismuth, substituting on the lead site) have high ionization energies, making them ineffective. Our recent density functional theory (DFT) calculations indicate that the deep donor behavior of bismuth (along with antimony) is due to their *p* orbitals giving rise to mid-gap states. Furthermore, the *s* orbitals of gallium dopants lie deep in the $CsPbBr_3$ band gap, also leading to deep defect behavior. In contrast, the group 3 elements scandium and yttrium do not give rise to such mid-gap states, and are thus shallow donors when incorporating on the Pb site. These donors are stable relative to other configurations and have modest formation energies. Analogous behavior is found in $FAPbI_3$ and $CsPbCl_3$, indicating that *n*-type conductivity could be achieved in lead halide perovskites with Y and Sc dopants [1].

A second issue is the potential for native defects (such as vacancies and interstitials) to compensate intentional dopants. Via a thorough first-principles inventory of native defects and hydrogen impurities, we determine the stability and electronic behavior of potential compensating species. We find that a number of relevant species exhibit deep levels (most notably the bromine interstitial and hydrogen interstitial) challenging the idea that "defect tolerance" in these materials is due to the shallow character of native defects [2]. Guided by the theoretical identification of these defects with DFT, growth efforts can take steps to mitigate trap-assisted non-radiative recombination to boost efficiencies of lead halide perovskites and aid in efforts at achieving controllable electrical conductivity.

Very Fast and Very Slow Ionic Processes and Charge Accumulation in Lead Halide Perovskite Solar Cells Brian ORegan[1], Michael McGehee[2], Caleb Boyd[3], Joseph Luther[4], Severin Habisreutinger[4] and Rohit Prasanna[5]; [1]BSL, United States; [2]University of Colorado Boulder, United States; [3]Unternehmertum Venture Capital Partners GmbH, Germany; [4]National Renewable Energy Laboratory, United States; [5]Swift Solar, United States

Using JV scan speeds from 0.01 to 4000 V/sec one can find that seemingly all lead halide perovskite solar cells show considerable photocurrent JV hysteresis somewhere between the 10 ms and 10 second time scales. The JV hysteresis generally shows up as a large change in fill factor (FF) and energy efficiency, although smaller hysteresis can be found in the dark current as well. Mobile ions (vacancies) seem to be able to explain most of the JV hysteresis, although there is still argument about the maximum mobility of the ions in relation to the fastest observed hysteresis.
In many perovskite cells, the fast JV hysteresis coexists with a reversible day/night cycle in the short circuit current (Jsc) and FF. This day night cycle varies strongly between cell types and fabrications, ranging from degradation in the dark and recovery in the light, to the complete opposite. I will discuss new measurements of the amount of excess charge stored during an 8 hour illumination cycle at the maximum power point (MPP), at short circuit, and at the MPP voltage in the dark. After an 8 hour illumination cycle, we find that measurable current continues to flow out of the cell for up to 10 hours after the light and voltage are removed. The amounts of stored charge can be large (e.g. up to 1% of the Pb ions in the absorber) without causing irreversible damage to the film. In some cells the amount of charge stored for a given illumination time is linearly related to the loss of efficiency over that time. I will discuss some experiments on the chemical nature and physical location of this charge, but, sadly, will not give a definitive answer.

Revealing Humidity-Dependent Mechanical Properties in Halide Perovskites Isaac Buchine[1], David Cahen[2,1], Sidney R. Cohen[2] and Irit Rosenhek Goldian[2]; [1]Bar-Ilan University, Israel; [2]Weizmann Institute of Science, Israel

Effects of humidity on the optoelectronic properties and degradation mechanisms of ABX_3 Halide Perovskites, HaPs, where A= Methylammonium (MA), Formamidinium (FA), or Cesium (Cs), B= Pb, X=Chloride (Cl), Bromide (Br), or Iodide (I), have been investigated thoroughly. However, no studies exist on how humidity influences their *structural and mechanical integrity*, which is critical for their successful integration into future technologies. The out-of-plane mechanical properties of HaPs are known to depend strongly on the Pb-X bond, but the effect of humidity remains ill-explored. This presents a difficulty in engineering devices, containing these materials, that are meant to function over a range of ambient conditions, as well as casting doubt on the generality of fundamental behavior, measured under uncontrolled humidity conditions.
Single crystals of five different HaP, $MAPbX_3$ (X = Cl, Br, and I) and $APbBr_3$ (A = Cs and FA) were grown and used to investigate the role that the different A and X ions play for humidity-dependence of mechanical properties. A two-pronged approach employing both instrumented nanoindentation (INI), and atomic force microscopy (AFM)-based nanomechanical measurements were used to measure *in situ* changes in elastic and plastic deformation under different humidity conditions. AFM measurements included both elastic modulus determination using the contact resonance technique and hardness measurements, using the AFM to both apply load to sample and to image the indentation profile in-situ using the same diamond tip. The INI was done at slightly larger loads and inferred the indentation area by standard calibration techniques and not from the imprint image. By combining analysis between AFM and INI methods, we are able to verify the significance of these results from two independent techniques which are based on similar but distinct measurement and analysis procedures.
Our results reveal that for $MAPbCl_3$, $MAPbBr_3$, and $FAPbBr_3$ the elastic modulus (E) increases by 4-10% while the hardness (H) decreases by ~25% when RH (relative humidity) increases from 10% to 60% and that these changes are reversible. E is a measure of the elastic response and H is related to the plastic response. $CsPbBr_3$ and $MAPbI_3$ show negligible humidity dependence within experimental uncertainty, with the latter showing differences between shallow and deep indentations. We propose an explanation for these observations incorporating the interplay between composition, lattice structure, and absorbed H_2O.

2:30 PM EN05.12.05
Strong Spin-Dependent Interactions of Photoexcited Charge Carriers with Magnetic Transition Metal Dopants in $MAPbBr_3$ Jonathan Zerhoch[1], Stanislav Bodnar[1], Timo Neumann[2], Barbara Sergl[1], Lissa Eyre[1] and Felix Deschler[1]; [1]Walter Schottky Institut, Germany; [2]Cavendish Laboratory, United Kingdom

Combining the advantageous electrical and optical properties of semiconductors with magnetic characteristics gives access to extraordinary phenomena and applications. Fully inorganic dilute magnetic semiconductors (DMS) have been known for decades, which show diverse functionalities like control of magnetism by electrical fields. Typically, the material class of DMS is obtained by introducing a substantial number of magnetic ions to an otherwise non-magnetic host semiconductor.
In this work we investigate the magneto-optical properties of the heavily doped hybrid semiconductors $MAPbBr_3$ ($CH_3NH_3PbBr_3$) with circularly polarized broadband femtosecond transient absorption (CTA), from which we find strong interactions between the excited charge carriers' angular momentum and the dopants' spin.
Due to their outstanding optoelectronic properties and high defect tolerance, organo-metal halide perovskites form an ideal system for efficient magnetic doping. We prepared a selection of magnetic perovskites using simple solution processing techniques by doping of the host $MAPbBr_3$ perovskite with three different magnetic ions Mn^{2+}, Co^{2+}, Ni^{2+}. We investigated the fundamental optical, structural and magnetic properties of the perovskites with absorption and photoluminescence spectroscopy, XRD and SQUID measurements. Doping of the host lattice leads in all cases to structural changes and an increase or decrease of the bandgap of several 10 meV for Co^{2+} and Mn^{2+}/Ni^{2+}, respectively. We observe paramagnetic properties for all dopants and different doping concentrations.
To reveal the impact of doping on excitation dynamics, we employ the technique of CTA at cryogenic temperatures down to 4 K and magnetic fields up to 700 mT to gain a better understanding of possible ultrafast processes and coupling mechanisms between the angular momentum of photoexcited charge carriers and the d-electron spin of the dopants. Measuring CTA with different combinations of right- and left-handed circularly polarized pump (λ_{ex} = 515 nm) and probe (super-continuum white light) at variable temperatures and magnetic fields with an exceptional spectral resolution of 0.1 nm enabled us to

precisely compare the energetic shifts and ultrafast dynamics of the charge carriers. For all investigated samples we observed an energy splitting of the CTA spectra for two different circular polarizations of the pump pulse even at zero magnetic field, which is substantially larger for the doped samples. Both, lattice deformations and remanent magnetism due to high doping concentrations could lead to an energetically preferred spin alignment of the photoexcited charge carriers mediated via spin-orbit coupling. We plan to employ transient circularly polarized photoluminescence spectroscopy (CPL) to show if this spin polarization is long-lived and if it will lead to a significant degree of circularly polarized PL, which would be of high interest for future light emitting diode applications.

Defect Densities in Halide Perovskite Thin Films and Single Crystals Johanna Siekmann[1], Sandheep Ravishankar[1] and Thomas Kirchartz[1,2]; [1]Forschungszentrum Jülich, Germany; [2]Universität Duisburg-Essen, Germany

The majority of halide perovskite solar cells are thin film devices.[1] This is not surprising if we look at the simplicity of making devices based on stacks of multiple thin films as opposed to making single crystal solar cells. However, single crystals seem to have some fundamental advantages relative to thin films, because their lack of grain boundaries apparently leads to defect densities that are orders of magnitude lower in single crystals as opposed to thin films.[2] The typically stated data in support of this claim is based mostly on two methods, namely the use of the so-called trap-filled limit in the current-voltage curve of single-carrier devices[3] and the use of capacitance-voltage measurements or related techniques[4,5] to determine defect densities via the width of space charge regions. Both methods have in common that they measure quantities that are affected by the charge density of a defect and not by the defect density itself. An important consequence is that bulk charge densities have to compete with surface charge densities of electrodes to be visible in a measurement. Furthermore, for a charge density to be visible in any measurement, the charge density has to be high enough that its associated Debye length is at least on the order of the film thickness (or shorter). Otherwise, the charge density will be unable to affect the electrostatic potential over the available distance and in consequence will be unable to visibly affect the current or capacitance measured in a device. From these simple electrostatic arguments, one can conclude that charge densities have to exceed a certain threshold value that depends on the permittivity ε and thickness d of the sample. Actually, both arguments noted above lead to a detection limit that could be expressed by noting that the density of charged defects has to exceed a minimum value $N_{\mathrm{min}} \propto \varepsilon/d^2$ that inversely depends on d^2. By doing a meta-analysis of literature data, we note that nearly no reported defect density of a thin film done by a charge-detecting method exceeds threshold criteria for both methods that are derived analytically and verified numerically. Only few of the single crystal data exceed the threshold, suggesting that defect densities might be much lower than originally thought in many cases and further suggesting that there is no reliable trend that would support the presence of superior electronic properties in single crystals. Furthermore, we use numerical simulations to identify possible reasons that may lead to the possible misinterpretation of data as being representative of a certain defect density. We find that in particular, small variations of injection barrier heights can lead to apparent trap-filled current regimes that may cause literature data to follow the detectability limit. Finally, we also do a meta-analysis of charge carrier lifetimes and non-radiative voltage losses that does not show any indication of a trend favoring single crystals which one would expect if there was a strong trend in defect densities.

Performance Losses Due to the Diffusion of Back Contact Metals in Perovskite Solar Cells Alexander V. Bordovalos, Biwas Subedi, Lei Chen, Marie Tumusange, Zhaoning Song, Yanfa Yan and Nikolas J. Podraza; University of Toledo, United States

Organic-inorganic metal halide ABX_3 (A: methylammonium-MA, formamidinium-FA, cesium-Cs; B: lead-Pb, tin-Sn; X: iodine-I, bromine-Br, chlorine-Cl) perovskite-based photovoltaics (PV) are of great interest in the field because they can be manufactured in a low-cost solution process, have desirable opto-electronic properties, and can produce high efficiency devices. When silver (Ag) is used as a back contact metal in perovskite solar cells, it can diffuse into the underlying charge transport and absorber layers of the device leading to optical and electronical losses. Mitigating these losses is essential to developing higher efficiency devices. Perovskite solar cells consisting of nominally soda-lime glass / tin doped indium oxide (ITO) /PEDOT:PSS / $MA_{0.3}FA_{0.7}Sn_{0.5}Pb_{0.5}I_3$/ fullerene($C_{60}$) / bathocuproine (BCP) with Ag and copper (Cu) metal back contacts are examined by spectroscopic ellipsometry over the photon energy range from 0.74 to 4.0 eV. The measured ellipsometric spectra are analyzed using a parametric model based upon the complex optical properties and thicknesses for each component layer as well as interfaces between materials. In these devices, it is observed that the metals used as back contact may diffuse into and mix with the electron transport and hole blocking layers, BCP and C_{60}, to form a physically mixed layer consisting of metal, BCP, and C_{60}. To further validate these results and to identify the optical and electronic losses in the device, external quantum efficiency (EQE) simulations are compared to experimental EQE. The physically mixed layer of metal, C_{60}, and BCP near the back contact can substantially absorb back reflected photons from the metal interface, thereby reducing the potential current generation in the perovskite absorber. The presence of this physically mixed layer shows an optical loss of up to 1 mA/cm^2 in terms of short circuit current density. Film stacks of glass/C_{60}/BCP or SnO_2/Ag or Cu are also measured using spectroscopy ellipsometry to study if SnO_2 can prevent diffusion of the back contact metal and prevent optical losses. The optical and electronic losses are quantified from these spectroscopic ellipsometry and EQE measurements for cells with Ag and Cu metal contacts with and without the presence of SnO_2. The film stacks containing SnO_2 shows that it can prevent diffusion of the back contact metal, and EQE simulations with SnO_2 show recovery of some of this optical loss arising from the formation of the physically mixed metal, BCP, and C_{60}.

4:03 PM EN05.13.05
Copper Dopant Incorporation for Bandgap Engineering of $MAPbBr_3$ Perovskite Thin Films with Enhanced Near-Infrared Photocurrent-Response Amr M. Elattar[1,2], Kosei Tsutsumi[1], Kodai Nakao[1], Hiroo Suzuki[1], Takeshi Nishikawa[1] and Yasuhiko Hayashi[1]; [1]Graduate School of Natural Science and Technology, Okayama University, Japan; [2]Ain Shams University, Egypt

Lead-based halide perovskite with B-site doping is an effective strategy to enhance its optoelectronic devices. Herein, we study the B-site doping of $MAPbBr_3$ thin films with copper (Cu^{2+}). Developing doped perovskites, $MA(Pb:Cu)Br_3$, thin films show darkness in their color from yellowish orange color for pristine $MAPbBr_3$ thin film to dark brown color for Cu-doped perovskite thin film, enlarged average grain boundaries area from 0.042 μm^2 for pristine $MAPbBr_3$ to 0.71 μm^2 for 40% Cu-doped $MAPbBr_3$, and lowering in the optical bandgap from 2.32 eV for pristine $MAPbBr_3$ to 1.85 eV for 50% Cu-doped $MAPbBr_3$. The Cu ions incorporation in the perovskite crystal lattice is confirmed by the X-ray diffraction (XRD) and Energy Dispersive Spectroscopy (EDS) measurements. Surprisingly, Cu-rich new phase was observed via EDS measurement at 50% Cu-doped perovskites. This new phase was further confirmed with the appearance of a new XRD diffraction peak which neither related to crystal structure peaks of $MAPbBr_3$ nor initial precursor. The absorption band edge of 50% Cu-doped $MAPbBr_3$ is developed to the near-infrared range. The conductivity of $MAPbBr_3$ increases over three orders of magnitude upon doping. More interestingly, photocurrent measurements of doped perovskites show the generation of band carriers upon excitation at the near-infrared region. This work provides an insight into the importance of doping over phase modulation and tailoring the optoelectronic and electronic properties of halide perovskites for a wide range of efficient optoelectronic devices.

4:06 PM EN05.13.06
Microfluidic Processing of Ligand-Engineered NiO Nanoparticles for Low-Temperature Hole-Transporting Layers in Perovskite Solar Cells Monika Michalska[1], Maciej A. Surmiak[1], Doojin Vak[2], Udo Bach[1] and Jacek Jasieniak[1]; [1]Monash University, Australia; [2]CSIRO, Australia

Perovskite solar cells (PSCs) have recently reached over 25% in power conversion efficiency and are emerging as a promising competitor to silicon technology. The key challenge that remains in further developing of the PSCs is their scaling towards commercial fabrication. Fully printed PSCs are still a major goal for the solar industry. As perovskites are inherently temperature sensitive, a key requirement for printing of these devices are low-temperature processed layers that can form the individual components of a solar cell device. Hole transporting layers (HTLs) among the entire structure are the most problematic ones, where the conventional spiro-MeOTAD, an organic molecule, is too expensive and unstable for commercial applications. Contrarily, inorganic nanomaterials can overcome the limitations of organic HTLs. Nickel oxide (NiO) has been widely used as an HTL in PSCs, however, the processing temperatures of such films is typically >250 °C to achieve sufficient crystallinity. The only way to omit high-temperature post-deposition annealing of solution-processed NiO HTLs is by spin-coating dispersion already containing metal oxide particles. However, for highly efficient perovskite solar cells additional interface engineering also needs to be studied to facilitate the charge transfer. Interestingly, ligand engineering approaches have been comprehensively investigated on a wide range of nanoparticles, yet these research outcomes are not sufficiently applied in perovskite devices. Our motivation was to fabricate NiO nanoparticle-based HTL inks for low temperature deposition, dedicated for perovskite solar cells. To achieve this, we have synthesized fine NiO nanoparticles via heat-up approach. The as-obtained NiO NPs are dispersible in nonpolar solvents, due to oleate (OA) ligands present at their surface. However, these long alkyl chain ligands are not favourable for efficient charge transfer. For that reason, our second aim was to apply ligand modification procedures to improve the hole transfer within the device after removal of long alkyl ligands, and also, to investigate how the introduced ligands impact the charge extraction at the perovskite/HTL interface.
Two different ligand exchange routes were applied, and for the very first time, deposited as NiO HTLs. In the first procedure, a Meerwein's salt Me_3OBF_4, was used where the resulting NiO nanoparticles are stabilized by BF_4^- ligands. The second procedure involved 4-hydroxybenzoic acid (HBA).To assess the performance of the synthesized and modified NiO HTLs we have fabricated PSCs of the inverted architecture. Before the deposition the NiO inks were processed through microfluidic mixer system for improved film morphology. All of the HTL films were annealed at a low temperature <150 °C to remove the residual solvent. Such processing parameters are in line with printing regime, especially on flexible substrates, which is an additional advantage of the developed materials. The fabricated devices exhibited stabilized PCEs of 17.9% and 17.1% for the ligand-exchange NiO BF_4 and NiO HBA HTLs, respectively, which were superior in comparison with control devices harnessing the native surface chemistry (OA) and a postprocessing oxygen-plasma treatment step (PCE of 16.1%). Furthermore, while all NiO HTLs exhibited good photostability factors, a significant enhancement was observed for the ligand-exchange NiO HTLs, which, for NiO-BF4, showed a 0.2% reduction in efficiency over a 300 h testing period compared with 0.9% for the NiO-OA-based PSCs. These findings showcase the importance of ligand engineering of NiO NPs for achieving efficient hole-transporting materials and its prospects for developing low-temperature-processable and high-stability PSCs. Future work will consider the printability of these dispersions to achieve fully printed flexible inverted PSCs.

Low Temperature Solution-Processed Antimony Chalcoiodide Films for Solar Cell Applications Yong Chan Choi; Daegu Gyeongbuk Institute of Science & Technology, Korea (the Republic of)

Despite the remarkable performance of lead perovskite (Pb perovskite) solar cells, many researchers are looking for an alternative to Pb perovskite to overcome its fatal problems, such as instability and Pb toxicity. Antimony chalcoiodides (SbChI, Ch = S, Se) are recently considered as potential absorbers due to their low-toxicity and photovoltaic properties [1].
In this presentation, we introduce a versatile solution-based method for the fabrication of antimony chalcoiodide films. The method consists of two steps: deposition of antimony chalcogenides Sb_2Ch_3 (step I) and its conversion to antimony chalcoiodides SbChI (step II). Antimony chalcogendies were fabricated by $SbCl_3$-thiourea/selenourea based solution approach. Conversion to SbChI was performed by spin coating SbI_3 solution on Sb_2Ch_3 and subsequent heating. Pure phase Sb(S,Se)I films with high crystallinity were obtained at low-temperature of 150–200°C. The absorption, structure, morphology, and electronic structure were controlled by tuning S/Se molar ratio and annealing temperature. In addition, Bi-alloyed SbChI films were fabricated using BiI_3 instead of SbI_3 in step II. Our results demonstrate that two-step solution method is applicable to the fabrication of various chalcoiodides.

Spatial External Luminescence Efficiency of Perovskite Solar Cells Mor Fiegenbaum-Raz[1], Tamir Yeshurun[1], Stav Rahmany[2], Lioz Etgar[2] and Gideon Segev[1]; [1]Tel Aviv University, Israel; [2]The Hebrew University of Jerusalem, Israel

Lead halide perovskites have recently emerged as one of the most promising future candidates for replacing silicon-based photovoltaics. Their unique optoelectronic properties, such as tunable and direct bandgap and high absorbance coefficient, in combination with a low-cost fabrication process, make them promising candidates for the use in next-generation and tandem solar cells. Although their photocurrents are reaching the theoretical maximum, the devices' open-circuit voltage can be improved significantly. Thus, an *operando* characterization method that can map the contributions to the device's photovoltage is called for.
With the progress in device performance, surface and SRH recombination are suppressed, making radiative recombination more dominant. In this process, electron-hole pairs recombine to generate photons that can be either reabsorbed elsewhere within the device or be emitted through photoluminescence. Since the photoluminescence quantum yield (PLQY) and the harvestable voltage are tightly coupled, mapping the contribution to photoluminescence

within the device can inform on the contribution to the buildup of photovoltage within it.
The spatial external luminescence efficiency (SELE) is the probability for a photon absorbed at a specific point in the device to contribute to the measured photoluminescence. The SELE can be extracted by combining wavelength-dependent PLQY measurements with detailed optical modeling. Hence, the SELE maps the contribution of different regions to the device photovoltage. In this contribution we apply SELE extraction to perovskite solar cells. This spatial information can shed light upon different loss mechanisms, quantify surface recombination at the interfaces between the different layers in the device, and discriminate between radiative and non-radiative recombination processes at the surface and in the bulk of the device.

The Effects of PEA Concentration on the Conversion of CsPbBr3 to Stable 2D/3D Perovskite Mmantsae M. Diale, Sadile J. Thubane and Juvet Fru; University of Pretoria, South Africa

While the power conversion efficiencies of perovskite solar cells have exceeded 24.2% in less than a decade of extensive research, the material still suffer from instability due to moisture and high temperatures, hindering scalability and commercialisation. In this work, we have synthesized the $CsPbBr_3$, which is known to have poor controlled microstructures. The perovskite was a 3D hybrid organic-inorganic material, which was then treated further with different amounts of PEABr concentrations (10%, 20%, 40%, 60%, 80% and 100%) to produce a 2D materials of the form $PEA_2Cs_{n-1}Pb_nBr_{3n+1}$. A gradual PL shift from 540 nm ($CsPbBr_3$) to 507 nm (100% PEABr) can be observed, indicating a shift of the distribution of average crystal size to smaller values as the PEABr ratio increases, which in turn indicates the formation of a 2D perovskite. An efficiency exceeding 15% can now be achieved through additive–controlled nanostructure tailoring for 2D perovskites.

Low Energy Ion Irradiation Effect on the Optoelectronic Properties of Perovskite Films Hironori Ogata, Tomoaki Nishimura, Tomohiro Watanuki, Keitaro Kikuchi and Yuki Matsui; Hosei University, Japan

Perovskite solar cells are an important photovoltaic technology with high efficiencies exceeding 20% due to their optimal band gap, large absorption coefficient, and high charge mobilities. One of these challenges is the understanding and control of their defect structures because perovskite compounds are relatively soft ionic crystals and ions are migrating in the crystals relatively low activation energy.
Several research groups have reported on the effects of proton irradiation on perovskite solar cells on perovskite compounds and solar cell characteristics. It has been reported that hardness and self-healing associated with defect formation in perovskite compounds by proton irradiation.
In this study, we have investigated the effect of low energy ion irradiation to both all inorganic and organic-inorganic mixed halide perovskite films on the structure, morophology, optical, electronic properties and photovoltaic properties systematically. Several kinds of halogen ion beam irradiations on the halide perovskite thin films were systematically investigated by using a tandem type ion accelerator with changing acceleration voltages and irradiation time. Detailed experimental results will be reported on the conference.

Late News: Sputtered Nickel Nitride Passivation for Stable Halide Perovskites Inverted Solar Cells Anat Itzhak[1] and David Cahen[1,2]; [1]Bar Ilan University, Israel; [2]Weizmann Institute of Science, Israel

Stability is one of the significant barriers in commercializing halide perovskite, HaP, solar cells, PSCs. Metal oxide (MO) selective contacts have already been shown to improve the stability of PSCs substantially. However, especially the surfaces of, and thus interfaces with MOs are reactive, as they readily adsorb water and or O_2 and form hydroxides when exposed to moist air. Adsorption of hydroxide can change the oxidation states of the MO, forming trap states at the interface with the HaPs and increase the MO reactivity and causing HaP degradation. Furthermore, the oxygen in the hydroxide groups themselves is electro-negative and can react with the methylamine in the HaP compounds, forming PbI_2. We demonstrate RF sputtering of nickel oxide (NiO_x) as a hole transport layer, followed by an ultra-thin nickel nitride passivation layer, which becomes a buffer layer at the interface between the NiO_x and the HaP, deposited on the passivated NiO_x. The thin, amorphous nickel nitride layer suppresses interfacial HaP degradation, as shown by the increased stability of PSCs with a nickel nitride layer. Using RF sputtering to deposit inorganic passivation layers is an innovative step towards a scalable procedure of stable HaP based solar cells.

Late News: Improving Thermal Stability of Perovskite Solar Cells by Suppressing Ion Migration Using Copolymer Grain Encapsulation Yuchen Zhou[1], Yifan Yin[1], Chang-Yong Nam[2] and Miriam Rafailovich[1]; [1]Stony Brook University, United States; [2]Brookhaven National Laboratory, United States

Thermal stability of organic−inorganic hybrid perovskites (OIHPs) remains as one of the critical challenges against the stable operation of perovskite solar cells (PSCs) in direct sunlight with elevated temperatures. Here, we show that the addition of a polystyrene-co-polyacrylonitrile (SAN) copolymer can significantly enhance thermal stability of OIHPs and improve the stability of the corresponding PSCs by suppressing the migration of organic cations in OHIP. The methylammonium lead iodide (MAPI) with SAN incorporated within the perovskite layer featured a superior thermal stability compared to pure MAPI without SAN, only displaying an average of 5−15% decrease in PCE even after continuous thermal aging for 24 h at 100 °C. The secondary ion mass spectrometry revealed that the thermal degradation of the pure MAPI was largely associated with MA+ out-migration. Conducting atomic force microscopy analysis further indicated that the incorporated SAN led to a suppression of ionic currents present at the grain boundaries of the perovskite film, which was understood by high immiscibility between SAN and MA+ components as confirmed by the experimentally estimated Flory−Huggins parameter between them. This study newly identifies a promising potential of using polymer grain encapsulation for enhancing thermal stability of OIHPs and their solar cell performance by suppressing the outdiffusion of cationic organic components.

4:27 PM EN05.13.17
Evaluation of Electron-Phonon Coupling in Halide Perovskites for Innovative Device Applications Yasuhiro Yamada[1], Yuto Kajino[1], Takumi Kimura[1], Hirofumi Mino[1], Kenichi Oto[1], Hidekatsu Suzuura[2] and Yoshihiko Kanemitsu[3]; [1]Chiba University, Japan; [2]Hokkaido University, Japan; [3]Kyoto University, Japan

Lead halide perovskites attract growing attention because they are promising for applications to solar cells, light-emitting diodes, and various optoelectronic devices. In recent years, we have demonstrated their unique optical properties, such as long excited-state lifetime and high photoluminescence quantum efficiency [1-7], which attribute to the excellent performance of the perovskite-based devices. In contrast, the carrier transport characteristics of this class of materials are poor compared with those of conventional semiconductors; the reported carrier mobility is below 100 cm^2/Vs at room temperature, which is a two-order magnitude smaller than that of GaAs. The origin of such a low carrier mobility has been discussed in terms of polarons due to large electron-phonon interactions. Moreover, it has been pointed out that polarons are also involved in the photo-accelerated ion migration and photodegradation. Therefore, it is essential to gain a thorough understanding of the nature of polarons in halide perovskites. However, the polaron formation mechanisms and its impact on the optoelectronic properties are still under active debate.
Determination of carrier masses is the direct way to discuss the polaron effect. The magneto-reflectance measurement is one of the most powerful tools to estimate carrier mass through the observation of Landau levels and high-order exciton Rydberg states. We recently performed high-sensitivity measurements using circular dichroism of reflectance at low temperatures (1.5 K) under relatively weak magnetic fields (< 7T), where the cyclotron energy is sufficiently small compared with the LO phonon energy [8]. We successfully observed the higher-order Rydberg exciton states and Landau levels in $CH_3NH_3PbX_3$ [X = I, Br, and Cl], which enabled us to determine the reduced mass and the exciton binding energy accurately. For $CH_3NH_3PbBr_3$ and $CH_3NH_3PbI_3$, we estimated heavier reduced mass compared with that reported in the previous strong-field experiments, which evidences the polaron mass enhancement. The degree of mass enhancement agrees well with the prediction by the Fröhlich large polaron model. This means that the carrier mass is enhanced only by 50 % even in the case of coupling constant $\alpha = 3$ (strong coupling regime), while $\alpha < 3$ holds for lead halide perovskites. Therefore, the large polarons might not be the origin of the small carrier mobility.
To confirm this idea, we performed highly sensitive carrier transport measurements using an AC photo-Hall technique [9]. This technique enables us to estimate carrier mobilities even in highly insulating materials. We find that both electron and hole mobilities are significantly enhanced by photo-doping and exceed 300 cm^2/Vs, which are comparable to the electron Hall mobilities of conventional inorganic semiconductors.
In the presentation, we will show the detailed experimental results and discuss the impact of polarons on optoelectronic properties of halide perovskites. We will also discuss the possible device application utilizing the strong electron-phonon interactions of lead halide perovskites.

Robust, Ultra-fast, Downscalable and Optically Programmable Resistive RAM with Three Dimensionally Integrated Perovskite Quantum Wire Array Swapnadeep Poddar, Yuting Zhang and Zhiyong Fan; The Hong Kong University of Science and Technology, Hong Kong

Resistive RAMs(Re-RAMs) have come to the fore as a promising candidate for next generation information and data storage because of their strikingly fast speed, prolonged data retention ability and high storage density. In a first, we developed an electrochemical metallization based Re-RAM with three-dimensionally integrated single-crystalline perovskite (methyl ammonium lead iodide) quantum wire (PQW) array rooted in a nano-engineered porous alumina membrane (PAM), as the switching medium. The PQWs grown by a vapor-solid-solid-reaction (VSSR) process was sandwiched between top silver (Ag) and bottom aluminium (Al) or gold (Au) contacts respectively. The PQW based Re-RAM demonstrated ultra-fast switching speed of 100 ps which is a record for perovskite Re-RAMs and also among the fastest for all types of Re-RAMs reported. The ultra-fast switching speed was ascribed to the engendered ionic (Ag^+) and electronic mobility and subsequent accelerated filament formation within the body of the monocrystalline PQWs. The PQW Re-RAM demonstrated a high ON/OFF ratio of 10^7, estimated data retention > 2 years and record high (for all perovskite Re-RAMs reported) cyclic endurance of 6×10^6 cycles. The excellent retention and endurance performance was attributed to the material and electrical stability instilled by the electrically insulating PAM to the PQWs. Compared to Re-RAMs based on perovskite nanowires of larger diameter (around 250 nm), the PQWs with diameter around 10 nm, portrayed a much lower proclivity of high resistance state (HRS) degradation to low resistance state (LRS) upon multiple cycles of operation owing to the relatively less number of remnant filamentary Ag paths formed due to prolonged cyclic operations. This rendered the PQW devices to be more electrically robust and power efficient for longer cycle operations. Also, utilizing the ultra-high density ($2\times10^{11}/cm^2$) of the PQWs, a 14 nm lateral dimension ultra-small memory cell was constructed. Coupled with multi-bit storage, an effective device footprint area of 76.5 nm^2 was achieved for single bit storage. As a concept proof, an 8×8 Re-RAM crossbar array device was fabricated which demonstrated temporally robust alphabetic data storage, with a unique metal-semiconductor-insulator-metal (MSIM) architecture to alleviate the sneaky path problem. The MSIM scheme based on quasi-self-selecting elements, exhibited a strong potential for unhindered scalability in the future, a problem often faced with integrating external selecting diodes and transistors. The PQW Re-RAMs also responded to light stimuli, demonstrating optical programmability of the LRSs. These intriguing characteristics, in conjunction, present an attractive potency of PQW Re-RAMs as a promising technology for multifunctional non-volatile memories with broad applications in future storage and advanced computing systems.

4:33 PM EN05.13.20
The Impact of the Rashba, Dresselhaus, and Overhauser Effects on the Magneto-Optical Properties of Bulk $MAPbBr_3$ Perovskites Alyssa Kostadinov-Mutzafi[1], Efrat Lifshitz[1] and Liang Z. Tan[2]; [1]Technion- Israel Institute of Technology, Israel; [2]Lawrence Berkeley National Laboratory, United States

Halide perovskites have been at the forefront of scientific and technological interest for a decade, triggered by the discovery of their noteworthy performance in solar cells, light sources, X/γ-ray detectors, and display devices. Furthermore, the potential for exploiting spin-properties of the halide perovskites for applications in spin-electronic and spin-optical devices has emerged, based on the materials' spin-orbit coupling, Rasbha/Dresselhaus effects, optically-induced spin polarization, and relatively long spin coherence and lifetime, compared to classic semiconductors. The current work presents optical experimental evidence for an intriguing phenomenon, related to the anisotropy of Rashba/Dresselhaus effects. The study explored different luminescence processes in a single bulk crystal of $MAPbBr_3$, using magneto-photoluminescence spectroscopy, monitored along several different crystallographic directions. The photoluminescence spectra were dominated by dual exciton emission peaks, each exhibiting a highly non-linear response to a magnetic field with an anisotropy from $-B_0$ to $+B_0$, a strong dependence on the axis of observations (parallel or perpendicular to a crystallographic symmetry axis) and on the detected spectral region. A theoretical model, implementing a dominant anisotropy in Rashba/Dresselhaus terms, anisotropy in the Landé g-factors, and a contribution from an Overhauser effect- the hyperfine interaction, corroborated the experimental results. Even though the

Rashba/Dresselhaus effects vary from location to location on the crystal, they show reproducible features such as MPL dips at low magnetic fields, and facet-dependent MPL trends at high magnetic fields. Our work shows that these are consequences of a multi-component Rashba/Dresselhaus effect and g-factor anisotropy. The Rashba/Dresselhaus couplings likely arise from different nano-crystallinities within the bulk of halide perovskites, such as grain boundaries.

***CW* Laser Deposition Yields Smooth, Oriented Pb Halide Perovskite Films** Naga Prathibha Jasti, Shay Tirosh and David Cahen; Bar Ilan University, Israel

Opto-electronic and mechanical properties of Pb Halide Perovskite (HaP) thin films, as well as ways to contact them, will be influenced strongly by morphology, and, for several physical properties, by crystallographic orientation. Thus, a method to grow smooth, well-oriented thin films in a pre-selected orientation in a scalable and potentially high-throughput way, is of interest.
We report that highly oriented, smooth HaP films, especially of methylammonium lead- bromide ($MAPbBr_3$) and -iodide ($MAPbI_3$) can be deposited by CW laser ablation. HaPs were time and again shown to be different from conventional (inorganic) semiconductors like Si, GaAs, CdTe, CIGS, both in terms of which preparation methods give high quality material and in their physical properties. While pulsed laser-based synthesis / deposition methods have been reported, our finding that a *low power continuous* laser (orders of magnitude less than the equivalent power used in pulsed laser, and significantly below that of flash deposition/annealing), can yield highly oriented, relatively smooth thin films on FTO (~ 20 nm rms) and Si (~3 nm rms) substrates of $MAPbBr_3$ (001) and $MAPbI_3$ (110), using their single crystals as targets, adds to the HaP surprises. The quality and homogeneity of the thin films were checked with XRD, AFM and Photoluminescence. The deposition is solvent-free, at room temperature and works in vacuum levels comparable to those used in laboratory physical vapor deposition (PVD). Further properties of the materials, and timer-permitting, of devices will be described.

4:39 PM EN05.13.22
Late News: Highly Stable and Red-Shifted Colloidal CsPbI3 Perovskites Quantum Dots with Photoluminescence Quantum Yield Efficiency Almost 100% Miguel Honorato[1], Wilma Luna[2], Alicia Alvarado[2], Ramon Carriles[3], Alejandro Torres[4], Miguel Vallejo[5], Gabriel Ramos[3] and Elder De la Rosa[2]; [1]Universidad DE La Salle Bajio, Mexico; [2]Universidad De La Salle BAjio, Mexico; [3]Centro de Investigaciones en Optica, Mexico; [4]UANL, Mexico; [5]Universidad de Guanajuato, Mexico

Recently, inorganic perovskite quantum dots (PQDs) have attracted a lot of attention for optoelectronic and photovoltaics applications because of tunability and stability. The case of $CsPbI_3$ deserves special attention for solar cells and LEDs devices. The inclusion of Cs and the small size of PQDs improve stability, however absorption band is blue-shifted that represent a drawback for solar cells design and LEDs. Therefore, bigger PQDs to redshift the absorption band with better stability and high photoluminescence quantum yield (PLQY) are desired. However, bigger nanocrystals are unstable and transform into yellow phase non-perovskite that is inactive under photoexcitaiton. Here in this work, we report the synthesis of $CsPbI_3$ QDs with a PLQY ~100% at 690 nm and FWHM~31nm with a reduction lower than 10% of efficiency after 12months, synthetized by hot injection at 170^{o}C. It is analyzed in detail the effect of precursors and temperature on the synthesis process and evaluates the spectroscopic properties such as decay time, band gap and emission. PQDs were tested to design an LED and solar cells devices showing excellent performance, and then offering good opportunities for non-linear photonics and photoelectronic devices.

4:42 PM EN05.13.25
Impact of Carbon Nanotubes Growth on the Interfacial Composition and Energetics of Organic Metal Halide Perovskites Javid Hajhemati[1], Rachelle Ihly[2], Mengjin Yang[2], David Moore[2], Roberto Felix Duarte[3], Regan Wilks[3], Kai Zhu[2], Jeffrey Blackburn[2], Marcus Baer[3], Joseph Berry[2] and Philip Schulz[1]; [1]CNRS, UMR 9006, Institut Photovoltaïque d'Ile-de-France (IPVF), France; [2]National Renewable Energy Laboratory, Chemical and Materials Science Center, United States; [3]Helmholtz Zentrum Berlin für Materialien und Energie GmbH (HZB), Germany

Halide perovskite (HaPs) solar cells have shown outstanding progress in performance in recent years, exceeding power conversion efficiency of 25%, thus promising to be a strong competitor for the current silicon solar cell technology. Limits to this trend originate from non-radiative recombination of electrons and holes as the dominant loss processes in photovoltaics. This phenomenon originating from defect states which arise imperfection of the crystalline quality in the bulk, and particularly at the interfaces of photovoltaic devices. Remarkably, the quality of the perovskite film as the light-harvesting materials has been improved to such a high level with accordingly long carrier diffusion lengths that recombination in the bulk of perovskite layers does not significantly limit the functionality of the device. Therefore, study of the defects states at the surface and at the interfaces in the layer stack has advanced to the center of attention. [1] Here, we focus on one of these interfaces and discuss the chemical properties and energy level alignment at the interface between HaPs absorber and carbon nanotube charge transport layers.
Single-walled carbon nanotubes (SWCNT) with their unique optoelectronic properties, show a strong potential to be integrated in various architecture of perovskite solar cells.[2] SWCNTs with high charge carrier mobility improve carrier collection which in turn, enhance HaPs solar cell performance. In addition, their high optical transmission in the visible range makes them an excellent candidate for charge transport layer in HaPs solar cells. Tunable electronic properties, via changing the design of the tubes and the doping characteristics, make them suitable for both electron and hole transport layers.
In the present study, we report on the electronic and chemical properties and the energy level alignment at the interface between HaPs materials, $MAPbI_3$ and $MAPbBr_3$, and SWCNTs overlayers. The SWCNT layers were grown by ultrasonic spray deposition at various thicknesses on top of the perovskite absorber. We then used synchrotron-based hard x-ray photoemission spectroscopy (HAXPES) to investigate the electronic characteristics and compositional gradient of the two systems at 2 keV and 6 keV excitation energy. HAXPES measurement provides similar features of the target layer as soft X-ray photoemission spectroscopy (XPS). However, the higher kinetic energy of the emitted electrons in HAXPES increases the information depth and therefore allows us to selectively probe the immediate interface and sub-surface region, respectively.
Our results show generally different surface and interface electronic and chemical characteristics between $MAPbI_3$ and $MAPbBr_3$ before and after SWCNTs film growth. We observe selective core level peak shifts which we attribute to the formation of new species at the interface. Furthermore, the compositional study shows the distribution of elements is different between buried and topmost perovskite layer for $MAPbI_3$ and $MAPbBr_3$ upon deposition of the SWCNT, respectively. These gradients result in deficiency and/or surplus of the perovskite components that in turn affect the landscape of interface defects and consequently the device performance.

Study of Capacitive Behaviour of CuI Passivated Perovskite Solar Cells Bidisha Nath, Praveen C Ramamurthy, Debiprosad R. Mahapatra and Gopalkrishna Hegde; Indian Institute of Science, India

Methylammonium lead iodide ($MAPbI_3$) perovskite has shown high defect tolerance. This is well known that defects in the perovskite absorber layer hinder the power conversion efficiency (PCE) of perovskite solar cells in approaching the Schockley-Queisser limit. Understanding the effect of defects in the performance of the perovskite solar cells is a very interesting area and needs further exploration.
Different types of intrinsic defects (vacancies, substitutions, and interstitials) are possible in $MAPbI_3$. Sources of defects in the perovskite layer can be from impurities. Even grain boundaries are considered as sources for high defect densities in solution-processed polycrystalline $MAPbI_3$ perovskite films. The quality of the films depends on factors like the purity of the precursors, solvents, process parameters, crystal growth, etc. The defect levels of both point and structural defects can be the contribution of breaking and addition of bonds i.e., wrong bonds or dangling bonds.
Cuprous iodide (CuI) has attracted extensive attention in p-i-n structured perovskite solar cells as a hole transport layer because of its high transmittance, optimal band matching, and ease of processibility. CuI has been used as the passivating material to improve the film quality by reducing defects. Cu^{2+} is expected to passivate the defects because of its small size and also prevent iodine from migrating from its place. I^- ion may help to overcome iodine deficiency caused due to ion migration. Iodine defects are much easier to create because of their low formation energy.
Passivation of defects and imperfections is expected to cause a reduction in ion migration to achieve improved efficiency and stability. J-V performance of the devices was analysed under dark and light conditions. There is no change in the crystal structure as confirmed from the XRD analysis. High intensity of PL peaks has been obtained in the passivated film which is related to more band-to-band recombination i.e., less number of traps in the film. Since the charge carrier density is different for passivated and non-passivated perovskite film, a difference in the capacitive behaviour of the films is expected. The capacitive behaviour is related to charge transport and charge accumulation. Hence analysis of the capacitive behaviour of the devices under the dark and light has been carried out to understand the change in polarization behaviour because of the addition of passivation material.

4:48 PM EN05.13.28
Hybrid Atomic Layer Deposition (ALD) for Deposition of Halide Perovskites Jacob Vagott, Kathryn Bairley, Carlo Andrea Riccardo Perini, Andres Felipe Castro Mendez, Christian Jamison and Juan Pablo Correa Baena; Georgia Institute of Technology, United States

Perovskite solar cells (PSCs) have quickly risen in efficiency since their initial fabrication in 2009, with the current record power conversion efficiency (PCE) being over 25%. Quickly approaching the Shockley—Queisser limit of 33% for single-junction solar cells, focus on stability and scalability has become crucial. While solution deposition of the perovskite absorber layer by spin-coating has resulted in the highest efficiency devices, vapor deposition methods have shown promise and may help resolve both the stability and scalability problems that PSCs are currently facing. Atomic layer deposition (ALD), as a vapor deposition process, provides advantages such as fine thickness control, improved conformity and uniformity, and the ability to be incorporated into existing industrial processes such as roll-to-roll manufacturing. The stoichiometry of the perovskite may also be easily tuned through manipulation of the precursor doses. This work focuses on depositing perovskite through a two-step ALD/ molecular layer deposition (MLD) hybrid process, with ALD referring to the inorganic aspects of the process and MLD incorporating organic materials. The first step, which we have recently achieved, is to deposit a conformal lead iodide film which may be converted to methylammonium lead triiodide ($MAPbI_3$) through exposure to methylammonium iodide (MAI). For the lead precursor, $Pb(tmhd)_2$ was chosen due to its adequate vapor pressure at relatively low source temperatures (less than 200°C) and higher reactivity when compared to other commonly utilized lead precursors such as $Pb(acac)_2$. HI (aq) was chosen as the iodine precursor due to its high vapor pressure and reactivity. The precursors involved are easily accessible through commercial means and do not require any additional processing before use. The second step, which we are currently developing, involves the introduction of a third precursor within every cycle of the previous recipe, which would allow for an effective ALD/MLD process for $MAPbI_3$. Once we are able to deposit highly uniform perovskite thin films by ALD/MLD, this will allow us the ability to deposit 2D perovskite passivation layers which will help improve stability by decreasing defects at the perovskite/charge transport layer interface. This will increase moisture and thermal stability in the PSCs while also being a scalable process.

Revealing 2D/3D Interface Energetics for Efficient and Stable Perovskite Solar Cells Giulia Grancini; University of Pavia, Italy

Engineering interfaces in perovskite solar cells is nowadays paramount in the optimization of multilayer perovskite device stack. This stem true for multi-dimensional (2D/3D) perovskite based solar cells, where high efficiency can be combined with promising device durability. However, the exact function of the 2D/3D interface in controlling the device behaviour and the interface physics therein are still vague.
Here I will discuss the 2D/3D functions which can simultaneously act as surface passivant, electron blocking layer, and driving efficient and selective charge extraction. In particular, I will demonstrate that the exact knowledge on the interface energetics is crucial to obtain for a smart interface engineering. As an example, I will discuss the case of thiophene-based 2D perovskite/ 3D perovskite interfaces forming a p-n junction. This leads to a reduction of the electron density at the hole transport layer interface and ultimately suppress the interfacial recombination. As a consequence, we demonstrate that photovoltaic devices with enhanced fill factor (FF) and open-circuit voltage (VOC) of 1.19V which approaches the potential internal Quasi-Fermi Level Splitting (QFLS) voltage of the perovskite absorber, nullifying the interfacial losses. We thus identify the essential parameters and energetic alignment scenario required for 2D/3D perovskite systems in order to surpass the current limitations of hybrid perovskite solar cell performances. This knowledge turns fundamental for device design, opening a new avenue for perovskite interface optimization.

Colored, Stable and Flexible Co-Evaporated Perovskites Solar Cells and Minimodules Jia Li, Hao Wang, Enkthur Erdeebileg, Herlina Dewi, Nripan Mathews, Subodh Mhaisalkar and Annalisa Bruno; Nanyang Technological University, Singapore

Metal-halide perovskites are one of the most promising active materials for photovoltaic and light-emitting technologies, due to their excellent optoelectronic properties and fabrication versatility. Within a decade, perovskite solar cells (PSCs) have achieved record power conversion efficiency (PCE) of 25.6% [1], for active areas smaller than 1 cm^2, and a constantly improving operational stability [2-5]. This rapid progress has triggered the interest in transferring the existing technology from small area devices into large-area perovskite modules, necessary for industrial development.

Recently we have demonstrated highly efficient, large-area, planar PSCs where the $MAPbI_3$ perovskite layer has been deposited by thermal co-evaporation of PbI_2 and MAI. The high-quality co-evaporated perovskite thin films are uniform over large areas showing low surface roughness, and a long carrier lifetime. The high-quality perovskite of the thin films translates PSCs with PCE above 20% in both n.i.p [6, 7] and p.i.n [8] configurations, and impressive thermal and environmental long-term stability [9] even without encapsulation. Furthermore, the first co-evaporated mini-modules achieved record PCEs of 18.13% and 18.4% for active areas of 20 cm^2 [6] and 6.4 cm^2 [10]
At the same time, looking forward to tandem integration and building-integrated photovoltaics we have also developed colored semi-transparent PSCs and mini-modules with transparency above 75% in near-infrared for all the range of colors realized.
These results represent a significant step towards the development of high-quality large-area perovskite solar cells and mini-modules, one of the main requirements for the commercialization of the technology.

Efficient, Stable and Scalable All-Perovskite Tandem Solar Cells Hairen Tan; Nanjing University, China

Organic-inorganic halide perovskites have received widespread attention thanks to their strong light absorption, long carrier diffusion lengths, tunable bandgaps, and low temperature processing. Single-junction perovskite solar cells (PSCs) have achieved a boost of the power conversion efficiency (PCE) from 3.8% to 25.5% in just a decade. With the continuous growth of PCE in single-junction PSCs, exploiting of monolithic all-perovskite tandem solar cells is now an important strategy to go beyond the efficiency available in single-junction PSCs. However, their actual efficiencies today are diminished by the subpar performance of mixed lead-tin narrow-bandgap subcells. We firstly reported a strategy to reduce Sn vacancies in mixed Pb-Sn perovskites that use metallic tin to reduce the Sn^{4+} to Sn^{2+} via a comproportionation reaction. We increased thereby the charge carrier diffusion length in narrow-bandgap perovskites from sub-micrometer to 3 micrometers. We further reported simultaneous enhancements in the efficiency, uniformity and stability of narrow-bandgap subcells using strongly-reductive surface-anchoring zwitterionic molecules. The zwitterionic antioxidant inhibits Sn^{2+} oxidation and passivates defects at the grain surfaces in mixed lead-tin perovskite film, enabling an efficiency of 21.7% (certified 20.7%) for single-junction solar cells. We obtained a certified efficiency of 24.2% in 1-cm^2-area all-perovskite tandem cells, and in-lab PCEs of 25.6% and 21.4% for 0.049 and 12 cm^2 devices, respectively. The encapsulated tandem devices retain 88% of their initial performance following 500 hours of operation under one-sun illumination in ambient conditions.

8:00 PM *EN05.11/EQ17.09.04
Efficient and Stable Tandem Solar Cells Enabled by Wide-Bandgap Perovskites Prepared with Anion-Engineered 2D Additives Daehan Kim[1], Hee Joon Jung[2], Ik Jae Park[3], Vinayak Dravid[2], Jin Young Kim[3], Kai Zhu[4], Dong Hoe Kim[4,5] and Byungha Shin[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Northwestern University, United States; [3]Seoul National University, Korea (the Republic of); [4]National Renewable Energy Laboratory, United States; [5]Sejong University, Korea (the Republic of)

Perovskite photovoltaic technology has advanced substantially, with the present record efficiency for single-junction devices reaching > 25%. One of the most promising strategies for commercializing these devices is to apply a perovskite top cell in tandem with a Si bottom cell to reach ultrahigh efficiency beyond the Shockley-Queisser limit for single-junction devices. The ideal band gap for the tandem configuration is ~1.67 to 1.75 eV for the top cell and 1.12 eV for the bottom cell, which, fortuitously, is the Si band gap. The band gap of perovskites can be tuned by (partial) replacement of iodine anions with bromine or chlorine. However, the replacement of I with Br by more than 20%, which is necessary to enlarge the band gap to ~1.7 eV, leads to stability issues under illumination through phase separation that forms I-rich and Br-rich structures. One approach to stabilize the perovskite is to create a two-dimensional (2D) phase in which sheets of $[PbX_6]^{2-}$ octahedra are separated by an excess number of long-chain (or aromatic) molecules that act as a passivation agent. Common long-chain or aromatic molecule-based 2D additives include n- butylammonium iodide (n-BAI) and phenethylammonium iodide (PEAI). Most of the recent studies have focused on the cation components of the 2D additives rather than focusing on the anions. We developed a 2D-3D mixed wide band gap (1.68 eV) perovskite using a mixture of thiocyanate (SCN) with the more conventional choice, iodine. Through a careful application of atomic resolution transmission electron microscopy, we demonstrated that electrical and charge transport properties as well as the physical location of 2D passivation layers can be controlled with anion engineering of the 2D additives. Moreover, we can use this approach to extend light stability and to improve device performance. For a perovskite device, we achieved a PCE of 20.7% that retained > 80% of its initial efficiency after 1000 hours of continuous illumination in working conditions. For a monolithic 2T perovskite/Si tandem solar cells, the champion 2T tandem device achieved a PCE of 26.7%. If time permits, I will also discuss our recent progress in perovskite/$Cu(In,Ga)Se_2$ tandem solar cells.

Metastability and Durability of Perovskite Solar Cells Anita W. Ho-Baillie; The University of Sydney, Australia

One of the challenges of perovskite solar cells is its instability. I will talk about our work on understanding intrinsic stability of perovskites and meta-stability of perovskite solar cells and strategies for boosting perovskite solar cells' durability against thermal extremes and humidity. Our perovskite solar cells were the first to exceed the strict requirements of International Electrotechnical Commission standards for thermal cycling damp heat and humidity freeze. Such a major breakthrough represents an important step towards commercial viability.

8:30 AM *EN05.14.01
Nanosheet-Based Interfacial Modifications for High Performance Planar Perovskite Solar Cells Tsutomu Miyasaka; Toin University of Yokohama, Japan

Planar or semi-planar type perovskite photovoltaic (PV) cells have been developed with various carrier transport materials in normal and inverse structures. Planar structures could be cost-efficient in device manufacture compared with mesoporous ones because of simplified layered structures in which deposition of a metal oxide electron transport layer (ETL) is replaced with a hole-blocking thin surface layer covering the electrode substrate. Successful modification of the electrode surface with organic or inorganic molecular layers as hole-blocking nanosheet materials leads to enhancement of efficiency and stability of the perovskite devices. Hysteresis in current-voltage (J-V) characteristics is also suppressed as a result of well-balanced electron/hole transports being accompanied by an increase in open-circuit voltage (Voc). As an inorganic nanosheet, thin films (<10 nm) of amorphous metal oxides such as TiOx and SnOx are effective in creating a void-less compact interlayer to connect ETL and perovskite. In fabrication of $CsPbI_2Br$-based semi-planar photovoltaic cells, we modified the surface of SnO_2 ETL with an amorphous SnOx (<5 nm) as an interlayer for junction of $CsPbI_2Br$ layer. Using a dopant-free polymer hole-transport layer (HTL), the $CsPbI_2Br$ device yielded a power conversion efficiency of 17% with a high Voc reaching 1.42V.[1] A reference device without the SnOx interlayer gave a poor J-V performance with a large hysteresis and a low Voc (<1.2V), indicating the essential role of the interlayer. Another example of inorganic nanosheet is MXene, a 2D layered material comprising Ti_3C_2. We treated a colloidal solution of MXene by oxidation to form nanosheets of HO-$Ti_3C_2T_x$, which show semiconductivity suitable for ETL. Thin layer (<20 nm) of the oxidized MXene works as a good ETL in a planar device with efficiency over 18%.[2] Efficiency reaches more than 20% when HO-$Ti_3C_2T_x$ is hybridized with SnO_2, which chemically interacts HO-$Ti_3C_2T_x$ via oxygen bonding. Being mechanically and thermally robust, MXenes are promising nanomaterials to modify the function of heterojunction interfaces. Organic small molecules also serve as modulators to passivate the defects at the junction interface. Among various molecules, we found an organic peroxide, artemisinin (water-insoluble anti-malarial drug), works to modify the interface of SnO_2 ETL and multi-cation perovskite ($Rb_{0.05}Cs_{0.05}(FA_{0.83}MA_{0.17})_{0.9}Pb(I_{0.95}Br_{0.05})_3$).[3] This redox-active molecule is considered to interreact with the oxide surface and lead cation in passivation process. Artemisinin-based passivation was applied to the SnO_2-perovskite interface of a plastic film flexible PV device. The device showed decreased hygroscopicity due to the effect of artemisinin, leading to an increase in shelf life. Its effects of enhancing Voc improved the device efficiency up to 21.1% with Voc of 1.13V; the efficiency is the highest value ever achieved for plastic perovskite PV device. All of the above inorganic and organic passivators are chemically and thermally stable non-ionic materials and inactive against their diffusion. Such properties will guarantee structural stability of ultra-thin hole-blocking interlayers involved in defect passivation.

SnPb Based Perovskites for Efficient and Stable Photovoltaic Devices Wallace C. Choy; University of Hong Kong, China

Sn-Pb perovskites have shown their potentials in wide-bandgap photovoltaics and near-infrared photodetection applications which could become alternatives to traditional silicon and inorganic devices. To achieve efficient devices, high-quality and thick Sn-Pb perovskite films featuring well-packed, smooth, pinhole/void-free are highly desirable. Besides, understanding the crystallization kinetics and tuning the crystallization are fundamentally important to reach the Sn-Pb perovskite films, and have been limitedly explored. Herein, we propose an approach of double-side crystallization tuning through low-temperature space-restricted annealing in MA-free Sn-Pb perovskite films. By simultaneously retarding the crystallization in the top of precursor films and promoting the crystal growth of the bottom of precursor films, we achieve high-quality and block-like 1 μm thick Sn-Pb perovskite films with improved crystallinity and reduced trap density [1]. The high-quality Sn-Pb perovskite can also be fabricated on metal/ silicon substrates for promoting direct integration with CMOS electronics and realizing an efficient photodiode imaging array [2]. Meanwhile, we develop the approach of in-situ tin(II) inorganic complex anti-solvent process for particularly tuning the perovskite nucleation and crystal growing process. Interestingly, we uniquely form the quasi core-shell structure of the Pb-Sn perovskite-tin(II) complex as well as heterojunction perovskite structure at the same time for suppressing the nonradiative recombination, extending carrier lifetime, and enhancing the carrier extraction. As a result, the mixed Pb-Sn low-bandgap perovskite device achieves a high power conversion efficiency up to 19.03% with a fill factor over 0.8, which is among the highest fill factor in high-performance Pb-Sn perovskite solar cells. Remarkably, the device fail time under continuous light illumination is extended by over 18.5 folds reaching 560 h [3]. To realize the integration of Sn-Pb perovskite for tandem cell applications, we also develop a new thermionic emission-based interconnecting layer (ICL) structure with the enhanced solvent-resistance feature. Fundamentally, the thermionic emission plays a critical role in the electron transport process in the ICL, which is confirmed through both experimental and theoretical studies [4]. The works not only demonstrate the solid potential of Sn-Pb perovskite in solar cells and photodetectors but also promoting all perovskite tandem solar cells for low-cost photovoltaics.

9:30 AM *EN05.14.03
MXenes and Other Two-Dimensional Materials for Perovskite Photovoltaics Aldo Di Carlo[1,2,3]; [1]ISM-CNR Institute for Structure of the Matter, National Research Council, Italy; [2]University of Rome Tor Vergata, Italy; [3]– National University of Science and Technology NUST-MISIS, Russian Federation

Two-dimensional (2D) material are playing an important role in perovskite photovoltaics. Halide perovskite and 2D materials, including 2D perovskites, can be combined to enhance efficiency and stability of solar cells. Recently, a new perspective class of 2D materials - MXenes demonstrated a beneficial result for interface engineering in perovskite solar cells (PSCs) [1,2]. In general, the MXenes are metal carbides/nitrides with single or multilayer 2D structures and have general formula of Mn+1XnTx (n = 1, 2, 3), where M represents an early transition metal, X is a carbon and/or nitrogen atom and T are surface functionalization groups (–F, –O, –OH). In this talk I will present the progresses made in the use of MXenes and other 2D materials such as Graphene, MoS2 to improve the performance and the stability of perovskite solar cells. %With a thorough multiscale experimental investigation, we point out that 2D materials can tune interfaces properties, reduce ion migration and modify the work-function of the perovskite absorber and charge transporting layers, all aspects that directly impact on the final efficiency and the stability under accelerated stress tests.
The use of 2D materials allows us to reach more than 26% efficiency in a tandem graphene-perovskite/silicon cell [3] and ≈20% on 10 cm^2 module, and improve the stability for light soaking stress beyond 2000 hours out of glove-box. By using 2D materials we realize a solar farm with 0.5 sqm panels obtained with single junction graphene-perovskite sub-modules with efficiency up to 16% (on a substrate area of more than 100cm2) and panel efficiency exceeding 10%

Structure, Defects and Performance of Perovskite Photovoltaics Joanne Etheridge[1], Wei Li[2], Mathias U. Rothmann[3], Ye Zhu[4], Weilun Li[1], Mengmeng Hao[5], Weijian Chen[6], Chenquan Yang[2], Yongbo Yuan[7], Yen Yee Choo[1], Xiaoming Wen[6], Lianzhou Wang[5], Udo Bach[1] and Yi-Bing Cheng[2,1]; [1]Monash University, Australia; [2]Wuhan University of Technology, China; [3]University of Oxford, United Kingdom; [4]The Hong Kong Polytechnic University, Hong Kong; [5]The University of Queensland, Australia; [6]Swinburne University of Technology, Australia; [7]Central South University, China

The perovskite structure is proving to be a versatile platform for creating photoactive compounds for application in solar cells, achieving excellent power conversion efficiencies, long carrier diffusion lengths and low recombination rates. However, a number of challenges remain, including current density-voltage hysteresis and structural degradation in air and light.

Many parameters impact on device properties from grain structure to the integrity of the interface between the transport and photoactive layers. Here we investigate the local crystal structure and intragrain defect structure of popular photoactive perovskite compounds and correlate these observations with device performance and properties.

We develop and apply specific strategies for pristine structure analysis using transmission electron microscopy (TEM). This includes the preparation of TEM foils using processes that mimic the preparation of the device photoadsorber (and avoids the use of ion beams) and the subsequent examination in the TEM using a total electron dose well below measured damage thresholds [1,2].

We investigate the crystal structure and associated defects in several photoactive perovskites: the mixed organic cation perovskite $MA_xFA_{1-x}PbI_3$ (with methylammonium, MA= $CH_3NH_3^+$ and formadinium, FA=$NH_2CH{=}NH_2^+$ and x=0, 0.15, 0.5, 0.8, 0.9 and 1) [3, 4], the more structurally stable pure inorganic $CsPbI_{(1+x)}Br_{(2-x)}$ [5] and the mixed cation $FA_xCs_{1-x}PbI_3$.

We reveal different types of point and planar defects induced by different elemental compositions and stoichiometries and measure the corresponding changes in device performance, including charge carrier lifetime, open-circuit voltage-deficit, and current-voltage hysteresis. We identify which structural defects are benign and which may be detrimental to device performance, suggesting further avenues for improving device properties and performance.

11:00 AM *EN05.15.02
Computational Materials Design—Focus on Perovskites Silvana Botti; Friedrich Schiller University Jena, Germany

Perovskite materials have attracted increasing attention in different application fields thanks to their composition diversity and extraordinary variety of electronic properties. Perovskite solar devices are nowadays the fastest advancing photovoltaic technology, but a large-scale application is restrained by open challenges that still delay their market entry.

How can the design of functional materials, and in particular perovskite materials, be accelerated using supercomputers?
In this talk I will discuss how to combine first-principles calculations and machine learning to speed up the discovery of new materials.

Characterizing the electronic properties of crystalline bulk materials can however be insufficient to evaluate their suitability for applications. Interfaces are in fact at the heart of electronic devices: the ability to shape potential gradients at interfaces opens up the possibility to manipulate electrons and develop new functionalities. The design of interfaces, as well as the deep understanding and control of their properties, is still beyond the current state of the art. I

will discuss some recent progresses in this direction.

11:30 AM *EN05.15.03
Interplay Between Structural and Optoelectronic Properties of Multilayered Perovskites Jacky Even[1], Hao Zhang[2], Wenbin Li[2], Siraj Sidhik[2], Xiaotong Li[3], Eugenia S. Vasileiadou[3], Justin Hoffman[3], Ioannis Spanopoulos[3], Yan Qin[4], Wei Li[4], Claudio Quarti[5], Boubacar Traore[6], Pedesseau Laurent[1], Mikael Kepenekian[6], Jean-Christophe Blancon[2], Mercouri G. The presentation will review recent experimental and theoretical results for 2D multilayered halide perovskites, dedicated to photovoltaic or light emission applications. The complex interplay between structural and optoelectronic properties will be emphasized, including the influence of light soaking, the ultrafast relaxation of the lattice induced by hot carriers and the localization of carriers at the layer edges.

12:00 PM EN05.15.04
Enhanced Operational Stability of Perovskite Light-Emitting Devices Through Differentiated Ion Motion Aditya Mishra and Jason D. Slinker; The University of Texas at Dallas, United States

Hybrid perovskites are emerging as highly efficient materials for optoelectronic applications, however, their operational lifetime has remained a limiting factor for their continued progress. In thin-film perovskite light-emitting devices, ionic redistribution may distort the perovskite crystal structure, lowering conductivity and light emission due to the formation of vacancies and other traps. Our strategy for enhanced lifetimes involves producing differentiated ion motion within a device with a rational materials blend. The materials selectively move additive ions while restricting the transport of perovskite ions. To accomplish differentiated ion transport with optimal thin-film morphology, we combine a perovskite, a polyelectrolyte such as poly(ethylene oxide), and a salt additive such as $LiPF_6$. The added mobile Li^+ and PF_6^- ions redistribute more favorably than the intrinsic ionic species and largely preserve the inherent structure of the perovskite film. At 0.5 wt% $LiPF_6$, $CsPbBr_3$ devices exhibit 100 h operation at high brightness in excess of 800 cd/m^2 under constant current driving, achieving a maximum luminance of 3260 cd/m^2. This performance extrapolates to a 6700 h luminance half-life from 100 cd/m^2, a 5.6-fold improvement over devices with no $LiPF_6$. For quantum dot blended devices, a 45 h half-life was obtained at 3640 cd/m^2, extrapolating to over 37000 h at 100 cd/m^2. We rationalize these findings through optical spectroscopy, impedance spectroscopy, X-ray photoelectron spectroscopy, scanning electron microscopy, and X-ray diffraction.

12:15 PM EN05.15.05
Late News: Charge Transfer Rates and Electron Trapping at Buried Interfaces of Perovskite Solar Cells Igal Levine[1], Amran Al-Ashouri[1], Artem Musiienko[1], Hannes Hempel[1], Artiom Magomedov[2], Aida Drevilkauskaite[2], Vytautas Getautis[2], Dorothee Menzel[1], Karsten Hinrichs[3], Thomas Unold[1], Steve Albrecht[1,4] and Thomas Dittrich[1]; [1]Helmholtz-Zentrum Berlin, Germany; [2]Kaunas University of Technology, Lithuania; [3]Leibniz-Institut fur Analytische Wissenschaften ISAS e.V., Germany; [4]Technical University Berlin, Germany

Identification of electronic processes at charge-selective interfaces is crucial not only for the further development of high efficiency solar cells based on metal halide perovskite (HaP) absorbers but also for other materials systems in photovoltaic research, photocatalysis etc. Transient surface photovoltage (SPV) measurements provide information about dynamics of charge separation and relaxation across interfaces from the nanosecond to the second range. Passivation of different hole-selective ITO / SAM / HaP contacts (SAM: self-assembled monolayer, here: carbazole-based molecules with a phosphonic acid linker group) is studied by transient SPV, compared with radiative bulk recombination (measured by transient photoluminescence) and correlated with the performance of solar cells. It is shown that transient SPV and transient photoluminescence provide complementary information on charge transfer kinetics and trapping/de-trapping mechanisms. Hole transfer rates to the ITO and densities of traps at ITO / SAM interfaces were obtained by fitting SPV transients with a minimalistic kinetic simulation model. The hole transfer rates and the density of interface traps depended strongly on the SAM`s structure, and densities of interface traps as low as 10^9 cm^{-2}, in par with highly passivated c-Si surfaces, were reached for Me-4PACz, which was previously used in record perovskite/silicon tandem solar cells. The extracted hole transfer rates and densities of interface traps correlated well with corresponding fill factors and open-circuit voltages of high efficiency solar cells based on HaP absorbers. Our results show that, aside tuning of barriers for charge transfer, SAMs can efficiently passivate defect states at interfaces.

A Matter of Mixing: Nanoscale Heterogeneity and Stability in Metal Halide Perovskite Solar Cells Laura T. Schelhas[1], Laura Mundt[2], Fei Zhang[1], Axel Palmstrom[1], Junwei Xu[2], Robert Tirawa[1], Leah Kelly[2], Kevin Stone[2], Kai Zhu[1], Michael Toney[3] and Joseph Berry[1]; [1]National Renewable Energy Laboratory, United States; [2]SLAC National Accelerator Laboratory, United States; [3]University of Colorado Boulder, United States

Halide perovskite photovoltaics (PV) are known to have a wide range of chemical compositions. The perovskite lattice is quite tunable and able to accommodate various ions of different sizes. To date, halide perovskite solar cells (PSC) yield the highest efficiency and stability when absorbers comprised of a mixture of ions are utilized. However, some compositions such as $FAPbI_3$ (FA = formamidinium) or the fully inorganic composition $CsPbI_3$ exhibit non-ideal geometric conditions, often measured using the Goldschmidt tolerance factor. When ions are too large or too small for the lattice non-perovskite δ-phases that are detrimental for PV applications are formed. Mixed compositions allow for a fine tuning of the geometric conditions and enables the formation of photoactive perovskite phases.[1] Nevertheless, chemical heterogeneity in the film can initiate phase segregation of the material into pure phases, which as noted prefer their non-perovskite δ-phases, and consequently lead to degradation of the device performance.

Spatially resolved analyses have repeatedly revealed microscopic heterogeneity in halide perovskite thin films, including compositional heterogeneity. Evidence has been found that decomposition during operation could be triggered/facilitated by local compositional variation from the averaged mixed phase.[2] However, characterizing the chemical heterogeneity on small length scales has proven challenging. Recently work by Barrier et al demonstrated an X-ray scattering based methods for probing this nanoscale heterogeneity in halide perovskites.[3]
In this talk, we use these methods reported by Barrier et al. to probe nanoscale heterogeneity in PSC absorber layers and couple these results to device level

stability studies to understand the role heterogeneity plays in device performance. This work relies on the hypothesis that the cubic to tetragonal phase transition width is a measure of the chemical heterogeneity in mixed halide perovskites. To measure the phase transition width from the tetragonal to the cubic phase, temperature-dependent in situ wide angle X-ray scattering is utilized. Barrier et al. report that the transition is abrupt for pure $MAPbI_3$ (MA = methyl ammonium), however, the transition is stretched over a larger temperature range for the mixed compositions measured in their study.

To build on this work we prepare a set of $FA_{0.83}Cs_{0.17}PbI_3$ perovskite thin films, choosing a variation of annealing conditions. The variation in annealing time and temperature can impact the compositional heterogeneity as measured using in-situ X-ray scattering. We couple these results to device level stability studies and ex-situ scattering studies of the degraded devices to understand how heterogeneity impacts the operational stability of these materials. In this talk, we will provide a summary of the approach used to characterize the heterogeneity in these films and comment on the loss in device performance and subsequent phase segregation induced by nanoscale heterogeneity.

Water-Accelerated Photo-Oxidation of Hybrid Perovskites—Mechanism, Rate Orders and Rate Constants Timothy Siegler, Wiley A. Dunlap-Shohl and Hugh W. Hillhouse; University of Washington, United States

Understanding the chemical reactions that hybrid organic-inorganic halide perovskite (HP) semiconductors undergo in the presence of moisture, oxygen, and light are essential to the commercial development of HP solar cells and optoelectronics. Here we use optical absorbance (105 degradations were conducted over 41 unique environmental conditions) to quantify the kinetics of methylammonium lead iodide ($MAPbI_3$) degradation in response to combinations of moisture, oxygen, and illumination over a range of temperatures. We discover and report a new chemical reaction pathway referred to as a water-accelerated photo-oxidation (WPO) pathway [1], which is the dominant chemical degradation pathway when light, oxygen, and humidity are present. At 25 °C in 50% RH air under 1 Sun illumination, the water-accelerated photooxidation proceeds with a rate of 2×10^{-7} mol/m^{2}s with an activation energy of E_A=0.07 eV. Commonly reported pathways based on: (i) dry photo-oxidative degradation (DPO, degradation in oxygen under illumination but without water as a reactant), (ii) humidity-driven hydrate formation (degradation with humidity with and without illumination but without oxygen), (iii) blue light exposure, and (iv) thermally driven degradation (without humidity and oxygen) are demonstrated to have rates that are respectively 50, 200, 1000, and >1000 times slower than the water-accelerated photooxidation processes. The activation energy of the DPO process is much higher at 0.62 eV, and at higher temperatures (85°C) the rate of the DPO process is roughly equivalent to the WPO process. Given the much lower activation energy and much faster rate of the WPO process, the overall rate of degradation is very sensitive to small amounts of water. Water thus behaves like catalyst. Since it is consumed in one step and later re-generated, we refer to it as an accelerant. The WPO process has significant implications for perovskite stability and encapsulation, which will be discussed. A detailed kinetic model is developed for both the WPO and DPO processes. The rate determining step for WPO is proton abstraction from water by superoxide radical that creates several different reactive oxygen species, which then react with the perovskite. However, the rate determining step for the DPO process is proton abstraction from methylammonium by superoxide radical. A detailed rate law for each process is derived from this mechanism, and the entire dataset is fit to extract rate constants for DPO and WPO processes. The presentation will focus on the kinetics of perovskite degradation and will include experiments on the broader (FA, MA, Cs)Pb(I,Br)3 space as well as discuss how chemistry inspired features (like the rate of chemical reaction) can be used in machine learning models for perovskite degradation.

Measurement of Radiative Decay Rate in Hybrid Metal-Halide Perovskites Angelica Simbula[1], Riccardo Pau[1,2], Fang Liu[1], Luyan Wu[1], Daniela Marongiu[1], Francesco Quochi[1], Andrea Mura[1], Alessio Filippetti[1], Michele Saba[1] and Giovanni Bongiovanni[1]; [1]Università di Cagliari, Italy; [2]University of Groningen, Netherlands

One of the main goals for perovskite materials is to approach ideal efficiency limits in solar cells or LEDs: being the radiative decay of optical excitations unavoidable, this can be done by reducing contributions from traps and defects. Despite all the advances in device performances, the bimolecular radiative recombination rate in metal halide perovskites is still not clearly established: coefficients derived under different assumptions can take very different values, and a lively debate is going on trying to conjugate their exceptionally long excitation lifetimes with large optical absorption coefficients. Here we provide a calibrated radiometric measurement of the instantaneous photoluminescence flux emitted by thin-films of hybrid perovskites with controlled carrier density under pulsed excitation. In all the analysed samples we uncover a radiative recombination rate much lower than the bimolecular recombination coefficient, revealing the presence of non-radiative bimolecular recombination rate that can be attributed to a population of dark states, possibly large polarons. Our findings suggest that to minimize unwanted decay channels for optical excitations one should also take account of non-radiative contributions to the bimolecular decay, that is due to extrinsic effects, like trapping and defects, and can be substantially reduced with materials optimization.

2:15 PM EN05.16.04
The Role of Photon Recycling and Scattering in High Efficiency Perovskite Solar Cells Changsoon Cho[1,2], Yeoun-Woo Jang[3], Seungmin Lee[4], Yana Vaynzof[2], Mansoo Choi[3], Jun Hong Noh[4] and Karl Leo[2]; [1]University of Cambridge, United Kingdom; [2]Technische Universität Dresden, Germany; [3]Seoul National University, Korea (the Republic of); [4]Korea University, Korea (the Republic of)

In the last decade, power conversion efficiencies (PCE) of thin-film perovskite solar cells (PSCs) have rapidly grown from 3.8% to 25%. As most of PSCs are already achieving efficient light absorption and charge collection, enhancing electroluminescence (EL) is the key for them to approach the Shockley-Queisser limit. While the classical optics restricts the EL quantum efficiency (ELQE) of thin-film optoelectronics to $1/2n^2$, which is 7.4% for perovskites (n=2.6), photon recycling (PR) and scattering can give a chance to overcome it by extracting photons trapped in waveguide and substrate modes. Here, we investigate the role of PR and scattering in a PSC with passivation of octylammonium (OA) bromide, having PCE of 24%. The device exhibits the high ELQE of 13.7% at 1-*sun* equivalent excitation, exceeding the classical limit. The primary evidence for PR is given by the self-excitation

experiment, where EL of one pixel induces photocurrents of nearby pixels through the reabsorption of photons trapped in substrate mode. Spectral analysis of the spatially resolved photoluminescence and electroluminescence prove that both PR and scattering contribute to the external radiation of PSCs. Moreover, by resolving the previous optical issues and establishing a new optical model, we quantify various optical parameters in PSCs. At open-circuit condition, 80% of out-coupled photons are shown to have undergone at least one PR or scattering event. Consequently, PR and scattering increase the ELQE of our PSC by a factor of 4.5 (3.1% à 13.7%), reducing the non-radiative voltage loss (V_{nr}) from 89 mV to 50 mV, and increasing PCE from 23.3% to 24.0%. We also discuss future strategies for further improvement in current state-of-the-art PSCs.

Lead Adsorbing Ionogel-Based Encapsulation for Impact-Resistant, Stable and Lead-Safe Perovskite Modules Xun Xiao and Jinsong Huang; University of North Carolina at Chapel Hill, United States

Despite the demonstrated high efficiency and low-cost prospect for perovskite solar cells, great concerns of lead toxicity and instability remain for the commercialization of this technology. Here, we report an encapsulation strategy for perovskite modules based on lead-adsorbing ionogel, which effectively prevents lead leakage even if the modules are completely damaged and help to withstand long-term stability tests. The ionogel can absorb lead up to 30% of its mass because of the lead absorbing polymer backbone and phosphate ionic liquid. The elastic ionogel layers are integrated on both metal electrodes and on top of front glass window of perovskite modules, which significantly enhances their impact resistance in simulated hail tests, and can hold the shattered broken glass. The self-healable ionogel can physically prevent the permeation of water into the perovskite layer by blocking the cracks of broken glass, and absorbs lead that might otherwise leak. With the thermal and mechanical compatibility of ionogel and commercial encapsulant, the encapsulated solar cells pass the Damp Heat and Thermal Cycling accelerated stability tests according to IEC 61215 standard. The encapsulated perovskite mini-modules with ionogel show an aperture efficiency of 18.5%. The ionogel encapsulation also reduces lead leakage to undetectable level (<1 part per billion) after the hail-damaged module is soaked in water for 24 hours. Even under extreme scenario of being rolled over by a car followed by water-soaking for 45 days, the ionogel encapsulation reduces lead leakage by three orders of magnitude. This work provides a new strategy to address lead leakage and multiple-facet device stability simultaneously for perovskite modules.

SESSION EN05.17: Poster Session III: Emerging Energy and Materials Science in Halide Perovskites

Impact of Doping/Photodoping and Bandgap Variation on the Efficiency of Perovskite Solar Cell Basita Das[1,2] and Thomas Kirchartz[1,3]; [1]Forschungszentrum Jülich GmbH, Germany; [2]RWTH Aachen University, Germany; [3]University of Duisburg-Essen, Germany

Creating functionality in electronic devices is often achieved by modulating carrier concentrations with doping. In photovoltaics, optimization of doping concentrations can be an important tool to reduce recombination losses e.g. in crystalline Si solar cells. In emerging photovoltaic technologies such as the halide perovskites, comparably little work is done so far on intentionally controlling carrier densities in order to maximize efficiency. Some recent publications have discussed the effect of doping on solar cell efficiency both experimentally and theoretically using similar arguments and concepts as in classical Si photovoltaics. A fairly unconventional concept was recently presented by Feldmann et. al , who proposed that photo−doping by small bandgap variations leads to increased external photoluminescence (PL) quantum efficiency Q_e^{lum} which might then lead to the increase in open-circuit voltage and potentially in photovoltaic efficiency. While it is an interesting thought that stoichiometric and energetic disorder could be beneficial for efficiency, the concept is in complete opposition to earlier findings in other photovoltaic communities working on multinary compounds (e.g. $Cu(In,Ga)Se_2$) where extensive theoretical work on the *negative* effect of band gap inhomogeneities was developed about 15 years ago.Hence, one motivation for the current study is the reconciliation of these opposing findings that have important consequences on how to optimize devices and how to explain performance gains or losses.
Here, we provide a theoretical basis for the findings of Feldmann et al. and explain the phenomenon of photodoping as well as its relation to conventional doping. We also aim to develop models to perform a critical assessment of the role of doping on PL quantum efficiency and photovoltaic device performance. To tackle the different questions, we use two approaches. First, we develop a simple analytical model to study the effect of small lateral band gap variations and conclude that it cannot possibly be the source of photodoping and thus the substantially increased Q_e^{lum} observed by Feldmann et.al. We also find that such lateral fluctuations in the bandgap of the material can have adverse effects on the device performance. We then explore the relation between doping and photodoping and describe the consequences of these two forms of modulating carrier densities on luminescence, charge transport and photovoltaic efficiency using numerical device modelling. Furthermore, we highlight how the effects of doping on device performance depend on the choice of asymmetric defect capture coefficients as well as mobility of the charge transport layers.

Two-Dimensional Overdamped Fluctuations of Soft Lattice in Halide Perovskites Xing He[1], Tyson Lanigan-Atkins[1], Matthew J. Krogstad[2], Daniel Pajerowski[3], Doug L. Abernathy[3], Guangyong Xu[4], Zhijun Xu[4], Duck Y. Chung[2], Mercouri G. Kanatzidis[5], Stephan Rosenkranz[2], Raymond Osborn[2] and Olivier Delaire[1]; [1]Duke University, United States; [2]Argonne National Laboratory, United States; [3]Oak Ridge National Laboratory, United States; [4]National Institute of Standards and Technology, United States; [5]Northwestern University, United States

The all-inorganic halide perovskite compounds are currently attracting interest for photovoltaic, radiation detection, and thermoelectric applications. They exhibit long lifetimes of photoexcited carriers beneficial for photovoltaics, and ultralow thermal conductivity of interest for thermoelectrics. Among the simplest members of this family, CsPbBr3 undergoes a typical sequence of phase transitions upon cooling, from cubic to tetragonal at ~400K and from tetragonal to orthorhombic at ~360K, associated with zone-boundary lattice instabilities. We have conducted inelastic neutron scattering (INS) of phonons on single-crystals of CsPbBr3, to probe anharmonic effects around lattice instabilities, and the origin of the ultralow thermal conductivity. Heavily overdamped Br-dominated acoustic modes were found with INS along the edges of the Brillouin zone in the tetragonal and cubic phases, forming a continuum of quasielastic scattering, which we associate to the strongly anharmonic potential energy surface against octahedral tilts. Further, we performed first-principles simulations of the anharmonic phonon self-energy that reproduce the observed overdamping. These large atomic fluctuations exhibit two-dimensional correlations of Br octahedra rotations in real-space and impact optoelectronic properties by modulating the Pb-Br derived electronic states at the edges of the bandgap. In addition, we show how other compositions of metal halide perovskites exhibit similar diffuse rods, including the double perovskite Cs2AgBiBr6 and CsSnBr3 or CsPbCl3, which indicates that anharmonic halide octahedral tilts are a common feature of the structure and its dynamics for this family of materials.

Strain in Metal Halide Perovskites—The Critical Role of A-Cation Yongtao Liu[1], Bobby Sumpter[1,1], Jong K. Keum[1,1], Bin Hu[2], Mahshid Ahmadi[2] and Olga Ovchinnikova[1,1]; [1]Oak Ridge National Laboratory, United States; [2]The University of Tennessee, Knoxville, United States

Adjusting A-site cation composition in metal halide perovskites (MHPs) is an important approach to modulate the static lattice strain and hence enhance the efficiency and stability of MHPs solar cells. However, an understanding of how A-site cation affects the lattice dynamic during the operation of MHPs devices is missing. In this work, we investigate the role of A-site cation in the lattice strain of MHPs upon light illumination and heating—two inevitable factors during the operation of photovoltaic devices. We reveal that A-site cation plays an important role in light-induced strain in MHPs. In particular, formamidinium (FA) cation is different compared to the other cations studied in this work, where FA-based MHP does not show light-induced strain but the other cations based MHPs show a light-induced strain. We also discovered that the MA distribution is strongly coupled with the strain distribution, and MA heterogeneity cab lead to a local light-induced strain heterogeneity under illumination. We further performed density functional theory (DFT) calculations to look at the photoexcitation induced lattice change in the atomic scale and explore the underlying mechanism. We found that hydrogen bonding interactions and ionization energy of A-site cation are potential reasons responsible for the light-induced lattice strain in MHPs. These findings offer an approach to modulate the light-induced strain in MHPs, which is critical for further improving the efficiency and stability of MHP photovoltaics.

Late News: Optimization of Optoelectronic Performance and Stability of Organic-Inorganic Halide Solar Cells with Hexagonal Boron Nitride Nanosheets Yifan Yin, Yuchen Zhou and Miriam Rafailovich; Stony Brook University, The State University of New York, United States

Organic-inorganic halide perovskite solar cells (PSCs) have been considered a viable
member of next generation photovoltaics, which can address the scalability changes with a low-cost solution process. The energy lose in the hybrid system has been approved to be principally caused by defects/traps at grain boundaries and surfaces as well as point defects such as interstitial defects or vacancies in the perovskite compounds crystal lattice. It has been approved that halide ions migrating into charge transporting layers will be detrimental to their transport properties, especially under solar cell working conditions. Inspired by the quasi-2D-perovskite which shows a great device maintenance in photovoltaic performance, here, the hexagonal boron nitride (h-BN) was incorporated into the perovskite absorber as a cationic diffusion barrier. This low-cost, lower dimensional material can work as a growth template which leads to a a larger grain size. On the other hand, the integration of h-BN enables a better device stability as the result from the efficient suppression on the ion-migration induced degradation. The H-BN/ perovskites has an initial PCE of 19.7% that shows no degradation exhibit in over 72 h, whereas the PCE of pristine MAPI devices diminishes by more than 30% within the first 24 h.

4:18 PM EN05.17.06
Role of Spin-Orbit Splitting on Optical Nonlinearities in Lead Halide Perovskite Single Crystals Takumi Yamada[1], Keiich Ohara[1], Tomoko Aharen[1], Hirokazu Tahara[1], Hideki Hirori[1], Hidekatsu Suzuura[2] and Yoshihiko Kanemitsu[1]; [1]Kyoto University, Japan; [2]Hokkaido University, Japan

Lead halide perovskite semiconductors $MAPbX_3$ ($MA = CH_3NH_3$, X = I, Br, and Cl) are attracting much attention as a new class of materials for optoelectrical device applications because of their outstanding optical properties. Recently, unique nonlinear optical responses such as large optical modulation [1], efficient higher-order harmonic generation [2–4], and strong spin-orbit coupling inducing Autler–Townes effect [5] were found in $MAPbX_3$ perovskites. The precise determination of nonlinear optical coefficients is important to understand their fundamental material properties and the origin of their large nonlinear optical responses.
Because of strong light scattering in their grain structures and surfaces, it is difficult to determine intrinsic nonlinear optical coefficients for polycrystalline and nanocrystals. To exclude these influences, we fabricated high-quality single crystal $MAPbX_3$ (X = Cl and Br) samples and clarified their third-order nonlinear optical coefficients for the wide wavelength range. The obtained spectra near the band gap can be quantitatively explained by a two-band model including the exciton effect and 4×4 Kane model. Based on this model, we successfully determined the Kane energy (23 eV) and exciton reduced mass (0.20 m_0), and found that the nonlinear optical coefficient is enhanced about twice by the exciton effect in $MAPbCl_3$ single crystal [6]. In addition, we studied the two-photon absorption spectra of $MAPbBr_3$ single crystal with circularly and linearly polarized excitation light [7]. We observed a dip structure in the linear-circular dichroism spectrum of two-photon absorption, which corresponds to the spin-orbit splitting energy according to the 8×8 Kane model. From the experimental results and a theoretical analysis of the two-photon absorption spectra, we successfully determined the spin-orbit splitting energy (0.8 eV), exciton binding energy (28 meV), and reduced exciton mass (0.089 m_0), which characterize the electronic structure of $MAPbBr_3$. Our results provide a direct experimental reference on the electronic structure of halide perovskites.

4:23 PM EN05.17.07
Late News: (Garcia High School Student) Polymeric Hole Transport Layer in Perovskite Solar Cells Grace Kyoko Wong[1], Miller Liao[2] and Miriam Rafailovich[3]; [1]St Paul's Girls' School, United Kingdom; [2]Shenzhen Middle School, China; [3]Stony Brook University, The State University of New York, United States

Perovskite solar cells (PSCs) have become one of the most promising types of next-generation solar cell ever since 2009 due to their excellent photovoltaic performance. Despite of decent photo conversion efficiency (PCE), PSCs with a Spiro-OMeTAD hole transport layer (HTL) have been shown to have poor device stability and noticeable current-voltage (J-V) hysteresis PV performance.
In our study, we used PTAA as a substitute for Spiro-OMeTAD and compared the PV parameters along with the device stability of both PSCs. To compare the parameters between doped PTAA and Spiro-OMeTAD PSCs, we used the regular n-i-p device with the structure of FTO/c-TiO2/m-TiO2/MAPbI3/HTL/Au. Three different HTLs were prepared: pristine PTAA, Li-TFSI doped PTAA and Spiro-OMeTAD. From the cross-section SEM

results, we found the Spiro-OMeTAD layer had a thickness of around 180 nm, while the thickness of the PTAA layer with and without Li-TFSI were all around 50 nm. The data for the current density-voltage (J-V) curves of the PSCs were collected using a PV test station. The MAPbI3 (MAPI) PSC with Spiro-OMeTAD showed typical PCE of 17.3% in reverse scan (RS) and 14.2% in forward scan (FS), while the MAPI PSC using doped PTAA as the HTL had typical PCE values of 16.6% in RS and 14.7% in FS. Although the Spiro-OMeTAD PSC showed a slightly higher PCE in RS, the sample showed a greater hysteresis in comparison to the PTAA one. Moreover, the continuous maximum power point (MPP) test in an ambient environment (humidity ~ 60%) with a Xenon solar lamp on non-encapsulated PSCs showed that the PSC using PTAA HTL presented a slightly more stable current output compared to the Spiro-OMeTAD counterpart. Using contact angle measurements, we found the typical water contact angles of 69.8° and 88.2° for Spiro-OMeTAD and PTAA layers, respectively, indicating that the PTAA was more hydrophobic than the Spiro-OMeTAD. We suggest that the higher hydrophobicity of the PTAA could contribute to better PSC stability when exposed to moisture with moderate high temperatures.

4:28 PM EN05.17.08
Fabrication and Characterization of Structurally Controlled Lead Halide Perovskite Single Crystal Thin Films for Optoelectronics Tomohiro Watanuki, Hironori Ogata, Keitaro Kikuchi and Yuki Matsui; Hosei University, Japan

Currently, the energy conversion efficiency(PCE) of perovskite solar cells (PSCs) has reached 25.5% and there is a great deal of interest in the practical application of perovskite solar cells (PSCs). Almost all reported PSCs use polycrystalline films as photoactive layers. However, since it contains many grain boundaries, it has been pointed out about the possibility of deterioration through the grain boundaries. Recently, solar cells using a perovskite single crystal thin film as a photoactive layer have been reported to improve durability and solar cell characteristics because they have a longer carrier diffusion length, a lower trap density, a higher light absorption coefficient, and a lower ion diffusion length. However, the world record for PCE has been achieved with polycrystalline thin films. It is important to develop manufacturing technology for precisely structurally controlled perovskite single crystal thin films. In this study, several kinds of lead halide perovskite single crystal thin films were prepared under various conditions by a space-limited reverse temperature crystallization method, and their structures and optoelectric properties were evaluated. .. We will report on the detailed experimental results.

Spectral conversion aims to tailor the incident solar spectrum such that it is better suited for particular photovoltaic absorber material; here an organometal halide perovskite semiconductor. In our perovskite solar cells with double cation perovskite absorber (bandgap 1.57eV), 41% of the incident spectrum is wasted by sub-bandgap losses. With the target to reduce these losses in the future, we research up-conversion (UC) crystal BaF_2:Yb^{3+}, Er^{3+} for the annihilation of two low-energy photons to form a high-energy photon. When tested under terrestrial sunlight representing one sun above the perovskite's bandgap and sub-bandgap illumination at 980 nm (via a laser), the BaF_2 crystal emits usable upconverted photons in the spectral range of 520 to 700 nm. In our bifacial PSC with the UC crystal beneath, these upconverted photons contribute to 0.38 mA/cm^2 enhancement in short-circuit current density at a laser intensity equivalent to 120 suns. We demonstrate that UC scales non-linearly with incident intensity, with an 880 suns equivalent intensity resulting in 2.09 mA/cm^2 enhancement in current. Our study demonstrates that UC is a potentially viable process to extend the response of PSC to a wider spectral range.

4:38 PM EN05.17.10
Late News: (Garcia High School Student) Methylammonium Chloride Assisted Growth of High Quality FAPbI3 Justin Shnayder[1], Adin Moskowitz[2], Shiqi Cheng[3] and Miriam Rafailovich[4]; [1]Staten Island Technical High School, United States; [2]Hebrew Academy of Nassau County, United States; [3]Illinois Mathematics and Science Academy, United States; [4]Stony Brook University, The State University of New York, United States

As greenhouse gas emissions rise and induce the complications associated with climate change, solar cells, devices which convert sunlight into electricity through the photovoltaic effect, are regarded as a promising solution to the issue. The use of the organic and inorganic hybrid perovskite (OIHPs) as the photoactive semiconductors for new generation of solar cells has been widely investigated due to panchromatic light absorption, high charge mobility, and low exciton binding energy, etc, which contributes to high performance perovskite solar cells (PSCs) with high photo conversion efficiency (PCE) surpassing other types of thin film solar cells and comparable to III-IV and II-IV types of solar cell devices. Among different compositions of OIHP, methylammonium lead iodide ($MAPbI_3$ or MAPI) is one of the most widely studied OIHP due to its overall simple processing and good moisture endurance. On the other hand, the formamidinium lead iodide perovskite ($FAPbI_3$ or FAPI) becomes more popular in the community due to its optimal bandgap, broader light absorption, as well as better thermal stability, etc, as compared with the MAPI perovskite. However, preparation of a high quality FAPI perovskite films with minimized surface and structural defects are more difficult than MA based perovskite, due to less favorable lattice parameters after replacing with FA cations. Previous studies have indicated that addition of methylammonium chloride (MACl) into the $FAPbI_3$ system can help improve the crystallinity and morphology of $FAPbI_3$ films. Thus, the objective of this study was to study the effects of various concentration of MACl (15, 30, and 45 mol%) addition for the fabrication of high quality $FAPbI_3$ films
Specifically, the FAPI with 30% MACl yielded optimal results with large and compact grains, while FAPI doped with 15% MACl and 45% MACl yielded imperfections such as rough surface with pinholes. Further analysis revealed that optimal FAPI-MACl (30%) formed grains with average size around 820 nm, more than double that of the grains on MAPI perovskite, which has an average value around 370 nm. In addition, the analysis of photovoltaic performance was also conducted. The typical reverse and forward J-V scans of the PSC based on pristine-FAPI revealed PCEs of 12.3% and 8.1% respectively. In contrast, the typical reverse and forward scans of the FAPI with 30% MACl revealed higher PCE of 16.5% and 16.4% respectively. The improved PCE with negligible hysteresis of the FA-based PSC indicates the improvement in crystallinity and quality of the perovskite films with the optimal MACl concentration. The XRD analysis further indicated that: 1) pure FAPI exhibited a dominant photo-inactive δ-phase, and 2) the addition of MACl, particularly at concentrations larger than 30%, promoted the photo-active α-phase and reduced the photo-inactive δ-phase. Lastly, UV-vis absorption spectra revealed that FAPI perovskites with or without MACl all have broader light absorption, with the onset wavelength of around 780 nm, as compared with 750 nm of MAPI perovskites. In conclusion, our results confirm that the addition of MACl as the processing additive, particularly at a concentration of 30%, produced good quality $FAPbI_3$ films, leading to high performance PSCs with decent PCE and low hysteresis.

4:43 PM EN05.17.11
Exploring Recombination Dynamics in Emerging Non-Fullerene Acceptor Based Organic Solar Cells Vinod K. Sangwan, Guoping Li, Liang-Wen Feng, Antonio Facchetti, Tobin J. Marks and Mark C. Hersam; Northwestern University, United States

Next-generation solar energy harvesting technologies rely on the discovery, refinement, and implementation of new organic photovoltaic materials with high quantum efficiency, excellent stability, and reliability. In recent years, organic bulk heterojunction (BHJ) solar cells based on non-fullerene acceptors

(NFAs) have emerged as potential candidates due to rapidly improving power conversion efficiencies, now exceeding 18% in single-junction cells. Improved performance of recent NFAs is attributed to wider solar spectral absorption, efficient exciton dissociation, and strong π-π interactions, leading to excellent charge transport and collection. Despite these innovations in synthetic chemistry, there remain significant losses in all steps of the photoconversion process from exciton dissociation within the BHJ to charge collection at the contacts. Especially, bimolecular recombination losses are known to dominate in BHJ cells due to non-ideal band energetics, disordered morphology of donor and acceptor domains, and poor interfaces and contacts. Electric charge- and photocurrent-based spectroscopies using impedance spectroscopy provide a direct probe to reveal these relatively slow processes not accessible to conventional ultrafast spectroscopies. Furthermore, the non-invasive nature of this measurement can quantify performance-limiting dynamical processes in fabricated devices operating at the maximum power point. In this presentation, an impedance and photocurrent spectroscopy method will be discussed to quantify bimolecular recombination rates in NFA-based organic solar cells.[1-5] Two emerging NFA-polymer BHJ systems, indacenodithienothiophene-, and Y6-based NFAs, will be used to demonstrate the effectiveness of the methodology to assess differences in cells resulting from different molecule structure and processing conditions such as thermal annealing. Extracted variation in device parameters is correlated with improved morphology and packing motifs. Overall, this in-situ analysis allows a more realistic device model that can distinguish the competing effects on functionalization in NFA molecules such as π-extension and fluorination. In this manner, the new understanding gained in these systems provides a rational strategy for further optimization of high-performance and stable organic solar cells.

Halide perovskites are a very promising class of material for optoelectronics. Employing inexpensive and scalable synthesis methods, earth-abundant semiconductors that exhibit desirable optical properties, including unity quantum yield, can be achieved. The composition of both the cation and anion (halide) sublattices of perovskite crystals can be manipulated over a wide range to engineer their light absorption and emission behavior. Halide ion phase separation is a well-known barrier for the application of mixed-halide perovskites in solar cells and LEDs, whereby the presence of large populations of photo-generated or electrically-injected carriers causes undesirable changes of the local band gap by demixing of initially homogeneous mixed halide ion compositions. Previous reports have established that illumination with above the band gap energy causes the phase separation of mixed iodide-bromide perovskites into iodide- and bromide-rich domains and is reversible in the dark, where evidence of structural changes in mixed-halide alloys has been observed by X-ray diffraction. The phase separation mechanism appears to involve a self-reinforcing demixing of Br- and I- ions driven by reducing the potential energies of photogenerated carriers that trap in regions of smaller bandgap. Subwavelength imaging has been performed to visualize the process in single crystalline and poly-crystalline organic perovskites. However, many aspects of the phase separation are not well understood, such as factors that influence the length scale, kinetics of the phase separation, and whether the mechanism involves spinodal decomposition or nucleation and growth.
We investigate the mechanism of phase separation in mixed-halide $CsPbI_xBr_{3-x}$ perovskite crystals driven by photocarrier generation and spatial redistribution during absorption of band gap light. We visualize the phase separation process and its dynamics at the nanoscale using Cryo-TEM-CL, where formation of iodide-rich regions is detected as locally red-shifted emission. An extracted length scale for the phase separation is ~ 200 to 500 nm depending upon the degree of phase separation. Using photoluminescence spectroscopy, ellipsometry, and x-ray diffraction, we demonstrate that the temporal dynamics of this phase separation can be modulated by controlling both 1) the intensity of illumination, which, when increased, promotes faster phase separation; and 2) the temperature, which, when increased has the opposite effect. Correlating the optical property modulation with structural changes via in-situ experiments reveals that both the amplitude and the length scale of this fully-reversible phase separation increase as a function of time. Combined with phase field modeling that accounts for the coupling between the electronic and chemical effects, this points to a diffusional transformation mechanism, similar to spinodal decomposition, combined with coarsening of the iodide-rich domains at longer time-scales.

A Novel Perovskite-Polymer Composite Piezoelectric Film—From Crystal Growth to IoT Application Asif Abdullah Khan[1,2], Md. Masud Rana[1,2], Guangguang Huang[1], Nanqin Mei[1], Resul Saritas[1,2], Boyu Wen[1,2], Steven Zhang[1], Weiguang Zhu[1], Peter Voss[3], Eihab-Abdel Rahman[1,2], Zoya Leonenko[1], Shariful Islam[3] and Dayan Ban[1,2]; [1]University of Waterloo, Canada; [2]Waterloo Institute for Nanotechnology, Canada; [3]Shimco North America Inc, Canada

Developing compact, efficient, and sustainable power sources are of the urgent demand for the next generation of self-powered micro/nano devices for IoT (Internet of Things). One of the most prospective routes is to harness environmental energy by piezoelectric nanogenerator (PNG), as it is compact, flexible and has high electricity generation capabilities. In this aspect, by dispersing highly-piezoelectric nanoparticles (NPs) in a flexible polymer, creating a composite film is an attractive, yet easier approach in terms of PNG fabrication scalability, and device performance; as it can be synergistically benefitted from the incorporated highly piezoelectric NPs & flexible host polymer matrix. The quest for that, we rationally designed a novel perovskite/ PVDF composite piezoelectric film, which simultaneously benefits from a self-assembled highly ordered porous structure of PVDF, and new hybrid halide perovskite-formamidinium lead bromine iodine (FAPbBr2I). Enhanced mechanical strain by the self-assembled highly porous PVDF, and reduced film conductivity by the FAPbBr2I (higher relative permittivity~13) , generates a strain-induced piezo potential of 85 V (peak-to-peak), and current of up to 30 µA (peak-to-peak) (138 g (gram) of applied load). Benefiting from the above, a high output peak power density of ~ 18 mW/cm^3 (while~ 3 mW/cm^3 at 7 MΩ load resistance) was obtained for the self-powered integrated wireless electronics node (SIWEN) and then extended it to the real application by realizing wireless structural health monitoring.
In order to synthesize the hybrid perovskite-polymer composite piezoelectric film, low temperature and fully solution-based growth processes were adopted. The FAPbBr2I precursor solution was prepared via dissolving FAI (formamidinium iodide ≥ 99%, Sigma-Aldrich) and PbBr2 (lead (II) bromide ≥ 98% , Sigma-Aldrich) of equal molar ratio (0.5:0.5) in N, N DMF (N, N-dimethylformamide ≥ 99%, Sigma-Aldrich) solvent, followed by stirring at 60 °C for 12 hours. The PVDF solution was dissolved in the N, N DMF with constant stirring at 50 °C for 24 h. The final concentrations of FAPbBr2I and PVDF in the N, N DMF were kept at 20 wt. % and 10 wt. %, respectively. Intentionally, the concentration of PVDF in the final solution was diluted by perovskite precursor and the thickness of preformed films was controlled to less than 50µm. The aim is to decrease the inner vapor pressure during the film growth and to form the highly ordered porous structure. The optimized 20 wt. % $FAPbBr_2I$ –PVDF solution was drop-casted on a glass substrate and stored about 1 hour for the degassing process (ambient condition). In order to obtain the composite films, an annealing process at 1200C for 2-3 hours was performed (self-assembled highly ordered porosity was confirmed by SEM-EDS mapping, and the crystallinity by the X-ray diffraction peaks). After peeling off, to align the dipoles, a high voltage electrical poling of the film (thickness ~30 µm) was performed with an electric field of (50-120 V/ µm) for 2-3 hours (β-phase was confirmed by FTIR spectrum analysis). Finally, the film was sandwiched between two copper/polyester substrates by using a thermal pressing

technique for the integration of PNG.
The generated output voltage and current of perovskite-polymer PNG (P-PNG) were measured at 30 Hz frequency by applying a periodic mechanical vibration from an electrodynamic shaker (ET-126-I from Labworks Inc.) and placing a 138 g (gram) metal block (stainless steel) on top of the device. The high piezo potential 85V (peak-to-peak), and current of 30 µA (peak-to-peak), was recorded by a commercial oscilloscope. Later, to assess a real-time application, we designed a self-powered integrated wireless electronics node (SIWEN) enabled by the PNG, that can communicate with personal electronics

High-Sensitivity Near-UV PES for Valence Band Determination and Observation of Defect Formation In Halide Perovskites Dorothee Menzel[1], Alvaro Tejada Esteves[1,2], Amran Al-Ashouri[1], Igal Levine[1], Jorge A. Guerra[2], Bernd Rech[1], Steve Albrecht[1] and Lars Korte[1]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]Pontificia Universidad Católica del Perú, Peru

Halide perovskites (HAPs) have attracted immense interest in the optoelectronic community over the past decade. While the power conversion efficiency of perovskite solar cells has rapidly increased during this time, fundamental material properties, such as the true arrangement of the valence bands and dispersion relation of halide perovskites or defects at/close to their surfaces are still under debate.
Here, we report on photoelectron spectroscopy investigations on a multi cation multi halide perovskite composition, which has been used for recently reported highest silicon/perovskite tandem solar cell efficiencies.[1]
Conventionally, He-I UPS is applied to study the valence band maximum, required for understanding the electronic formation of semiconductor interfaces. He UPS suffers from a rather high noise floor and the need for correction of He-satellite lines. As we show in our study, the characteristically low density of states close to the valence band maximum[2,3] can only be revealed by very high sensitivity PES techniques. To this end, we apply a “classical” but rarely used technique: near-UV photoemission spectroscopy in constant final mode (CFSYS) and can directly trace the density of states over a very high dynamic range of seven orders of magnitude. This is four orders of magnitude better compared to conventional He-I UPS. Additionally, with the low photon energy, the information depth is strongly enhanced to up to 10 nm and thus, the gained information is significantly less distorted by changes of material composition in the first monolayers or surface contaminations, as compared to He-I UPS.
Using a newly developed model[4] to describe the valence band edge and exponential band tail, we can distinguish between two valence band maxima, at two different positions in k-space, in one angle-integrated spectrum. Furthermore, it becomes apparent, that the widely applied method to determine the valence band maximum (by an extrapolation of the leading valence band edge on a semi-logarithmic scale) strongly depends on the noise level and can thus not provide reliable results. Importantly, we also show that there is a fundamental caveat to such extrapolation approaches: The highest valence band maximum at the R-point of the Brillouin zone overlaps with a distinct defect band and can thus only be located by combining the analysis of experimental data with DFT calculations.
The low detection limit of CFSYS further reveals occupied gap states, i.e. defect states that will influence recombination and thereby device performance. By rescaling our data to published DFT calculations[5], we can quantify these depending on the damage by illumination (UV, X-Rays) or storing condition (vacuum, short air exposure). To our knowledge, this is the first time that such defects are not only observed, but also quantified from photoelectron spectroscopy data. These unprecedented results show the decomposition of HAP films and creation of defect states at a sensitivity level, which can hardly be reached by any other PES technique.

High Carrier Mobilities of Lead Halide Perovskite Single Crystals Evaluated by AC Photo-Hall Measurements Takumi Kimura[1], Kouhei Matsumori[1], Kenichi Oto[1], Yoshihiko Kanemitsu[2] and Yasuhiro Yamada[1]; [1]Chiba University, Japan; [2]Kyoto University, Japan

Lead halide perovskites have recently attracted attention as high-quality semiconductors with excellent optical properties, promising for various device applications. In contrast, the reported carrier mobilities in lead halide perovskites are relatively low compared to other high-quality inorganic semiconductors. The low mobilities have been discussed in terms of polarons, which enhance the carrier mass through electron-phonon coupling and reduce the carrier mobility. However, the impact of polarons on carrier transport of lead halide perovskite still remains unclear. To reveal the physical origin of the low carrier mobility, we need to perform the reliable Hall measurement in high-quality single crystals and evaluate their intrinsic mobility. Nevertheless, lead halide perovskite materials have very high resistivities; therefore, it is difficult to measure the Hall mobility of carriers by the conventional method.
In this study, we performed an AC Hall measurement of a $CH_3NH_3PbBr_3$ bulk crystal at room temperature under light irradiation [1]. We illuminated the sample by a green laser (λ=555 nm) to generate photocarriers uniformly. We can estimate the mobilities of holes and electrons independently from conductivities and Hall coefficients under different photoexcitation intensities based on two-carrier analysis [1]. The conductivities were measured by van der Pauw method. We evaluated the resistivities from the slope of I-V profiles to eliminate the photovoltaic effect. To obtain the Hall voltage in a low-current regime, we performed the Hall measurement under ac-magnetic field (0.4 T / 0.1 Hz) by a lock-in technique. We prepared undoped single crystals of $CH_3NH_3PbBr_3$ by the anti-solvent crystallization method [2]. The crystals were thinned to 50 µm in order to increase the current density and generate the photocarrier more uniformly. We fabricated Au/rubrene electrodes at the four corners of the sample. The intermediate layer of rubrene between $CH_3NH_3PbBr_3$ and Au reduces the contact resistance.
The observed carrier mobilities were enhanced drastically with increasing photocarrier density and show the square-root dependence on photocarrier density [3]. We consider that the dependence of photocarrier density is attributable to the screening of the charged dislocations by photocarriers [4]. We obtained the hole and electron mobilities of 322 cm^2/Vs and 318 cm^2/Vs at the maximum photocarrier density, and these mobilities would further increase with carrier density. The mobilities obtained from this research are much higher than those reported in previous studies. The result implies that polarons do not have a large impact on the carrier mobilities, which is consistent with our recent magnetoreflectance study [5]. Rather, we consider that the scattering by defects is more important in room-temperature carrier transport in lead halide perovskite. Therefore, it is significant to reduce defects, which could help deliver the full potential of this material.

Highly Piezoelectric Organic-Inorganic Hybrid Vacancy-Ordered Double Perovskite for Energy Harvesting Asif Abdullah Khan[1,2], Md. Masud Rana[1,2], Guangguang Huang[1], Chao Xu[1,2], Shuhong Xu[3], Resul Saritas[1,2], Steven Zhang[1], Weiguang Zhu[1,2], Eihab-Abdel Rahman[1,2], Pascal Turban[4], Soraya Ababou-Girard[4], Chunlei Wang[3] and Dayan Ban[1,2]; [1]University of Waterloo, Canada; [2]Waterloo Institute for Nanotechnology, Canada; [3]Southeast University, China; [4]Univ Rennes, CNRS, France

To maximize the output power of PNGs, the piezoelectric charge (d_{33}) and voltage (g_{33}) coefficients of the piezoelectric materials are both important, which will determine the output current and voltage respectively. However, in the past decades, it is difficult to combine them in one material for piezoelectric energy harvesting, such as piezoelectric nanogenerators (PNGs). In this work, we firstly report a combined large d_{33} of 137 pCN^{-1} and giant g_{33} of 980 $\times 10^{-3}$ VmN^{-1} in a novel vacancy-ordered double perovskite of $TMCM_2SnCl_6$ (TMCM is trimethyl chloromethyl ammonium). The piezoelectric origin is demonstrated as the halogen-bonding mediated synergistic movements of atom displacement in inorganic $[SnCl_6]^{-2}$ octahedrons and dipole reorientation of organic molecular TMCM via a combined density functional theory (DFT) and experimental study. The piezoelectric composite films are grown via dispersing $TMCM_2SnCl_6$ into the polydimethylsiloxane ($TMCM_2SnCl_6$@PDMS). The final PNGs exhibit the highest outstanding outputs with an open-circuit voltage of 149 V (peak-to-peak), short-circuit current density of 1.54 μAcm^{-2} (peak-to-peak), and total power of 26 μW under periodically vertical compression (4.8 N). Moreover, the PNGs are used as the power source of self-powered wire-less electrics (SPWLE) and enable communication successful. Our studies not only innovatively open a door for a new green piezoelectric perovskite design but also extend its further application in energy harvesting and its SPWLE.

Advances in Hybrid Perovskite Film Deposition by Slot-Die Coating Method Yaneth A. Florez Velasquez, Juan P. Velasquez, Rafael A. Betancur, Daniel E. Ramírez, Juan F. Tirado, Juan F. Montoya and Franklin Jaramillo; Universidad de Antioquia, Colombia

Among the emerging photovoltaic technologies, hybrid perovskite solar cells (PSCs) provide the highest energy conversion efficiencies years (Phaometvarithorn, Chuangchote, Kumnorkaew, & Wootthikanokkhan, 2018; Tang & Yan, 2021) however, it is necessary to promote the transition from laboratory-scale to large-area manufacturing ensuring high throughput and comprising the analysis of perovskite film formation and the scalable deposition techniques, aiming to improve the perovskite thin-film stability and homogeneity (Burkitt et al., 2020; Burkitt, Searle, A.Worsley, & Watson, 2018; Patidar, Burkitt, Hooper, Richards, & Watson, 2020).

Slot-Die Coating technique has been extensively applied in industry, where a great effort is directed to stabilize the coating process (Miller, 2012; O. J. Romero, Suszynski, Scriven, & Carvalho, 2004; Oldrich Joel Romero, Scriven, & Carvalho, 2006; X. Ding, J. Liu, 2016). In this direction, a prior condition is achieving a uniform volume distribution along the slot-die head and related to the crystallization process for uniform film formation, which to the best of our knowledge this has not been studied for perovskite inks. In this paper we propose to explore the nature of the flow patterns inside the slot-die head and the influence of this study in the fabrication of hybrid perovskites films by slot-die processing.

We included an analysis of the volume uniformity inside a lab-scale slot-die head, as a function of the head angle and inlet flow, designed for the fabrication of perovskite solar cells, is accomplished. We identify issues such as poor filling of the shim apertures and a non-fully developed laminar flow inside the slot-die head for the common lab processing conditions, as the main causes of non-uniform volumetric flow and the result is nonhomogeneous films and crystallization defects of the perovskite. These results contribute to pave the way towards highly reproducible and scalable perovskite solar devices by slot-die coating.

Green-Synthesized Tungsten-doped Zinc Oxide as Promising Electron Transport Material for Perovskite Solar Cells Munkhtuul Gantumur[1], Md. Shahiduzzaman[1], Md. Shahinuzzaman[2], LiangLe Wang[1], Masahiro Nakano[1], Makoto Karakawa[1,1,1], Jean Michel Nunzi[1], Md. Akhtaruzzaman[2] and Tetsuya Taima[1,1,1]; [1]Kanazawa University, Japan; [2]The National University of Malaysia, Malaysia

Organic-inorganic hybrid halide perovskite solar cells (PSCs) have been extensively researched and achieved impressive power conversion efficiency (PCE) of 25.5% at laboratory scale. To date, several metal oxides, such as ZnO, TiO_2, and SnO_2 are used as electron transport layer (ETL) for the fabrication of efficient PSCs. Particularly, ZnO showed favorable energy level, smooth surface coverage and most importantly low-cost deposition capabilities are highly desired for efficient photovoltaic performances and their future commercialization and market adoption. However, the application of ZnO ETL to PSCs remains limited by drawbacks such as low conductivity and large amounts defects, which inevitably lead to carrier recombination. Notable efforts have been made by using doping, nanocomposites or interface engineering strategies to resolve these drawbacks to enhance the performances of PSCs. Tungsten (W) is one of the candidates for doping ZnO due to the similar ionic radius of Zn^{2+} (0.074 nm) and W^{6+} (0.064 nm). In this study, we introduced W-doped ZnO synthesized using Aloe Vera leaf extract as the ETL and investigated their influences in PSCs performance. Our results demonstrated a smooth and dense surface morphology of W-doped ZnO deposited on ITO-patterned substrate. Higher crystallinity was observed for $Cs_{0.1}FA_{0.9}PbI_3$ perovskite layer formed on W-doped ZnO because the as-prepared W-doped ZnO material started with better crystallinity. Ultimately, PSCs with W-doped ZnO ETL exhibited PCEs as high as 16.2%, which is superior to those of PSCs with pristine ZnO as the ETL (12.9%). The integrated J_{sc} values of the IPCE spectra are 20.4 and 22.5 $mAcm^{-2}$ for the pristine ZnO and W-doped ZnO based PSCs, respectively. These values are coherent with the J_{sc} values extracted from the *J–V* curves. Hence, the present study provides a significant advance to the design of photovoltaic devices with respect to charge transport and electron-hole recombination.

SESSION EN05.18: Perovskite Composition Versatility

9:00 PM *EN05.18.01
Unraveling the Hysteretic Behavior at Double Cations-Double Halides Perovskite–Electrode Interfaces Dohyung Kim[1], Yongtao Liu[2], Anton V. Ievlev[2], Kate Higgins[1], Olga Ovchinnikova[2], Sergei V. Kalinin[2] and Mahshid Ahmadi[1]; [1]University of Tennessee, Knoxville, United States; [2]Oak Ridge National Laboratory, United States

Despite over a decade of research on metal halide perovskites (MHPs) in the context of photovoltaic applications, understanding the nature of electronic and ionic processes associated with current-voltage (*I-V*) hysteretic behavior has been limited. In this study, we explore the hysteretic behavior in $(FAPbI_3)_{0.85}(MAPbBr_3)_{0.15}$ perovskite devices with lateral Cr and Au electrodes by applying first order reversal curve (FORC) bias waveform in *I-V*, Kelvin probe force microscopy (KPFM) measurements, and in-situ chemical imaging by time-resolved time-of-flight secondary ion mass spectrometry (tr-ToF-SIMS).
Previous studies suggested that *I-V* hysteresis in MHP devices is associated with various interfacial phenomena such as space charge layers, resulting from ion migration[1,2], interfacial charge accumulation and recombination[3], and charge trapping and de-trapping at the interface[4]. Particularly, ion migration has a critical role in the hysteresis and transient phenomena in MHPs devices.[4,5] Many intriguing properties in MHPs are highly associated with the interplay between electronic charge carriers and multiple mobile ion species. The ion migration is in fact one of the most acute issues that perovskites community faces, due to the key role it plays on device stability and performance. Although, double cations and double halides perovskites have been attracted much attention due to their high efficiencies and remarkable long-term stability in photovoltaics. More complex interplay between electronic and ionic charge carries is expected in the double cations and double halides perovskites due to the presence of multiple mobile ions.
Here, we strategically utilize the combination of time- and voltage-dependent I-V and KPFM, with in-situ chemical imaging by tr-ToF-SIMS measurements to identify spatial localization and nature of the involved species. To study the time dynamics, we use a bias waveform referred as FORC that allows separating bias-induced chemical effects in dark and under illumination. The FORC waveform is also applied to the KPFM measurements to clarify spatial- and time-resolved contact potential difference (CPD) in the devices. The time- and bias-dependent ion distribution is explored using tr-ToF-SIMS to directly investigate the chemical changes in operando devices. This approach supported by machine learning analysis provides the correlation between ion dynamics and the hysteresis phenomenon in I-V and CPD-V curves. Some of the key findings in this study include: i) We discovered that Br^- ions accumulate at the interface between $(FAPbI_3)_{0.85}(MAPbBr_3)_{0.15}$ perovskites and drain electrode in both on- and off-fields. ii) The low mobility of MA^+ ions result in transient behavior and contribute to the hysteretic phenomena in the *I-V* and KPFM results. iii) It was shown that Pb^{2+} ions can be reduced at the interfaces due to electrochemical reactions with the electrode in the presence of charge injection and photogenerated charge carriers. iv) The ion migration can be fully or partially reversible while the electrochemical reaction at the interface can result in non-reversible and permanent damage to the device performance and stability.
Overall, our results clearly show the important role of interfacial phenomena and highlight that appropriate interface engineering is critical for highly efficient and stable MHPs-based devices. Our study suggests that lower concentration of Br^- and MA^+ ions can result in higher interfacial stability and less hysteretic behaviors in double cations and double halides perovskite devices.

This article is already submitted and currently under review.

Late News: Halide Perovskite Formation Mechanism Unveiled by Synchrotron-Based *In Situ* GIWAXS Minchao Qin, Yuhao Li, Zhaotong Qin and Xinhui Lu; The Chinese University of Hong Kong, Hong Kong

Solution-processed halide perovskite solar cells (PSCs) have attracted tremendous attention due to their skyrocketing power conversion efficiency (PCE) from 3.8% to 25.5% in recent years. The rapidly rising efficiency is mainly attributed to the improved perovskite film quality, which is usually achieved through precursor engineering, compositional regulation, and optimization of the film fabrication process. However, most developments of these methods are empirical, and few efforts have been devoted to the fundamental studies of the perovskite film formation mechanism. In this work, the underlying perovskite crystallization process from the initial precursor solution to the final polycrystalline film was investigated and unveiled with the aid of synchrotron-based in situ grazing-incidence wide-angle X-ray scattering (GIWAXS) measurements. Specifically, the detailed crystallization pathways of mixed perovskites ($MA_{0.17}FA_{0.83}Pb(I_{0.83}Br_{0.17})_3$) during the one-step spin-coating process were monitored via state-of-the-art in situ GIWAXS. Three crystallization stages were successfully identified: the precursor solution (stage I), hexagonal δ-phase (2H) (stage II), and complex phases (stage III) including the intermediate phase, hexagonal 4H, 6H polycrystals, and perovskite α-phase. In the light of in situ GIWAXS results, we revealed the existence of an “annealing window” for the first time. The as-cast film should be timely annealed within stage II (annealing window) before the formation of complex phases, in order to obtain a high-quality perovskite film. Intriguingly, the incorporating of Cs^+ can significantly extend the annealing window by inhibiting the formation of complex phases, thereby improving the device performance and reproducibility. This work provides insightful guidelines for manipulating the perovskite crystallization pathways towards higher performance. Furthermore, in situ GIWAXS was employed to monitor the perovskite crystallization kinetics during the two-step spin-coating process, including a first step of depositing the PbI_2 layer and a second step of converting PbI_2 into perovskites with organic salts (e.g. MAI, FAI). It was found that incorporating Cs^+ in the first step induced an alternative pathway from δ-$CsPbI_3$ to perovskite α-phase, which is energetically more favorable than the conventional pathways from PbI_2. However, the new phase transition caused an imbalance between the perovskite nucleation and crystal growth, resulting in pinholes in the film. Fortunately, introducing GA^+ in the second step can promote crystal growth and eliminate pinholes, boosting efficiencies by over 23%. This work demonstrates an unprecedented advantage of the two-step process over the one-step process, allowing precise control of the perovskite crystallization kinetics by decoupling the crystal nucleation and growth processes.

Optoelectronic Functionality of the A-Site Cation in Prototypical Lead Halide Perovskites—Combined Synchrotron-Based Core Level Spectroscopy and Computational Studies Gabriel J. Man[1], Pabitra K. Nayak[2], Håkan Rensmo[1] and Sergei M. Butorin[1]; [1]Uppsala University, Sweden; [2]Tata Institute of Fundamental Research, India

Lead halide perovskite (HaP) materials of the form ABX_3 have attracted substantial global research interest for over a decade and commercial solar cell and light-emitting diode (LED) applications are starting to appear on the market [1]. The A-site cation (A-cation) can be an organic or inorganic cation (methylammonium, formamidinium, cesium), the B-site cation is lead in the most well studied HaPs, and the X-site cation can be iodide, bromide,

chloride. In spite of the recent research interest and a history of basic research dating back to as early as the 1970's, there are fundamental questions to be answered. One concerns the optoelectronic function of the A-cation [2]. Solar cell and mechanical nano-indentation studies suggest the A-cation does not play an optoelectronic role, while time-resolved photoluminescence studies suggest it does.

Here we report our findings that are relevant for unraveling this scientific mystery, utilizing the first application of core level spectroscopy to single crystals of HaPs. In the first part of my talk, I will present a comparative study of three archetypal lead bromide perovskite ($APbBr_3$) compounds using Br *K*-edge high energy resolution fluorescence detection X-ray absorption spectroscopy (HERFD-XAS) and simulated XAS spectra. We find a nearly linear correlation between relative Goldschmidt tolerance factor, a widely used structural descriptor that is affected by the size of the A-site cation, and the energetic width of the conduction band [3]. These findings are potentially relevant for understanding the mechanism of slow hot electron cooling in HaPs. Using Br *K* X-ray emission spectroscopy (XES), we find relative differences in lead-bromide bond ionicity. These results are potentially relevant for understanding the origin of A-cation-related trends in device-relevant energy levels, which are crucial for designing HaP device interfaces. In the second part of my talk, I will present a study which utilizes N *K*-edge Resonant Photoelectron Spectroscopy (RPES) to search for electronic coupling between the organic and inorganic sub-lattices of methylammonium lead tri-iodide ($MAPbI_3$), the prototypical hybrid organic-inorganic HaP. We find that the occupied states are weakly coupled, but find substantial coupling in the unoccupied states via the observation of normal Auger decay upon resonant excitation [4]. I will also talk briefly about findings from a complementary computational-oriented study [5]. Our studies challenge a notion based on previous studies that the A-cation is electronically inert.

Optical Gain Performance of Lanthanide-Based Chloride Double Perovskite in the Near Infrared Daniela Marongiu[1], Fang Liu[1], Stefano Lai[1], Fabio Manna[2], Maria Laura Mercuri[2], Michele Saba[1], Francesco Quochi[1], Andrea Mura[1] and Giovanni Bongiovanni[1]; [1]Universita di Cagliari, Italy; [2]Università degli Studi di Cagliari, Italy

Codoping chloride double perovskites of general formula $Cs_2Na_xAg_{1-x}InCl_6$ with Bi^{3+} and Ln^{3+} (Ln = Yb,Er) ions is attracting increasing interest owing to the potential of this class of materials as broad-band phosphors across the visible and near infrared (NIR) spectrum [1-4]. Beside the application in phosphors, it is interesting to assess the suitability of these materials as NIR gain and laser media when lanthanide concentration is raised up towards the level of 100% at.
Here, we explore the optical performance of a number of Ln-based chloride double perovskites with special emphasis on Ln optical cross-sections, excited-state lifetimes and radiative efficiencies. We compare double perovskites' optical gain figures of merit with those of a conventional Ln-doped crystal, that is, yttrium aluminium garnet (YAG).
All chloride double perovskites were synthesized as polycrystalline powders by solvent evaporation of acidic solutions of precursor salts.
$Cs_2Na_{0.8}Ag_{0.2}InCl_6$ doped with Yb^{3+} and Er^{3+} at ~1% at. level displayed unprecedentedly long excited-state lifetimes of ~3 ms (Yb) and ~21 ms (Er), from which radiative efficiencies for the emissions at ~1030 nm (Yb) and 1530 nm (Er) were estimated to be ~60% and ~80%, respectively. In $Cs_2NaYb_{0.9}Bi_{0.1}InCl_6$ and $Cs_2NaYb_{0.9}Bi_{0.1}InCl_6$, where Ln concentration is $\sim 3\times10^{21}$ at/cm^3 (equivalent to YAG doping level of ~20% at.), Ln emission lifetimes exhibited only a minor decrease to ~2.5 ms (Yb) and ~12 ms (Er), demonstrating that Ln concentration quenching processes are relatively ineffective in these materials.
Absorption and emission cross-section spectra, inferred from measurements of diffuse absorptance, allowed to estimate optical gain coefficients and, consequently, derive all-optical figures of merit for end-pumped lasing. These estimates were also done for reference laser crystals, Yb:YAG and Er:YAG [5]. Owing to the largely suppressed concentration quenching, chloride double perovskites effectively emerge as interesting materials for NIR solid-state lasers.

Chiral Lead-Free (R/S-CHEA)$_4$Bi$_2$Br$_x$I$_{10-x}$ (x = 0 to 10) Semiconductors with Color Tunable Circular Dichroism Shangpu Liu[1], Gregor Kieslich[2], Markus W. Heindl[1], Natalie Fehn[2], Aras Kartouzian[2], Ian Sharp[1] and Felix Deschler[1]; [1]Walter Schottky Institut and Physik-Department, Technische Universität München, Germany; [2]Fakultät für Chemie Technische, Universität München, Germany

Hybrid organic inorganic perovskites are optoelectronic materials with tunable chemical and electronic structures. Incorporating chiral organic molecules into perovskite networks also attracts great attention due to their potential optical communication applications. Nevertheless, most reported chiral perovskite materials possess high toxic Pb, which potentially limits their practical applications. Here, we introduce chiral organic molecules R/S-1-cyclohexylethylamine (R/S-CHEA) into lead-free bismuth based materials with perovskite motif, and grow color tunable chiral lead-free (R/S-CHEA)$_4$Bi$_2$Br$_x$I$_{10-x}$ (x = 0 to 10) crystals and thin films. We perform single crystal XRD measurement and DFT calculation to identify their crystal structure and electronic band structure. We further investigate their optical properties. We find the absorption peak position is shifted from 386 nm to 493 nm, while Circular Dichroism (CD) signals can be turned widely from 366 nm to 535 nm, by changing the ratios of bromide and iodide anions in (R/S-CHEA)$_4$Bi$_2$Br$_x$I$_{10-x}$. Specifically, we employ steady-state and time-resolved PL spectra measurements on (R-CHEA)$_4$Bi$_2$Br$_{10}$ film, which has a broad emission peak located at around 520 nm and shorter lifetime compared with that of $Cs_2AgBiBr_6$. Besides, temperature and fluence dependent time-resolved PL spectra are also performed to investigate the charge carrier dynamics in (R-CHEA)$_4$Bi$_2$Br$_{10}$. Our demonstration of color tunable chiral lead-free perovskites gives the possibility to discover high performance and nontoxic optical spintronic materials.

10:30 PM EN05.18.06
Compositional Screening of Bi and Br Incorporation to Stabilize Black γ-CsPbI$_3$ Films via Pulsed Laser Deposition Wiria Soltanpoor[1], Yorick A. Birkholzer[1], Vivien Kiyek[1], Martin Ledinsky[2] and Monica Morales-Masis[1]; [1]Mesa+ Institute for Nanotechnology, University of Twente,

Netherlands; [2]Institute of Physics, Academy of Science of the Czech Republic, Czechia

Halide perovskites have lured enormous attention due their unique optoelectronic properties. However, the complex stoichiometry of stable halide perovskite compounds motivates the search for volatility- and solubility-insensitive deposition methods.
Pulsed Laser Deposition (PLD) is a versatile method capable of multi-element ablation off a solid target irrespective of its chemical complexity, allowing single-source deposition of complex halide perovskite compositions [1–3]. This relaxes concerns of thin film formation such as incompatible solubility issues with solution process or different elemental volatilities in the case of co-evaporation [4]. Here we use PLD to trigger the structural instability of $CsPbI_3$ at room temperature by partial replacement of Pb with Bi or that of I with Br. The link between the PLD parameters and the film crystallinity and morphology was investigated proving compact, smooth and highly crystalline black orthorhombic $CsPbI_3$. The stoichiometric control was implemented by the precursors molar concentration in the PLD target. The correlation between different levels of Bi concentration and the crystallinity, film stoichiometry, and optoelectronic structure of $CsPbI_3$ was monitored using X-ray diffractometry (XRD), X-ray florescence (XRF), photoluminescence and photothermal deflection spectroscopy (PDS) analyses. The incorporation of Bi in the structure of $CsPbI_3$ resulted in improved stability of the film up to 154 hours. In a similar fashion, introducing Br to $CsPbI_3$ resulted in films stable over 100 days.
The stabilization of halide perovskites through adding chemical species during PLD unlocks its grave potential in growing optimal halide perovskite films and optoelectronic devices. In addition, the solvent-free nature of PLD, nearly stoichiometric transfer, scalability, and control over the chemical composition and thickness, make this technique particularly interesting for composition screening of dopants and multicompounds, as well as to fabricate and study multi-layered solar cells such as all-perovskite tandem solar cells.

Chirality and Structure-Property Tunability within Hybrid Metal Halide Perovskites David B. Mitzi; Duke University, United States

Hybrid organic-inorganic perovskite (HOIP) semiconductors based on metal halide frameworks offer unprecedented opportunity to tailor structural and materials properties using the full flexibility afforded by the associated inorganic and organic components,[1,2] and such tunability points towards wide-ranging potential for applications including solar cells, light-emitting devices, detectors, transistors and advanced computing devices. In this talk we will focus on the role that organic cation chirality can have on HOIP structure and properties including, for example, the impact on chiroptical and electrical transport (e.g., circularly polarized absorption and chirality-induced spin selectivity[3]), electronic structure (e.g., spin splitting of the conduction band[4]) and thermal properties (e.g., accessing a low-melting temperature and glassy state[5]). The above examples point to the great potential of using chirality for enabling and coupling control over light, charge and spin within the important HOIP semiconductor family.

Novel Film Annealing Process and Durable Perovskite Solar Cells Huanping Zhou; Peking University, China

Recently, solution processed hybrid perovskites show intriguing electronic and optoelectronic properties applicable in various device application, and the developing of high quality materials with improved homogeneity and less defects is crucial. In this talk, I mainly focused on the rational design and fabricate perovskite films, and the construction of efficient and stable photovoltaic devices. Two related aspects are discussed: 1) Develop liquid medium annealing process that leads to the films with high crystallinity, less defects, desired stoichiometry, and overall film homogeneity, to achieve high performance photovoltaics with certified efficiency of 24.5%; 2) Propose methods such as "redox ion pair" and "multiple non-covalent bond synergistic effect" to suppress defect pairs in a sustainable way, which greatly improved the long-term stability of perovskite solar cells for over 2000 h under the stressors, e.g. light, heat, and electricity. Corresponding degradation mechanism of hybrid perovskite films and devices under operational conditions are revealed on the molecular and atomic scales.

9:00 AM *EN05.19.03
Molecular Additives in Perovskite LEDs—From Defect Passivation to Crystallization Manipulation Feng Gao; Linkoping Univ, Sweden

Metal halide perovskites have shown promising optoelectronic properties suitable for light-emitting applications. The development of perovskite light-emitting diodes (PeLEDs) has progressed rapidly over the past several years, and molecular additives have played an important role in these advances. By rational design of these molecular additives, we can significantly enhance the interaction with defects sites and minimize non-radiative recombination losses. In addition, we also demonstrate that the molecular additives can manipulate the perovskite crystallization and help to enhance the radiative recombination. As such, we have been able to demonstrate perovskite LEDs with high external quantum efficiencies over 20%. We find that our devices can also work efficiently in an emitting/detector switchable mode, with tens-megahertz speed for both functions. We further demonstrate the potential of

the dual-functional diode for biomedicine diagnosis applications (as a monolithic heart pulse sensor) and for inter- and intra-chip bidirectional optical communications.

9:30 AM EN05.19.04
Large Area Defects Compensation for Highly Efficient and Stable Formamidinium-Cesium Perovskite Solar Modules Yehao Deng[1,2] and Jinsong Huang[1]; [1]University of North Carolina at Chapel Hill, United States; [2]Perotech Inc., United States

After several years of rapid development of scalable printing of perovskites thin films, the obtainable film morphologies have been well optimized with desired smoothness, compactness, and full coverage on substrates, which are all indispensable for making a good solar cell. Now the next step is scalable defect controlling for further promoting the solar cell efficiency and stability. Two important issues arise:
(1) What types of defects are detrimental to perovskite solar cells? How do they impact efficiency or stability?
(2) How can we eliminate such defects with scalable, industry-compatible process?
This talk will discuss our recent efforts in answering these two questions. We start with formamidinium-cesium perovskite, which are known to be thermally more stable than methylamine perovskite. However, the former is found to be less photostable. We studied the light-induced degradation mechanism and found that it is the generation of iodine interstitials that capture photo-generated holes and degrade the solar cell photocurrent. We investigated the mechanism of iodine interstitial generation process and invented a defect compensation strategy by choosing a slightly AX (A is formamidinium or cesium cation and X is iodine) excessive composition to effectively suppress the process. Eventually, we improved the large area perovskite solar module's photostability with the highly-industry-compatible defect compensation strategy.

9:45 AM EN05.19.05
New Deposition Method for Pb-Free Halide Perovskite Thin Film, with Tunable Bandgap and Improved Stability Adi Kama, Anat Itzhak and David Cahen; Bar Ilan University, Israel

Pb- based halide perovskite, HaP, single-junction solar cells have improved dramatically to over 25% for small laboratory cells. Considering the toxicity of lead ions, substituting Pb with other non-toxic elements in the perovskite structure has become one of the most significant challenges associated with these materials. In this work, we replace Pb with Sn + Ge in an all-inorganic HaP for improved stability, focussing on $CsSn_xGe_{1-x}Br_3$. We do so by using a new deposition technique for thin film formation. The choice of Br as the halide is influenced by the fact that we have (much) smaller divalent cations on the B site. Naturally, doing so leads to a larger bandgap than the corresponding iodide, with enhanced environmental stability, already aided by having inorganic Cs instead of organic cations. X-Ray Diffraction results show that $CsSn_xGe_{1-x}Br_3$ forms a homogeneous solid solution, and up to 70% Ge, maintains the cubic structure of pure $CsSnBr_3$ with a shift to smaller lattice spacings with increasing Ge concentration. The optical bandgap is found to be tunable from 1.7 eV to 2.3 eV, from pure Sn to pure Ge, respectively. In N_2 atmosphere, the stability of the mixed Sn-Ge HaP is improved compared to that of the pure Sn one.

Correlating Complex Synthesis with Defect Formation in Wide Bandgap Perovskites Carolin M. Sutter-Fella; Lawrence Berkeley National Laboratory, United States

Wide bandgap mixed-halide perovskites as the top absorbers in tandem solar cells typically exhibit a larger voltage deficit in contrast to their corresponding tri-iodide-based perovskites. With this work we are tackling the challenge of directly correlating the multi-stage synthesis of bromide-containing perovskites with optoelectronic properties and consequently device performance. Our results show that the incorporation of bromide occurs via a halide homogenization process where the perovskite composition transitions from an initial bromide-rich phase to the final target stoichiometry. In situ photoluminescence measurements during synthesis reveal that bromide inclusion alters the formation dynamics. By combining experiments with first-principle calculations we suggest that the formation of $FAMACsPb(I_{1-x}Br_x)_3$ starts with the nucleation of a bromide-rich phase from solution during supersaturation followed by a retarded growth stage. The retarded growth stage is associated with a halide homogenization process that brings the composition of crystallized material to the target stoichiometry. This homogenization process not only changes the formation dynamics of mixed-halide perovskites but also promotes defect formation, which consequently leads to increased non-radiative recombination losses in the final perovskite film and thus, could explain the larger voltage deficit.

11:00 AM EN05.20.04
Emission Properties of Double Perovskites with Alloyed Bi and Ag Fang Liu[1], Daniela Marongiu[1], Angelica Simbula[1], Stefano Lai[1], Alessio Filippetti[1,2], Francesco Quochi[1], Andrea Mura[1], Giovanni Bongiovanni[1] and Michele Saba[1]; [1]Universita di Cagliari, Italy; [2]Istituto Officina dei Materiali (CNR - IOM), Italy

Lead-free halide perovskites have gained interest in competition to the lead-based counterparts which are affected by toxicity and instability over moisture. Among them, double perovskites have been developed to alternatively substitute the divalent cations Pb2+ in single perovskite with a combination of a monovalent and trivalent cation, forming structure as $A_2BB'X_6$.
Here we report the highly stable $Cs_2Na_{1-x}Ag_xIn_{1-y}Bi_yCl_6$ compounds, with Silver (x) and Bismuth (y) fractions ranging from 10% to 1 ppm, that exhibit efficient and stable broadband, white-light emission ideally suited for lighting applications.
Double perovskites were synthesized in small crystals by a super-saturation precipitation method followed by filtration and their photoluminescence quantum yield (PLQY) was measured. The highest PLQY was found to be very close to 100% and the optical properties of the crystals were studied by a combination of time resolved photoluminescence and differential transmission, in order to establish the nature of the light-emitting excited states. The measurements confirmed that emission is produced by self-trapped exciton states; the two key elements to achieve such outstanding emission properties are Bi, whose 6p states enhance the lifetime for electrons in the conduction band, and Ag, with 4d states at the top of the valence band allow efficient radiative recombination of excitons. A systematic study as a function of Bi and Ag content was employed to reveal the diffusion length for optical excitations, localization processes as well as the intrinsic limits for the excited state lifetime.
The results provide guidance for rational optimization of such compounds in view of the use as phosphors and active materials for LEDs and displays.

11:15 AM EN05.20.05
Late News: Unraveling the Surface States of Photovoltaic Perovskite Thin Film Rui Wang[1,2]; [1]Westlake University, China; [2]University of California, Los Angeles, United States

Semiconductor surfaces play an important role in the behavior of their electronic devices. The vulnerable lattice of metal-halide perovskite renders a fragile surface, where defect states can easily form. Very recently, most of the highly efficient perovskite optoelectronic devices have been reported to employ effective surface passivation strategies, further confirming the significance of surface states in regulating their device performance. Here, we present methodical studies towards understanding the surface states in perovskite thin films utilizing a strategy of molecular "defect indicator" that is able to interact with specific surface defects. In formamidinium (FA)-methylammonium (MA) mixed cation perovskite thin films, a nonuniform distribution of cations is uncovered with FA cations being close to the top and MA close to the bottom of the film, leading to unique surface defect energetics. Antisite FA_I was found to become a dominant deep trap on the surface of this system.

11:30 AM EN05.20.06
In Depth Study of Complex Perovskite-Solvent Interactions by *In Situ* Photoluminescence Spectroscopy Mehmet Derya Özeren, Bea Botka, Áron Pekker and Katalin Kamarás; Wigner Research Centre for Physics, Hungary

Lead halide perovskites have undergone rapid developments in recent years to become well established semiconductors for future optoelectronic applications. These advancements are achieved through the understanding of the solution and surface chemistry of perovskites. A selection of functional molecules lead to better control of the film formation dynamics and passivation of surface and bulk defects. These molecules are capable to form coordinate bonds, known as Lewis acid/base interactions, with perovskites. Especially Lewis bases are in the centre of attention, because they have a great impact on the performance: they promote long term stability, heal surface defects and improve the morphology of the films. However, some solvents (e.g. water) which passivate perovskite defects can cause degradation upon longer exposure. This indicates a more complex interaction which needs to be explored.
Photoluminescence (PL) is a simple and effective tool that allows us to track interactions between perovskite and reactive molecules in a controlled environment. We have evaluated by in-situ PL measurements a variety of solvents that are commonly used in perovskite processing to understand photobrightening and photodegradation responses regarding the interactions between the functional groups and the surface. Establishing the mechanism behind these interactions will provide a better understanding on how the stability of perovskites can be improved.

11:45 AM EN05.20.08
Spatially Resolving the Inhomogeneous Degradation in Perovskite Solar Cells Using Electroluminescence Mapping Zahrah S. Almutawah[1,2], Tamanna Mariam[1,2], Prabodika N. Kaluarachchi[1,2], Kshitiz Dolia[1,2], Abdul Quader[1,2], Zhaoning Song[1,2], Adam J. Phillips[1,2], Yanfa Yan[1,2] and Michael J. Heben[1,2]; [1]Wright Center for Photovoltaics Innovation and Commercialization, School for Solar and Advanced Renewable Energy, Department of Physics and Astronomy, University of Toledo, United States; [2]University of Toledo, United States

Electroluminescence (EL) mapping technique is a non-contact, non-destructive, fast, and simple testing method that spatially resolves the inhomogeneity in the electrical and optical properties of solar cells and detects micro-cracks or pinholes. It is an essential diagnostic tool for the quality control of commercial solar cells and modules. However, it is less commonly used for characterizing small-sized thin-film solar cells fabricated in laboratories.

Here, we assemble a fast EL imaging system with a high spatial resolution of ~1 μm/pixel to investigate the inhomogeneity and decomposition processing in a variety of perovskite solar cells (PSCs) with different absorber layer compositions and device configurations. We observe that most high-efficiency (>22%) PSCs show uniform and bright EL signals, while defective cells exhibit weak and spatially non-uniform EL intensity. Under different aging conditions (e.g., electric field, thermal stress, humid air, light soaking, etc.), PSCs with different absorber compositions exhibit different degradation behaviors. To explore the degradation mechanism in detail, we quantitatively compare the spatially-resolved and time-resolved EL images of FA/Cs-based PSCs with different Cs contents ranging from 0 to 40% aged in humid air with controlled humidity. Interestingly, we find that the perovskites with a high Cs content (>20%) exhibit more severe phase segregation and faster degradation in humid air, while the perovskites with too little Cs (< 10%) are phase-unstable and lose EL signal rapidly. The findings shed light on compositional engineering to enable uniform, efficient, and stable PSCs.

Optical Design for High-Efficiency White Perovskite LEDs Hin-Lap Yip[1,2], Ziming Chen[2] and Zhenchao Li[2]; [1]City University of Hong Kong, Hong Kong; [2]South China University of Technology, China

Metal halide perovskite light-emitting diodes (PeLEDs) show great potentials to be the next-generation lighting technology, with external quantum efficiencies (EQEs) exceeding 20% for infrared, red and green LEDs. However, the efficiencies of blue and white devices severely lag behind. To improve the performance of blue PeLEDs, we employed an integrated strategy combining dimensional engineering of perovskite film and recombination zone modulation in the LED device to obtain an EQE up to 5 %.[1] While further incorporating the strategy of interfacial engineering, highly efficient blue PeLEDs with EQEs over 10% have been successfully realized in our group, establishing an excellent platform for white-light emission. In our latest work, we demonstrated efficient white PeLEDs by optically coupling a blue PeLED with a red emitting perovskite nanocrystal layer in an advanced device structure, which allows to extract the trapped optical modes (waveguide and SPP modes) of blue photons in the device to the red perovskite layer via near-field effects. As a result, a white PeLEDs with EQE over 12% is achieved, which represents the state-of-the-art performance for white PeLEDs.[2]

Surface Passivation of Metal Halide Perovskites for Optoelectronics Biwu Ma; Florida State University, United States

Metal halide perovskites have attracted tremendous attentions as new generation functional materials for applications in a variety of optoelectronic devices, such as solar cells and light emitting diodes (LEDs), owing to their exceptional optical and electronic properties, as well as low temperature solution processability. While remarkable progresses have been achieved for highly efficient perovskite solar cells (PSCs) and LEDs (PeLEDs) during the last decade, numerous issues and challenges remain, including stability, lead toxicity, large scale manufacturing, etc. To achieve high efficiency and stability simultaneously, surface passivation of perovskite thin films and nanocrystals by organic/inorganic species is one of the most effective approaches, which could not only reduce surface defects, but also protect the surface from atmospheric moisture. In this talk, I will discuss our recent efforts on the development and study of various types of surface passivation agents for halide perovskite thin films and nanocrystals, with which highly efficient and stable PSCs and PeLEDs are achieved. For instance, a low-cost industrial organic pigment, quinacridone (QA), has been investigated as surface passivation agent for PSCs by solution processing of a soluble QA derivative followed by thermal annealing to convert it into insoluble QA. Passivation with strong interactions between QA and metal halides, together with the hydrophobicity of QA coating, enabled highly efficient PSCs with remarkable stability.

2:00 PM EN05.21.04
Double N-Type Interconnection Structure of C_{60}/SnO_{2-x} for Efficient and Stable All-Perovskite Tandem Solar Cells Zhenhua Yu and Jinsong Huang; University of North Carolina at Chapel Hill, United States

The efficiencies of all-perovskite tandem devices are improving quickly. However, their complex interconnection layer (ICL) structures – with typically four or more layers deposited by different processes – limit their prospects for applications. Here, we report an ICL in all-perovskite tandem cells consisting merely of a fullerene layer and a SnO_{2-x} ($0<x<1$) layer. The C_{60} layer is unintentionally n-doped by iodine ions from the perovskite and thus acts as an effective electron collecting layer. The SnO_{2-x} layer, formed by the incomplete oxidization of tin ($x=1.76$), has ambipolar carrier transport property enabled by the presence of a large density of Sn^{2+}. The $C_{60}/SnO_{1.76}$ ICL forms Ohmic contacts with both wide and narrow bandgap perovskite subcells with low contact resistivity. The ICL boosts the efficiencies of small-area tandem cells (5.9 mm^2) and large-area tandem cells (1.15 cm^2) to 24.4% and 22.2%, respectively. The tandem cells remain 94% of its initial efficiency after continues 1-sun illumination for 1,000 hours. The efficnecy of all-perovskite tandem solar cell is further improved to beyond 25% by increasing the carrier diffussion length of Sn-Pn NBG perovskite to ~2um via doping modification.

2:15 PM EN05.21.05
High Carrier Mobility Hybrid Organic–Inorganic Perovskites Quantum Wells Pan P. Adhikari[1], Yao Gao[2], Chendi Xie[1], Letian Dou[2] and Jianbo Gao[1]; [1]Clemson University, United States; [2]Purdue University, United States

In contrast to the traditional inorganic semiconductors quantum wells, solution-processed hybrid organic–inorganic perovskites (HOIP) quantum wells, as emergent new materials, can be a vital player in optoelectronics such as solar cells, LEDs, transistors, and photodetectors. The molecular engineering of organic semiconductors, combing with the composition engineering of monolayer perovskites offer the tunability of electrical and optical property.
In this report, we investigate the carrier transport dynamics of the $(4Tm)2PbI_4$ and $(4Tm)2SnI_4$, where 4Tm is a π-conjugated oligothiophene ligand of 2-(3‴,4′-dimethyl-[2,2′:5′,2″:5″,2‴-quaterthiophen]-5-yl)ethan-1-ammonium. By using the state-of-the-art ultrafast photocurrent spectroscopy with a sub-20 ps time resolution, the $(4Tm)2PbI_4$ and $(4Tm)2SnI_4$ HOIP quantum wells demonstrate > 10 cm^2/Vs carrier mobility, and the transport dynamics can be described by a band-like transport mechanism with a rapid trapping time of 60 ps after photoexcitation. Our work demonstrate the promising applications of HOIP quantum well in high-speed photodetection and optical quantum communication.

2:30 PM en05.12.06
The Non-Inocent Role of HTMs in Perovkite Solar Cell Development—The Case of CuSCN Francesco Lamberti[1], Min Kim[2], Gaudenzio Meneghesso[1], Silvia Gross[1], Annamaria Petrozza[3] and Teresa Gatti[4]; [1]University of Padova, Italy; [2]Jeonbuk National University, Korea (the Republic of); [3]Istituto Italiano di Tecnologia, Italy; [4]Justus-Liebig-Universität Giessen, Germany

The development of novel hole transporting materials (HTMs) which can improve the stability of lead-halide perovskite solar cells (PSCs) operating in ambient conditions is a valuable strategy to address the future commercialization of this ultra-cheap photovoltaic technology. Among other HTMs, we have identified poly(3-hexylthiophene) (P3HT), a highly soluble and easy-to-process from solution semiconducting polymer, to be a good compromise for ensuring decent efficiencies to PSCs at relatively low-costs in comparison with the benchmark HTM based on the Spiro-OMeTAD small molecule. Spiro-OMeTAD indeed requires doping with LiTFSI and tert-butyl pyridine additives to be sufficiently active for hole transport and, in this regard, we have recently demonstrated an up-to-now unknown mechanism of de-doping induced by the latter additive, that we will discuss in this contribution.[1] We then looked for other possible nanomaterials to couple with P3HT for the development of even more efficient HTMs and stable PSCs. We will thus discuss here the outcomes of our most recent contribution, [2] in which we suggest that a CuSCN nanoplateletes/P3HT composite, combining hole extraction and transport properties with water oxidation activity, transforms incoming water molecules and triggers the in situ p-doping of the conjugated polymer, improving transport of photocharges. Insertion of the nanocomposite into a lead perovskite solar cell with a direct photovoltaic architecture causes stable device performance for 28 days in high-moisture conditions. Our findings demonstrate that the engineering of a hole extraction layer with water-splitting additives could be a viable strategy to reduce the impact of moisture in perovskite devices. Stable Ambient Processed Mixed-Cation Perovskite Solar Cells Ivy M. Asuo[1], Riad Nechache[1], Sylvain G. Cloutier[2] and Alain Pignolet[1]; [1]INRS, Canada; [2]École de Technologie Supérieure, Canada

The fabrication of stable and efficient halide perovskite solar cells under ambient conditions is a formidable challenge due to the sensitivity of halide perovskites to moisture, oxygen, and thermal stress effects [1–4]. In order to simplify the synthesis processes and consequently bring down the production cost, there is an imperative interest to develop a method for fabricating perovskite solar cells with long term stability under ambient conditions.
This work presents a method for synthesizing efficient and stable mixed-cation halide perovskites by tuning their physical and microstructural properties entirely under ambient conditions. We highlight the essential contribution of lead thiocyanate additives and solvent treatment in the fabrication of

perovskite thin films and the very promising performance and stability of their solar cells made using this method [4,5]. The developed approach leads to a significant improvement of both the morphology and the crystallinity of the films. As a result, the optimized solar cells without encapsulation retained ~80% of their initial performance after ten months of storage, resulting in a lifetime T_{80} of approximately 5000 hours (i.e., ~7 months). Our findings suggest that the efficiency and stability of the perovskite solar cells are highly dependent on the processing conditions, thin film morphology, trap density, and carrier mobility in the device before and after storage. The ability to develop these perovskite solar cells entirely under ambient conditions coupled with their high performance paves the way towards the industrial production of low-cost, efficient, and long-term stable solar cells.

8:15 AM EN05.09.15
Late News: Colloidal Synthesis of Lead-Free Cs2TiBr6-xIx and Cs2Ti1-xSnxI6 Vacancy-Ordered Perovskite Nanocrystals Shanti Maria Liga[1] and Gerasimos Konstantatos[1,2]; [1]ICFO, Spain; [2]ICREA, Spain

Perovskites now play a pivotal role as an emerging class of semiconductors after their first introduction in solar cells in 2009, but their commercialization has been hindered so far by the toxicity of lead and by their instability. For this reason, in the last few years, part of the perovskite community has focused on the search for alternative elements to lead that are not a threat to the environment and that can produce a stable perovskite structure. Vacancy-ordered halide perovskites, with general formula $A_2B^{+4}X_6$, are one of the alternative structures that have been designed to replace Pb^{2+} with non-toxic tetravalent cations. Among these, cesium titanium(IV) bromide perovskite is an environmentally friendly material that has attracted attention in the last three years for its application in solar cells with power conversion efficiencies reaching 3.3% [1]. However, a solution method suitable for the preparation of thin films has not yet been developed. We present here the first colloidal synthesis of pure and mixed bromide–iodide cesium titanium perovskite nanocrystals (NCs), carried out using the hot-injection method [2]. With this method, we were able to synthesize stable solutions of mixed bromide/iodide $Cs_2TiBr_{6-x}I_x$ NCs that can be easily deposited as thin films. In our approach, titanium and cesium organic salts are dissolved in octadecene with oleic acid and a zwitterionic ligand and react at 140 °C with a mixture of trimethylsilyl bromide and trimethylsilyl iodide. The resulting perovskite NCs show the expected cubic structure, with lattice parameter increasing with the higher amount of iodide in the structure, and exhibit bandgap tunability from 2.3 eV to 1.2 eV going from a pure bromide to a pure iodide perovskite. Moreover, we have observed that the method used to quench the reaction plays a fundamental role in determining the shape of the NCs. Finally, we measured that the Cs_2TiBr_6 NC films are stable for 1 hour at 100 °C and after 4 hours of UV light irradiation in a nitrogen atmosphere. However, they decompose quickly in air. Their fast decomposition in air motivated us to look for strategies to stabilize them. Since cesium tin(IV) halide perovskites have the same crystal structure as cesium titanium(IV) halide perovskites and are stable in air, we decided to replace partially or fully the titanium with tin, using the same synthetic method developed for pure titanium vacancy-ordered perovskites. A series of new materials, namely mixed titanium-tin $Cs_2Ti_{1-x}Sn_xI_6$ vacancy-ordered perovskite nanocrystals, was synthesized and characterized. The lattice parameter slightly increases from a pure titanium to a pure tin perovskite, going from 11.5 Å to 11.7 Å, and the bandgap increases up to about 1.55 eV when replacing all the titanium with tin.

Low Voltage Edible Electronic Devices—Organic Transistors and Circuits Based on Natural Electrolytes Alina Sharova[1,2] and Mario Caironi[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Milano, Italy

Edible electronics is an evolving field of research whose ultimate goal is to develop a new class of microelectronic devices that are edible. The concept of this unconventional approach implies the use of natural and food-based materials, and their electronic properties for realization of safe for ingestion devices. The unique combination of electronic functionality, low cost, and safety for both human and environment suggests broad application opportunities for smart medications and food safety monitoring.
In this framework, we explore the potential of natural edible substances, honey and chitosan, to be used as electrolytic gate dielectrics in complementary organic transistors and integrated logic circuits, namely, inverting logic gates and ring oscillators. Low voltage operation in air < 1 V and compatibility with both hole and electron transporting materials are the feature characteristics of the designed devices. In addition, a strong responsivity of the devices to relative humidity levels suggests their possible use as humidity indicators, in perspective, for moisture monitoring of dried or dehydrated food. Lastly, we realize the arrays of lightweight fully printed devices on edible flexible and conformable substrates.

10:45 AM EN06.01.03
Late News: All-Polymer Field Effect Transistors Printed on Biodegradable Substrates Fabrizio A. Viola, Elena Stucchi and Mario Caironi; Italian Institute of Technology, Italy

The growing demand of disposable electronics raises serious concerns for the corresponding increase amount of electronic waste (e-waste), with severe environmental impact. Organic and flexible electronics have been proposed long ago as a more sustainable and energy efficient technological platform with respect to established ones. Yet, such technology is inevitably leading to a drastic increase of plastic waste if common approaches for flexible substrates are followed. In this scenario, biodegradable solutions can significantly limit the environmental impact, actively contributing to eliminate the waste streams (plastic or electronic) associated with disposal of devices. However, achieving suitably scalable processes to pattern mechanically robust organic electronics onto largely available biodegradable substrates is still an open challenge. In this work, all-organic and highly flexible field-effect transistors, inkjet printed onto biodegradable and compostable substrates (such as commercial Mater-Bi and polyhydroxybutyrate - PHB - biopolymer) are demonstrated. The degradation behavior of the final system shows unaltered biodegradability level. Furthermore, the electrical characterization of the devices showed a proper current modulation, which remained almost unaltered also after intensive mechanical stresses as bending and rolling. Such mechanical stability and flexibility together with the biodegradability, make these devices great candidates for new demanding applications in the field of biomedical electronics or food packaging. These results represent a promising step toward sustainable flexible and large area electronics, combining energy and materials efficient processes with largely available biodegradable substrates.

11:00 AM EN06.01.04
Evidence of Exclusive Electronic Transport in Sepia Melanin Ink-Printed Films Manuel Reali[1], Anthony Camus[1], Mike Rozel[2] and Clara Santato[1]; [1]Polytechnique Montréal, Canada; [2]Institute of Graphic Communication and Printability, Canada

Over the last few years, the terrific technological advancements in the field of electronics paralleled by higher purchasing power, large scale urbanization and industrialization, shorter lifetime and replacing cycles, lead to the generation of unbearable amounts of Waste Electrical and Electronics Equipment (E-Waste).[1,2] Only in 2019, 53.6 Mt of E-Waste were produced worldwide and such amount is expected to growth up to 74.7 Mt by 2030.[1] E-Waste contains toxic elements that if buried in landfill or inhaled, can seriously put in danger the health of the current and future generations.
A paradigm shift from linear to circular economy, focusing on eco-design, durability, refurbishment and recycling is needed.[3,4] A viable route to reduce the carbon footprint of electronics is the development of Sustainable Green Organic Electronics, using ubiquitous biosourced (bioinspired), biocompatible, compostable and possibly biodegradable materials.[5] Among the biosourced matarials available in nature, eumelanin is one of the most fascinating.[6] The synergy between electronic conjugation (alternance of single-double carbon bonds) and hydration dependent electrical response, make eumelanin a mixed protonic-electronic conductor.[7–10] Furthermore, eumelanin is a quinone-based redox active biopigment, which makes it an ideal candidate for energy storage applications.[11] However, the poor solubility of eumelanin in the majority of organic solvents is a real setback and often limiting its range of applications. Herein, we report on a green ink formulation method to fabricate Sepia melanin films from powders extracted from S*epia Officinalis* cuttlefish ink. Our ink-formulation leads to a reproducible, effective printing of Sepia melanin on flexible substrates (i.e. polyethylene terephthalate (PET), paper) and carbon paper. Sepia ink can be also spin-coated and/or brushed on several patterned substrates. Sepia melanin films exhibit high electrical conductivity and environmental stability. Our results open the debate whether Eumelanin features exclusive electronic transport under certain conditions. Work is in progress to study structural aggregation of Sepia particles in the ink to shed light onto the efficient charge carrier transport properties herein observed.

11:15 AM EN06.01.05
High Performance Organic Electronic Devices Based on a Green Hybrid Dielectric Mathieu Tousignant, Nicole Rice, Jukka Niskanen and Benoit Lessard; University of Ottawa, Canada

Smart packaging has become a multi billion-dollar industry that relies on the integration of flexible and inexpensive sensors within product packaging to provide critical quality assurance information such as temperature and humidity. However, these sensors need to be flexible, biodegradable, and low cost in order to be incorporated into a wide variety of packaging.[1]
One way to address these issues is by using organic thin film transistors (OTFTs) which are fabricated using carbon-based active materials, can be integrated onto flexible substrates, and have found many sensing applications. The dielectric is one of the active layers within an OTFT. It facilitates charge accumulation at the organic semiconductor interface when a source-gate voltage is applied. The ideal dielectric should have low leakage currents and a high dielectric constant. Unfortunately, most polymer dielectrics that meet these requirements are not environmentally friendly.
Poly(vinyl alcohol) (PVA) is a biodegradable, water soluble, high-k dielectric polymer however it is moisture sensitive, has poor film forming properties with large leakage currents. Recently we found that the film forming capabilities could be improved through the addition of low weight percentages of cellulose nanocrystals which increase the viscosity of the solutions.[2] Building upon these findings, a thin layer of polycaprolactone (PCL) was deposited on top of our PVA dielectric to reduce the moisture sensitivity and leakage currents of PVA. PCL is a hydrophobic, biodegradable, low-K polymer with good insulating properties. The PCL layer was functionalized with toluene diisocyanate (TDI). The functionalized TDI-PCL can then be thermally cross-linked to the hydroxyl groups of PVA at the TDI-PCL/PVA interface. Crosslinking at the bilayer interface increased the thin film stability and facilitated orthogonal processing of the semiconducting layer. TDI-PCL/PVA metal-insulator-metal capacitors were fabricated and found to be highly stable, even after being exposed to 95% relative humidity, unlike pure PVA based devices. Finally, the TDI-PCL/PVA dielectric was used in the fabrication of single walled carbon nanotube top gate bottom contact OTFTs. The TDI-PCL/PVA dielectric showed greater average mobilities of 0.42 cm^2/Vs compared to 0.032 cm^2/Vs for PVA, a reduced average hysteresis, better output curve saturation, a negative threshold voltage shift and greater on/off ratios with a lower device variation. When compared against silicon dioxide the TDI-PCL/PVA dielectric had a six-fold decrease in operating voltage for both the output and transfer curves. These results demonstrate a novel method for incorporating a green bilayer dielectric in high performing OTFTs while mitigating challenges associated with thin film processing and moisture sensitivity.

11:30 AM EN06.01.06
Facile Fabrication of Multifunctional and Transient All-PVA Based Green Electronics Mete Batuhan Durukan, Melih O. Cicek, Doga Doganay, Mustafa C. Gorur, Simge Cinar and Husnu E. Unalan; Middle East Technical University, Turkey

Over the last decade, rapid progress in wearable devices including consumer electronics and healthcare monitoring devices resulted in an excessive increase in electronic waste. Hazardous content and limited recyclability of these electronic devices is a great threat to the environment. Thus, research and development on the “green” electronics with non-hazardous materials and facile, low-cost fabrication is a must. This requirement paved a way for a new emerging field; transient electronics. Transient electronics disintegrates at the end of their use or when it is required with almost zero waste. To achieve totally green electronics, rather than focusing on a single component in an electronic system, all of the components must be designed and engineered as transient. Herein, we successfully fabricated transient supercapacitors, capacitive sensors and triboelectric nanogenerators by engineering PVA based layers including the electrodes, electrolyte, insulating layer and the encapsulant. Fabricated supercapacitors achieved a specific capacitance of 1.8 $F.g^{-1}$ with excellent rate capability up to 1 $V.s^{-1}$. Capacitive sensors based on PVA showed a promising sensitivity of 0.49 kPa^{-1} up to 44 kPa. These flexible and transient capacitive sensors were used to monitor both small and large movements in different muscle groups on human body. Fabricated single electrode triboelectric nanogenerators, on the other hand, showed an open circuit voltage and short circuit current of 18 V and 3.5 µA, respectively, charged up small sized capacitors and used as self-powered sensors.

SESSION EN06.02: Electronics Synthesis I
Session Chair: Federico Rosei
Wednesday Afternoon, December 1, 2021
Hynes, Level 3, Room 308

1:30 PM *EN06.02.01
Processing Organic Semiconductors from Green Solvents Thuc-Quyen Nguyen; University of California, Santa Barbara, United States

Organic semiconductors have potential applications in various low cost, large area, flexible, light-weight devices ranging from sensors, light-emitting diodes (LEDs), displays, transistors, solar cells, photodetectors, thermoelectrics, and ratchets. Most organic semiconductors are processed in chlorinated solvents such as chlorobenzene and chloroform. In this talk, I will discuss the design, synthesis, and applications of conjugated polyelectrolytes (CPEs), a class of organic semiconductors characterized by a conjugated backbone and pendant ionic side chains. The conjugated backbone endows CPEs with the optical and charge transport properties of organic semiconductors, while the ionic functionalities render CPEs soluble in high dielectric constant media and in particular water. CPEs have been used as charge transporting layers in OLEDs, organic solar cells, perovskite solar cells, thermoelectrics, and organic electrochemical transistors.

2:00 PM EN06.02.02
A Green Edible Electrically Conductive Paste for Fruit Ripening Detection Pietro Cataldi[1], Leonardo Lamanna[1], Claudia Bertei[2], Federica Arena[1], Mufeng Liu[3], Dimitrios Papageorgiou[2], Alessandro Luzio[1] and Mario Caironi[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Queen Mary University of London, United Kingdom; [3]The University of Manchester, United Kingdom

Ingestible electronics was introduced as a powerful tool to control physiological parameters and deliver drugs with tunable rates and in a specific intestinal tract but is limited by the use of standard rigid electronics components, the risk of retention after ingestion, and the need to collect the device after expulsion, which is made of non-degradable and long-lasting materials.[1,2,3] Edible electronics, which bridge ingestible with green electronics, propose to shift from ingestible to digestible components, ensuring a safe administration without medical supervision and enabling the degradation of the device in the body/environment after performing a specific function.[2,3]
Producing edible electrical conductors with green methods, degradable and conformable materials, and industrially compatible processes will enable passive eatable electronics components if coupled with already abundant edible dielectrics. Such electrodes will also permit the monitoring of the maturation of vegetables through degradable and edible devices that can measure the electrical impedance of fruits, which is currently performed via Ag/AgCl electrodes.[4] Indeed, state-of-the-art ingestible/edible conductors are rigid metals that are not safely eatable at high amounts (g/Kg), have a high price, and are not degradable in the body/environments after performing their function.[3]

We present conductive pastes made entirely of food-grade materials with a high tolerable upper intake limit (g/Kg). A matrix made with biodegradable and digestible polymers and a micrometric size eatable conductive filler constitutes the conductors. The composite pastes are the first designed specifically for edible and sustainable electronics. These conductors can reach a resistivity in the order of 100 Ω cm, are fabricated without solvents' employment, and with processes that involve a low temperature (100°C) therefore using a small amount of energy. They exhibit tunable electromechanical features and adhesion depending on the composition. The composites are compatible with green and large-scale production processes such as extrusion, direct ink writing, and injection molding and thus are ideal for an industrial scale-up. Moreover, they feature antibacterial and hydrophobic properties, avoiding food contamination and possible adverse effect upon ingestion and the variation of their properties interacting with the body/environment.
The edible conductors are assembled as a food label that can monitor the maturation of fruit through simple electrical impedance measurements.[4] The device can monitor the impedance change on different fruits for 14 days showing reliable results compared with standard Ag electrodes used for food monitoring. [4] Such technology could constitute the first building block towards green and sustainable substitutes of current ingestible conductors and the monitoring of the fruit production chain from the three to the table.

Biocompatible Composites or Heterojunctions for Biological Modulation Bozhi Tian; University of Chicago, United States

Biocompatible and biodegradable devices for modulation of cells and tissues have many potential impacts on medical and industrial technologies. In this talk, I will present several recent projects in this area. First, I will discuss a bottom-up synthesis to construct a soil-like material consisting of nanostructured minerals, starch granules, and liquid metals, to mimic immobile inorganic and organic materials and the mobile phases in soil. The soil-like material is biocompatible and recyclable. It possesses chemical, optical, or mechanical responsiveness to yield write-erase electrical functions. We show this soil-like material can enhance microbial metabolism and biofuel production in vitro. It can also enrich gut bacteria diversity under a pathological condition and rectify bacterial dysbiosis in vivo. Next, I will showcase a class of granules-enabled hydrogel composites, with multiple naturally occurring biopolymers and synthetic hydrogels as the key components. The composites have many tissue-like properties, such as strain-stiffening behaviors. The granules-enabled tissue-like materials have enabled the pneumatically actuated bioelectronic devices for applications such as recording the heart electrocardiogram signal *ex vivo*. Moreover, I will present a newly developed nanoporous/non-porous heterojunction for improved biointerfaces. Without any interconnects or metal modifications, the heterojunction enables efficient non-genetic pulse stimulation of isolated rat hearts *ex vivo* and sciatic nerves *in vivo* with radiant exposure similar to that used in optogenetics. At the end of my talk, I will discuss future composite or heterojunction development towards more efficient biological modulation.

Recycled Critical Elements from Batteries as Catalysts for Hydrogen-Rich Gas and Biofuel Production Ange Nzihou; Université de Toulouse, France

The increase in the share of renewable energies is essential to move towards the sustainable economy. In 2020, the share of energy from renewable sources in gross final energy consumption reached 20% in the EU, while at least 32% is targeted by 2030. In this strategic vision, the European Commission intends to highlight the advantages of biofuels in terms of reducing emissions of greenhouse gases. Accordingly, new advanced biofuels are needed and should be sustainably produced from biomass and bio-feedstock. Reforming of methane is one of the potential routes to achieve this Transition. Nevertheless, it suffers from the lack of robust catalysts to take off the ground. Dry reforming of methane (DRM) converts methane (CH4) and carbon dioxide (CO2) into syngas (CO, H2), that can be directly used or further converted into green hydrogen and/or olefins, alcohols, and other hydrocarbons. An energetic optimization of this process is possible, by considering complementary oxidant agents, such as H2O and O2. In this regards, two other reforming routes named Steam (SRM) and Bireforming (BRM) have been considered. SRM consists of the conversion of methane in the presence of steam whilst BRM transforms a mixture of CH4, CO2 and H2O into syngas. This process is one that allows the direct valorization of biogas (CH4 and CO2) for instance. Then, the syngas can be further converted into higher rate hydrogen and/or valuable chemicals via Fischer-Tropsch (FT) synthesis.
The reforming reactions require noble-supported catalysts with SiO2, Al2O3, CeO2 and ZrO2 as most common support materials and metals (Ni, Fe, Ru, Pd, …) as active phases. We have developed a new approach of catalysts for the reforming of methane, that overcome the main hurdles in the field namely (1) deactivation, (2) metal sintering, (3) coke deposition, (4) lack of robustness to the variation of feedstock composition resulting in the decrease of the efficiency. The catalysts we have developed are free of rare and noble metals and made of Hydroxyapatite, Ca10(PO4)6(OH)2 as support material, and Ni and or Co as active phases. Hydroxyapatite is a hierarchical structure with tunable physicochemical, mechanical, and thermal properties. The phosphate (PO4) utilized has been recycled from used Lithium-ion batteries. The results obtained show highest performance in hydrogen production from DRM, BRM and SRM, and in hydrocarbons production in FT reaction. This lecture will summarize the research carried out and the main findings in this field, towards the sustainable use and recycling of critical chemical elements from batteries for energy and biofuel production.

3:15 PM BREAK

SESSION EN06.03: Urban Mining I
Session Chair: Clara Santato
Wednesday Afternoon, December 1, 2021

4:00 PM EN06.03.01
Cold-Sintering Process—Sustainable Recycling Technology for $Li_{6.95}Mg_{0.15}La_{2.75}Sr_{0.25}Zr_2O_{12}$ (LLZO) and $Li_{1+x+y}Al_xTi_{2-x}Si_yP_{3-y}O_{12}$ (LATP)-Based Solid-State Composite Electrolytes Yi-Chen Lan and Enrique D. Gomez; The Pennsylvania State University, United States

As the demand for high-performance and safe batteries increases, researchers anticipate that all-solid-state batteries are the key to satisfy the market's needs. As large-scale production becomes possible, the unprecedented number of spent batteries will trigger disposal issues. Unfortunately, little effort is

placed in recycling solid-state electrolytes. Recycling composite electrolytes is in particular complicated due to the differences in the chemical and thermal stability of each component. Herein, we propose a sustainable recycling technology, cold-sintering process, to recycle composite electrolytes, $Li_{6.95}Mg_{0.15}La_{2.75}Sr_{0.25}Zr_2O_{12}$ with polypropylene carbonate and lithium perchlorate (LLZO–PPC–$LiClO_4$), and $Li_{1+x+y}Al_xTi_{2-x}Si_yP_{3-y}O_{12}$ with bis(trifluoromethanesulfonyl)imide salts (LATP–LiTFSI). Due to the low sintering temperature, cold-sintering process can repair mechanical defects by reintegrating ceramic, polymer, and salt materials without significantly compromising their properties. LLZO–PPC–$LiClO_4$ and LATP–LiTFSI demonstrate extraordinary recyclability. As reprocessed samples show a similar compactness as the pristine samples and ionic conductivities are above 10^{-4} S cm^{-1} at room temperature after four-times recycling. The recycled LATP–LiTFSI is electrochemically stable in lithium titanate symmetric cells over 1300 h at 0.1 mAh cm^{-2}. This work demonstrates the first sustainable way to recycle solid-state composite electrolytes in order to move towards a circular economy.

4:15 PM EN06.03.02
Regenerating and Up-Recycling Aged Lithium-Ion Battery Cathode Materials in a Green Process Claire Zhang, Jerry Xiang and Xiaofang Yang; Princeton NuEnergy, United States

Lithium-ion batteries (LIBs) have emerged as the battery of choice for rapidly growing markets in electric vehicles (EVs) and grid electricity storage. This spurs a great demand for lithium, graphite, cobalt, and nickel that could outstrip the supply of virgin materials. Thus, there is an enormous interest in the development of new sustainable technologies for recycling and recovery of valuable materials from secondary resources, especially from used lithium-ion batteries. Compared to conventional high temperature pyrometallurgical or hydrometallurgical methods, the direct recycling of LIBs is a promising method because it can directly regenerate the cathode materials by relithiation without destroying the compounds. Additionally, direct recycling is a comparatively low-cost and less resource intensive method of recovering LIB materials.

However, complete regenerating the full capacity and long-term performance is still particularly challenging. For instance, the cathode materials are often coated with a nanometer-thick protecting layer, which is engineered to reduce the degrading effect on the cathode due to the direct contract with the electrolyte. The long-term charge-discharge cycling causes damage to the coating layer and it thus needs to be repaired in order to recover the material performance. To address this challenge, we have developed a novel process that can regenerate and upgrade cathode materials from aged lithium-ion batteries, as well as creating a new coating layer to improve the cathode materials' performance. In this presentation, we will provide a case study to show the performance improvement of recycled lithium cobalt oxide (LCO) materials by forming an alumina coating layer on the surface. By controlling the thickness and sintering temperature, this surface alumina coating can be an effective way to improve the stability and cyclability of recycled LCO cathode materials. Material characterizations by XPS, SEM, STEM, and XRD help to reveal the structure and composition of the surface Al coating layer, and provides insights of the healing and protective roles of this layer for recycled LCO particles.

Sustainable Gold Peeling from E-Waste via Food Waste Byproducts Teresa Cecchi; ITT MONTANI, Italy

Recovery of non-leaching gold from e-waste gold coatings was achieved using aqueous chemistry with hydrogen peroxide and friendly organic acids that are food chain byproducts. The oxidation of the base metals, also part of the edges, enables the release of gold in its original metallic state in the form of flakes subsequently separated via simple filtration. Our route avoids crushing and chemical refining steps, reduces the losses of gold, thus saving cost and time, and decreases environmental pollution. Moreover, recovered gold, characterized by scanning electron microscopy and X-ray photoelectron spectroscopy to gain insight into the structure of the flakes and their chemical composition, was used to fabricate organic field-effect transistors making use of photolithographically patterned electrodes made of the recycled gold.

Biochar-Based Composites for Hybrid Supercapacitor Applications Thomas Sadowski[1,2], Jules Scanley[1,2], Kaleb Roman[1,2], Monica Kiehnle-Benitez[1,2], Daniel Shibu[1,2], Rahul Singhal[3,2] and Christine Broadbridge[1,2]; [1]Southern Connecticut State University, United States; [2]CSCU Center for Nanotechnology, United States; [3]Central Connecticut State University, United States

As renewables become an increasing percentage of the global energy portfolio, finding and implementing cost-effective, environmentally friendly, and sustainable grid-scale electrical energy storage devices to maintain a continuous and reliable power supply will be critical. From this perspective, hybrid supercapacitors represent an attractive alternative to batteries, being typically fabricated from more environmentally benign and easily sourced materials coupled with a cycling lifetime that often exceeds batteries by several orders of magnitude. The performance of these devices is ultimately tied to the choice of electrode material, with carbon nanotube (CNT) - manganese dioxide (MnO_2) composites receiving focus recently due to the promise of energy storage approaching that of conventional batteries. MnO_2 is an ideal material from an environmental and sustainability standpoint due to its natural abundance, low toxicity, and simple synthesis routes; however, CNT synthesis typically requires hydrocarbons as feedstock and present potential health risks via inhalation and dermal contact. Biochar, on the other hand, represents a sustainable alternative to CNT with lower predicted health risks. The fabrication of biochar is carbon negative, and significant opportunities exist to engineer the morphology through rational choice of biomass precursor. In this study, biochar-MnO_2 composites were investigated to assess their potential in hybrid supercapacitors. Biochar was obtained from a variety of commercial sources and the initial concentrations varied to synthesize a range of composites via a hydrothermal method. The morphology and microstructure were characterized using scanning and transmission electron microscopy and x-ray diffraction. Supercapacitive performances were investigated using cyclic voltammetry, charge-discharge, and rate capability studies. The resulting characterization and performance data of biochar-MnO_2 will be presented and compared to CNT-MnO_2 of identical weight composition.

5:00 PM EN06.04.02
Effect of Multi Wall Carbon Nanotubes on Electrochemical Performances of MnO_2 Rahul Singhal[1], Bhagirath Saini[2], Monica Kiehnle-Benitez[3], Thomas Sadowski[3], Christine Broadbridge[3], Jules Scanley[3] and Rakesh Sharm[2]; [1]Central Connecticut State University, United States; [2]Indian Institute of Technology Jodhpur, India; [3]Southern Connecticut State University, United States

Due to the continuous depletion of the fossil fuels, scientists are looking for alternative energy sources and energy storage devices. Supercapacitors are energy storage devices with higher power density and high energy density than conventional capacitors. Manganese oxides have attracted a lot of attention because of their easy preparation, environmental friendliness, and relatively low cost. However, MnO_2 suffers from low electronic conductivity, which severely limits its fast charge/discharge behavior. This can be overcome by mixing it with electronically conductive materials such as carbon black or carbon nanotubes (CNTs). Composites of MnO_2/ MWCNT were prepared using different weight ratios of MWCNTs:$KMnO_4$ (1:2, 1:5, 1:10, 1:15, 1:20, 1:25). The synthesized materials were physically characterized using X-ray diffraction (XRD) and transmission electron microscopy (TEM). TEM studies confirm that MnO_2 is homogeneously entangled with MWCNT. The electrochemical performances evaluation was carried out in a 3-electrode system using MnO_2/ MWCNT electrode coated onto Ni mesh as working electrode, Pt foil as counter electrode and Ag/AgCl as reference electrode. An aqueous solution of 1 M Na_2SO_4 was used as electrolyte. The specific capacitance was obtained from charge discharge studies at various current densities between 0.5 A/g – 5 A/g. The specific capacitance of MWCNTs-$KMnO_4$ (1:10, 1:15, 1:25) samples were obtained as 111 F/g, 159 F/g, and 161 F/g, respectively at a current density of 1 A/g. The detailed morphological and electrochemical results will be presented.

5:15 PM EN06.04.03
Late News: Poly (3,4-ethylenedioxythiophene) (PEDOT) Modified with Carbon Nanotubes as Counter Electrode and Bipyridine Cobalt(II/III) Complexes as Redox Mediator in Solar Cells Sensitized with Membrane Protein-Pigment Complexes Stephanie Monge[1,1,1], Alexandra H. Teodor[2], Dariana Aguilar[1,1], Alexandra Tames[1,1], Roger Nunez[3], Juan J. Montero Rodríguez[1], Jesse Bergkamp[3], Ricardo Starbird[1,1], Barry D. Bruce[2,2,2] and Claudia C. Villarreal[1,1,1]; [1]Instituto Tecnológico de Costa Rica, Costa Rica; [2]University of Tennessee at Knoxville, United States; [3]California State University Bakersfield, United States

In nature, light is captured by different classes of membrane protein-pigment complexes. Two proteins of interest are retinal-containing proteins (RMP) and chlorophyll-pigment protein complexes (CPP) associated with photosynthesis. Bacteriorhodopsin (BR) is an example of an RMP that functions as a light-driven proton pump. Photosystem I (PSI) is one of two CPP associated with oxygenic photosynthesis that catalyzes photoactivated unidirectional electron transfer. Interestingly, although these proteins come from highly divergent prokaryotes, bR from archaebacteria, and PSI from cyanobacteria, they form trimeric complexes that are highly thermostable, and both are exceptionally well characterized at the structural, functional, and spectroscopic level. Both complexes have been integrated into new eco-centric, photovoltaic (PV) devices built from flexible, biodegradable, renewable carbon materials. More importantly, PSI and bR stand out as some of the best performing natural light absorbers in the bio-PV devices reported. The best power conversion efficiencies have been obtained in bio-sensitized solar cell architecture, using nanostructured wide-bandgap semiconducting electrodes to assemble these proteins. The membrane protein-pigment complexes in these devices can directly donate either electron or protons upon light absorption, enabling photo-catalyzed hydrogen production, electric power generation, chemical catalysis, and other redox reactions. Despite the progress in these bR- and PSI-sensitized solar cells, little attention has been devoted to the development of alternative counter electrodes and electrolytes to the commonly used Pt and I^-/I_3^-. A careful selection of the redox mediator and the electrolyte and counter electrode components is a core part of the design of low resistance, high photocurrent protein bio-PV devices. This work explores using a counter electrode of poly (3,4-ethylene dioxythiophene) (PEDOT) modified with carbon nanotubes for both PSI and bR devices. We also explore using hydroquinone/benzoquinone and aqueous-soluble bipyridine cobalt(II/III) complexes as direct redox mediators. It is a novel discovery that the same counter electrode and redox mediator system can perform well for two different biomolecules that have developed independently over millions of years to harvest solar energy in nature. Such compatibility of PSI and bR with a common mediator and counter electrode may be helpful to realize the uptake of a larger portion of the sun spectrum with these two natural light absorbers that have complementary absorption spectra. The improvement of bio-PVs design is an advancement towards more energy-efficient and green chemistry principles-based manufacturing paradigms as the biosynthesis of biomolecules like bR and PSI for PV feedstock contributes to CO_2 fixation from the atmosphere and solar energy is used multiple times across fabrication and device use.

5:30 PM EN06.04.04
Untapped Potential of Polymorph MoS_2—Tuned Cationic Intercalation for High-Performance Symmetric Energy Storage Devices Nageh K. Allam; American University in Cairo, Egypt

Supercapacitors have been the key target as energy storage devices for modern technology that need fast charging. Although supercapacitors have large power density, modifications should be done to manufacture electrodes with high energy density, longer stability, and simple device structure. The polymorph MoS_2 has been one of the targeted materials for supercapacitor electrodes. However, it was hard to tune its phase and stability to achieve the maximum possible efficiency. Herein, we demonstrate the effect of the three main phases of MoS_2 (the stable semiconductor 2H, the metastable semiconductor 3R, and the metastable metallic 1T) on the capacitance performance. The effect of the cation intercalation on the capacitance performance was also studied in Li_2SO_4, Na_2SO_4, and K_2SO_4 electrolytes. The performance of the electrode containing the metallic 1T outperforms those of the 2H and 3R phases in all electrolytes, with the order 1T > 3R > 2H. The 1T/2H phase showed a maximum performance in the K_2SO_4 electrolyte with a specific capacitance of 590 F g^{-1} at a scan rate of 5 mV s^{-1}. MoS_2 showed a good performance in both positive and negative potential windows allowing the fabrication of symmetric supercapacitor devices. The 1T MoS_2 symmetric device showed a power density of 225 W/kg with an energy density of 4.19 Wh/kg. The capacitance retention was 82% after 1000 cycles, which is an outstanding performance for the metastable 1T-containing electrode.

Toward a Structure-Properties Relationship Phase Diagram for Eumelanin Films Manuel Reali[1], Anthony Camus[1], Jennifer MacLeod[2], Alessandro Pezzella[3] and Clara Santato[1]; [1]Polytechnique Montréal, Canada; [2]The University of Queensland, Australia; [3]Università degli Studi di Napoli Federico II, Italy

The charge transfer and transport properties of bio-sourced materials are complex, due to their chemical and structural composition. Their biosynthesis generates chemical heterogeneity, e.g. macromolecules resulting from more than one building block (monomer), and physical disorder, e.g. π-π stacked regions coexisting in the supramolecular structure. Chemical and physical disorder are key factors limiting the performance of organic electronics[1–3]. Among the plethora biomaterials available in nature, eumelanin, a black-brown bio-pigment of the melanin family, is an interesting candidate for study[4–6]. It is a redox-active[7–10] quinone-based bio-macromolecule featuring electronic conjugation (alternating single and double Carbon bonds bonds), broadband

UV-Vis absorption and hydration-dependent electrical response[11–16]. Eumelanin originates from the oxidative polymerization of 5,6-dihydroxyindole (DHI) and 5,6-dihydroxyindole-2-carboxylic acid (DHICA) monomers (building blocks). DHI and DHICA have several polymerization sites and co-exist in different redox states (fully reduced hydroquinone, semi-reduced semiquinone, and fully oxidized quinone). Therefore, eumelanin features chemical heterogeneity[17–19]. Monomers and oligomers generate several supramolecular structures, such that eumelanin also features physical disorder[20]. Recently, we showed that the early stages of DHI and DHICA films formation is driven by both chemical (covalent) and physical (self-assembly) interactions[21]. Particularly, self assembly of DHI is expected to deliver films featuring higher degree of pi-pi stacking with respect to DHICA, this last being a critical condition to the rational design of eumelanin-based functional devices[22].
Herein, we investigate the role of oligomeric composition, relative humidity and type of solvent during DHI film processing. Preliminary results show that DHI films undergo to de-wetting[23,24] or diffusion limited aggregation (DLA) phenomena[25,26] depending on specific combination of solvent, relative humidity and molar mass distribution. Our investigation is a step forward to establish a phase diagram correlating film processing and structural properties of eumelanin films.

Regenerating and Up-Recycling Aged Lithium-Ion Battery Cathode Materials in a Novel Gas-Phase Process Jerry Xiang, Claire Zhang and Xiaofang Yang; Princeton NuEnergy, United States

Lithium-ion batteries (LIBs) have emerged as the battery of choice for rapidly growing markets in electric vehicles (EVs) and grid electricity storage. This spurs a great demand for lithium, graphite, cobalt, and nickel that could outstrip the supply of virgin materials. Thus, there is an enormous interest in the development of new sustainable technologies for recycling and recovery of valuable materials from secondary resources, especially from used lithium-ion batteries. Compared to conventional high temperature pyrometallurgical or hydrometallurgical methods, the direct recycling of LIBs is a promising method because it can directly regenerate the cathode materials by relithiation without destroying the compounds. Additionally, direct recycling is a comparatively low-cost and less resource intensive method of recovering LIB materials. However, since the aged materials are usually 5 to 10 years older than the current materials, the regenerated materials may not meet new market needs due to due to due to improvements in material properties and emerging new chemistries. In order to meet this challenge, we have developed a novel gas-phase process that can regenerate and upgrade cathode materials from aged lithium-ion batteries, as well as adding new functionality to improve the cathode materials performance. In this presentation, we will provide a case study to show the upgrading of old chemistries of cathode materials (e.g., NCM 111 and NCM 523) to newer chemistries (NCM 622 and NCM 811) After upgrading, the performance and long-term cycle performance of the high-nickel NCM cathode material are comparable to those of commercial battery materials.

This new direct battery recycling technology has the potential to create a new lithium-ion battery cathode material manufacturing process from recycled batteries as it offers systematic advantages in costs, energy efficiency, and environmental protection by reusing, recycling, and reproducing lithium-ion batteries within an optimized system.

EN06.05.03

Late News: A Novel Ion-Na Batteries—Synthesis and Characterization of Nanostructured Sodium Rhodizonate Cathodes Emilio Navarrete[1], Eduardo Cisternas[1], Fabian Dietrich[1] and Eduardo Muñoz[2]; [1]Universidad de la Frontera, Chile; [2]Pontificia Universidad Católica de Valparaíso, Chile

Several studies have emerged that seek to solve the energy deficit that we face as a society, where energy storage plays an important role. In this regard, Ion-Sodium batteries (Ion-Na) represent an excellent alternative to the Ion-Li batteries currently on the market. These new Ion-Na batteries have adequate charge densities and at a lower cost. Taking this issue into account, there is great interest in studying the composition, structure, and morphology of cathodes as active materials to optimize this type of battery. **[i],[ii]**.

In this study, the synthesis and characterization of sodium rhodizonate nanostructures to be used as cathode material in Sodium-ion batteries was carried out. In a first stage, a two-level factorial design was used as an exploratory stage to evaluate the statistical significance of the variables involved in the synthesis: i) temperature, ii) reaction time, iii) molar ratio of precursors and iv) addition time. The nanostructuring of the sodium rhodizonate crystals was carried out by the ultrasonic crystallization method and was characterized by X-ray Diffraction (XRD) and Scanning Electron Microscopy (SEM). The electrochemical characterization was performed using cyclic voltammetry, galvanostatic charge/discharge profiles, and cyclability. The results show that

the nanostructuring of the material causes an increase in the storage capacity of sodium ions in the sodiation/desodiation process. This shows a strong size-dependence in the Na + ion intercalation process. Finally, these results will allow the generation of causal relationships that lead to the optimization of the electronic properties of alternative Na-ion batteries.

6:30 PM *EN06.06.01
Fabrication of Transient Printing Circuits Through Low-Cost Water Sintering Techniques Xian Huang; Tianjin University, China

Transient electronics refer to emerging types that only last limited periods of time and disappear after completing their functions and generating environmentally-friendly by-products. Among many approaches that have been developed for fabricating transient circuits, printing techniques are suitable methods for mass fabricating large-area transient circuits in high printing speed. However, inks and pastes as well as the processing methods of the printed patterns remain to be developed for high-performance transient circuits with excellent electrical conductivities and mechanical robustness. This presentation will focus on our recent effort in developing transient circuits based on bioresorbable zinc nanocomposites printed on bioresorbable substrates and sintered through low-cost and high-efficient water sintering. The entire printing and sintering processes can be conducted at room temperature and in atmosphere conditions, leading to the maximum conductivity of 307664.4 S/m and the capability to withstand repeated bending for more than 8000 times. The techniques have led to the development of dissolvable consumer electronics that have the same functions as conventional devices but dissolute in the liquid environment to facilitate recycling. The materials and techniques developed in these works may reform the electronics recycling industry by reducing the cost of recycling and minimizing environmental pollution.

7:00 PM EN06.06.02
Eumelanin, from Molecular State to Film Manuel Reali[1], Anthony Camus[1], Guillaume Beaulieu[1], Jordan De Angelis[2], Christian Pellerin[3], Alessandro Pezzella[4] and Clara Santato[1]; [1]Polytechnique Montréal, Canada; [2]Università di Bologna, Italy; [3]University of Montreal, Canada; [4]University of Naples Federico II, Italy

Melanins are ubiquitous biopigments responsible of manifold functionalities in living organisms[1]. Eumelanin is a hygroscopic, black-brown biomacromolecule belonging to the family of melanin biopigments. Eumelanin originates from the oxidative polymerization of (5,6)-dihydroxindole (DHI) and (5,6)-dihydroxindole 2-carboxyl acid (DHICA) building blocks. Different available polymerization sites and co-existing redox states, as well as distinct supramolecular arrangements, bring chemical and physical disorder to the biopigment[2]. Eumelanin features fascinating physicochemical properties such as broadband optical absorption, free radical scavenging, metal-ion chelation and hydration dependent electrical response[3,4], this last mainly attributed to protonic transport. Being non-toxic, abundant, solution processable and potentially biodegradable[5], eumelanin is a promising candidate for green electronics[6].
Owing to its complex structural organization, the charge carrier transport properties of eumelanin, are still elusive[7–11]. Our observations of exclusive electronic transport in dry eumelanin pellets[12] reopen the debate whether the biopigment would be a mixed protonic-electronic conductor in the hydrated state and an amorphous semiconductor in the dry state[13]. Correlating supramolecular self-assembly to fundamental optical and electrical properties of eumelanin is paramount to fill such a knowledge gap.
Herein[14], we investigated the early stages of formation of DHI and DHICA films at technologically relevant surfaces. We observe that the monomers aggregate, possibly eventually polymerizing in a time scale of few hours at ambient condition. Atomic Force Microscopy (AFM) images of DHI and DHICA acquired at ambient conditions (AC) show the formation of well-defined *fern-like* structures and regular rod-shaped structures, respectively. We attribute the growth of fern-like and rod-shaped structures to diffusion limited aggregation (DLA) and Ostwald ripening processes, respectively.
The increase of UV-Vis absorbance overtime for AC-DHI and AC-DHICA films suggests an improved -electron delocalization of oligomeric structures. Fourier Transform Infrared (FTIR) and UV-Vis spectroscopy suggests that the interplay between chemical (oxidative polymerization) and physical interactions (hierarchical self-assembly) plays a key role during the early stages of film formation over time. Preliminary investigation into the electrical response of eumelanin films were also conducted.
Our results add a piece of knowledge to unravel structure-properties relationship in eumelanin, a condition *sine qua non* to design and develop eumelanin-based functional devices.

Green Monomers and Polymers for Green Electronics Mario LeClerc[1], David Gendron[2], Louis-Philippe Boivin[1] and William Dupont[1]; [1]Laval University, Canada; [2]Kemitek, Canada

The growth of consumer electronics has drastically changed our daily routine. For instance, those electronic products (cellphone, laptop, camera, etc.) have become essential tools in our modern reality to facilitate access to information or to maintain our social activities. However, even though new performing technologies (OLED or OPV) have now emerged, the fact remains that their lifespan is limited and the resources utilized for their manufacture are demanding on the environment.

Therefore, a change in the way we harness resources and manage electronic waste is required to minimize negative impacts on the environment. Organic electronic represent a promising alternative to the traditional inorganic electronic as it is carbon-based, printable and the optoelectronic properties can be easily tuned to match the requirements. Hence, in order to eliminate electronic waste, materials from renewable and recyclable sources are sought. In this regard, forest biomass is considered the only sustainable source of organic carbon and therefore the ideal replacement for petroleum products for the production of chemical compounds. One of the resources derived from biomass, lignocellulose, is the most abundant bio-based material on earth. Indeed, the main added-value compound obtained from the depolymerization of lignin is vanillin. Vanillin is an aromatic compound with three functional groups that can be chemically modified. The present work describes how the vanillin moiety can be expanded into several building blocks for the preparation of bio-based conjugated polymers. Moreover, our synthetic approach involved direct heteroarylation polymerization (DHAP), which avoids the generation of toxic side products usually present in the preparation of conducting polymers. At last, the optoelectronics properties of the materials and their corresponding devices' performances will be discussed.

7:45 PM *EN06.06.05
Why Soft, Solution Processing(=Low-Energy Production) of Advanced Nano- Materials is Difficult but Necessary for Sustainable Society? Masahiro Yoshimura[1,2]; [1]National Cheng Kung University, Taiwan; [2]Tokyo Institute of Technology, Japan

Modern our society has been developed with various Advanced Materials. Most of advanced materials, Metallurgical materials, Semiconductors, Ceramic materials and Plastics have been used in wide area of applications like structural, mechanical, chemical, electrical, electronic, optical, photonic, biological, medical, etc. Most of them except for bio-polymers & bio-minerals have never been produced via biological systems & processes. Thus they have been fabricated artificially and/or industrially by so-called High-Technology, where using Sophisticated Equipment & High Energetic Conditions:high temperature, high pressure, vacuum, molecule, atom, ion, plasma, etc. for their fabrications, then consumed huge amounts of resources and energies thus exhausted huge amounts of wastes: Materials, Heats and Entropy. To save this tragedy, we must consider Cascade use of Heats, and (SSP) Soft, Solution Processing (=Low-Energy Production of Advanced Materials via solution-based processing). SSP is Bio-inspired process, which means that Learn from Bio-systems then Exceed them. We have challenged to fabricate those advanced inorganic materials with desired shape/size/location,etc. directly in low energetic routes using aqueous solutions since 1989 when we could fabricate BaTiO3 film on Ti substrate in a Ba(OH)2 solution by Hydrothermal Electrochemical method at low temperatures of 60-200 C. We proposed in late 90's an innovative concept and technology, Soft Processing or Soft, Solution Processing, that aims low energetic (=environmentally friendly) fabrication of shaped, sized, located, and oriented inorganic materials in/from solutions(1,2). It can be regarded as Green processing, or Eco-processing by other groups. When we have activated/stimulated interfacial reactions locally and/or moved the reaction point dynamically, we can get patterned ceramic films directly in solution without any firing, masking nor etching: i.e. Direct Patterning of CdS, PbS and CaWO4 on papers by Ink-Jet Reaction method, furthermore, we have succeeded to fabricate BaTiO3 patterns on Ti by a laser beam scanning(3) and carbon patterns on Si by plasma using a needle electrode scanning directly in solutions. Successes in TiO2 and CeO2 patterns by Ink-Jet Deposition, where nano-particles are nucleated and grown successively on the surface of substrate thus become dense even below 300 C. Other nano-structured 2D/3D films could be prepared without firing. Soft Processing for various 2D: Graphene, MXene,MoS2 have been established including the preparation of functionalized Graphene Ink via successive processes under ambient temperature and pressure conditions.(4-6)

Monday Afternoon, December 6, 2021
EN06-Virtual

9:00 PM EN06.07.01
Flowing Electrolyte System of Bifacial Dye-Sensitized Solar Cells Under Low-Concentrated Light Tika E. Putri, Lesley Fadzai F. Chawarambwa, Pankaj Attri, Kunihiro Kamataki, Naho Itagaki, Kazunori Koga and Masaharu Shiratani; Kyushu University, Japan

DSSCs are promising for future photovoltaics due to their good price/performance ratio and ability to work at wider angles. In low light, long life, mechanical robustness, ability to operate at lower internal temperatures.[1, 2] Although DSSCs coupled with a concentrator increase the power out (Pout),[3] applying a concentrator increases the device temperature to limited operation lifetime and electrolyte evaporation. Therefore, a suitable cooling system is needed to prevent temperature rise in the DSSCs coupled with a concentrator. In this study, we applied an electrolyte-flowing cooling system to prevent the temperature rise of DSSCs.

Bifacial DSSCs were fabricated with FTO/TiO2/N719dye/electrolyte/Pt/FTO structure. Adjustable external concave mirror concentrators were placed at both sides of the DSSC. Z-100 Electrolytes flowed through DSSCs equipped with silicon pipes and hydraulic pumps as a cooling system. The photovoltaic performance and device temperature rise of cells under flowing continuously (FC) and flowing with a stopping period (FS) of electrolyte were compared with those of normal cells without the flowing system (NC).

The flowing electrolyte system with FC (161.7°C) and FS (167.8°C) have a lower temperature than NC (221.8°C) after 3 hours of operation. The open-circuit voltage (*Voc*) decreases from around 0.75 V to 0.52 (FC), 0.53 V (FS), and 0.36 V (NC) due to the effect of temperature rise. Short-circuit current (*Jsc*) in both flowing systems gradually is reduced due to improper transfer of electrons in the flowing electrolyte. This reduction corresponds to increases in Z1 resistance value from 9.3 Ω to 92.1 Ω (FC) and 6.5 Ω to 33.9 Ω (FS) from electrochemical impedance spectroscopy (EIS) analysis. Pout of FS and NC are almost the same, around 7.5 mW/cm^2 after 3 hours operation, whereas Pout of FC decreases to 1 mW/cm^2. In conclusion, an electrolyte-flowing cooling system with a stopping period can reduce the temperature rise and improper transfer of electrons in electrolytes caused by flow.

Fractal Based EDS Design for Increased Solar Panel Dust Removal Efficiency Asaad Alduais, Abdulrahman Javaid, Miswar Syed, Jhonathan P. Rojas and Mosab Alhrtomi; King Fahd University of Petroleum and Minerals, Saudi Arabia

Solar power is one of the fastest growing renewable energy technologies in the world. However, dusty weather conditions pose a threat to the solar panel's efficiency and reduce the power produced. The lack of an effective and long-term solution that successfully cleans solar panels while consuming low energy has been a challenge for the industry. Hence, the idea of a more reliable method that is more effective and cost-efficient to employ is appealing. Among the different proposed alternatives, a very promising cleaning technique involves the utilization of an Electrodynamic Screen (EDS) to actively remove the dust. The advantages of this technique include self-cleaning, high cleaning efficiency, and the eradication of manual labor, robots, and water-based cleaning techniques. An EDS consists of a transparent dielectric laminate with electrodes embedded in it. Commonly, the electrodes are arranged in a parallel configuration. In this work, we propose and analyze the employment of different electrode arrangement configurations for the EDS based on the fractal concept. This research aims to improve the EDS performance in terms of its cleaning efficiency, power consumption, and time taken. Finite element analysis results conclude that the Hilbert fractal-based electrode arrangement design performs better than the parallel design in terms of dust repulsion. Additionally, it results in low area coverage by the electrodes, ensuring an increased transparency of the EDS, hence increasing the overall irradiance absorbed by the solar panel. Specifically, as compared to the parallel design, the proposed Hilbert design reduces the power consumption and the area ratio by 25.25% and 33.83%, respectively and it also increases the maximum electric field intensity by 30%. This increase in the electric field intensity is directly associated with higher cleaning efficiency.

9:30 PM EN06.07.04
Carbon Dots Based Transparent Film for Efficient UV and High-Energy Blue Light Screening Barun K. Barman[1], Ørjan Sele Handegård[1,2] and Tadaaki Nagao[1,2]; [1]National Institute for Materials Science, Japan; [2]Hokkaido University, Japan

On the Earth's surface, the incoming radiation comprises ~5 % of ultraviolet, visible light, 43 %, and infrared light, 52%. Exposure to high-energy UV radiation can be harmful to humans, increasing the risk of skin cancers and damage to the eyes. Not only UV light, a major part of visible light is high-energy blue light (HEBL), ranging from 400-450 nm. HEBL can also have huge negative impacts on human health. It damages our eyes and can even affect mental health. In the past decade, the dramatic evolution of electronic gadgets such as smartphones, tablets, and flat televisions that use back-lighted technology, such as compact fluorescent lamps (CFLs) and LEDs, exposes us to large amounts of harmful radiation. These devices emit HEBL and small amounts of UV. Natural blue light can regulate our sleep and wake cycles, boost alertness, modulate mood, etc., but prolonged exposure to blue light at night can disrupt circadian rhythm, and can cause many additional health issues, such as diabetes, heart disease, and depression. Most importantly it can cause permanent eye damage and age-related macular degradation, leading to vision loss. It is essential to block all UV and HEBL light with tunable filters having high visible light transparency to protect our health from these hazardous light sources. Carbon dots (CDs) are a newly discovered class of carbon-based nanomaterials that are composed only of earth-abundant, light elements such as carbon, oxygen, hydrogen, and nitrogen, which are non-toxic and completely metal-free. By utilizing the absorption and emission properties of CDs, we have developed a new hybrid film composed of carbon dots (CDs) and cellulose film combined via H-bonding. CDs encapsulated cellulose films (CDs@Cel) are highly transparent in the visible spectral region. These films efficiently absorb UV light and HEBL, simultaneously down-converting them to longer wavelengths in the visible spectrum.

Biodegradable Materials for Transient Batteries and Electronic Medicine Lan Yin; Tsinghua University, China

Biodegradable devices represent a new type of electronics that is built on fully biodegradable materials and is capable of degrading in aqueous environments, which can therefore eliminate a second surgery for device retraction and minimize environmental footprints. Such devices could play important roles in many therapeutic and diagnostic processes, as well as handling electronic waste. Herein, we introduce novel materials strategies and fabrication schemes that enable fully transient batteries based on magnesium anodes that can provide energy supplies for consumer electronics and implantable devices. The battery systems can offer sufficient energy density and prolonged operational lifetime. Self-powered nerve conduit for peripheral nerve regeneration based on biodegradable galvanic cells are also achieved. Successful nerve regrowth and motor functional recovery are realized in rodent models. These works provide new insights for building energy devices for green electronics and implantable electronic medicine.

10:15 PM EN06.07.06
Transient Rechargeable Battery with a High Lithium Transference Number Cellulosic Separator Neeru Mittal[1], Alazne Ojanguren[1], Erlantz Lizundia[2] and Markus Niederberger[1]; [1]ETH Zurich, Switzerland; [2]University of the Basque Country, Spain

Transient/degradable technology is a flourishing research area aimed at designing materials, devices, or systems that undergo controlled degradation processes after a period of stable and reliable operation. Transient devices work exactly like their conventional analogs but have an extra advantage; these devices can disintegrate into the environment in a controlled fashion without leaving any toxic products behind. Transient technology is rapidly gaining ground for biomedical applications, zero waste electronics, and data-secure hardware, to name a few. To power such devices, transient batteries are required. To date, there are very few reports on transient batteries in literature, mainly due to the lack of suitable soluble materials, fabrication schemes, and battery designs that must fulfill entirely different requirements than traditional batteries.
Here, we reported the development of a fully transient lithium-ion battery (LIB) with competitive electrochemical performance. At first, we designed a degradable separator based on polyvinyl alcohol and cellulose nanocrystals that offer several unique advantages: electrolyte (organic solvent-based) uptake

up to 510%, the ionic conductivity of 3.077 mS/cm, electrochemical stability up to 5.5 V *vs.* Li/Li^+, and a high transference number of 0.56. As a result, a stable lithium metal deposition and a high specific capacity of 105 mAh/g in $Li/LiFePO_4$ cell for over 250 cycles were achieved for the separator soaked in organic electrolyte. The toxic organic electrolyte was replaced with a biodegradable ionic liquid, providing an ionic conductivity of 0.988 mS/cm and a specific capacity of 87 mAh/g in $Li/LiFePO_4$ cell. Finally, the ionic liquid-separator pair was assembled into a fully transient lithium-vanadium(V) oxide ($Li-V_2O_5$) cell, which can be cycled over 400 times and degraded in 15 minutes once an aqueous trigger was applied. This prototype of a transient LIB represents a proof of concept to develop innovative transient energy storage systems with a long lifecycle.

Resource Recovery from Wastewater Using Bioelectrochemical Systems Praveena Gangadharan; Indian Institute of Technology Palakkad, India

The rapid growth of population generates huge waste, and its management is extremely challenging. In fact, wastewater is a well-recognized valuable source of renewable resources like water, energy, nutrients, heavy metals, etc. Considering the overall depletion of renewable resources from the earth, wastewater treatment facilities need to be upgraded as renewable resource recovery facilities. Such advancement replaces the use of fossil fuels for energy source and facilitates clean water production and cradle-to-cradle waste management. In this context, the bioelectrochemical system (BES) has gained much attention as it converts organics in wastewater to electrical energy by microbial interactions on the electrode. Beyond pollutant removal, BES exhibits critical functions like recovery of water, nutrients, and heavy metals from wastewater/industrial effluents. In recent years, extensive studies on BES have grown up with more research articles from different countries making this technology truly comprehensive.

The present talk will throw light into the various applications of BES, especially energy production from organic wastewater, concentrating nutrients and recovering water from urine, water recovery by desalination, and chromium and copper recovery from industrial effluents. The presentation will also brief on the prospects of recycling/reusing e-waste for synchronized removal/recovery of heavy metals along with energy production using BES.

8:30 AM *EN06.08.02
Circular Economy in Electronics and Electronic Waste Recycling Maria Holuszko[1] and Nani Pajunen[2]; [1]The University of British Columbia, Canada; [2]The Finnish Innovation Fund Sitra, Finland

Circular economy and the role of life-cycle analysis in the design and manufacturing of small electronic devices is the focus of this presentation. The transition towards a carbon neutral and circular economy as well as sustainability in the manufacturing of small electronic devices may be necessary and possible sooner that one could expect. There are enormous prospects in the recovery of valuable components and critical materials from e-waste as well as the promotion of eco-design and design for recyclability, all of which could be coupled with the business opportunities. According to some, if the circular economy were to be carried out extensively, it could reduce the consumption of new materials substantially - possibly by more than 50% by 2050. There are many barriers to moving from our currently-practiced cradle-to-grave economy, discussed in this presentation in the context of electrical and electronic equipment (EEE) devices as well as material design and development. This presentation provides perspective on recycling, life cycle analysis in the design process, challenges for e-waste recycling, and drivers for change in the complex industrial system.

9:00 AM EN06.08.03
Backscattered Visible Light Sensing—Towards Ecologically Aware Sensor Systems Andreas P. Weiss, Kushal Madane, Christian Fragner, Andreas Kröpfl, Stefan Schantl and Franz P. Wenzl; Joanneum Research Forschungsges mbH, Austria

Today it becomes more and more apparent that the conception of the Internet of Things (IOT) in the manner of objects equipped with a multitude of electronic sensors that all communicate with one another will pose serious problems both from ecological (energy consumption, e-waste) and technical (bandwidth limitations) point of views.
Nowadays, with the rise of light-emitting diode (LED) based luminaires also functionalities beyond illumination become more and more of relevance. For example, light can take over communication tasks and thereby offload the RF-spectrum. In this so-called visible light communication (VLC) scenario, the data are encoded into intensity modulations of the light emitted by the LEDs of the luminaires. Subsequently, these modulations are recorded by a photosensitive device, for example a photodiode. Furthermore, besides its application for communication, this infrastructure ((modulated) LEDs and photosensitive elements), can be also applied for another promising functionality future luminaires can provide, visible light positioning (VLP), which is on the way to play a decisive role in indoor localization.
While an enormous number of research studies focus on VLC and VLP, at present another potential functionality of artificial lighting, which again takes advantage of the same infrastructure as VLC and VLP, emerges: Visible Light Sensing (VLS). VLS expands the scope of functionalities of lighting into the domains of sensing and detection. In VLS, the photosensitive element records that light emitted from the luminaire that is reflected backwards from an object. Based on this principle and by equipping the objects with tailored reflective materials that purposively modulate the spectrum and/or the intensity of the light reflected from the object, information can be conveyed. Most notably, the basic concept of VLS only necessitates to equip the object with optical structures, but does not require any active device to be placed on the object. The basic conception of VLS relies on backscattering, which, in general, is one of the most promising technologies to be added in the 6G era of wireless communication technologies. Although most discussions on backscatter communication currently focus on RF-backscatter, similarly to the complementary role of VLC and RF for communication, also visible light-based backscatter technologies have a huge potential to complement RF-based ones.
An appropriate coding strategy for exploiting the visible light spectral range in this regard is to equip surfaces with colored “codes”, consisting of tailored sequences of different colors and the reflected light from this surface is detected with the help of an RGB-photodiode and further on analyzed. Appropriate machine learning algorithms can support this analysis and allow to maintain a high percentage of correct classifications even in case that the lighting conditions are changed.
Here we discuss appropriate system designs for artificial lighting sources, which allow for tunable artificial illumination (dimming and variation of color temperatures of the luminaires) while still being able to perform sensing tasks in parallel. Examples include the identification and velocity determination of indoor moving objects, the determination of the rotation direction and the rotation velocity of a robotic arm or the determination of the rotation of a human wrist by using a colored wristband. All these examples do not require any active devices to be placed on the objects. We show how the sensing tasks can be operated in parallel with tunable illumination and in parallel with communication (VLC). With this, artificial lighting, which is obligatory at least in indoor

environments, including VLC, VLP and VLS functionalities turns out as a promising technology for fulfilling one of the crucial challenges of 6G, which is to amalgamate sensing, positioning and communication, while drastically reducing energy use and e-waste.

9:15 AM *EN06.08.04
Commercially-Relevant, Cadmium-Containing Qdots as Models to Study Environmental Fate and Toxicity of TV Display Components Audrey Moores, Aude Bechu, Subhasis Ghoshal, Saji George, Maureen McKeague, Niladri Basu and Ke Xu; McGill University, Canada

Cadmium-containing quantum dot nanoparticles (QDs) are integrated into electronic displays because of their ability to efficiently convert colors. There are conflicting accounts as to whether these particles present a hazard to the environment, as they have been studied either as (1) embedded QDs in display screen films or (2) as model QDs with small, hydrophilic ligands. Both approaches have limitations that we addressed by synthesizing QDs featuring the core-shell structure and the thick polymer coating present in commercial devices. These models are used to probe the effect of environmental fate, in the form of low pH conditions, aeroby and anaeroby, as well as their transformation. Toxicity with liver cells is analyzed for both pristine QDs and the ones exposed to different fate conditions. We also studied the fate of these model systems in gastrointestinal track (GIT) conditions and studied how each step leads to transformation of the QDs. GIT cells toxicity was also studied and cellular uptake explored.

9:45 AM EN06.08.05
Late News: Using the Ostrom Framework for Sustainable Social-Ecological Systems to Create Circular Economies Carol A. Handwerker; Purdue University, United States

Creating circular economies requires creating resilient, sustainable, and self-managing communities of people who see circularity as vital to their livelihoods. Dr. Elinor Ostrom (2009 Nobel Laureate in Economics) laid out a framework for how people and organizations are able to develop voluntary, community-based solutions involving adaptive, self-governing systems that effectively manage “the commons,” without the need for government regulations or privatization. I’ll present examples where this framework of viewing products as “commons” has been applied, including creating a circular economy for hard disk drives. We will discuss how these concepts can be applied not only to other systems, but also to create a university community to train students to view materials, components, and products as parts of potential circular economies.

Ecofriendly Materials for Digitally Printed Organic Light-Emitting and Electrochromic Devices Gerardo Hernandez-Sosa[1,2]; [1]Karlsruhe Institute of Technology, Germany; [2]InnovationLab, Germany

The field of *Green Electronics* strives for the sustainable fabrication and utilization of electronics via responsible use of resources and elimination of negative environmental effects. The most direct way to mitigate negative sustainability issues in most end-of-life phases would be the utilization of inherently sustainable materials and processes from the very conception of a technology. this would effectively simplify or reduce the economic, energetic and environmental burden on regulation, recycling or recovery of electronic waste.

In this contribution, we will discuss our efforts towards the fabrication of ecofriendly organic electronic devices. We will present the investigation of biodegradable electrolyte systems based on gelatin, DNA, poly(lactic-co-glycolic acid) and *Polycaprolactone* for the fabrication of light-emitting electrochemical cells (LEC) and electrochromic (EC) devices. We will present inkjet-printed LECs exhibiting maximum luminance over 12,000 Cd/m^2 operational lifetimes > 100 h and emission covering all the visible spectrumwhich while containing > 90% ecofriendly materials. Furthermore, we will show EC devices which biodegradation was certified via an independently performed ISO (14855) test. These devices were integrated into a flexible inkjet-printed display demonstrating the potential of the industrial relevant printing techniques for the up-scalable fabrication of solution-processed ecofriendly electronics.

8:30 AM *EN06.09.02
One-step Conversion from Elemental Sulfur to Sulfur-Containing Functional Polymer Materials Rongrong Hu; South China University of Technology, China

Sulfur-containing polymers have attracted increasing attention, owing to their fascinating properties such as metal coordination ability, high refractive indices, self-healing capability, optoelectronic property, and so on. However, the rapid development of sulfur-containing polymer materials are hindered by the lack of economic monomers and efficient synthetic approaches. On the other hand, the utilization of elemental sulfur is a global concern considering its large surplus from petroluem industry and the safety/environmental problems caused during its storage, which is an idea source for the preparation of sulfur-containing polymers with the challenges of the poor solubility of sulfur in organic solvents and its toxicity to transition metal catalysts.
In this talk, a series of elemental sulfur-based multicomponent polymerizations (MCPs) will be introduced to directly convert elemental sulfur to sulfur-containing polymers such as polythioamides, polythioureas, polycarbamothioates, and polythiophenes with well-defined structures, good solubility, high yields, and high molecular weights in one step. These MCPs can generally proceed smoothly with catalyst-free condition, at mild temperature such as room temperature, in air atmosphere, which also usually enjoy high atom economy and wide monomer scope, enabling facile construction of sulfur-containing polymer with great structural diversity. With the cost-effective monomers, mild conditions, and no harmful smelly side product released, several MCPs are proved to be scalable.
Besides the high refractive indices, potential high dielectric constants and semiconducting property for the potential application in sustainable electronics, these sulfur-containing polymers can also be applied in gold recovery from the abundantly discarded electronic wastes. They can extract trace amount of Au^{3+} selectively, rapidly, and efficiently from aqueous solution in the practical condition with strong acidity and other metal ion interferences, directly affording elemental gold with high purity through in situ reduction or simple pyrolysis.
These sulfur-based MCPs are economic, efficient, and convenient tools for the direct conversion from sulfur at mild condition to profitable sulfur-containing functional polymers, which could make use of both abundantly existing sulfur waste and trace amount of gold residue in electronic wastes, and accelerate the development of sulfur-containing polymers with diversified structures and functionalities, demonstrating their great potential in resource

utilization and sustainable electronics.

9:00 AM *EN06.09.03
***In Vivo* Polymerization of Conjugated Oligomers for Self-Organized Electronics in Plants and Animals** Eleni Stavrinidou; Linköping University, Sweden

Leveraging the biocatalytic machinery of living organisms for fabricating functional bioelectronic interfaces in-vivo not only enables seamless integration of microdevices into the tissue but also a greener solution for advanced microfabrication. Previously we have demonstrated that plants can polymerize conjugated oligomers in-vivo forming conductors within their structure. We showed that the polymerization is enzymatically catalyzed by endogenous peroxidases and we developed a series of conjugated oligomers that can be enzymatically polymerized in physiological conditions. The conjugated polymers integrate within the plant cell wall structure adding electronic functionality into the plant that is then explored for energy storage. Recently we have extended this concept into an animal model system. We demonstrate that Hydra, an invertebrate animal can polymerize intracellularly conjugated oligomers in cells that expresses peroxidase activity. The conjugated polymer forms electronically conducting and electrochemically active domains in the µm range integrated within the hydra tissue. Our work paves the way for self-organized electronics in plant and animal tissue for modulating biological functions and in-vivo bio-fabrication of hybrid functional materials and devices.

10:30 AM *EN06.10.01
Next Generation, Low Embodied Semiconductors for Local Power and Light Sensing Paul Meredith, Ardalan Armin, Greg Burwell, Oskar Sandberg and Wei Li; Swansea University, United Kingdom

Next generation semiconductors such as the perovskites and organics can be sourced from earth abundant elements and processed from solution or via low temperature vapour deposition. This means they have intrinsically low embodied manufacturing energy and much reduced environmental footprints relative to more traditional semiconductor systems. In addition, organic semiconductors in particular (and in a more limited sense the perovskites) can be tuned at the molecular level to provide a vast palette of different materials with engineered electro-optical properties such as optical gap, absorption coefficient, electron affinity and ionization potential, etc. These ‘unique selling points’ are increasingly recognized as essentials for creating more sustainable electronic and optoelectronic technologies, including in areas such as the internet of things (power sources and sensors), wearable and bioelectronic healthcare, and mobile, local clean energy generation.
In my talk I will specifically focus on the development of bespoke, spectrally tuned photovoltaics and photodetector systems. I will discuss the latest advances in perovskite and organic semiconductor PV in relation to (for example) indoor local power generation including considerations such as materials design, thermodynamics, spectral matching and the constraints of the crucial transparent conductive electrode. I will also outline recent results and latest thinking on the development of organic and perovskite semiconductor photodetectors – both greyscale and color sensitive, and show how it may be possible to engineer so called ‘illuminant independent’ full color imaging photodetectors of the sort required for true machine / artificial vision.

11:00 AM *EN06.10.02
Natural Materials Selection for High Performance and Low Energy Fabrication Avenues for Electronics Mihai Irimia-Vladu; Johannes Kepler Universität Linz, Austria

Through its appealing avenues of processing the component devices at room temperature and from low-cost precursor materials, organic electronics has a tremendous potential for the development of products able to achieve the goals of production sustainability as well as environmental and human friendliness for electronics. In an effort to stave off the e-waste growth, the presenter and his research group went further down the path opened by organic electronics research and investigated a large number of biomaterials as substrates, dielectrics, semiconductors and smoothening layers for the fabrication of organic field effect transistors, integrated circuits and organic solar cells. The seminar presentation will focus on the highlights of our recent research, especially with respect to materials investigated, devices fabricated and the immense potential for follow up research:
-Flexible natural and biodegradable substrates with high resistance to solvent exposure and temperature stability
-Natural dielectrics
-Bio-origin, H-bonded semiconductors in the families of indigos, anthraquinones and acridones
-Bio-degradation protocols for organic semiconductors
The potential of follow-up research in the bioelectronics field is immense, with large area electronics fabrication, biomedical implants, bio-sensing and smart labeling, representing only the tip of the iceberg of many more immediate possibilities of high interest for our group. Natural and nature-inspired materials have the unrivalled capability to create “safe-first” electronic markets for human and environment, with minimal or even neutral carbon footprint.

SESSION EN07.01: Mechano-Thermal and Electrical Coupling in Emerging Energy Materials I
Session Chair: Jingjie Yeo
Tuesday Morning, November 30, 2021
Sheraton, 3rd Floor, Hampton

10:30 AM *EN07.01.01
Modulating Polyelectrolyte Mechanical Properties with Electric Fields Meredith N. Silberstein[1], Prathamesh Raiter[1], Hongyi Cai[1], Zhongtong Wang[1] and Yuval Vidavsky[2]; [1]Cornell University, United States; [2]Soreq NRC, Israel

Multifunctionality in polymers facilitates their application in emerging energy technologies. Electrical fields are a preferred stimulus because of the speed and ease of application to bulk polymers. While a wide range of electrically triggered actuators have been developed, and electrically controlled adhesion between gels has been demonstrated, modification of bulk mechanical properties via electrical stimuli remains elusive. Such a function could be particularly useful in electrochemical devices such as batteries and low temperature fuel cells that rely on polymer membranes to conduct ions while maintaining mechanical integrity. Fields vary temporarily and tend to deviate locally, for example from dendrite growth, and an electric field adaptive polymer could help avoid short circuits that lead to device failure. Polymers with covalently incorporated ionic charge should be well suited to achieving this goal since the mechanical properties depend on electrostatic interactions and these charges are intrinsically susceptible to electric fields. I will present our work investigating whether electric fields can modulate the mechanical properties of polyelectrolytes and our efforts to understand potential governing mechanisms. I will focus primarily on our molecular dynamics (MD) simulations. These simulations reveal the importance of polymer chain architecture and show how chain orientation and ion clustering relates to bulk mechanical properties. I will also share some of our theoretical, synthetic, and experimental work that builds from these MD simulations towards a physical realization of the idea.

11:00 AM EN07.01.02
Electrochemical Energy Harvester Driven by Eye-Blinking as a Power Supply to the Smart Contact Lenses Erfan Pourshaban, Mohit Karkhanis, Adwait Deshpande, Aishwaryadev Banerjee, Chayanjit Ghosh, Hanseup Kim and Carlos Mastrangelo; University of Utah, United States

Biomedical implantable and wearable electronic devices are promising tools to improve human wellness by real-time monitoring health indicators and curing disease more effectively. The development of smart contact lenses is of great importance mainly due to their wide range of applications, from vision correction to drug delivery. Accordingly, there are numerous research studies taking place to commercialize smart contact lenses. One of the main roadblocking issues toward its commercialization is the power supply and management for the microelectronics, which should be mounted on the device. Batteries, photovoltaics, and wireless power transfer are the most well-known strategies to supply power to smart contact lenses. However, all of these techniques suffer from several drawbacks. For instance, radio power scavenging either requires large antennas or the ranging distance is lower than 10 cm. Besides, batteries need periodic charging, which is a cumbersome practice for a contact lens user. On the other hand, mechanical to electrical energy conversion can supply power to the smart contact lenses by natural human eye blinking that is an environmentally independent source of energy. Triboelectricity based on contact electrification and electrostatic induction, piezoelectricity based on applying stress to a non-centrosymmetric crystal structure, and electrostatic generator based on capacitance gradient are among the most famous mechanisms to convert mechanical energy to electricity. However, herein, we demonstrate the performance of our recent mechanical to electrical energy harvester operating based on electrochemical reactions and charge transfer. A 300nm SiO_2 was thermally grown on a 5×5 mm^2 p-type silicon piece, followed by the spin coating of 2 µm Cytop as a hydrophobic layer. A 5×1 mm^2 of the SiO_2/Cytop stack was photolithographically patterned and etched utilizing CF_4 and oxygen gases with the flow rate of 50 and 5 sccm, respectively. A silver paste was used as the bottom contact of the device. Employing a linear actuator, the device has a back-and-forth motion (speed = 20 $mm.s^{-1}$) on a moisturizing eye drop in contact with a metal foil. In the present study, we have experimentally measured the electrical output of the sliding electrochemical electrifier using three metal foils, including copper (Cu), aluminum (Al), and gold (Au). The voltage outputs were directly detected at the Siglent oscilloscope with the input impedance of 1 MΩ. The current outputs were detected using the SR570 low noise amplifier.
Results demonstrate the maximum voltage of 80, 200, 620 mV while using Cu, Au, and Al metals, respectively. The corresponding maximum currents are 17.5, 8, and 80 µA. Accordingly, we used a 4.7 µF capacitor to experimentally measure the energy and power output of the electrochemical sliding energy harvester. 15 nJ (0.075 $\mu W.cm^{-2}$), 94 nJ (0.47 $\mu W.cm^{-2}$), and 0.9 µJ (3.6 $\mu W.cm^{-2}$) are the energy (power density) output of the device while using Cu, Au, and Al metals. The electrical output was recorded when the eye drop touches the device's contact (silver paste). The ascending voltage and energy outputs of the harvester is clearly following the electrochemical potentials of the metals. Physically speaking, the electrochemical reactions between the moisturizing eye drop and metals' surface resulting in redox reactions. Hence, the liquid either loses or gains electrons which will be dragged and transferred to the silver paste using the frequent sliding motion. This phenomenon can be optimized and used to supply power to the smart contact lenses through a natural eye blinking.

Manipulating and Understanding Barocaloric Effects in Metal–Organic Materials Jinyoung Seo[1], Ryan McGillicuddy[1], Adam Slavney[1], Selena Zhang[1], Andrey A. Yakovenko[2], Shao-Liang Zheng[1] and Jarad A. Mason[1]; [1]Harvard University, United States; [2]Argonne National Laboratory, United States

Barocaloric materials—which exhibit pressure-induced thermal changes—can be used to drive solid-state cooling cycles that offer an environmentally friendly alternative to vapor compression refrigeration. The development of efficient, scalable barocaloric cooling will benefit from a class of materials featuring a phase transition mechanism that provides large entropy changes, minimal hysteresis, high sensitivity to hydrostatic pressure, and chemical tunability. Here, we describe a mechanism for realizing a new class of materials that feature colossal and tunable barocaloric effects. This mechanism is

based on conformational order–disorder transitions of long-chain organic molecules—confined in space—that give rise to large changes in volume and entropy. Additionally, we demonstrate how the synthetic tunability of this system can be leveraged to control structural and chemical factors that influence the thermodynamics and kinetics of pressure-induced phase transitions. Through these efforts, we report a library of materials that feature a combination of colossal entropy changes, high barocaloric coefficients, and ultralow hysteresis. Further, the excellent processability of these materials, in combination with their unique mechanical properties, offers particularly simple strategies for harnessing barocaloric effects in prototype cooling devices across length scales. This work provides new insights into barocaloric effects of metal–organic materials, with a particular emphasis on understanding and manipulating thermodynamics and kinetics of pressure-induced phase transitions.

SESSION EN07.02: Mechano-Thermal and Electrical Coupling in Emerging Energy Materials II
Session Chair: Jingjie Yeo

1:30 PM *EN07.02.01
Modelling Biobased Materials—From Quantum Chemistry to Large-Scale Simulations Anna Bachs-Herrera[1], Isaac Vidal-Daza[2], Daniel York[1], Tristan Stephan-Jones[1], Jingjie Yeo[3] and Francisco Martin-Martinez[1]; [1]Swansea University, United Kingdom; [2]Universidad de Granada, Spain; [3]Cornell University, United States

The ability to valorise waste is a cornerstone of circular economy. Developing
materials from waste biomass requires fundamental understanding of biomass degradation and biobased materials structure-property relationships. In this talk, we will provide an overview of ongoing work and future perspectives on multiscale modelling and simulations of biomass and biobased functional materials, including lignin, nanocellulose, chitin, biocrude oils, and carbon nanoparticles. By coupling modelling and simulations to hydrothermal processing (HTP) experiments we develop fit-for-purpose biobased materials with applications in energy harvesting and storage, infrastructure and precision agriculture, among others. We apply Density Functional Theory (DFT), Molecular Dynamics (MD) simulations, and coarse-grained (CG) modelling to simulate materials behaviour from the
nanoscale to the mesoscale. We simulate chemical reactivity, electron transport,
mechanical properties, and degradation mechanisms.

2:00 PM EN07.02.02
In-Plane Thermo-Mechanical Property of 2D Hybrid Organic-Inorganic Perovskites Doyun Kim[1], Eugenia S. Vasileiadou[2], Ioannis Spanopoulos[2], Mercouri G. Kanatzidis[2] and Qing Tu[1]; [1]Texas A&M University, United States; [2]Northwestern University, United States

2D hybrid organic-inorganic perovskites (HOIPs) are low-cost, high-performance semiconductor materials with great potential demonstrated in various fields, including photovoltaics, light-emitting diodes, lasers, and field-effect transistors. During device fabrication and device operation, 2D HOIPs will go through various temperature statuses. Because of the hybrid organic and inorganic nature, the temperature fluctuation will cause a significant influence on the mechanical behavior of 2D HOIPs, which is vital for material processing and device durability, but is largely unknown. Here we measured the in-plane elastic modulus E of a prototypical 2D HOIP, $(C_4H_9\text{-}NH_3)_2(CH_3NH_3)_2Pb_3I_{10}$ as a function of temperature across a range of technological interest (*i.e.,* -15 ºC to 65 ºC) by AFM stretching suspended 2D HOIP nanosheets. Compared to the values at room temperature, E varies by more than 20% and exhibits a non-monotonic temperature dependence, which does not follow the general anharmonic expectation of the thermo-mechanical behavior for materials, where a higher temperature usually leads to weaker bonds and lower E. The observed abnormal trend can be explained by temperature-induced melting and stacking of the organic spacer molecules, which modulates the interlayer interactions of the 2D HOIPs at the van der Waals interface. Our results reveal the critical role of the organic layers in determining the mechanical behaviors of 2D HOIPs, unlike the negligible influence of the organic cations on the mechanical properties of their 3D counterparts, and provides indispensable insights into the processing and device applications of 2D HOIPs involving temperature fluctuations

2:15 PM EN07.02.03
Topographically-Modified Triboelectric Nanogenerator by Controllable Phase Seperation of Polymer Blend Films Kuan Cheng, Haleh Ardebili, Hadi Ghasemi and Alamgir Karim; University of Houston, United States

Conventional methods to harvest and supply energy can hardly satisfy the rapid expansion of the Internet of Things (IoT). As an emerging solution, flexible triboelectric nanogenerators (TENGs) have been invented and developed for over a decade to scavenge mechanical energy from the ambient environment. The operation of TENGs mostly depends on contact electrification, which exists between any two materials with electrostatic charge potential difference which makes it a portable solution to energy generation on demand in the future. Much research has focused in recent years on enhancing the output power of TENGs to its maximum limit. To optimize the performance of TENGs, choosing the desirable material pair with high work function difference, increasing contact surface area between materials, and designing an efficient device structure are deemed to be the three most dominant tasks. Even though many strategies have been applied to enhance contact electrification, for instance, adding nanoparticles or nanofiller, plasma treatment, soft lithography, dry-etch, etc., most of them are still restricted by the materials selection, cost of chemical processing, and loss of mechanical properties. Herein, we present a robust and unique route to fabricate a surface-modified triboelectric nanogenerator to harvest wind energy, realized by the phase separation of polymer blend films. Among many nature and organic matter, polyvinylidene difluoride(PVDF) has been experimentally proven as excellent dielectric materials in TENGs and other energy harvesting technologies, owing to its good formability and flexibility, large dipole moment, and low acoustic impedance. Our proposed approach is based on the increase of surface roughness in nanoscale derived from the controlled phase separation of PVDF containing blend film. This strategy is aimed to enhance the performance of PVDF films in TENGs by regulating the contact surface area and the mechanical energy induced by relative friction force. The topographically designed films, along with metal electrodes, fixed on a supporting device is seamlessly assembled by additive manufacturing (3D printing). The fabrication of future TENG devices followed our proposed methods will be cost effective, and target high power density output in the competition for power via next-generation flexible devices and electronics.

We acknowledge Kostas Research Institute(KRI) At Northeastern University Grant #555033-78055 for the support of the work.

2:30 PM EN07.02.04
Understanding the Metal-Insulator Transition in Transition Metal Oxides Jonathan Paras and Antoine Allanore; Massachusetts Institute of Technology, United States

Developing a stronger understanding of the metal-insulator transition in transition metal oxides (TMOs) is key for modulating the performance of TMO devices. Two TMO materials (NbO_2 and VO_2) exhibit metal-insulator transitions whose thermodynamics have proven difficult to describe using conventional electronic structure calculation methods. We develop a formalism that links electronic transport properties to the state electronic entropy and apply this formalism to calculate the change in the electronic entropy of transition. Our electronic entropy calculations agree with estimates of the vibrational entropy and calorimetrically measured totals. Further, these calculations suggest a method for quantifying the effect of doping on the transition entropy, thereby enabling the engineering of the metal-insulator transition as a function of chemistry. For systems where the thermodynamics of the transition are well understood, our formalism provides estimates of the electronic transport properties, including Seebeck coefficient and resistivity.

2:45 PM EN07.02.05
Electro-Chemo-Mechanical Coupling—A Novel Approach to Micro Actuation Evgeniy Makagon[1], Ellen Wachtel[1], Lothar Houben[1], Sidney R. Cohen[1], Yuanyuan Li[2], Junying Li[2], Anatoly Frenkel[2] and Igor Lubomirsky[1]; [1]Weizmann Inst of Science, Israel; [2]Stony Brook University, United States

The chemo-mechanical effect in solids refers to dimensional change due to change in stoichiometry. Dimensional change due to electrochemically-induced compositional change has been termed the electro-chemo-mechanical (ECM) effect. The mechanical instability inherent in this effect is clearly deleterious for batteries or fuel cells, but, as recently suggested, has potential for use in actuation[1]. The structure of an actuator device that operates on the ECM principle comprises a micrometer thick solid electrolyte (SE) sandwiched between two ECM-active, working body (WB) layers. An electrochemical reaction must occur in these layers, causing them to alternately expand or contract. In order to facilitate the ECM response, the WB layers should have mixed ionic and electronic conductivity and a large chemical expansion coefficient.
We have constructed a 2mm diameter thin film membrane ECM actuator device comprising 20mol% Gd doped CeO_2 (20GDC) as the SE and [$TiO_{2-\delta}$\20GDC] or [$V_2O_{5-\delta}$\20GDC] composites as the WBs[2]. Selected area electron diffraction measurements showed the composite to be nanocrystalline, a morphology that promotes interfacial oxygen ion diffusion. Synchrotron X-ray absorption (XAS) measurements detected a mixture of Ce^{3+}/Ce^{4+} (~[0.4]/[0.6]) and Ti^{3+}/Ti^{4+} (~[0.1]/[0.9]) oxidation states in the WB. XAS measurements under bias showed changes in the short-range order of Ti and V oxides supporting the presence of a redox reaction. The deformation of the ECM actuator was observed to be in the bending regime producing large vertical displacements (~3 μm) and ~4 MPa stress. The stress/voltage ratio yields a pseudo piezoelectric stress coefficient of e_{31}=1.26 C/m^2, comparable to common lead-free piezoelectrics such as lithium niobate, lithium tantalate and alkali niobates.

Late News: Ultrafast Spectroscopy of Hot Electrons and Chemical Potential Shifts in Al During Conditions of Strong Non-Equilibrium William Riffe, Md. Rafiqul Islam and John A. Tomko; University of Virginia, United States

Metals remain the prototypical test-bed for understanding ultrafast energy transfer amongst non-equilibrium carrier populations, such as electron-phonon scattering rates, due to their dynamics being well-described by the two-temperature model (TTM). The majority of experimental studies in this area of research have devoted their efforts to pump-probe measurements of gold films due to its relatively simple electronic band structure and corresponding optical response. Aluminum, on the other hand, has received significantly less attention, despite a number of works demonstrating interesting and unique processes such as preferential phonon scattering times and non-thermal phonon populations that greatly affect the ultrafast dynamics. Additionally, the understanding of ultrafast energy processes in Al is more relevant than ever, particularly at low temperatures, due to its applicability in quantum sciences. In this work, we perform a series of wavelength-resolved ultrafast thermometry measurements to directly monitor the dynamics of both the lattice and hot electrons near the interband transition threshold of Aluminum thin films. By monitoring the ITT energy as a function of both incident fluence and pump-probe time delay, we extract changes in the Fermi energy, and thus electronic chemical potential, based on varying electron temperatures. Further, by relating the wavelength-dependent response, an accurate model of the electron temperature of Aluminum upon ultrafast heating is extracted, allowing for measure of an average electron-phonon coupling factor.

Engineering of Carbon and Silk Materials Toward Flexible Electronics Yingying Zhang; Tsinghua University, China

Flexible and wearable electronics are attracting wide attention due to their potential applications in wearable human health monitoring and care systems. It is of great importance to explore low cost and scalable preparation approaches for high performance flexible and wearable electronics. Carbon materials have combined superiorities such as good electrical conductivity, intrinsic and structural flexibility, light weight, high chemical and thermal stability, ease to be chemically functionalized, as well as potential mass-production, enabling them to be promising candidate materials for flexible and wearable electronics. In the last several years, based on the unique properties of nanocarbon materials, we have been working on the rational design and controlled fabrication of flexible electronics based on carbon nanotubes, graphene, silk and their hybrid materials and explored their applications in human health monitoring and human-machine interfaces. For examples, we have used carbon materials, including carbon nanotubes, graphene, and natural mass derived carbon as the key materials and develop a series of flexible wearable sensors (strain sensors, pressure sensors, temperature sensors, airflow sensors, sweat monitoring patch etc.), wires and flexible energy devices. The hierarchical structures of the carbon materials plays important roles in achieving flexible devices with desired performance. We have also explored the application of silk in flexible sensors by developing a carbonization strategy of silk

nanofibers and fabric and by combing nanocarbons with natural silk materials. High performance strain/pressure/temperature sensors, E-skin, silk/graphene E-tattoos, and silk based conductive wires have been developed. We also developed new technique for the 3D printing of nanocarbon-silk-based smart fibers/textiles. Based on the above, the applications of the obtained electronics in human health monitoring (such as pulse, breath, and temperature and environmental risks), human motion tracking, and human-machine interfaces have been demonstrated. These strategy provide new approaches for the low-cost production of high performance flexible and wearable electronics, which may promote the development of next generation smart electronics.

Electro Curing of Oriented Bismaleimide Between Aligned Carbon Nanotubes for High Mechanical and Thermal Performances Lin Qiu; University Of Science and Technology Beijing, China

Aligned assembly of carbon nanotubes (CNTs) is the key for high mechanical, electrical and thermal properties for CNT fibers. To overcome the weak van der Waals interactions between the CNTs, thermosetting polymers can be introduced into the fibers because efficient strengthening can be realized after a thermal curing. Here a better curing strategy, namely electro curing, is applied to bismaleimid (BMI)-impregnated CNT fibers to improve the inter-tube thermal transport. As the electric current is conducting along the CNT surface and induces the strongest Joule heating right there, the aromatic BMI resins can be cured into an oriented structure. Under the optimal curing current whose Joule heating is strong without inducing the BMI degradation, the fiber's intrinsic thermal conductivity can be improved from 30 to 177 W $m^{-1}K^{-1}$, and the apparent conductivity can be up to 374 W $m^{-1}K^{-1}$ at a sample length of 12 mm. The effect of thermal radiation is also semi-quantitatively studied by estimating the real surface area that radiates heat in the 3ω method.

Molecular Dynamics Simulations of the Structure-Thermal-Mechanics Relationship of Polyvinyl Alcohol and Its Composite Materials Junbo Zhou[1,2] and Zhao Qin[1]; [1]Syracuse University, United States; [2]Shanghai Starriver Bilingual School, China

Plastic, though once is considered a miracle material with its durability and malleability, now poses a significant environmental problem by creating hazardous wastes, because of its massive application to single-use products and difficulty in degradation in nature. Our team aims to create a substitute of plastic with better mechanical strength, low cost, and biodegradability for fields like agriculture, packaging, and more. Polyvinyl alcohol (PVA) is a water-soluble synthetic polymer that can be used to make non-toxic bags/films which break down over time. Its production keeps increasing and it has been used in food and drug packaging, as well as biomedical fields including cartilage replacements and contact lenses. Its massive use can effectively reduce land and ocean pollution. However, it lacks thermal stability and is easy to absorb water from a humid environment. We are thus motivated to investigate the large-scale molecular structures of PVA and reveal its structure-thermal-mechanics relationship by using molecular dynamics simulation. We obtain the folded PVA structure from a fully extended state and unfold it in steered molecular dynamics to reveal its nanomechanics, as well as how it interfaces to other biomolecules. We find that the PVA structure folded at room temperature is stabilized by the randomly formed hydrogen bonds between hydroxyl groups but there is a lack of ordered structure, making the structure easy to unfold by temperature fluctuation and interaction with water molecules. A smaller amount of crystallinity and less energy dissipation is found by comparing to the PVA sheet-like structures folded through the annealing process. We study the hybrid mixture of PVA and collagen and investigate how the PVA structure and mechanics are stabilized by forming the interface with collagen. Our study provides insights into mixing PVA to collagen to construct a biodegradable composite material with higher thermal and humidity, enabling its durability in use but still friendly to the environment.

9:15 AM EN07.04.04
A Micromechanical Study of Creep Fracture of FeCoNiCrMn at High Temperature Chi Hua Yu[1,2], Wei-Tang Huang[1], Chang-Wei Huang[3], Yu-Chieh Lo[4] and Shian-Ching Cheng[5]; [1]National Cheng Kung University, Taiwan; [2]Massachusetts Institute of Technology, United States; [3]Chung Yuan Christian University, Taiwan; [4]National Yang Ming Chiao Tung University, Taiwan; [5]National Central University, Taiwan

High entropy alloys have attracted extensive attention due to the complex formation from several metal elements and their extraordinary performances, such as lightweight, high ductility in extreme working temperatures. In this study, we studied the intergranular creep fracture of FeCoNiCrMn by exploiting micromechanical modeling. We considered a dislocation-based crystal plasticity model for grain interior and a cohesive zone model for grain boundary sliding and separation. We developed an integrated computational framework to simulate the mechanical properties of FeCoNiCrMn by implementing user-defined material (UMAT) for grain interiors and user-defined element (UEL) for grain boundaries in commercial finite element software Abaqus. We first performed a parametrical study to examine the robustness of the model. The simulation results agree well with the experimental research. Furthermore, we discussed the effects of strain rate, grain boundary separation, and grain boundary viscosity on the mechanical behaviors. We found that the stress concentration occurs at the grain boundaries with a larger disorientation angle, making the grain boundary prone to separate from alleviating this severe strain inhomogeneous. Finally, the competition mechanisms of creep fracture for FeCoNiCrMn were studied. The simulation result suggested that the creep fracture is dominated by grain boundary separation, consistent with the experimental observation. Thus, our model can be applied to study grain interior and grain boundary mechanical behavior at high temperature for different high entropy alloys with great potential in automobile, aerospace, and high-performance alloy design.

Biaxial Strain and Electron-Phonon Coupling Effects on Thermal Transport Properties of GaN Bingyang Cao; Tsinghua University, China

GaN-based electronic devices has been widely applied in energy, information and vehicle areas. Strain inevitably exists in practical GaN based devices due to the mismatch of lattice structure and thermal expansion brought by heteroepitaxial growth and band engineering with strain, and significantly influence phonon thermal properties of GaN. In this work, phonon properties and thermal conductivity of GaN including contribution from electron-phonon coupling (EPC) as well as the effects of in-plane biaxial strain are systematically investigated using the first principle calculation method and phonon Boltzmann transport equation. Thermal conductivity of free GaN is 263 and 257 W/mK for in-plane and cross-plane directions, respectively, which is consistent better with the maximum experimental values in literature than previous theoretical reports, and shows a nearly negligible anisotropy of thermal conductivity. Under strain state, thermal conductivity changes remarkably both in absolute values and anisotropy. For instance, under +5% tensile strain state, average thermal conductivity at room temperature decreases by 63% while it increases by 53% under -5% compressive strain state, which is mostly attributed to the

changes of phonon relaxation time. Besides, anisotropy of thermal conductivity changes under different strain states, which may result from the weakening effect from strain induced piezoelectric polarization. EPC is also calculated from first principles, and it decreases the lattice thermal conductivity significantly. Specifically, the decrease shows significant dependence on strain state, which is due to the relative changes between phonon-phonon and electron-phonon scattering rates, as well as the absolute value of lattice thermal condutivity without including EPC. Under compressive strain state, decreases of lattice thermal conductivity are 15% and 18% for in-plane and cross-plane conditions, respectively, comparable with those under free state. However, the decreases become very small under tensile strain state, especially for cross-plane condition, which results from the decreased electron-phonon scattering rates and increased phonon anharmonicity.

9:30 PM *EN07.05.02
Liquid Thermocells with High Thermopowers for Low-Grade Heat Harvesting Yang Han[1], Jian Zhang[1], Run Hu[2] and Dongyan Xu[1]; [1]The Chinese University of Hong Kong, Hong Kong; [2]Huazhong University of Science & Technology, China

Low-grade heat is abundant in the ambient environment and provides a sustainable energy source for health monitoring devices and wireless sensor network. Liquid thermocells offer a promising solution for converting the widespread low-grade heat directly into electricity due to the advantages of relatively high thermopower, low cost, and high flexibility. Recently, we developed a polarized ternary electrolyte that switches from n-type to p-type when the hot electrode temperature is heated above the gelation temperature of methylcellulose. The ternary electrolyte achieves ultrahigh thermopowers of -8.18 mV K^{-1} for n-type and 9.62 mV K^{-1} for p-type. The polarization switching can be attributed to the strong hydrophobic interaction between methylcellulose and I_3^- ions, while the giant thermopowers mainly come from the thermogalvanic effect of the I^-/I_3^- redox couple enhanced synergistically by methylcellulose and potassium chloride. With the developed electrolyte, a single p-type liquid thermocell gives rise to an open-circuit voltage of 134 mV and a maximum power of 80.47 mW under a temperature difference of 15°C, corresponding to a normalized maximum power density of 0.36 mW m^{-2} K^{-2}, which is far superior to other reported I^-/I_3^--based liquid thermocells. Our work demonstrates a cost-effective, high-thermopower polarized electrolyte for low-grade heat harvesting.

10:00 PM *EN07.05.03
Strain-Engineering the Thermal and Electronic Properties of 2D Semiconducting Materials Yong-Wei Zhang[1], Zhun-Yong Ong[1], Gang Zhang[1], Zhi-Gen Yu[1] and Kah-Wee Ang[2,3]; [1]Institute of High Performance Computing, Singapore; [2]National University of Singapore, Singapore; [3]Institute of Materials Research and Engineering, Singapore

Two-dimensional (2D) semiconducting materials, such as phosphorene, MoS_2, InSe, et al. have attracted a great deal of interest due to their unusual structures and fascinating physical properties promising for many novel applications. Since these 2D materials are able to sustain a large tensile strain, which can cause significant changes in electronic and thermal properties, strain engineering is an effective approach to tune their physical properties, which can greatly widen their applications. To do so, however, it is both important and necessary to understand and further tune these properties by applying strain.

In this talk, we report our research work on the strain engineering of 2D semiconducting materials to tune their electronic and/or thermal properties by using computational study. Using first-principles calculations and the non-equilibrium Green's function method, we investigate ballistic thermal transport in 2D monolayer phosphorene. A significant crystallographic orientation dependence of thermal conductance is observed. Furthermore, we find that the thermal conductance anisotropy with the orientation can be tuned by applying strain. In particular, the zigzag-oriented thermal conductance is enhanced when a zigzag-oriented strain is applied but decreases when an armchair-oriented strain is applied; whereas the armchair-oriented thermal conductance always decreases when either a zigzag- or an armchair-oriented strain is applied. The present work suggests that the remarkable thermal transport anisotropy and its strain-modulated effect in single-layer phosphorene may be used for thermal management in phosphorene-based electronics and optoelectronic devices. Next, using first-principles calculations, we design a 2D transition metal compound, Ni-MoS_2, to investigate its HER catalytic performance. We reveal that with strain engineering, the bandgap can be reduced and a semiconductor-to-metal transition can be induced, which lead to an enhancement in the charge transfer and HER performance. Moreover, together with strain engineering, the thermoneutral condition can be achieved at the S vacancy concentration of only ~2.5%, which is in strong contrast to ~12.5% required for MoS_2. Finally, we report our work of using 2D InSe to fabricate a flexible and ultrasensitive three-terminal strain sensor. The strain sensor shows a prominent enhancement of sensitivity through gating effect. We also demonstrated InSe based flexible transistor and Boolean inverter circuit, which achieves a high mobility and an on/off current ratio. This work highlights the potential of using InSe as a common material platform for next generation flexible electronics and strain sensors applications.

10:30 PM EN07.05.04
Strain Engineering for Tailored Thermoelectric Performance in Metal Halide Perovskites from First-Principle Calculations Shangchao Lin[1], Lifu Yan[2] and Lingling Zhao[2]; [1]Shanghai Jiao Tong University, China; [2]Southeast University, China

Emerging metal halide perovskites have attracted attentions in thermoelectric energy conversions due to their ultralow thermal conductivity and excellent carrier transport properties. Using first-principle calculations, we find that halogen mixing (alloy) in $CsPb(I_{1-x}Br_x)_3$ not only leads to suppressed thermal conductivity, but also anisotropic carrier transport due to symmetry-breaking induced residue strains. External strain engineering strategies could tailor various thermoelectric properties, including carrier effective mass, carrier lifetime, and lattice thermal conductivity, in a more controllable manner to achieve the optimal thermoelectric figure of merit (ZT). Anisotropic ZT values predicted for $CsPb(I_{1-x}Br_x)_3$ upon uniaxial or biaxial loading show a wide range of variations from 20% to 400% compared to the unstrained cases with an enhanced ZT up to ~1.5 at 300 K. In addition, they could be used to reduce the optimal carrier concentration to achieve the maximum ZT by an order of magnitude compared to the unstrained cases, providing a new avenue to tackle the challenge in heavily-doping perovskites.

Energy-Conversion Efficiency of Twisted-Filament Artificial Muscles Zhiping Xu; Tsinghua University, China

Artificial muscles are materials or devices producing work or motion under external stimuli. Recently, twisted-filament artificial muscles (TFAMs) have

been demonstrated to meet the demands of miniaturization and multi-functionality in smart systems. TFAMs share a two-step process in triggering rotation or contraction: volumetric expansion and tension-torsion coupling. Various actuating mechanisms such as thermal expansion, electrochemical cues, solvents absorption were proposed. To understand the performance of TFAMs, we simulate the actuating processes by numerical simulations using the discrete elastic model (DER). Theoretical analysis is also conducted for models with a symmetric cross section in supplementary to the simulation results, revealing the basic principles that direct the actuating performance. We estimate the energy conversion efficiency as a function of the material properties and microstructural characteristics, which identifies the upper limits for realistic artificial muscles. We conclude that artificial muscles of twisted-microfilaments still have much space to improve in terms of the energy-conversion efficiency and work capacity.

8:30 AM *EN07.06.02
Tailoring Piezoelectric Polymer Nanofibers for Energy Harvesting Miso Kim; Sungkyunkwan University, Korea (the Republic of)

Piezoelectric polymer nanofibers have emerged as a competitive platform for shape-adaptive energy harvesting and sensing applications because of mechanical flexibility, lightweight, and relatively low-temperature processing. However, a key challenge has been the relatively low piezoelectric coefficients of these organic piezoelectric materials when compared to their inorganic counterparts. Here, we summarize a collection of advances that push the boundaries to achieve a drastic enhancement of mechanical energy harvesting performance by tailoring both material and structural properties of electrospun piezoelectric polymer fibers at multi-scales. Engineering structural morphology of piezoelectric materials from molecular to device scales will be discussed as a route to achieving improvement in the key figures of merit for energy harvesting and sensing, along with our unfolding new understanding of the underlying physics.

9:00 AM EN07.06.03
Neural Network-Assisted Optimization of Segmented Thermoelectric Power Generators Using Active Learning Based on Genetic Optimization Algorithm Wabi Demeke and Seunghwa Ryu; KAIST, Korea (the Republic of)

Because the best performing temperature range of thermoelectric (TE) materials differ from each other, segmented TE legs stacked with multiple TE materials has been studied as a mean to improve the performance of thermoelectric generators (TEGs). However, due to the inherent nonlinearity that limits the application of conventional optimization approaches, the optimal segmented TEGs (STEGs) had to be sought heuristically. In this study, we propose a systematic approach enabling the efficient exploration and exploitation of vast design space of STEG by leveraging the fast inference of deep learning. First, we train a neural network (NN) model using dataset generated from FEM simulations for a single TE leg stacked with 4 segments out of 18 TE materials by varying segment lengths and external load. We then conduct a genetic optimization algorithm (GOA) using our trained NN model to search for high-performing design candidates. The performance of the new candidates are computed with FEM, which is used to update the neural network by active transfer learning technique. After iteratively performing the procedure, we are able to fine-tune the TE legs with optimal efficiency, optimal power, as well as a given combination of both. Furthermore, we discuss the physical origin of the optimal performing STEGs.

9:30 AM *EN07.06.04
Thermoelectric Efficiency Theory for Temperature-Dependent Thermoelectric Properties Byungki Ryu, Jaywan Chung and SuDong Park; Korea Electrotechnology Research Institute, Korea (the Republic of)

Thermoelectric effects refer to the direct energy conversion between thermal and electrical energies. When a temperature difference is applied on a thermoelectric element, a thermoelectric generator module can generate electrical power with induced electrical voltage and current while the thermoelectric heat current flows with Fourier (diffusion) and Peltier heat.
Traditionally, thermoelectric efficiency is estimated using a simple metric called a dimensionless figure of merit, expressed as $zT = (\alpha^2/\rho\kappa)T$, where α, ρ, κ, and T are the Seebeck coefficient, electrical resistivity, thermal conductivity, and temperature, respectively. In the constant property model (CPM), in which thermoelectric properties are constant, the maximum thermoelectric efficiency η_{max} is simply given as $\eta_{max} = (T_h-T_c)/T_h \times [(1+zT_m)^{0.5}-1]/[(1+zT_m)^{0.5}+T_c/T_h]$, where T_h and Tc are hot- and cold-side temperatures, respectively, and T_m is $(T_h+T_c)/2$ [1]. With a monotonic nature of zT_m in efficiency, it has been widely used to guide thermoelectric material discovery.
However, as the thermoelectric conversion module works under a non-zero temperature difference ($T_h-T_c > 0$), the crucial assumption of CPM that thermoelectric properties are constant no longer holds. Some studies have attempted to find a suitable efficiency metric for wide temperature applications [1–7]. However, many recent studies have shown that discrepancies between the CPM and efficiency are unavoidable [8–14]. Although a few cumulative approaches have been investigated to correct thermoelectric heat current equations [12,13], the accuracy of efficiency prediction remains questionable. In addition, a counterintuitive example between ZT and efficiency highlights the need for a highly accurate efficiency evaluation method [14]. This type of non-negligible mismatch becomes an obstacle for further material optimization and device design for higher efficiency.
In this work, we develop the general efficiency theory of thermoelectric conversion with temperature-dependent thermoelectric properties to overcome the limitation of zT. We derive thermoelectric equations for power conversion and heat transfer, where the thermoelectric differential equation is successfully transformed into the T integral equation. By introducing two additional indices in addition to the proper definitions for device parameters, we formulate heat current equations at boundaries. As a result, we derive an efficiency equation determined by three thermoelectric degrees of freedom (DOFs): Z_{gen}, tau, and beta, where the existence of non-zero τ and β well explains the origin of the discrepancy between CPM and efficiency. Our thorough data-driven investigation on approximately 300 published materials confirms that our method is sufficiently accurate. Furthermore, we find that efficiency is a monotonic function of each DOF, which indicates the potential use of a DOF as a figure of merit. Finally, with suitable temperature approximation, we derive highly accurate approximate analytical expressions for thermoelectric module performance that can be easily applied to segmented leg design and p/n-leg pair module performance estimation even with interfacial contact resistance.

Trapping of Ionic Defects and Long-Lived Electret States in Methylammonium Lead Halides—Insights from Classical Molecular Dynamics Alessandro Mattoni and Claudia Caddeo; Istituto Officina dei Materiali - IOM Materials Foundry Consiglio Nazionale delle Ricerche - National Research Council, Italy

Hybrid organic-inorganic perovskites have attracted enormous attention for low-cost solution-processable photovoltaics. In addition to the excellent defects-tolerant optoelectronic properties of the metal halide inorganic lattice, hybrid perovskites have peculiar properties associated to the hybrid organic/inorganic and covalent/ionic nature, giving rise to phenomena coupling electronic properties and ionic dynamics, of relevance for sensing, thermoelectricity, spintronics and many others.
We start discussing the ability of classical interatomic force-fields[1], to reproduce the main structural and thermodynamical properties of 3D and 2D hybrid perovskites[2] and we review a selection of properties associated to ionic dynamics: the dielectric response and macroscopic polarization[3]; the ultra-high and anisotropic mobility of ionic defects[4]; the interaction of defects with extended defects[5,6] and their relevance for hysteresis and memory effects. In particular we report evidence of the formation of long-lived electret states associated to the interaction of defects and ferroelastic domains in the tetragonal phase[7].

Late News: Enhancing Thermophotovoltaic Performance Using Graphene-BN-InSb Heterostructures Rongqian Wang, Jincheng Lu and Jian-Hua Jiang; Soochow University, China

Near-field Thermophotovoltaic (NTPV) cells have attracted a wide range of research interest due to their enhanced performances compared to far-field counterparts. However, most of the existing studies are focused on the regime where the thermal emitter has very high temperature, e.g., higher than 1000 K, corresponding to solar radiations or heat radiations from a secondary emitter which receives the solar energy. Besides, due to the considerable frequency mismatch between the thermal emitter and the PV cell, the near-field effect becomes ineffective and the performance of the NTPV systems is significantly reduced.
In our previous paper [1], We focus on the situation where the temperature of the thermal emitter is in the range of common industrial waste heat, i.e., 400 K ~ 800 K. To convert such mid infrared thermal radiation into electricity and to make the photon tunneling efficient, we propose to use graphene-h-BN heterostructures as the emitter and the graphene-covered InSb p-n junction as the TPV cell. We show that the optimal output electrical power can reach 76000 Watts per square meters and the best efficiency is achieved with 33% of the Carnot efficiency. These results show that the performances of near-ield thermophotovoltaic systems can be comparable with or even superior to the state-of-the-art thermoelectric devices. The signiecant improvement of the thermophotovoltaic performance is understood as due to the resonant coupling between the emitter and the p-n junction, where the surface plasmons in graphene and surface-phonon polaritons in boron nitride play crucial roles.
It is remarked that our findings are consistent with the study in Ref. [2], where the synergy between near-field thermal radiation and inelastic thermoelectricity is shown to have considerably improved performance even in the linear-transport regime. Apart from this, our work is also based on the previous studies where the near-field effects are shown to improve the heat radiation flux by orders of magnitude via infrared hyperbolic metamaterials [3-4].

Organic Inorganic Hybrid Thermoelectric Generator Using Low Cost Non-Toxic Materials Y.M.D.C.Y. Bandara[1], L.K. Narangammana[1], Ajith DeSilva[2] and T. M. W. J. Bandara[1]; [1]University of Peradeniya, Sri Lanka; [2]University of West Georgia, United States

The search of alternative energy resources, the development of novel technologies and devices to fight against the use of fossil fuel is indeed a subject of interest worldwide. Thermoelectricity which transforms heat energy directly into electricity, can be utilized to covert waste heat into electricity. The

thermoelectric generators that consist of an array of *p*-*n* junctions made of two different thermoelectric materials (TEMs) that create a potential difference as the result of a temperature difference across the junction. Widely used and the best known TEMs are hazardous in nature such as Bi_2Te_3 and Sb_2Te_3, therefore, there is a need for a search of new non-toxic TEMs. In this study, thermal, electrical as well as thermoelectric properties of organic polymer of polyaniline (PANI) and inorganic ceramic material of Zinc oxide (ZnO) are investigated. The study is extended to fabricate a novel organic/inorganic *p*-*n* junction as a hybrid thermoelectric generator using PANI and ZnO, whereas organic *p* and inorganic *n* type material respectively using compressed pellets of HCl doped PANI and Al doped ZnO. Electrical conductivity, thermal conductivity and Seebeck coefficient were investigated, and the figure of merits was calculated for PANI, ZnO and Al -doped ZnO. Fourier-transform infrared and XRD spectra confirmed the synthesis of PANI, ZnO and Al-doped ZnO. The pellets of PANI, ZnO and Al-doped ZnO exhibited electrical conductivities of 63.6 (90 °C), 313 (100 °C) and 356 S m^{-1} (100 °C) respectively. The thermal conductivities of respective pellets are 7.38 (90 °C), 23.8 (100 °C), 14.0 W m^{-1} K^{-1} (100 °C) respectively. PANI showed a positive Seebeck coefficient (confirming the *p*-type nature) of 34.6 µV K^{-1} at 90 °C. ZnO and Al-doped ZnO showed negative Seebeck coefficients (confirming the *n*-type nature) of -165 µV K^{-1} and -225 µVK^{-1} respectively at 100 °C. The PANI/ZnO junction generator exhibited a voltage of 21.9 mV for a temperature difference of 78 °C across the junction.

Frequency, Temperature, Voltage Tunability and Optical Constant Measurement of $VO_2/V_{1-x}W_xO_2$ Thermochromic Films for Device Applications Golali Naziripour[1], Jincheng Zhao[2], Guru Subramanyam[2], Eunsung Shin[2], Andrew Sarangan[2], Chin-Cheng Chiang[1] and Zhihong Chen[1]; [1]Purdue University, United States; [2]University of Dayton, United States

Vanadium dioxide (VO2) and W-doped Vanadium dioxide (VO_{2-x}) are known to be reliable thermochromic materials for their insulating/metal transition temperature, which can be controlled by the doping concentration level (x), in $VO_2/V_{1-x}W_xO_2$. In this paper, the deposition of various thicknesses VO_2 and W doped V1-xO_2 films on R plane substrate, with two different techniques including (a) pulse laser deposition (PLD) and (b) by reactive electron beam deposition was described.
Various parameters including resistance, refractive index, extinction coefficient, as a function of temperature from 25 to 80 degree C and wavelength ranging from 500 to 3000nm using direct TR, are set up in addition to conventional ellipsometry.
Comparison between reflectance and transmission of spectra obtained from doped and un-doped vanadium shows that below the IMT temperature or in the insulating state, the doped VO_2 is more reflective and less transitive. The real and imaginary parts show that the doped materials produce a loss in the results, which has been confirmed by n and k and RT at various temperature and frequencies, a lower doping level and higher oxygen concentration is needed
Moreover, the influence of temperature and dopping on direct and indirect optical has been reported and various phases have been identified by comparing the transition temperature for direct and indirect bandgap data at room and elevated temperature. Comparison of various batches synthesized at different temperatures shows intermediate phases including VO_2(B) and V_2O_5 shows at a lower temperature less than 500 degree C, single phase is produced by heating the film at elevated temperature and adjusting oxygen pressure. Finally, We are able to adjust various parameters to make the film more suitable for practical applications including frequency detector and memory devices for NIR frequencies.

Mechanical and Thermal Effects of Low Dimensional Materials on Nanocomposites Arun K. Nair; University of Arkansas, United States

Nanocomposites have tremendous application in many industries due to their superior mechanical, and unique thermal properties. In automobile industry this class of composites are used for door panels, engine cover, tire, and for improving gas mileage. In energy and aerospace sector, it is used to make windmill blades and aircraft components. Low dimensional materials-based nanocomposites are also gaining interest in the scientific community. For all broad applications possible in industry, the quest for composites with superior mechanical and thermal properties are common factors. Low dimensional materials are prime candidates to achieve these properties. This talk focuses on the mechanical and thermal properties of low dimensional materials in nanocomposites and investigates different types, shape, and bonding characteristics of low dimensional materials on metallic substrates.
We use different computational methods to predict the thermal stability of low dimensional materials on nickel and copper substrates. We then studied the mechanical and interface properties of low dimensional materials-based nanocomposites and investigated the use of low dimensional materials as a fiber in nanocomposites. The result of these studies show that the mechanical properties of a metal matrix can be improved with the addition of these low dimensional materials and provide an insight into the design of metal-based nanocomposites.

Fundamental Study on Phonon Modulation Nuo Yang; Huazhong Univ of S&T, China

Recently, with the rapid development of smart society, our demand for new functional materials and hardware is urgent. Thermal functional materials play an important role in thermal management, energy storage and energy conversion. Phonons are lattice vibrational waves, which are the main energy carriers in dielectric solids. After electronic engineering and photonic engineering, the research progress of phonon engineering has attracted much attention. Phonon engineering is the discipline of designing and controlling phonon transport and conversion by using phonon devices with micro/nano structure, which plays a leading role in the design of thermal functional materials. The research objects of phonon engineering include lattice wave quantum transport, thermoelectric conversion, phonon devices and so on. The progress of nanotechnology has also promoted the development of phonon engineering, so there is an urgent need to understand the mechanism of phonon regulation and transport.
Professor Nuo YANG and the Nano Heat Group [1] focus on the fundamental and applied research of heat transfer, thermal control and energy conversion in micro/nano scale. The report will introduce the research progress of the Nano Heat Group in the following aspects: nanoscale heat conduction [2-6], thermal control [7-12], thermoelectric conversion [13-15], etc.

Interfacial Thermal Resistance Between Two-Dimensional Materials and Their Dielectric Substrate Xiangfan Xu; Tongji University, China

Interfacial thermal resistance (ITR) plays an important role in thermal dissipation across different materials and it has been widely investigated in recent years. An example is the integrated electronic circles in which heat dissipating issue has recently become the bottleneck. With further miniaturization of electronics, the accumulated waste heat has increased the operating temperature to a high value where thermal management and heat dissipation become crucial for the performance of devices [1]. The severe thermal management problem has prevented the operating frequency from going beyond several GHz when the dissipated waste heat exceeds 100 Wcm^{-2}. This work is separated into two parts: (a) Chemical vapor deposition (CVD) method was utilized to fabricate monolayer transition metal dichalcogenides (TMDCs) depositing directly onto SiO_2/Si substrate; we demonstrated that the interfacial thermal conductance of TMDCs/oxide was significantly promoted by introducing a phonon vibration bridge at the interface of TMDCs/oxide [2-5]. (b) We introduced an additional electron-phonon coupling channel in the thermal transport across graphene-dielectric interfaces and the scanning thermal microscopy technique measurement of graphene electronic devices gave direct evidence of an enhanced heat dissipation by tuning the surface carries concentration [6].

Coherent Phonon Transport in Nanostructures Jie Chen; Tongji University, China

The particle nature of phonons has been widely studied in the past, and the control of thermal transport is mainly focused on the *incoherent scattering mechanisms* via various approaches, such as defect, roughness, isotope and etc. Thanks to the advances in the synthesis technology of nanostructures with ultra-fine features, the study on the wave nature of phonons, namely the coherent phonons, is receiving increasing attention recently. In this talk, I shall first discuss the physical mechanism for storing monochromatic and coherent phonons in a host-guest system built by carbon schwarzite structure. Interestingly, the coherent phonons stored in this phonon nanocapacitor can also be released separately via uniaxial strain. Then, I will demonstrate that a phononic rectifier, which has asymmetric thermal transport in two directions, with large rectification efficiency can be realized based on such host-guest system. Finally, I will discuss how to achieve total-reflection and total-transmission of individual phonons in the periodic nanostructures. Our study reveals that the control of coherent phonons offers a new path to regulate the thermal and phonon transport in nanostructures.

10:30 PM *EN07.08.04
Illusion Thermotics-Enabled Thermal Metamaterials Run Hu; Huazhong University of Science and Technology, China

Thermal metamaterials have attracted increasing attentions in recent years as they can be used to manipulate heat almost at will by resorting to specific-designed anisotropic thermal properties beyond natural materials. Most thermal metamaterials are designed by the prevailing transformation thermotics, an extended version of transformation optics in the thermal field. However, the tradiational transformed thermal metamaterials only work well without heat sources. To cope with it, we develop the illusion thermotics techniques and proposed some new thermal functionalities such as thermal camouflage, thermal printing, and so on. Both the transformation thermotics and topology optimization were used to achieve illusion thermotics. In this talk, I will introduce the illusion thermotics and the state-of-the-art progress of thermal metamaterials.

Colossal Barocaloric Effects—A Delicate Tuning of Heat by Pressure Bing Li; Shenyang National Laboratory for Materials Science, Institute of Metal Research, Chinese Academy of Sciences, China

Colossal barocaloric effects (CBCEs) have been discovered in a class of disordered solids called plastic crystals as the cooling effects of pressure-induced phase transitions [1]. CBCEs are characteristic of huge entropy changes up to several hundred joules per kilogram per kelvin under a small pressure change, which are attributed to the combination of extensive molecular orientational disorder, giant compressibility, and highly anharmonic lattice dynamics of these materials [1,2].

Following this physical scenario, a diversity of colossal barocaloric materials have been found, which exhibit very distinct performances including thermal conductivity, thermal hysteresis, critical pressure, transition temperature spans under pressure, and so forth. In particular, NH_4SCN has been identified as the first system with inverse CBCEs [3]. A compromise would be made based on the systematical considerations of these factors and practically promising colossal barocaloric materials can be expected. In this regard, our efforts will be reported in detail.

In addition to refrigeration, the application of colossal barocaloric materials in thermal energy storage has been exploited as well. Compared to the conventional phase-change materials, pressure is an extra dimension and enhances the controllability of heat. In the presentation, the concept of barocaloric thermal batteries will be demonstrated.

Late News: The Synergy of Electronic and Geometry Structure Leads to Ultra-Low Thermal Conductivity—A Comparison of Graphene-Like Compounds Linfeng Yu and Guangzhao Qin; Hunan University, China

The design of new systems with specific technical interests through structural properties and bonding promotes the vigorous development of materials informatics. Here, we propose the concept of component reconstruction, which based on combination the structural and bonding characteristics of initial materials. With this strategy, we developed a new two-dimensional graphene-like compound, named as g-B_3N_5, which has light atomic mass but counter-intuitive ultra-low thermal conductivity of 21.08 W/mK. The ultra-low thermal conductivity is attributed to the component reconstruction of g-BN and nitrogene, which will lead to a synergy of electronics and geometry on thermal transport. Thus, the dominant acoustic branches are strongly softened, and simultaneously the scattering absorption and Umklapp process are suppressed, resulting in low thermal conductivity. Furthermore, based on the component reconstruction strategy, we also constructed g-B_3P_5 and g-B_3As_5 with ultra-low thermal conductivity of 2.50 and 1.85 W/mK, respectively. The ultra-low thermal conductivity materials with lightweight atomic mass cater to the need for lightweight development of momentum machinery, such as aerospace vehicles, high-speed rail, and automobiles.

8:45 AM EN07.09.04
Atomistic Simulation of Ferroelectric Domain Growth in $BaTiO_3$ by Applied Electric Field: Effects of Vacancies Takahiro Tsuzuki[1], Shuji Ogata[1], Ryo Kobayashi[1], Masayuki Uranagase[1], Seiya Shimoi[1], Saki Tsujimoto[1], Frank Wendler[2] and Dilshod Durdiev[2]; [1]Nagoya Institute of Technology, Japan; [2]Friedrich-Alexander University of Erlangen-Nürnberg, Germany

$BaTiO_3$ (BT) is a well-known ferroelectric and piezoelectric material, widely used in various devices as, e.g., capacitor for electric circuit, stress sensor, and actuator. However, little is known about the atomistic dynamics of ferroelectric domain growth. Depending on the production procedure (e.g., solidification from melt), doping (e.g., La), and oxygen gas pressure, various point defects are expected to form in BT. The oxygen vacancies (V_O) exist at a relatively low oxygen pressure. As for the barium vacancy (V_{Ba}) or titanium vacancy (V_{Ti}) that exist in oxygen-rich BT, the experiment and DFT calculations predicted that such negatively charged monovacancies may combine with positively charged V_O to form the divacancy V_{Ba}-V_O or V_{TI}-V_O.
In this study, we comprehensively analyze the effects of mono- and di-vacancies on the domain growth of BT by using the MD simulation with the core-shell inter-atomic potential. We consider not only the monovacancies V_{Ba}, V_{Ti}, and V_O but also the divacancies of 1st- and 2nd-neighbor V_{Ba}-V_O and V_{Ti}-V_O. We also compare the domain growth speed between the parallel and perpendicular directions to the applied electric field.
We found the following: (1) One kind of monovacancy, V_{O1}, located on the TiO plane perpendicular to the applied electric field direction, acts to hinder the polarization inversion induced by the applied electric field. The monopole electric field produced by V_{O1} either hinders or assists the local polarization inversion in accordance with the local intensity of the total electric field. (2) The 1st-neighbor divacancies V_{Ba}-V_O and V_{Ti}-V_O, as compared to the 2nd-neighbor divacancies, asymmetrically affect the domain growth with respect to the applied electric field, determining the hysteresis behavior of applied electric field vs. polarization. The domain grows even at a small electric field when the directions of the applied electric field and the divacancy dipole are mutually the same. (3) The domain growth speed towards the applied electric field direction is about 2 orders of magnitude higher than that towards the perpendicular direction.

8:50 AM EN07.09.05
Inverse Domain-Size Dependence of Piezoelectricity in Ferroelectric Crystals Bo Wang[1], Fei Li[2] and Long-Qing Chen[1]; [1]The Pennsylvania State University, United States; [2]Xi'an Jiaotong University, China

Piezoelectricity of ferroelectric crystals has been widely utilized in electromechanical devices such as sensors and actuators. It is broadly believed that the smaller the ferroelectric domain size, the higher the piezoelectricity, arising from the commonly assumed larger contributions from the domain walls. Here we theoretically analyze the domain-size dependence of piezoelectric coefficients of prototypical ferroelectric crystals, guided by phase-field simulations. We reveal that the inverse domain-size effect, i.e., the larger the domain size, the higher the piezoelectricity, is just as common. The nature of the domain-size dependence of piezoelectricity is shown to be determined by the propensity of polarization rotation inside the domains instead of the domain wall contributions. We establish a simple, unified analytical model for predicting the domain-size dependence of piezoelectricity, which is valid regardless of the crystalline symmetry, the materials chemistry, and the domain structures of a ferroelectric crystal, and thus can serve as a guiding tool for optimizing piezoelectricity of ferroelectric materials beyond the "nanodomain" engineering. The same strategy can be extended to understand the microstructural size effect of multiple-physical coupling properties in ferroic material systems to achieve a combination of seemingly conflicting properties.

9:05 AM EN07.09.07
Large Non-Classical Electrostriction in Aliovalent and Isovalent Doped Ceria Maxim Varenik, Ellen Wachtel, Elad Gaver and Igor Lubomirsky; Weizmann Institute of Science, Israel

The majority of commonly used electrostrictive ceramics are based on lead manganese niobate. These ceramics display large electrostriction strain coefficients $\approx 10^{-16}$ m^2/V^2 at frequencies up to a few kHz; however they suffer from two major drawbacks: large dielectric constants (>10000), which require high driving currents, and incompatibility with thin-film Si-microfabrication techniques. We have recently reported that aliovalent doped ceria exhibits electrostriction coefficients >100-fold larger than estimated on the basis of Newnham's scaling law for classical electrostrictors, despite ceria's large Young's modulus (~ 200 GPa and low dielectric constant (~ 30). This "non-classical" behavior has been attributed to the formation of highly polarizable, elastic dipoles reorienting under external electric field.
For 10mol% Sm- or Gd-doped ceria, the measured longitudinal electrostriction strain coefficient, |M|, reaches 10^{-16} m^2/V^2; however, relaxation to < 10^{-}

^{18} m^2/V^2 is observed at frequencies > 1 Hz, well below the technologically important frequency range 100Hz-100 kHz. The introduction of aliovalent lanthanide dopants with smaller radii than that of Gd, such as Lu or Yb, succeeds in increasing |M| at 100Hz to » 10^{-17} m^2/V^2. Nevertheless, aliovalent dopants with radii smaller than that of Lu do not continue the trend.
We have found that partially reduced, 10 mol% Zr^{4+}-doped ceria displays $|M| \approx 10^{-16}$ m^2/V^2 throughout the 0.1-150 Hz frequency range. However, practical application of these ceramics may be hindered by the relatively large, room-temperature electrical conductivity (10^{-10} S/m), a result of the formation of Ce^{3+} which can promote electron hopping. Formation of Ce^{3+} also raises the dielectric constant to »200, as measured by impedance spectroscopy. Suppression of Ce^{3+} by co-doping with 0.5mol% Yb produces a dramatically reduced electrostriction strain coefficient (at f = 0.1-150Hz), ~ $4*10^{-18}$ m^2/V^2. If the Yb concentration is raised to 10 mol% , |M| increases to ~ $2*10^{-17}$ m^2/V^2 but is sharply lowered to $2*10^{-18}$ m^2/V^2 at 15 mol% Yb. Co-doping with a large radius, aliovalent lanthanide, *e.g.* 0.5-10mol% La, returns the measured high frequency |M| to $4*10^{-18}$ m^2/V^2.
Taken together, these results suggest that elastic dipoles induced in ceria ceramics by small aliovalent dopants, give stronger electrostrictive response at high frequencies (>10 Hz) than the larger aliovalent dopants. For the case of isovalent doping with Zr of reduced ceria, the presence of Ce^{3+} seems to be essential for large |M|. Noting that Ce^{3+} is almost as large as La^{3+}, we may conclude that the elastic dipoles operating in Zr-doped, reduced ceria are fundamentally different from those observed for aliovalent doping. Our results imply that by systematically adjusting the composition of ceria-based solid solutions, the potential exists for development of technologically useful electrostrictive materials which are, at the same time, fully compatible with Si-microfabrication.

Nanoslot Patterns to Tune the Phonon Transport within Thin Films Qing Hao; University of Arizona, United States

Nanoporous thin films with periodic circular pores have been extensively studied for their potential applications such as thermoelectrics, heat waveguides, thermal cloaks, thermal diodes, and heat imaging [1]. Fundamentally, it is acknowledged that diffusive phonon scattering by pore edges, as classical phonon size effects, is the major mechanism for the observed thermal conductivity reduction. Despite some earlier debates, phononic effects due to coherent phonon transport within a periodic structure are found to be only critical at cryogenic temperatures [2-4].
Based on classical phonon size effects, new nanoporous patterns have been pursued to better tune the thermal conductivity of thin films [5, 6]. As one new pattern, periodic nanoslots can be employed to effectively tune the in-film phonon transport. When phonons travel ballistically through the narrow neck between adjacent nanoslots, a ballistic thermal resistance is introduced to lower the thermal conductivity. As a result, the lattice thermal conductivity can be largely reduced along the direction perpendicular to nanoslot rows, while keeping a much higher thermal conductivity along the direction parallel to nanoslots. The in-plane thermal anisotropy can be further enhanced with offset nanoslot patterns [7], which can largely benefit the thermal management of thin-film devices.
In analytical modeling, an accurate characteristic length can be derived for nanoslot patterns to predict the thermoelectric properties of such films [8, 9], whereas an accurate characteristic length is hard to be found for thin films with periodic circular pores [1]. For representative nanoslot patterns, the thermoelectric properties can be predicted and compared with nanostructured bulk Si [7, 8]. The predicted thermal conductivities agree well with the experimental data on some nanoslot-patterned Si thin films. A bulk-like specific heat is also measured for these thin films, indicating negligible phononic effects to change the phonon dispersion.
In nanoslot-patterned thin films, the in-plane thermal resistance is a strong function of the neck width between nanoslots. By measuring a series of samples with varied neck widths, inverse phonon transport analysis can be used to reconstruct the in-plane phonon MFP distribution down to ~10 nm [9, 10]. In this aspect, pump probe measurements using nanofabricated heating patterns [11-12] are not suitable for suspended thin films because phonon modes and scattering can be remarkably affected with deposited metal patterns [13]. In practice, nanoporous patterns can also be used to achieve two-dimension thermal cloaking or thermal camouflaging [7]. This new application will also be discussed.

Electrical and Mechanical Properties of Thermally Drawn Multimaterial Fibers Xiaoting Jia; Virginia Tech, United States

Recent advancement in the thermal drawing of multimaterial fibers have enabled unique material properties and functions in a scalable manner. Here we present the electrical and mechanical properties of thermally drawn multimaterial fibers which make the fibers advantageous for biomedical and wearable applications. First, we demonstrate that thermal drawing promotes unidirectional alignment of carbon nanofibers (CNFs) in a polymer composite. The resultant CNF-composite shows a significant increase in the electrical conductivity by two orders of magnitude compared to that before thermal drawing. Therefore, these highly conductive fiber electrodes can enable miniaturized devices for neural recording in the brain. Next, I will introduce the thermal drawing of other polymer composites such as carbon black in thermoplastic elastomers (TPEs). The scalable fabrication of conductive elastomers can be used for strain sensors in ropes or smart textiles. The electrical and mechanical performance of these fibers will be presented. Finally, thermally drawn piezoelectric fibers will be presented which consist of PVDF-TrFE as the sensing layer and two carbon-loaded polymer layers as the electrodes. The

piezoelectric performance of these fibers will be discussed. These results show that thermal drawing provides a unique platform for producing flexible and miniatured multifunctional devices with unique electrical and mechanical properties.

11:30 AM EN07.10.04
Hierarchical Micro-Nano Patterned Modified PDMS Triboelectric Nanogenerator Enhanced by Carbon Based Nanofillers Mina Shanbedi, Haleh Ardebili, Hadi Ghasemi and Alamgir Karim; University of Houston, United States

Triboelectric nanogenerators (TENGs) have received recent interest for converting unconventional mechanical energy to electricity, particularly as a sustainable form of energy generation from sources such as wind and friction. Energy conversion in TENGs is based on the triboelectrification and electrostatic induction effects. In this regard, Polydimethylsiloxane (PDMS) elastomer has been widely used as a good triboelectric active layer in TENG owing to its high electronegativity as ranked in the triboelectric series of different materials. The casting process is simple for PDMS having comparatively low surface energy, and more importantly, their formability is superior to many other counterparts in polymers. The TENGs based on PDMS exhibit a relatively high energy conversion efficiency, however, its output electrical characteristics still need more development. One critical key device parameter to enhancing the output performance of TENG is increasing the contact area between triboelectric active material layers. Patterning the surface, and changing the shape and density of patterns on the surface, is assumed to be an effective strategy for this purpose. However, the origin of the output enhancement by patterning and the role of surface roughness on the charge generation aspects needs further investigation. We present research on what makes the shape of the patterns more effective by their contribution to enhancing surface roughness and contacting area, and thereby higher efficiency, with mechanical pressure and sliding contact. On the other hand, increasing the triboelectric polymer conductivity significantly enhances the current density by facilitating the charge transfer from the contact surface towards electrodes. Many nanoparticles have been used to enhance charge transfer in TENGs owing to having high conductivity. In this research, we investigate this proposed hypothesis to relate pattern size and roughness to the output performance of aluminum/polydimethylsiloxane (Al/PDMS) TENG, modified by carbon-based nanoparticles including carbon nanotube (CNT), reduced graphene oxide (r-GO) and carbon black (CB). The uniform and periodic nanoscale morphology of optical discs (CD and DVD) were replicated onto PDMS films. The procedure is followed by a sequential development of hierarchical low amplitude patterns made by oxygen plasma and ultraviolet ozone wrinkling method, to create a hierarchical pattern as a superposition on the optical disc pattern. The patterning procedure is repeated after replacing PDMS with a nanocomposite of PDMS and polytetrafluoroethylene (PTFE) to take advantage of both the molding capability of PDMS and the higher triboelectric affinity of PTFE. Our hierarchical topographic designed TENG led to a considerably higher current and voltage output, due to the efficient shape and roughness compared to CD and DVD patterns alone, useful to rationally design TENGs with high efficiency for capturing energy from unconventional sources.
We acknowledge DoD Grant #555033-78055 (Contract: Kostas Research Institute (KRI) at Northeastern University) for support of the work.

Analyzing Thermal Transport in Strained $MAPbI_3$ Crystals Jin Yang, Yuan Zhou and Wee-Liat Ong; Zhejiang University, China

The thermal conductivity of pseudo-cubic $MAPbI_3$ was studied using classical molecular dynamics and found to be invariant under compressive strains below 3 %. Such invariance contrasts with the rapid thermal conductivity increase seen in other solids with a similar Young modulus value. Larger compressive strains increase the thermal conductivity as observed in most solids.
Hybrid halide perovskites have attracted a lot of interest due to their excellent energy conversion efficiency. The need for improving its thermoelectric performance in thermoelectrics as well as enhancing its thermal stability in photovoltaic cells has spurred thermal transport investigations. As temperature will unavoidably increase during operation, stress will be induced on a piece of mounted perovskite, changing its properties. Additionally, further enhancement to its solar conversion efficiency by applying structural compression was recently reported. It is, therefore, quintessential to understand how straining a perovskite crystal will affect its thermal transport.
The full phonon dispersion and the respective phonon lifetimes under various pressures were calculated. Stable acoustics phonon branches are obtained at these pressures. The vibration modes in these branches are participated by atoms mainly from the inorganic framework. These modes contribute about 40% to the thermal conductivity in $MAPbI_3$ at pressures between 0 to 1 GPa, but more than 60% at 30 GPa. The almost invariant thermal conductivity contribution at the lower pressure range arises from the canceling effect between the changes in the heat capacity, group velocity, and lifetime of these acoustic phonons. On the other hand, the increase in both the phonon group velocities and lifetimes are responsible for the larger thermal conductivity contribution at higher pressure.

9:30 PM *EN07.11.02
Performance Regulation of Heat Transfer in Semiconductors Guangzhao Qin; Hunan University, China

High-performance thermal management is of great significance to the operational stability of integrated chip and electronic devices, where the heat transfer performance of the core semiconductors plays a key role. In this talk, I would like to introduce our recent work on the performance regulation of heat transfer focusing on few typical semiconductors, such as gallium nitride, boron nitride, boron arsenide, silicene, *etc*. Based on a concise strategy of accelerating evaluation of converged lattice thermal conductivity, the regulation effects of lots of manners, such as temperature controlling, strain engineering, applying external field, alloying, *etc*, have been systematically investigated. The fundamental mechanism is revealed based on the deep analysis of the electronic structures. The performance regulation of heat transfer and the underlying mechanism would be helpful on future studies of thermal and electrical coupling in emerging energy materials.

10:00 PM EN07.11.03
Thermal Characteristics of a Cylindrical Battery Module Based on Lateral Thermoelectric Cooling Hengyun Zhang; Shanghai University of Engineering Science, China

The threats of oil depletion, automotive emission and global warming are on the horizon for many years. Clean and environmentally friendly, electric vehicles have the advantages of energy conservation and emission reduction, which greatly alleviates the dependence on traditional energy sources and are expected to usher in new transportation era in the near future [1, 2]. As the power source of electric vehicles, the lithium-ion battery features salient

advantages such as high energy density, high discharge voltage, minimal self-discharge rate and long cycle life, and so on [3, 4]. However, the safety and efficiency of lithium-ion batteries are closely related to their operating temperature. When the batteries work under high load, the battery module and pack produce large amount of heat due to the associated electrochemical exothermic reaction, resulting in the unfavorable rise of battery temperature in the battery. This would lead to the decline in battery capacity, or even cause the battery thermal runaway [5-7]. An effective battery thermal management system (BTMS) is then required to maintain the battery thermal environment, thereby preventing potential operating risks. Existing battery thermal management techniques include air cooling [8-9], liquid cooling [10, 11], phase change material (PCM) cooling [12] and a combination of these cooling methods [13]. Nonetheless, all the above techniques would fail to work if the climatic temperature is close to the battery threshold temperature around 40-50 °C, especially in hot summer days.
Thermoelectric cooling has attracted attention for thermal management of batteries in a module or pack. Thermoelectric cooling is an advanced cooling technique taking advantage of the Peltier effect. Compact in size and silent in operation, the TEC is able to provide sub-ambient cooling as well as heating in cold winter days, which is a potential technique for thermal management of battery module for electric vehicles. In this paper, the thermal characteristics of thermoelectric cooler (TEC) for thermal control of cylindrical battery module is investigated both experimentally and theoretically.
The battery module under investigation consisted of 18650 test batteries in 3x5 matrix embedded in the composite paraffin wax for accelerated heat dissipation. In the experimental test, the transient and steady-state thermal performances were examined based on the thermoelectric cooling in comparison with the natural convection and liquid cooling conditions. Either one lateral side or two lateral sides of the battery module were attached with the thermoelectric cooler to minimize the temperature of the battery module. In comparison, the thermoelectric cooling reduced the battery temperature and prolonged the working time significantly. The optimal current was experimentally obtained to be about 6.0-6.5A based on the highest cooling power or lowest battery temperature. One-dimensional steady-state thermal resistance network is also developed for the battery module with TEC. The theoretical analysis agrees with the optimal current range obtained from the experimental measurements. Further analysis shows that the optimal current is affected markedly by the hot-side thermal resistance, but little by the cold-side thermal resistance. The two-side TEC cooling is also compared with the one-side TEC cooling. The two-side TEC cooling has a better thermal performance, but with an additional liquid cooled heat sink, which may add complexity to system setup. The cooling performance can be further enhanced such as by increasing the pair of TEC arms. Increasing the number of TEC thermoelectric arms has a favorable effect in both minimizing the maximum temperature and increase the coefficient of performance (COP) of the TEC module. Detailed results will be given in the final presentation.

10:30 PM *EN07.11.04
Characterization of Acoustic Deformation Potential of Mg_3Sb_2 by Femtosecond Spectroscopy Liang Guo; Southern University of Science and Technology, China

As a promising thermoelectric material, Mg_3Sb_2 has kindled intense research interest in recent years. Since acoustic phonons are the main heat carriers and thermoelectric materials in applications are usually doped at high carrier concentration, coupling of acoustic phonons and carriers determines the thermoelectric performance to a large extent. In this work, acoustic deformation potential coupling constant, the key parameter for quantifying acoustic phonon-carrier interaction, of Mg_3Sb_2 is measured through coherent phonon detection by femtosecond spectroscopy. Agreement between experiment and first-principles calculation results is achieved in terms of acoutic deformation potental quantification. The information about acoustic deformation potental extracted in this work could guide the study on thermal and electrical transport of Mg_3Sb_2 and the performance optimization of this thermoelectric material.

Dynamics of Multicomponent Halide Perovskites Probed by *In Situ* Experiments Using Synchrotron Light Ana F. Nogueira; University of Campinas (UNICAMP), Brazil

Multicomponent perovskite solar cells have reached the recent efficiency breakthrough of 25.5%, higher than silicon polycrystalline photovoltaics. Such fantastic result was only possible due to a precise control and engineering of the morphology, interfaces and the use of multiple cations in perovskite A-site. For tandem perovskite solar cells, a mixture of different anions, as Br and I is also desired to adjust the band gap. Such cocktail of different cations and anions influences the formation of intermediates, new phases, favours halide homogenization, etc; so that at the end, the efficiency of the device is closely related to not only the optical quality of the film (e.g. crystallinity), but morphology and composition.
In this presentation, we will summarize important results using *in situ* experiments to probe perovskite formation (2D and 3D), stability and composition. We employed time-resolved grazing incidence wide angle x-ray scattering (GIWAXS), small angle x-ray scattering (SAXS) and high-resolution XRD taken at the Brazilian Synchrotron National Laboratory.
In situ GIWAXS experiments allowed us to understand the influence of the relative humidity and time to drop the antisolvent during the preparation of perovskite films and get important information about final composition and morphology [1]. It is well known that a 2D layer on the top of a 3D bulk perovskite improves stability and performance. *In situ* GIWAXS revealed us that during thermal annealing the 2D layer transforms itself into a disorder layer, improving hole transfer and stability [2]. This technique was also employed to identify the first intermediates formed during the degradation of different Cs and Br perovskite compositions under ambient conditions [3].
In situ SAXS is another powerful technique to follow the first stages of the 2D perosvkite's formation. Our results suggest that the formation of the individual slabs in $BA_2[FAPbI_3]PbI_4$ is quite fast (within the first 10 s) and, then, these slabs self-assemble into bulk crystallites during the next 40 minutes [4].
Another topic of interest is the photoinduced phase segregation in FACs-based perovskite films. We investigated this phenomenon by photoluminescence (PL) studies and *in situ* high-resolution XRD (dark and under illumination). We found out that cubic-tetragonal transition is able to stabilize the samples with higher Br and Cs content, however this is not true for the films with 17% Br. Thus, other mechanisms must be operating and ruling phase segregation [5].

11:00 AM EN08.01.02
Integrating Emissive 0D Perovskites into a 3D Perovskite Matrix for Efficient and Stable Single-Layer Electroluminescent Devices Aditya Mishra, Jason D. Slinker, Riya Bose and Anton Malko; The University of Texas at Dallas, United States

Zero-dimensional (0D) inorganic perovskites have emerged as promising candidates over their higher dimensional (3D, 2D) analogs by showing superior photoluminescence quantum yield (PLQY) and significant physiochemical stability under ambient conditions. In previous efforts, the inclusion of the 0D phase into a 3D perovskite matrix improved photoluminescence (PL) characteristics by passivating surface defects. Nonetheless, the 0D phase itself is generally non-luminescent, limiting its applicability. Given this, we designed a novel solvent engineering method to incorporate highly emissive 0D perovskite nanocrystals (NCs) into a 3D perovskite composite film ($CsPbBr_3$, a polyelectrolyte and Li salt) to form the emissive layer in single-layer perovskite light-emitting electrochemical cells. An optimized 3D-0D composite achieved a maximum luminance of 11200 cd m^{-2}, an external quantum efficiency of 8.2%, a current efficiency of 33 cd/A, and a power efficiency of 31 lm/W. Constant current driving of the 3D-0D composite exhibited 150 h operation at over 400 cd m^{-2} brightness. Extrapolating this to a 100 cd m^{-2} initial luminance, a luminance half-life of over 37000 h is obtained, among the highest for perovskite devices to date. The inclusion of 0D NCs increases photoluminescence lifetime by surface passivation, suppresses non-radiative losses, induces thin-film smoothness, produces smaller crystallites for efficient charge confinement.

11:15 AM EN08.01.03
Shedding Light on the Stability and Structure-Property Relationships of 2D Hybrid Lead Bromide Perovskites Eugenia S. Vasileiadou[1], Ido Hadar[1], Mikael Kepenekian[2], Jacky Even[2], Qing Tu[3], Christos Malliakas[1], Daniel Friedrich[1], Ioannis Spanopoulos[1], Justin Hoffman[1], Vinayak Dravid[1] and Mercouri G. Kanatzidis[1]; [1]Northwestern University, United States; [2]Univ Rennes, France; [3]Texas A&M University, United States

2D thick-layer lead bromide perovskites remain an unfathomed phase space with the lack of systematic studies to establish the structure, photophysical properties and stability behavior of this family of 2D halide perovskites. Herein, we present new members of n=2 lead bromide perovskites $(C_mH_{2m+1}NH_3)_2(CH_3NH_3)Pb_2Br_7$ (m = 6−8) that belong to the Ruddlesden-Popper structure type, incorporating long chain alkyl-monoammonium cations ($C_mH_{2m+1}NH_3$) of hexylammonium (m=6), heptylammonium (m=7) and octylammonium (m=8). A universal solution synthetic methodology for bulk, thick-layer lead bromide perovskites is presented with all structures solved single crystal X-ray diffraction. The studied bilayer lead bromide perovskites demonstrate a decrease in the lattice rigidity and lattice match of the inorganic perovskite layer - organic layer, as the monoammonium chain length increases. In comparison to their iodide analogues, the bilayer lead bromide compounds exhibit elongation of their stacking axis despite the smaller dimensions of the $[PbBr_6]^{4-}$ lattice with a reduced calculated internal lattice strain, inferring a greater lattice match between the inorganic $[PbBr_6]^{4-}$ perovskite layer and organic layer. The titled compounds exhibit narrow-band green emission near 2.5 eV. Time-resolved photoluminescence (PL) displays longer carrier lifetimes compared to their iodide analogues, where electronic structure calculations indicate that the increase of the monoammonium chain length and thus, lattice softness enhances non-radiative recombinations. A complete set of air, light and heat stability tests on unencapsulated thin films of $((C_mH_{2m+1}NH_3)_2(CH_3NH_3)Pb_2Br_7$ (m = 4, 6−8) and $MAPbBr_3$ show they are stable in ambient air for at least 5 months. Extraordinarily, 3D $MAPbBr_3$ films prove to be more stable than films of 2D lead bromide perovskites, in contrast to $MAPbI_3$ which is less stable than the 2D lead iodide perovskites.

11:30 AM EN08.01.04
Composition Engineering of 2D Ruddlesden-Popper Perovskites Susana Ramos Terrón[1], Cristóbal Verdugo Escamilla[2], Luis Camacho Delgado[1] and Gustavo de Miguel Rojas[1]; [1]University of Córdoba, Spain; [2]CSIC-University of Granada, Spain

The partial incorporation of large organic cations into the octahedral sites of 3D perovskites has been widely investigated but few works have reported their addition in 2D Ruddlesden–Popper (RP) perovskites. Here, the gradual substitutiont of the methylammonium (MA) cation in thin films of 2D RP perovskites $(BA)_2(MA)_2Pb_3I_{10}$ (BA = *n*-butylammonium) by guanidinium (Gua), dimethylammonium (DA), ethylammonium (EA), rubidium (Rb), propylammonium (PA), cesium (Cs) or formamidinium (FA) to synthesize mixed A-cation $(BA)_2(MA_{1-x}A_x)_2Pb_3I_{10}$ perovskites has been studied. The limit

in the percentage of the A-site cation at which it is homogeneously incorporated in all *n* phases without destabilizing the overall structure is determined. It is found that the structural changes in the 2D RP perovskites may lead to modifications of the optoelectronic properties as larger bandgap (EA), blue-shift of the PL peak position (above the threshold), strong quenching of the PL (Cs) or reduced concentration of trap states (Gua and EA). Solar devices fabricated with the different mixed A-cation 2D RP display an enhanced performance for those perovskites containing low percentages of Gua or EA cations. This characterization is very valuable to correlate the size and shape of the A-cation with the changes of the properties of the material.

SESSION EN08.02: Application of Low Dimensional Perovskites in Optoelectronics

Printable Optoelectronics Based on Perovskites and Organic-Perovskite Composites Thomas D. Anthopoulos; King Abdullah University of Science and Technology, Saudi Arabia

Metal-halide perovskites offer numerous opportunities for use in large-area optoelectronics due to their strong optical absorption, long charge carrier diffusion lengths, low trap densities and processing versatility. However, full exploitation of these important attributes for the development of large-area opto/electronics remains challenging. In this presentation I will present and discuss results from our recent efforts to utilize perovskite semiconductors for a variety of applications. Particular emphasis will be placed on our recent work that aims to combine organic with perovskite semiconducting materials to produce prototype devices with unusual microstructural characteristics and advanced functionalities. Devices to be discussed include nanogap photodiodes, phototransistors, transistor memories, memtransistors, and light-emitting devices.

2:00 PM EN08.02.02
Deposition Scheme for Low-Dimensional Hybrid Perovskite Thin Films with Functional Molecules Niara E. Wright and Adrienne Stiff-Roberts; Duke University, United States

The applications of two-dimensional (2D) hybrid organic-inorganic perovskites (HOIPs) have broadened as functional molecules are explored and incorporated into this emerging material.[1] However, obtaining quality films of HOIPs with functional molecules remains a challenge.[1] One group successfully engineered and incorporated new conjugated functional molecules that changed the band alignment, but only created small crystals, not contiguous films.[2] Mitzi et al. created layered perovskites with functional molecules via single source thermal ablation, however film thickness was difficult to control and the risk of organic cation damage remained.[3] Solution processing is challenged by finding a single solvent for both the inorganic and organic precursor materials. Two-step solution-processing partially avoids the single solvent criterion, but solvent choice is still a critical challenge and a limiting factor for synthesis of 2D HOIPs with functional molecules.[4]

Herein, a deposition technique is presented that better accommodates organic cation deposition to address the challenge of consistently producing controlled, quality thin films of HOIPs with functional molecules. Resonant-infrared, matrix-assisted pulsed laser evaporation (RIR-MAPLE) is a modified pulsed laser deposition technique that uses a frozen target solution with precursor materials. The laser energy is resonantly absorbed by the matrix solvent (monoethylene glycol), the sublimation of which ejects the inorganic and organic precursor materials onto the substrate, making this method gentle on the organic precursor unlike physical vapor deposition. RIR-MAPLE has been used previously to successfully deposit high quality thin films of oligothiophene-based HOIPs.[5] This demonstration was enabled by an extremely low solution concentration (22 mM) of the organic and inorganic precursors in a single target solution (known as simultaneous deposition scheme). However, this simultaneous deposition scheme may not suffice for other large, functional molecules for which a low concentration target solution is not adequate to address solvent incompatibility between the organic and inorganic precursors.

Therefore, this work investigates an alternative deposition scheme to demonstrate a potential benefit of RIR-MAPLE: the ability to completely separate the inorganic and organic precursor target solutions. In this sequential deposition scheme, the frozen inorganic and organic precursor solutions are spatially separated within the target. Each precursor is deposited alternately according to the laser raster pattern on a time-scale less than that needed for full substrate coverage. The RIR-MAPLE sequential deposition scheme has been demonstrated for polymer-nanomaterial composites.[6,7] In this work, film characterization (including X-ray diffraction, energy dispersive spectroscopy, photoluminescence, UV-vis absorbance spectroscopy, scanning electron microscopy, and atomic force microscopy) will be used to compare film quality resulting from simultaneous and sequential deposition schemes. Specifically, thin films of $(C_8H_{12}N)_2PbI_4$ are investigated, instead of oligothiophenes, to confirm film quality because phenethylammonium-based HOIPs have been well characterized by other deposition techniques. The conclusive demonstration of high-quality 2D HOIPs by the RIR-MAPLE sequential deposition scheme will expand eligible functional molecules by circumventing the well-known solubility and vapor deposition challenges.

Light-Induced Enhancement of Organo-Metal Halide Perovskite Lithium-Ion Batteries Angus Mathieson and Michael De Volder; University of Cambridge, United Kingdom

Increases in the global energy demand necessitate the development of new approaches to energy conversion and storage. In particular, the utilisation of solar energy could provide a basis of evolving technologies capable of meeting modern and future demands.

By combining the photovoltaic and newfound electrochemical properties of organo-metal hybrid perovskite materials in a single device, a novel

photobattery technology is proposed [1]. Utilising the photovoltaic performance of perovskite materials in combination with the intercalation and conversion mechanisms available to Lithium ion species [2], a device with the ability both to convert light to electrochemical energy and store it is demonstrated. The motivation for such a device will be discussed, with its inherent impact in areas such as off-grid energy solutions and the internet of things. The fabrication techniques are described and characterisation techniques common to both photovoltaic and electrochemical disciplines, with their recent results are discussed. Modifications are made to conventional electrochemical coin cells and pouch cells, in order to facilitate optical access to the electrode material. Using in-*operando* x-ray diffraction and optical probing, the fundamental mechanisms of charge storage and ion conversion are investigated both in the presence of light, to replicate a light-charging cycle and in the absence of light.

Room-Temperature Amplified Spontaneous Emission and Lasing of Sequentially Thermally Evaporated $CsPbCl_3$ Perovskite Thin Films Manuel Runkel[1,2], Tobias Haeger[1,2], Huiyue Ping[1], Johannes Bahr[1], Lena Merten[3], Selina Olthof[4], Detlef Rogalla[5], Alexander Hinderhofer[3], Ralf Heiderhoff[1,2], Frank Schreiber[3], Klaus Meerholz[4] and Thomas Riedl[1,2]; [1]University of Wuppertal, Germany; [2]Wuppertal Center for Smart Materials & Systems, Germany; [3]University of Tübingen, Germany; [4]University of Cologne, Germany; [5]Ruhr University Bochum, Germany

Inorganic cesium-lead-halide perovskites are of interest for optoelectronic applications such as solar cells, LEDs and lasers, since they not only exhibit excellent optical properties, but are also more thermally stable [1]. However, inorganic perovskites frequently come with serious processing challenges and high-quality thin films (no pinholes, high photoluminescence quantum yield) are difficult to achieve. Amplified spontaneous emission (ASE) in thin films of these materials, which is an important prerequisite for lasing, can often only be reached at cryogenic temperatures. The blue to ultraviolet spectral range, which would be reached by $CsPbCl_3$, is a particular challenge in this regard. Solution-based deposition of $CsPbCl_3$ is extremely hampered by the poor concomitant solubility of the precursor salts $PbCl_2$ and CsCl.

Within this study, the preparation of wide-gap $CsPbCl_3$ perovskite thin films is presented by the use of thermal evaporation of the individual salts. Specifically, a stack of alternating layers of $PbCl_2$ and CsCl is designed, that leads to some kind of self-limiting formation of the desired 3D - $CsPbCl_3$ perovskite at the interfaces of the superlattice. We analysed the formation of CsPbCl3 by photoelectron spectroscopy and X-ray diffraction as well as grazing incidence wide angle x-ray scattering (GIWAXS), to unravel the appearance of the various phases (0D-Cs_4PbCl_6, 2D-$CsPb_2Cl_5$, 3D-$CsPbCl_3$). The insights gained from these studies allowed us to optimize the superlattice architecture.

The resulting $CsPbCl_3$ shows an intense photoluminescence at 413 nm with a narrow line width of 10 nm (FWHM), which agrees with reports of $CsPbCl_3$ single crystals [2]. Most notably, we were able to optimize the $CsPbCl_3$ thin film to support amplified spontaneous emission in the deep blue spectral region at 427 nm (line width 2.2nm) under pulsed optical excitation (355nm, 300 ps) above a threshold energy density of 190 μJ/cm^2 at room-temperature (RT). This is the first report of $CsPbCl_3$ thin films showing ASE at RT. The integration of this active material in a resonator to achieve the first thin film $CsPbCl_3$ lasers at RT will be presented.

Lead-Free Halide Light-Emitting Diodes with External Quantum Efficiency Exceeding 7 Percent Using Vacuum Thermal Evaporation Process Gijun Seo[1], Hyocheol Jung[1], Tielyr D. Creason[2], Vishal Yeddu[1], Matthew Bamidele[1], Elena Echeverria[1], Ji-Hoon Lee[3], Dave N. McIlroy[1], Bayram Saparov[2] and Do Young Kim[1]; [1]Oklahoma State University, United States; [2]The University of Oklahoma, United States; [3]Korea National University of Transportation, Korea (the Republic of)

Perovskite-based visible light-emitting diodes (LEDs) with blue, green, and red emissions have successfully been demonstrated with high external quantum efficiencies (EQEs) and bright luminance for next-generation display and solid-state lighting applications. In spite of the high performances of perovskite-based visible LEDs, however, their applications will be limited due to the toxicity of lead-based halide perovskites. While there have currently been many reports about lead-free metal halide emitters to solve this toxicity issue, most lead-free halide LEDs show still significantly low performance, resulting in below 1 %.
In this work, lead-free halide LEDs are fabricated using non-toxic and earth-abundant $CsCu_2I_3$ with a strong yellow emission at a peak wavelength of 568 nm. $CsCu_2I_3$–based host-dopant emitters are formed by vacuum thermal evaporation (VTE) film co-deposition process instead of the commonly-used solution-based film deposition process. Using the VTE process, extremely thin (30 nm) host-dopant emitters have successfully been formed with the $CsCu_2I_3$ dopant and various organic host molecules. A bright yellow emission with a photoluminescence quantum yield value of 84.8% is achieved in the 0.5% $CsCu_2I_3$-doped halide emitter film due to the successful spatial localization of charge carriers and excitons using an organic host with appropriate energy levels to $CsCu_2I_3$. With the further enhancement in charge balance using the co-host system, a record-breaking lead-free halide LED has been fabricated with an EQE of 7.4%. The lead-free halide LEDs are also highly stable in the device operation with LT70 of 20 hours at 100 cd/m^2.

Low Dimensional Perovskite and Their Applications in Photovoltaic Cells, Nanostructures and Semitransparency Lioz Etgar; Hebrew University of Jerusalem, Israel

Recent discoveries have revealed a breakthrough in the field using inorganic-organic hybrid layers called perovskites as the light harvester in the solar cell. The inorganic-organic arrangement is self-assembled as alternate layers, being a simple, low cost procedure. These organic-inorganic hybrids promise

several benefits not delivered by the separate constituents. In this lecture I will discusses new directions in low dimensional perovskite and their applications in solar cells.
In low dimensional systems, stability of excitons in quantum wells is greatly enhanced due to the confined effect and the coulomb interaction. The exciton binding energy of the typical 2D organic-inorganic perovskites is up to 300 meV and their self-assembled films exhibit bright photoluminescence at room temperature.
In this work we will show the dimensionality in the perovskite structure. The 2D perovskite structure should provide stable perovskite structure compare to the 3D structure. The additional long organic cation, which is added to the perovskite structure (in the 2D structure), is expected to provide hydrophobicity, which will enhance the resistivity of the perovskite to humidity. We will demonstrate the use of 2D perovskite using unique barrier molecultes in high efficiency solar cells.
Moreover, we will show a highly efficient semitransparent perovskite solar cell. The semitransparency was achieved through an inkjet printing of "holes" in the perovskite film. The "holes" in the perovskite allows to control the semitransparency of the solar cell.
Organic-inorganic halide perovskite is used mainly in its "bulk" form in the solar cell. Confined perovskite nanostructures could be a promising candidate for efficient optoelectronic devices, taking advantage of the superior bulk properties of organo-metal halide perovskite, as well as the nanoscale properties. In this talk, I will present our recent progress related to the synthesis and characterization of perovskite NPs- i.e. Inorganic and hybrid organic-inorganic NPs. New nanostructures such us: NRs and NWs will be presented and the introduction of other cations such us Rb will be shown.

Challenges and Opportunities for Bismuth-Based Low-Dimension Halide Perovskites Mikael Kepenekian[1], Boubacar Traore[1], Claudine Katan[1], Jacky Even[2], Matthieu Manceau[3], Nicolas Mercier[4], Xiaotong Li[5] and Mercouri G. Kanatzidis[5]; [1]Univ of Rennes, France; [2]INSA Rennes, France; [3]Univ. Grenoble Alpes, France; [4]Université d'Angers, France; [5]Northwestern University, United States

The impressive flexibility exhibited by halide perovskites [1] offers many opportunities for chemists to design application driven materials [2,3]. Among the challenges still to be overcome is the replacement of toxic lead in materials for optoelectronic devices. If bismuth seems to be an ideal candidate owing to its low toxicity and natural abundancy, the performances of 3-dimensional (3D) Bi-based materials in solar cells remain far from their Pb-based competition [4]. However, the low-dimension side of the family (2D and 1D) still holds promises.

Here, we focus on 2D and 1D Bi-based halide perovskites thanks to joint experimental characterization and computational investigations. By highlighting, among others, the key aspects of connectivity between octahedra, we will describe the challenges of designing efficient lead-free materials, as well as the opportunities offered by this not yet fully explored territory [5,6].

Between Chemical Exfoliation and Direct Nucleation—Understanding the Formation Process of 2D Lead Bromide Perovskites at the Nanoscale Jakob Dahl[1,2,2], Samuel Niblett[1], Xingzhi Wang[1,2], Emory Chan[2], David Limmer[1] and A. Paul Alivisatos[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

2D materials have captured the imagination of the materials science community, yet the chemical processes leading up to the formation of these materials are often difficult to probe. Working with colloidal nanomaterials allows us to use wet-chemical control and fast in-situ techniques to understand the reactions occuring during synthesis. In this study, we demonstrate that 2 D perovskites can form through two processes at the nanoscale: Either from a layer-by-layer chemical exfoliation process from lead bromide nanocrystals or through direct nucleation from precursors. We study these processes in detail through in-situ spectroscopy in a stopped flow chamber. Chemical exfoliation appears to leave entire layers of the lead bromide nanocrystal intact – stopped flow experiments show little lateral confinement of the 2D exciton peak at short time scales, and the level of confinement is correlated to the size of the initially synthesized lead bromide nanocrystals. Direct nucleation leads to initial exciton peaks that are about 200 meV higher in energy compared to bulk values. The ratio of organic amine to lead controls which formation pathway dominates, as well as the size at which lead bromide nanocrystals exfoliate into 2D perovskite nanoflakes. We demonstrate qualitative agreement with simulations of a kinetic nanocrystal growth model with a single layer exfoliation step. Isotropic absorption, measurable lateral confinement and observations of growth kinetics make in-situ experiments of colloidal nanomaterials an ideal platform for understanding the complicated processes of nucleation, growth and phase transformation of 2D perovskites and 2D materials more generally. Deeper understanding of the formation processes, especially in their initial stages, will be important for ongoing development of synthetic procedures in this field.

5:00 PM EN08.03.04
Effect of Co-Solvents on the Crystallization and Phase Distribution of Quasi-2D Perovskites Alessandro Caiazzo[1], Kunal Datta[1], Junke Jiang[1], Maria C. Gélvez-Rueda[2], Junyu Li[1], Shuxia Tao[1], Ferdinand C. Grozema[2], Martijn Wienk[1] and Rene Janssen[1]; [1]Eindhoven University of Technology, Netherlands; [2]TU Delft, Netherlands

Quasi-2D perovskites (q2D PVKs) are promising candidates for stable and highly efficient solar cells. On top of the superior environmental stability compared to their 3D counterparts, q2D PVKs possess tunable optoelectronic properties, as it is possible to change the number of inorganic layers (*n*) sandwiched between the organic spacers to tune bandgap and exciton binding energy. However, centering the phase distribution on a specific *n*-value is challenging. Together with a variety of processing techniques, solvent engineering has previously been used in the literature to tune both phase purity and device efficiency. Nevertheless, no reports have investigated the effect of co-solvents on the crystallization mechanism and the reasons behind the changes in phase distribution.

To fill this gap, we first investigated the kinetics of film formation of $BA_2MA_3Pb_4I_{13}$ processed from DMF/co-solvent mixtures (DMSO and NMP) via in-situ absorption measurements conducted during room-temperature spin coating or thermal annealing. By combining these results with photoluminescence (PL) spectroscopy and angle-dependent grazing-incidence wide-angle X-ray scattering (GIWAXS), we concluded that the crystallization starts as a 3D-like perovskite from the liquid-air interface, both when the q2D PVK forms during spin coating (low amounts of DMSO or NMP in the solvent mixture) and during annealing (high amounts). The structure of the 3D-like perovskite on the top of the film, however, is impacted by the crystallization at the bottom, as suggested by the redshift of the absorption onset.

In agreement with previous reports, we observed a 2D-3D gradient in the film, with q2D PVKs formed mostly at the bottom of the film and 3D-like PVKs at the top. Even though the crystallization mechanism is the same when using DMSO and NMP as co-solvents, the phase distribution at the bottom of the film is different. More specifically, for the 4:1 DMF/NMP ratio, the distribution shifts toward small *n*-values, mainly $n = 2$. On the contrary, when using DMSO as a co-solvent with the same volumetric ratio, a broader phase distribution appears. During the crystallization, as described before, a 3D-like layer is initially formed on the top of the film, while underneath a wet film consisting of perovskite precursors has yet to crystallize. The interactions of the co-solvents with the precursors in the wet film are important in shifting the resulting phase distribution, as they influence the availability of MAI or BAI molecules to participate in the crystallization process. We investigated the ternary interactions between BAI or MAI, PbI_2, and the solvents with FT-IR and DFT. By analyzing the S=O and C=O stretching peaks, we observed that NMP interacts more strongly with MAI-PbI_2 than with BAI-PbI_2, indicating that BAI is less bound to the ternary complex, compared to MAI, and thus more available to participate in the formation of quasi-2D perovskite phases. This explains the phase distribution shifted to smaller *n*-values when using NMP. The same analysis showed that DMSO, instead, interacts similarly in ternary complexes with both MAI and BAI, agreeing with a broader phase distribution.

Overall, we propose a crystallization mechanism for $BA_2MA_3Pb_4I_{13}$ in a DMF/co-solvent mixture where 3D-like perovskites crystallize first at the liquid-air interface. While the crystallization proceeds, the phase distribution in the underlying perovskite layer is influenced by the availability of MAI and BAI molecules, which is in turn influenced by the co-solvent's choice. This conclusion confirms the importance of the co-solvents (or additives) in the challenging formation of phase-pure quasi-2D perovskites. By carefully tuning the DMF/co-solvent ratio, we finally fabricated a more phase-pure q2D PVK with device efficiencies up to 11%, a low degree of 2D-3D vertical gradient, and a narrow phase distribution.

Electronic Confinement Effects in Nominally Bulk and Nanocrystalline Metal Halide Perovskite Thin Films Laura Herz; University of Oxford, United Kingdom

In this presentation, we discuss how the electronic landscape of metal halide perovskites may be modified under two scenarios, first, through intrinsic quantum confinement effects found to occur in a nominally bulk semiconducting perovskite [1], and second, in thin films of nanocrystals within the weak electronic confinement regime [2].

We have recently reported the surprising presence of above-bandgap oscillatory features in the absorption spectra of formamidinium lead triiodide thin films [1]. We attribute these discrete features to intrinsically occurring quantum confinement effects, for which the related energies change with temperature according to the inverse square of the intrinsic lattice parameter, and with peak index in a quadratic manner. By determining the threshold film thickness at which the amplitude of the peaks is appreciably decreased, and through ab initio simulations of the absorption features, we estimate the length scale of confinement to be 10-20 nm. Such absorption peaks present a new and intriguing quantum electronic phenomenon in a nominally bulk semiconductor, offering intrinsic nanoscale optoelectronic properties without necessitating cumbersome additional processing steps. We discuss two potential explanations for the formation of such quantum well or superlattice structures, the inclusion of thin electronic barrier layers of hexagonal delta phase, or the presence of ferroelectric domains.

We further discuss the vibrational and electronic transport properties of thin films comprising metal-halide perovskites nanocrystals (NCs) which offer an effective approach for processing films from inks for low-cost, high-performance device fabrication. We disentangle the effects of surface ligands, morphology, and boundaries on charge-carrier transport in thin films fabricated with these high-quality NCs [2]. We employ terahertz (THz) spectroscopy to optically probe the photoconductivity of $CsPbBr_3$ NC films. The vibrational and optoelectronic properties of the NCs are compared with those of the corresponding bulk polycrystalline perovskite and significant deviations are found. Charge-carrier mobilities and recombination rates are demonstrated to vary significantly with the NC size. Such dependences derive from the localized nature of charge carriers within NCs, with local mobilities dominating over interparticle transport. It is further shown that the colloidally synthesized NCs have distinct vibrational properties with respect to the bulk perovskite, exhibiting blue-shifted optical phonon modes with enhanced THz absorption strength that also manifest as strong modulations in the THz photoconductivity spectra. Such fundamental insights into NC versus bulk properties will guide the optimization of nanocrystalline perovskite thin films for optoelectronic applications.

Charge Screening Behavior of 2D Hybrid Organic-Inorganic Perovskites Mohammed Shyikh[1], Eugenia S. Vasileiadou[2], Ioannis Spanopoulos[2], Doyun Kim[1], Mercouri G. Kanatzidis[2] and Qing Tu[1]; [1]Texas A&M University, United States; [2]Northwestern University, United States

2D hybrid organic-inorganic perovskites (HOIPs) are low-cost, high-performance semiconductor materials with great potential demonstrated in various fields, including photovoltaics, light-emitting diodes, lasers, and field-effect transistors. In these applications, it is common for 2D HOIPs to encounter charged species, including defects, molecular dopants, interfacial dipoles, and excitons, which could modulate the carrier transport properties inside the functional materials. How the 2D HOIPs will re-arrange the internal charges to screen the Coulombic interaction and how this charge screening behavior is related to the structure and composition of the 2D HOIPs are vital for the device design and optimization and yet largely remain unknown. Here we report a systematic study of the charge screening length of prototypical 2D HOIPs with a general formula of $(C_4H_9\text{-}NH_3)_2(CH_3NH_3)_{n-1}Pb_nI_{3n+1}$ (n= 1 to 5) by measuring the work function of 2D HOIP flakes on a charged dielectric surface SiO_2 using kelvin probe force microscopy. The work functions of the 2D

HOIP nanoflakes monotonically change as the flake thickness increases, showing a progressive screening of the influence from the SiO_2 surface charges. The screening length is short, less than 20 nm, which decreases monotonically with respect to the n number, i.e., the thickness of the inorganic slab within each repeating unit. 2D HOIP with n = 5 exhibits the shortest screening length, which could completely shield the electrostatic interaction with only 2 repeating units. The screening lengths of 2D HOIPs are much larger than, comparable to, and shorter than those of graphene, MoS_2, and h-BN, respectively. While the inorganic framework dominates the charge screening behavior, the organic spacer molecules can affect the charge screening by modulating the interlayer charge coupling through the van der Waals interfaces. Our results can provide valuable insights from the charge screening perspectives into the carrier dynamics and device design involving 2D HOIPs.

11:15 AM EN08.04.04
Solvent Polarity of Antisolvent Influences the Surface Chemistry and Optoelectronic Properties of Purified Lead Halide Perovskite Nanocrystals. Junzhi Ye[1], Zhenchao Li[2], Dominik Kubicki[1], Yunwei Zhang[1], Linjie Dai[1], Clara O. Martinez[3], Manuel A. Scheel[4], Zahra Andaji-Garmaroudi[1], Yi-Teng Huang[1], Zewei Li[1], Ziming Chen[2], Peter Müller-Buschbaum[4], Hin-Lap Yip[2], Samuel D. Stranks[1], Neil Greenham[1], Richard H. Friend[1], Lakshminarayana Polavarapu[3], Akshay Rao[1] and Robert Hoye[5]; [1]University of Cambridge, United Kingdom; [2]State Key Laboratory of Luminescent Materials and Devices, China; [3]Universidade de Vigo, Spain; [4]Technische Universitaat Muunchen, Germany; [5]Imperial College London, United Kingdom

Lead-halide perovskite colloidal nanocrystals (LHP NCs) have emerged over the past decade as leading candidates for next-generation, efficient light-emitting diodes (LEDs). Owing to their high photoluminescence quantum yields (PLQYs), LHPs efficiently convert injected charge-carriers to light and vice versa. In the synthesis of high-quality LHP NCs, the purification process is a critical step that influences the final PLQY, transport properties and polydispersity of the NCs. Despite the important role of the antisolvent in the purification process, a detailed understanding of how the antisolvent influences the surface chemistry of the NCs is missing in the field. Here, we address this knowledge gap, using $CsPbBr_xI_{3-x}$ NCs as the model system. We find that as the polarity of the antisolvent increased (from methyl acetate through to butanol), there was an increased blue-shift in the photoluminescence (PL) peak of the NCs, along with a decrease in PLQY. Through transmission electron microscopy and X-ray photoemission spectroscopy measurements, we identify the change of PL spectra to be due to solvent-induced iodide removal, which leads to a change in halide composition and band-gap. By using detailed nuclear magnetic resonance (NMR) measurements, along with density functional theory calculations, the mechanism we propose is that the oleic acid and oleylamine ligands undergo an amide condensation reaction at the surface of NCs in the presence of the polar antisolvent during purification. The conversion of amine to amide lead to ligand and surface halide detachment. Solvent polarity plays an important role in this reaction, in which solvents with higher polarity tend to remove more surface ligands and halides. This leads to higher surface halide vacancy densities, resulting in decreases in the PLQY. Furthermore, washing with high polarity solvent would cause an inhomogeneous distribution of surface halides, and reduces electroluminescence spectral stability of LED devices. Our work shows that maintaining high-PLQY NCs with low defect density requires the use of low-polarity antisolvents during

11:30 AM EN08.04.05
Broad Tunability of Carrier Effective Masses in Two-Dimensional Halide Perovskites Herman Duim[1], Mateusz Dyksik[2,3], Xiangzhou Zhu[4], Zhuo Yang[5], Masaki Gen[5], Yoshimitsu Kohama[5], Sampson Adjokatse[1], Duncan K. Maude[2], Maria Antonietta Loi[1], David Egger[4], Michael Baranowski[3] and Paulina Plochocka[2,3]; [1]University of Groningen, Netherlands; [2]Laboratoire National des Champs Magnétiques Intenses, France; [3]Wroclaw University of Science and Technology, Poland; [4]Technical University of Munich, Germany; [5]The University of Tokyo, Japan

The effective mass of charge carriers is a crucial parameter for the design of any optoelectronic device, as it is directly linked to key material characteristics such as the carrier mobility, exciton binding energy, and diffusion length. Consequently, a precise determination of its value is of paramount importance for the in-depth understanding of any semiconductor. The estimated values of the effective mass of 2D halide perovskites currently span a broad range, providing a source of uncertainty in this promising material system.

Using high magnetic fields up to 65 T we were able to observe multiple interband Landau level transitions in the absorption spectra of $(PEA)_2SnI_4$ and $(PEA)_2PbI_4$, providing us with a direct measure for the reduced effective mass of charge carriers in these systems. The determined reduced effective masses are found to be very close to or even lower than that of their 3D analogues, which is atypical in the presence of quantum confinement effects. We highlight how the distortion imposed by the organic spacers, and orbital hybridization effects by the metal cation, govern the effective mass in 2D halide perovskites. Combining the experimental results with electronic band-structure calculations, we propose a scaling diagram for the effective mass value versus the distortion of the octahedra imposed by the organic cations. As a result, we postulate that the effective mass in these systems can be easily tailored over a wide range by appropriate selection of organic spacers and metal ions.

SESSION EN08.05: Photophysics and Applications of Low Dimensional Perovskites

Green Synthesis of Dual-Color $CsPbBr_3$ Quantum Dots and poly(methyl methacrylate)-$CsPbBr_3$ Films with Deflection-Endurable Photoluminescence Fuqian Yang; Univ of Kentucky, United States

Perovskite nanocrystals have attracted great interest due to tunable optoelectronic characteristics and potential applications in photonics, energy storage, lighting and display. To date, most synthesis methods have involved organic solvent, such as N,N-dimethylformamide and dimethyl sulfoxide, which poses a potential threat to the environment, health and security. In this work, we develop an environmental-friendly and cost-efficient method to synthesize $CsPbBr_3$ powders at room temperature with water. Using ultrasonication and centrifugation, we obtain $CsPbBr_3$ nanocrystals with green (~522 nm) and blue (~493 nm) emissions from the powders. The photoluminescence quantum yield of the blue-emitting nanocrystals is 80%, much larger than 61.4% of the $CsPbBr_3$ nanocrystals made by an anti-solvent method. We prepare polymer composite films with PMMA and the green-emitting $CsPbBr_3$ nanocrystalz on a polyethylene terephthalate plate. The composite films exhibit deflection-endurable photoluminescence, i.e. there is no observable change in the PL characteristics for local radius of curvature up to 10.07 mm. The method developed in this work provides a unique approach to produce halide perovskite nanocrystals without harmful organic solvents in precursor solutions.
This work is supported by the NSF through the grant CMMI-1854554 and CBET- 2018411.

1:45 PM EN08.05.02

Direct Optical Lithography of $CsPbX_3$ Nanocrystals via Photoinduced Ligand Cleavage with Post-Patterning Chemical Modification and Electronic Coupling Jia-Ahn Pan, Justin C. Ondry and Dmitri Talapin; University of Chicago, United States

Microscale patterning of solution-processed nanomaterials is important for integration in functional devices. Colloidal lead halide perovskite (LHP) nanocrystals (NCs) can be particularly challenging to pattern due to their incompatibility with polar solvents and lability of surface ligands. Here, we introduce a direct photo-patterning approach for LHP NCs through the binding and subsequent cleavage of a photosensitive oxime sulfonate ester. The photosensitizer binds to the NCs through its sulfonate group and is cleaved at the N-O bond during photo-irradiation with 405 nm light. This bond cleavage decreases the solubility of the NCs which allows patterns to emerge upon development with toluene. Post-patterning ligand exchange results in photoluminescence quantum yields up to 76%, while anion exchange provides tunability in the emission color. The patterned NC films also show photoconductive behavior, proving that good electrical contact between the NCs can be established.

2:00 PM EN08.05.03
Chlorinated Interface Modifier for Improving the Microstructural and Electronic Properties of Inorganic Lead-Free Cesium Bismuth Iodide Perovskite Vincent O. Eze, Lucas Braga Carani and Okenwa Okoli; Florida State University, United States

Recently, inorganic lead-free metal halide perovskites have gained attention as promising optoelectronic materials for various applications due to their nontoxicity, environmental moisture, and thermal stability. In particular, the lead-free cesium bismuth halide perovskites with the general formula $A_xB_yX_z$; $z = x + 3y$, where A=Cesium (Cs), B=Bismuth (Bi), X=Iodide (I), Bromide (Br) have generated enormous interest among the perovskite research community as emerging materials for optoelectronic applications. Among the Bi-based perovskites, the $CsBi_3I_{10}$ perovskite (where x=1, y=3, and z=10) has the lowest bandgap of about 1.77 eV with a broad light absorption spectrum that is beneficial for solar cell, broad photodetection, and mechanoluminescence pressure sensing application. However, studies focused on understanding the microstructural and electronics properties of solution-processed $CsBi_3I_{10}$ perovskite is still lacking. Moreover, it is still challenging to prepare uniform, compact, and void-free $CsBi_3I_{10}$ perovskites. Herein, we systematically study the microstructural, optical, charge transport, defect density, and electronic properties of $CsBi_3I_{10}$ perovskite with and without the incorporation of the chlorinated interface modifier. The experimental results show that the interface modifier led to enhanced light absorption, crystallinity, and microstructural features. Furthermore, this work explores the underlying mechanism for such enhancement and assesses the influence of chlorinated interface modifiers for improving the performance of a self-powered photodetector for mechanoluminescence pressure sensing applications.

The 2D Halide Perovskites Mercouri G. Kanatzidis; Northwestern University, United States

Two-dimensional (2D) halide perovskites have emerged as outstanding semiconducting materials thanks to their superior stability and structural diversity. However, the ever-growing field of optoelectronic device research using 2D perovskites requires systematic understanding of the effects of the spacer on the structure, properties, and device performance. So far, many studies are based on trial-and-error tests of random spacers with limited ability to predict the resulting structure of these synthetic experiments, hindering the discovery of novel 2D materials to be incorporated into high-performance devices. In this presentation, we provide guidelines on successfully choosing spacers and incorporating them into crystalline materials and optoelectronic devices. Useful insights are emerging on what kind of spacer cations can stabilize 2D perovskites thanks to an extensive collection of spacer cations, which have been shown to stabilize 2D perovskites. There will be emphasis on the effects of the spacer on the structure and optical properties.

4:00 PM EN08.06.01
Surface Defect States Act as Excitonic Quenching Layers in 2D Perovskites Thin Films Giulia Folpini, Jetsabel M. Figueroa Tapia, Daniele Cortecchia, Mirko Prato and Annamaria Petrozza; Istituto Italiano di Tecnologia, Italy

The optoelectronic properties of two-dimensional metal halide perovskites (2D MHPs), such as large exciton binding energies, narrow excitonic emission and small Stokes shifts, make them excellent candidates for light emitting applications. However, the purely 2D MHPs, characterized by large organic cations (e.g. phenetylammoinum PEA, butylammonium BA, naphtylammonium NMA), are outperformed in LED and lasing devices by other low-dimensionality systems such as fully inorganic nanoparticles or multidimensional perovskites based on a mixture of smaller and bulkier organic cations. Importantly, an unexpected limitation comes from 2D MHPs poor luminescence efficiency: to rationalize this, different mechanisms have been proposed involving recombination on defects and grain boundaries, competing multi-exciton processes, poorer charge transport qualities and effects on luminescence of exciton-phonon coupling. [1-4]. However, the lower radiative recombination efficiencies of 2D MHPs compared to 3D counterparts is not yet fully understood.
In this work, we investigate exciton transport properties in the prototypical 2D MHP phenethylammonium lead iodide ($(PEA)_2PbI_4$) to identify the effect of surface states on the excitonic luminescence, and assess their role in photoluminescence (PL) quenching compared to bulk defects. More specifically, we investigate exciton transport in polycrystalline thin films, establishing an exciton diffusion length of 150 nm in good agreement with values reported in other 2D MHPs [5, 6]. By comparing the radiative lifetime and luminescence efficiencies in films of varying thicknesses [7], we identify the role of the surface as a quencher of excitonic radiative recombination. In films thicker than the diffusion length, where most excitons recombine before interacting with the surface, the PL lifetime is comparable to that of single crystals, indicating a limited role of grain boundaries as non-radiative recombination centers. In thinner films however, a significant quenching of radiative lifetime is observed. The quenching role of surface defects is further confirmed by comparison with $(PEA)_2PbI_4$ nanoparticles, where no quenching is observed despite their characteristically smaller spatial scale. Finally, we relate surface defectivity to the presence of undercoordinated lead atoms, and explore how ad-hoc passivating strategies may be exploited to reduce exciton quenching at the film surface.

Exciton and Lattice Dynamics of One-Dimensional Halide Perovskite Nanowires Mengyu Gao and Peidong Yang; University of California, Berkeley, United States

Many electronic and structural properties of halide perovskite evade conventional categorization. In the talk, we will present two synthetic platforms consisting of atomically-defined one-dimensional halide perovskite nanowires, where we will address the lingering scientific questions of the intriguing optical and structural behaviors of halide perovskite nanostructures.
In the first synthetic platform, we synthesized uniform colloidally stable nanowires with fixed diameter but varied aspect ratios. Using this system, we revealed the scaling laws of photoluminescence quantum yield and radiative lifetime with respect to the aspect ratio of nanocrystals. The scaling laws derived herein are not only a phenomenological observation but proved a powerful tool disentangling the carrier dynamics of microscopic systems in a quantitative and interpretable manner. The investigation of our model system and theoretical formulation bring to light the dimensionality, as a hidden constraint on carrier dynamics, and identify the diffusion length as an important parameter that distinguishes nanoscale and macroscale carrier behaviors.
In the second synthetic platform, we successfully encapsulated single-unit-cell thick halide perovskite nanowires inside single-walled carbon nanotubes. State-of-art transmission electron microscope coupled with a fast electron detection camera was employed to observe the transient structure dynamics of the atomically-thin halide perovskite nanowires. We found that due to the protection of carbon nanotubes, the notoriously beam-sensitive perovskite nanostructure behaved “resiliently” to the electron beam so that their lattice is dynamic but maintain a degree of integrity throughout the acquisition.
Overall, with the atomic-level synthetic control we created two types of 1D halide perovskite nanowires, and due to their structural and morphological uniqueness, new photophysics and structure dynamics were explored. We will demonstrate in the talk how to use these systems and their interesting properties to articulate the explanatory gaps in the field of low dimensional halide perovskite.

4:30 PM EN08.06.03
Strongly Anharmonic Octahedral Tilting in 2D Hybrid Halide Perovskites Matan Menahem[1], Zhenbang Dai[2], Sigalit Aharon[1], Rituraj Sharma[1], Maor Asher[1], Yael Diskin-Posner[1], Roman Korobko[1], Andrew M. Rappe[2] and Omer Yaffe[1]; [1]Weizmann Institute of Science, Israel; [2]University of Pennsylvania, United States

Two-dimensional hybrid halide perovskites (2D HHPs) intrigue material scientists from both the scientific and technological points of views. They exhibit pronounced and easily tunable excitonic properties, which are strongly coupled to thermal fluctuations. The structure of 2D HHPs is closely related to that of their extensively studied 3D counterparts, in which the electronic properties are strongly influenced by anharmonic lattice dynamics.
In this presentation, I will show a study[1] of the structural dynamics of the prototypical 2D HHP $(CH_3(CH_2)_3NH_3)_2PbI_4$ (BAPI) by comparing it to its 3D counterpart $CH_3NH_3PbI_3$ (MAPI) and aromatic counterpart $(C_6H_5\text{-}(CH_2)_2NH_3)_2PbI_4$. We use single-crystal x-ray diffraction and temperature dependent Raman scattering to show that stronger intermolecular interactions between the organic molecules force the structure to a lower symmetry with more harmonic thermal fluctuations. Moreover, we use polarization-orientation Raman scattering and density-functional-perturbation-theory to relate the low-temperature thermal fluctuations of MAPI and BAPI, showing strong similarities between the structural dynamics of the materials. Finally, we uncover the mechanism of the order-disorder phase transition in BAPI which preserves the crystal symmetry due to a skewed double-well potential, biased by the hydrogen bonding between the organic amine and the inorganic scaffold. The phase transition involves unlocking of an anharmonic octahedral tilting motion which increases the anharmonicity of the lattice dynamics and decreases other phonons’ lifetime.
These anharmonic fluctuations are important for technological applications and novel designs of materials and devices since they induce charge carrier localization and affect the optoelectronic performance.

Metal Halide Ruddlesden-Popper Phases for Efficient Blue-Emitting Light Emitting Diodes Maria Antonietta Loi; University of Groningen, Netherlands

Ruddlesden-Popper (RP) perovskite phases of nominal composition $PEA_2(Cs_{0.75}MA_{0.25})Pb_2Br_7$ with and without the addition of the isopropylammonium additive, are demonstrated to emit in the wavelength range around 480 nm and 500 nm, respectively. The sample with isopropylammonium when deposited on a PEDOT-PSS coated substrate displays an exceptional PL QY as high as 64%. Cross correlation of the optical and structural investigations indicate that the RP phase is composed of domains of n=3 phases surrounded by higher dimensionality phases, which allow the efficient transport of charge carriers towards the low dimensional domains. Interestingly, the funneling of the photoexcitations towards the low dimensional phases is blocked in samples using the isopropylammonium additive, mostly due to the random orientation of very small crystalline domains. All the features of this new RP phase allowed us to fabricate LEDs emitting at an average wavelength of 483 nm, with FWHM of the electroluminescence of 25 nm and an external quantum efficiency up to 6%.
These results demonstrate that there is an opportunity to achieve high efficiency LEDs also in the blue spectra range by engineering RP phases.

11:00 AM EN08.07.02
Growth Controls Phonon-Coupled Emission in 2D Perovskite Films Rhiannon M. Kennard[1], Clayton Dahlman[1], Juil (Jay) Chung[1], Ben Cotts[2], Alexander Mikhailovsky[1], Lingling Mao[1], Ryan DeCrescent[1], Kevin Stone[2], Naveen Venkatesan[1], Yahya Mohtashami[1], Sepanta Assadi[1], Alberto Salleo[2], Jon Schuller[1], Ram Seshadri[1] and Michael L. Chabinyc[1]; [1]University of California, Santa Barbara, United States; [2]Stanford University, United States

2D/3D perovskites are attractive for a variety of applications due to their enhanced stability over their 3D perovskite-based counterparts. However, improvements to 2D/3D perovskite-based devices are hampered by missing knowledge about the 2D perovskite itself. In particular, greater understanding

is needed about how processing and composition engineering affect film structure and optoelectronic properties. Because charge generation in 2D perovskites is primarily excitonic, understanding excitonic emission and its link(s) to film processing is crucial for improving 2D/3D perovskite-based devices.

Here, we show that film processing can turn on or off exciton emission that is phonon-coupled. We made thin films of (EA)4Pb3Br10, where EA is ethylammonium. The films are found to be phase-pure; this phase-purity is attributed to using a single A/A'-site cation in the Ruddlesden-Popper n=3 structure, which prohibits crystallization of off-target phases. Composition engineering can thus be used to select for specific Ruddlesden-Popper phases in films. Thin films and bulk crystals (EA)4Pb3Br10 have three emission features: a narrow feature at higher energy, and two features at lower energy. Temperature dependent luminescence measurements reveal that the lower-energy features are phonon-coupled, and are perhaps either phonon replicas or self-trapped excitons. Notably, the intensity of the broad, lowest-energy emission feature depends on film casting kinetics. This intensity dependence is attributed to the presence/absence of film strain imparted by the casting. These results provide an additional knob with which to change the proportions of different types of exciton emission in films. We anticipate that the results here will lead to new 2D/3D perovskite heterostructures with better control over composition and excitonic transitions. [1]

Color Tunable Quasi 2D Blue Perovskite Light-Emitting Diode Utilizing Double Side Amido Ligand Masoud Alahbakhshi[1], Aditya Mishra[1], Grigorii Verkhogliadov[2,3], Ross Haroldson[1], Qing Gu[1], Jason D. Slinker[1] and Anvar Zakhidov[1,2,3]; [1]The University of Texas at Dallas, United States; [2]ITMO University, Russian Federation; [3]The university of Texas at Dallas, United States

Metal halide perovskite, as an emerging semiconductor, provides a unique opportunity for high-definition display and solid-state lighting. Rapid and breakthrough improvements have been achieved in green, red, and near-infrared perovskite light-emitting diodes (PeLEDs). However, blue PeLEDs are still far behind with much lower performance. Herein, we introduce a new dual ligand strategy of 2D/3D perovskite thin film preparation by using the appropriate ratio of Ethane-1,2-diammonium bromide (EDBr) and Phenethyl ammonium bromide (PEABr). The steady-state photoluminescence spectra demonstrate that double side amido terminals EDBr ligand can suppress efficiently the small n domains and non-radiative recombination, leads to strong energy transfer to larger n domains. Based on such films, a sky blue PeLED at 485 nm with about 730 cd/m2 brightness and low turn-on voltage (2.8v) was achieved.

11:30 AM EN08.07.04
Exciton Diffusion in Two-Dimensional Hybrid Perovskites Jonas D. Ziegler[1], Jonas Zipfel[1,2], Barbara Meisinger[1], Matan Menahem[3], Xiangzhou Zhu[4], Takashi Taniguchi[5], Kenji Watanabe[5], Omer Yaffe[3], David Egger[4] and Alexey Chernikov[1,6]; [1]University of Regensburg, Germany; [2]Molecular Foundry, Lawrence Berkeley National Laboratory, United States; [3]Weizmann Institute of Science, Israel; [4]Technical University of Munich, Germany; [5]National Institute for Materials Science, Japan; [6]Dresden University of Technology, Germany

Two-dimensional hybrid perovskites have attracted renewed interest of the condensed matter community due to their intriguing electronic and vibrational properties. They offer excellent platforms to study fundamental many-body physics with promising opportunities for optoelectronic applications. Composed by self-assembly from nanometer-thin sheets of inorganic molecules separated by organic spacers, layered perovskites represent natural, two-dimensional quantum wells. An important consequence of the reduced dimensionality together with weak dielectric screening is the formation of tightly bound electron-hole complexes, commonly known as excitons. In these systems, the excitons are exceptionally robust and, most importantly, couple strongly to light. Following photon absorption, they not only serve as the main energy carriers in the crystal, but also determine the conversion of that energy back to light. Motivated by these properties, a wealth of recent research activities emerged, aimed at the study of *exciton transport* in two-dimensional hybrid perovskites.
A central question in this context is how the excitons move as a function of temperature. In close analogy to *electrons*, temperature-dependent transport is considered key to understand the physics of the *excitonic* mobility. Here, we present the results of our study of exciton propagation in two-dimensional hybrid perovskites, performed from liquid helium up to room temperature conditions [1]. The exciton diffusion is directly monitored by optical means using spatially- and time-resolved photoluminescence microscopy. To avoid material degradation under illumination, the samples are fully encapsulated between thin layers of hexagonal boron nitride. At all studied temperatures our measurements demonstrate that the excitons are highly mobile during their nanosecond lifetimes. The extracted diffusion coefficients range from 1 up to 30 cm^2/s and the corresponding diffusion lengths are as high as 1 micrometer. Two distinct regimes of exciton transport are identified. For all temperatures above 50 K, the excitons propagation follows the conventional diffusion law. Moreover, the extracted diffusion coefficient is either constant or decreases with increasing temperature. This behavior is a characteristic hallmark of free exciton propagation, that is one of our key results. In the temperature regime below 50 K, however, the diffusion is anomalous. First, the exciton cloud expands rapidly after the excitation and then the expansion slows down over time. At liquid helium temperature, the exciton distribution even shrinks again after 100 ps. This observation corresponds to an effectively negative diffusion coefficient that subsequently converges towards zero at longer timescales. Our findings are discussed in the context of an effective mass model from first-principles calculations and temperature-dependent collision broadening based on spectral linewidth analysis. Further considered is the potential impact of non-equilibrium dynamics and exciton localization. Finally, we demonstrate the apparent applicability of a semi-classical diffusion model and provide an outlook towards understanding exciton transport in two-dimensional halide perovskites.

1:30 PM *EN08.08.01
Two-Dimensional Organic-Perovskite Hybrid Materials and Heterostructures Letian Dou; Purdue University, United States

Two-dimensional halide perovskites are exciting new semiconductors that show great promising in low cost and high-performance optoelectronics devices

including solar cells, LEDs, photodetectors, transistors, *etc*. In the first part of this talk, I will present a molecular approach to the synthesis of high-quality organic-inorganic hybrid perovskite quantum wells through incorporating widely tunable organic semiconducting building blocks as the surface capping ligands. By introducing sterically tailored groups into the molecular motif, the strong self-aggregation of the conjugated organic molecules can be suppressed, and single crystalline organic-perovskite hybrid quantum wells and superlattices can be easily obtained via one-step solution-processing. Energy transfer and charge transfer between adjacent organic and inorganic layers are extremely fast and efficient, owing to the atomically-flat interface and ultra-small interlayer distance. Furthermore, this conjugated ligand design greatly enhances materials chemical stability and suppresses halide anion migration. Based on this, we demonstrate for the first time an epitaxial halide perovskite heterostructure with near atomically-sharp interface. Finally, we demonstrate stable and efficient LEDs and FETs using the novel 2D hybrid materials.

2:00 PM EN08.08.02
Synergetic Molecular Treatment for Efficient and Stable Quasi 2D Perovskite LEDs Miguel Anaya, Linsong Cui, Kyle Frohna and Samuel D. Stranks; University of Cambridge, United Kingdom

Metal-halide perovskites have emerged over the past years as a versatile class of semiconductors for high-performance optoelectronic devices.[1] However, despite their unique properties, this family of perovskites has been observed to display strong instability, especially when electrostimulated, limiting their definitive integration in real-world light-emitting devices.[2-4]

In this talk, we will present a detailed photophysical characterisation of quasi 2D green-emitting halide perovskite films in which different passivation strategies are employed to improve both their optical and electrical properties. We will introduce a new powerful technique with which we can evaluate the performance of perovskite-based LEDs at the nanoscale by hyperspectral wide-field imaging. We show how to obtain maps at the diffraction limit scale for their External Quantum Efficiency (EQE), luminance, and luminous efficacy. Our observations reveal the degradation pathways of this emerging class of LEDs, induced by microscale heterogeneities that hamper the ultimate device performance. The lessons learned from our multimodal microscopy approach allow us to identify a novel dual molecular treatment that selectively 1) optimises the thin film quality (e.g. suppression of pinholes while maximising light outcoupling) and 2) enhances the intrinsic optoelectronic quality of the quasi 2D perovskite (e.g. PLQE, IQE). This methodology results in bright (>14,000 cd/m2) and efficient (>20% EQE) green LEDs with operational lifetimes surpassing 100 h. Our work represents a step forward in diagnosing the in-operando properties of low dimensional perovskite-based devices at the nanoscale and opens avenues to identify strategies for stable and efficient LEDs with spatially maximised performance.[5]

2:15 PM EN08.08.03
Defective and Double Perovskites—*Ab Initio* Excitonic Properties in Lower-Dimensional Inorganic Halides Christopher Savory; University College London, United Kingdom

While 3-dimensional inorganic and hybrid halide perovskites have rightly seen great success in photovoltaics and LEDs, lower dimensional perovskites and perovskite-like materials, whether layered or ordered defect '0D', have also shown similarly promising optoelectronic properties. The onset of self-trapped excitonic behaviour that has also been observed and associated with reduction in structural or electronic dimensionality make this class of materials highly promising as light emitters.[1] In the stable, wholly inorganic low-D perovskites, such strong excitonic behaviour has been seen in the '0D' perovskite-like $Cs_2M^{(IV)}X_6$ compounds,[2] as well as at room temperature in the 2D ordered-defect pnictide-based perovskites of the $Cs_3M^{(III)}{}_2X_9$ family,[3] and also resulting in high quantum efficiency in the highly promising $Cs_2M^{(I)}M^{(III)}X_6$ double perovskites,[4] which while 3-dimensional in structure, can demonstrate a '0D'-like electronic structure due to the substitution of the perovskite 'B' site;[5] all of these materials maintain the added benefit of moving away from toxic Pb.
Nevertheless, a reliable theoretical description of the physical origin of these phenomena across the range of different structures available to lower-dimensional perovskites is lacking due to the inability of standard 'independent particle' methods such as Density Functional Theory (DFT) to describe excitons. In this study, we select example compounds from each of the aforementioned materials families and use ab-initio calculations to establish their electronic, optical and excitonic properties: $Cs_2M^{(IV)}X_6$ ($M^{(IV)}$ = Zr, Sn; X = Cl, Br), $Cs_3M^{(III)}{}_2X_9$ ($M^{(III)}$ = Bi, X = Br) and $Cs_2M^{(I)}M^{(III)}X_6$ ($M^{(I)}$ = Ag, Na; $M^{(III)}$ = Bi, In; X = Cl, Br). We initially establish a comparison in the electronic structures predicted through accurate standard ab-initio methods, such as hybrid DFT, and higher level many-body perturbation methods (QSGW) available within the open-source code Questaal.[6] Then, where standard DFT fails, we calculate the excitonic spectrum, within the Bethe-Salpeter Equation, of each material to establish a consistent understanding of the excitonic properties and establish the influence of both structure and composition. We also computationally examine the dynamic and thermodynamic stability of these materials to confirm whether the advantage of stability attributed in both lower-dimensional and inorganic perovskites is maintained. In performing this survey across a range of inorganic perovskite-like structures, we hope to establish the structure-property relationships that can potentially provide insight into the behaviour of current inorganic or hybrid inorganic-organic low-dimensional perovskites and also guide future syntheses of lead-free, efficient light emitters.

4:00 PM EN08.09.02
Synthesis of Lead-Free $Cs_3Bi_2Br_9$ NCs with Enhanced Photocatalytic Activity in the Degradation of Organic Pollutants in an Aqueous Environment Alexander G. Aragon, XIao Ma and Scott Geyer; Wake Forest University, United States

Over the past decade, metal halide perovskites, with a particular focus on traditional structures such as $CsPbX_3$ (X = Br^-, Cl^-, I^-) have garnered much interest as potential photocatalysts for many reactions such as solar fuel production (CO_2 reduction, HER), and in the degradation of organic pollutants. The fully ionic nature of these materials, however, has resulted in major challenges for their practical use. More stable perovskite alternative structures such as $Cs_3B_2X_9$ (B = Sb^{3+}, Bi^{3+} X = Br^-, Cl^-, I^-) have shown great promise as novel photocatalysts and have not been heavily studied yet, especially at the 0D structural level in the form of NCs. Thus, this study was aimed at investigating the photocatalytic capabilities of $Cs_3Bi_2Br_9$ NCs synthesized by hot injection method. As synthesized $Cs_3Bi_2Br_9$ NCs with an observed optical bandgap of 2.85 eV were applied to the photocatalytic degradation of Rhodamine G (RhG) dye in an aqueous environment. For comparison, $CsPbBr_3$ NCs synthesized by hot injection method and P25 TiO_2 (Sigma) were also tested. The degradation of RhG follows pseudo-zeroth order kinetics with $Cs_3Bi_2Br_9$ NCs reaching catalytic efficiencies near 90%. Furthermore, the observed stability of the $Cs_3Bi_2Br_9$ NCs is much greater than the $CsPbBr_3$ NCs in that near zero catalytic efficiency was observed for $CsPbBr_3$. This is due to the degradation of $CsPbBr_3$ NCs in water occurring at a much faster rate than RhG degradation. Despite this, it was observed that as synthesized $Cs_3Bi_2Br_9$ NCs do degrade over time and thus the overall stability of the system must be improved for practical use. Current efforts to enhance the stability of the system include overcoating via ALD in order to passivate the surface and protect the perovskite layer, with an overall goal of producing a suitable water stable photocatalyst with high efficiency for wastewater purification.

4:15 PM EN08.09.03
Colloidal Synthesis of Metal Halide Layered Double Perovskite Nanocrystals with Composition Engineering and Structural Transformation Tong Cai, Wenwu Shi, Hanjun Yang and Ou Chen; Brown University, United States

Lead halide perovskites have been well explored in various optoelectronic applications due to their unique properties. While issues like toxicity and instabilities hinder their further use, which aroused great interest for the development of alternative lead-free perovskites. Recently, a new family of layered double perovskites (LDPs) with a chemical formula of $Cs_4M(II)M(III)_2X_{12}$ provide a new route to solve these problems by combining two main strategies including composition substitution and dimensionality reduction. On the one hand, Pb^{2+} cations are substituted by a combination of M(II) and M(III) cations with the enlarged composition tuning space. On the other hand, the layered structure consists of one layer of $[M(II)X_6]^{4-}$ octahedra sandwiched by two layers of $[M(III)X_6]^{3-}$ octahedra in between two adjacent vacancy layers. However, accessibilities to this class of perovskite-type nanomaterials remain inadequate, hindering their practical implementations in various applications. Here, we report the colloidal synthesis of several types of LDP NCs using a modified hot-injection method, such as $Cs_4CuSb_2Cl_{12}$, $Cs_4MnBi_2Cl_{12}$, $Cs_4CdBi_2Cl_{12}$ and $Cs_4CdSb_2Cl_{12}$ LDP NCs. The resulting LDP NCs show unique optical, electronic and magnetic properties with different crystal structures, inspiring to build the composition-structure-property relations between various LDP NCs. Therefore, a series of $Cs_4Cu_xAg_{2-2x}Sb_2Cl_{12}$, $Cs_4Cd_{1-x}Mn_xBi_2Cl_{12}$, and $Cs_4Cd_{1-x}Cu_xSb_2Cl_{12}$ perovskite-type NCs ($0 \leq x \leq 1$) are synthesized to investigate the composition-induced crystal structural transformation, and thus, the evolution of electronic bandgap, magnetic ordering and charge carrier dynamics. These transformation processes are explored by experimental observations and further confirmed by theoretical DFT calculations on the band structures, charge density differences and electron localization function. Photo-generated charge carrier dynamics of the LDP NCs are investigated using ultrafast spectroscopic techniques. Taking advantage of both the unique electronic structures and solution processability, we demonstrate that the LDP NCs can be solution-processed as high-speed photodetectors with ultrafast photo-response and narrow bandwidth. We anticipate that our study will prompt future research to design and fabricate novel and high-performance lead-free perovskite-type NCs for a range of photovoltaic applications in the future.

Lead-Based Perovskites: How Toxic are These and What are the Prospects of Alternatives Like Cs2AgBiBr6 Huygen J. Jöbsis[1], María C. Gélvez-Rueda[2], Reiny Sangster[3], Valentine M. Caselli[4], Sven Askes[2], Erik C. Garnett[2], Charlotte M. Gommers[3], Bruno Ehrler[2], Ferdinand C. Grozema[4], Freddy T. Rabouw[1], Tom Savenije[4] and Eline M. Hutter[1]; [1]University of Utrecht, Netherlands; [2]AMOLF, Netherlands; [3]Wageningen University & Research, Netherlands; [4]Delft University of Technology, Netherlands

Cs2AgBiBr6 (CABB) has been proposed as a less toxic and more stable alternative to lead halide perovskites. However, low charge carrier collection efficiencies remain an obstacle for the incorporation of this material in optoelectronic applications. In this talk, I will elaborate on the dynamics of charge transport, localization and recombination in CABB thin films, studied using time-resolved photoconductivity and transient absorption/reflectance measurements. Temperature-dependent photoconductivity measurements indicate band-like charge transport of free charges, similar to lead-based perovskites.[1] We find that replacement of Bi with Sb shifts the absorption onset, while preserving the charge transport mechanism. However, as charges lose mobility within tens of nanoseconds, diffusion lengths remain relatively short in these lead-free materials. While mobile charges have a nanosecond-lifetime, we observe microsecond-long lifetimes in transient absorption measurements.[3] This suggests that the conductivity loss in CABB films is due to a combined effect of carrier recombination and localization. Moreover, we find that the charge carrier diffusion length is similar to the and sample thickness, suggesting that charge localization occurs at the materials surface. Therefore, improving surface quality could be a strategy to optimize performance of CABB-based optoelectronic devices. In parallel to investigating CABB, we performed a toxicity study of methylammonium lead iodide perovskites on *A. Thaliana* plants, and found that the iodide was actually much more toxic than the lead.[2] Altogether, these results stress the importance of further understanding which perovskites are most harmful to the environment, while optimizing the optoelectronic quality of materials with the lowest toxicity.

Lead-Free Metal Halide Nanocrystals Combining High Photoluminescence Quantum Yield with Picosecond Radiative Lifetime Osman M. Bakr; King Abdullah University of Science and Technology, Saudi Arabia

Lead halide compounds, including lead halide perovskite nanocrystals (NCs), have attracted the interest of researchers in optoelectronics and photonics due to their high photoluminescence quantum yields (PLQYs) coupled with relatively short PL lifetimes (on the order of a few nanoseconds). However, lead-free metal halides of high PLQY, including double perovskites and their doped NCs, typically possess long PL lifetimes (up to microseconds), due to the nature of their excitons, which limits their application space. Here, I introduce $CsMnBr_3$ NCs, which are lead-free and combine a high PLQY with an exceptionally short radiative lifetime (on the order of picoseconds). We find that the octahedral coordination of Mn^{2+} in $CsMnBr_3$ induces a red emission centered at ~643 nm with a PLQY of ~54% and a fast radiative decay rate. Femtosecond transient absorption and transient PL spectroscopies reveal the existence of a low-lying excited state of Mn^{2+} that relaxes to the ground state within ~600 ps by emitting light at ~643 nm. At greater excitation energies, higher excited states of Mn^{2+} relax within a sub-nanosecond timescale to this low-lying excited state. A similarly positioned PL peak with a short picosecond-scale PL lifetime and a PLQY of ~ 6.7% was also detected in bulk $CsMnBr_3$ single crystals – a relatively high quantum yield for a bulk material. Our experimental results and density functional theory modelling show that the crystal structure and the strong coupling among Mn^{2+} ions govern those luminescence properties of $CsMnBr_3$ NCs and single crystals. These findings pave the way for new lead-free materials that combine high PLQY and ultrafast luminescence.

Layer Number Dependent Ferroelasticity in 2D Ruddlesden-Popper Organic-Inorganic Hybrid Perovskites Xun Xiao and Jinsong Huang; University of North Carolina at Chapel Hill, United States

Ferroelasticity represents material domains possessing spontaneous strain that can be switched by external stress. Three-dimensional perovskites like methylammonium lead iodide are determined to be ferroelastic. Layered perovskites have been applied in optoelectronic devices with outstanding performance. However, the understanding of lattice strain and ferroelasticity in layered perovskites is still lacking. Here, using the in-situ observation of switching domains in layered perovskite single crystals under external strain, we discover the evidence of ferroelasticity in layered perovskites with layer number more than one, while the perovskites with single octahedra layer do not show ferroelasticity. Density functional theory calculation shows that ferroelasticity in layered perovskites originates from the distortion of inorganic octahedra resulting from the rotation of aspherical methylammonium cations. The absence of methylammonium cations in single layer perovskite accounts for the lack of ferroelasticity. These ferroelastic domains do not induce non-radiative recombination or reduce the photoluminescence quantum yield.

9:15 AM EN08.10.05
Expanding the 0D $Rb_7M_3X_{16}$ (M=Sb, Bi; X=Br, I) Family—Dual-Band Luminescence in $Rb_7Sb_3Br_{16}$ Kyle M. McCall[1,2], Bogdan M. Benin[1,2], Michael Woerle[1], Thomas Vonderach[1], Detlef Guenther[1] and Maksym V. Kovalenko[1,2]; [1]ETH Zurich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Low-dimensional metal halides have been the focus of intense investigations in recent years following the success of the three-dimensional (3D) hybrid lead halide perovskites as optoelectronic materials for solar cells, semiconductor radiation detectors, and narrow emitters. In particular, the light emission of zero-dimensional (0D) metal halides have found utility in a variety of applications (including X-ray scintillation and remote thermometry) that are complementary to those of the 3D halide perovskites, thanks to their unusual properties including intrinsic broadband emission and highly temperature-dependent lifetimes. Inorganic, lead-free compositions are especially sought after thanks to their enhanced stability and reduced toxicity.
Here, we flesh out the family of fully inorganic, 0D pnictogen halides based on the $Rb_7M_3X_{16}$ (M=Sb, Bi; X=Br, I) stoichiometry by solvothermal and solid-state synthesis of the heavier halides, namely $Rb_7Sb_3Br_{16}$, $Rb_7Bi_3Br_{16}$, and $Rb_7Bi_3I_{16}$.The title compound exhibits a 0D structure comprised of two isolated units: $[SbBr_6]^{3-}$ octahedra and edge-sharing bioctahedra $[Sb_2Br_{10}]^{4-}$ dimers which order into layers along the *c*-axis. The compound is air-stable and exhibits weak orange-red photoluminescence (PL) at room temperature, but intriguingly at low temperatures has two distinct emission bands with different excitation characteristics. Temperature-dependent PL and PL excitation spectra reveal that these bands correspond to these two motifs, and that there is a crossover near 150 K where the high-energy emission quenches as the units begin to interact.

We are also able to obtain $Rb_7Bi_3Br_{16}$ and $Rb_7Bi_3I_{16}$ which both crystallize in orthorhombic symmetry, with $Rb_7Bi_3Br_{16}$ presenting weak low-temperature luminescence while $Rb_7Bi_3I_{16}$ is non-luminescent. These trends in PL intensity with changing composition can be directly linked to the lone pair activity, which is maximized in the Sb analogues with lighter halides, yielding insight into how to design optically emissive materials. This work expands the library of emissive inorganic metal halides and provides further evidence for the efficacy of low-dimensional Sb-X luminescent centers based on octahedral and edge-sharing $[Sb_2X_{10}]^{4-}$ dimers.

Superlattices from Lead Halide Perovskite Nanocrystals Maksym V. Kovalenko[1,2]; [1]ETH Zurich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Lead halide perovskite nanocrystals (LHP NCs, NCs, A=Cs^+, FA^+, FA=formamidinium; X=Cl, Br, I) exhibit spectrally narrow (<100 meV) fluorescence, tunable over the entire visible spectral region of 400-800 nm [1,2]. Owing to their high oscillator strength, slow dephasing (long coherence times of up to

80 ps), minimal inhomogeneous broadening of emission lines, and a bright triplet exciton character with orthogonal dipole orientation [2], these NCs make for a highly versatile platform for creating controlled, aggregated states exhibiting collective phenomena. Long-range ordered superlattices (SLs) with the simple cubic packing of cubic perovskite NCs exhibit sharp red-shifted lines in their emission spectra and superfluorescence (a fast collective emission resulting from coherent multi-NCs excited states) [4]. We now present perovskite-type ABO_3 binary and ternary NC SLs by a shape-directed co-assembly of $CsPbBr_3$ nanocubes (occupying B- and/or O-sites) with spherical dielectric Fe_3O_4 or $NaGdF_4$ NCs (A-sites) and truncated-cuboid PbS NCs (B-site) [5]. Such ABO_3 SLs, as well as other newly obtained SL structures (binary NaCl- and AlB_2-types, columnar assemblies with disks, *etc.*), exhibit a high degree of orientational ordering of $CsPbBr_3$ nanocubes. These mesostructures exhibit superfluorescence as well, characterized, at high excitation density, by emission pulses with ultrafast (22 ps) radiative decay and Burnham-Chiao ringing behavior with a strongly accelerated build-up time.

Broad Band Emission from Excitons in Layered Ruddlesden-Popper Hybrid Perovskites with Tailored Layer-Phase Composition Anna Stadlbauer[1], Lissa Eyre[1], Miguel Anaya[2], Samuel D. Stranks[2] and Felix Deschler[1]; [1]Walter Schottky Institut - Technical University Munich, Germany; [2]University of Cambridge, United Kingdom

Lighting applications require cheap and sustainable materials for broadband white-light emission generation. Recently, layered hybrid perovskites have been proposed as a potential material system, in which broad emission from self-trapped excitons was reported, among varying optical properties and unfortunately with low stability [1], [2].

Here, we report the generation of broad spectra from free, bright excitons by producing thin films of layered Ruddlesden-Popper lead iodide perovskites with tailored composition of multiple phases with varying layer number.

We investigate structure and photophysics of our hybrid perovskite films with selected linear and aromatic monoammonium cations [3], and a range of small cations (Cs, FA, MA). The chosen materials were produced by optimizing fabrication parameters, which were reported to influence the optical and structural properties [3]. We find best performance from the Cs containing compositions.

The resulting optimized materials are optically investigated with time resolved photoluminescence spectroscopy and transient absorption spectroscopy both at room temperature and at cryogenic temperatures. Furthermore, we characterize photoluminescence quantum efficiency. A detailed structural analysis with X-ray diffraction spectroscopy, atomic force microscopy and scanning electron microscope is performed to correlate structural and optical properties.

For the materials which show the broadest emission spectrum and best optoelectronic performance, we fabricate LEDs and use them as the emitter layer in combination with a blue LED for broadband white light emission.

Our findings have promise as a new approach for using Ruddlesden-Popper lead iodide perovskites in the broader application of white LEDs, which could result in lower cost and more efficient lighting.

Estimation of Emission Properties of 2D Halide Perovskites Using DFT and Machine Learning Hiromitsu Takaba, Kouta Miura, Yasuo Suzuki and Masaya Miyagawa; Kogakuin Univ, Japan

Recently, 2-dimension (2D) organic-inorganic halide perovskites have become one of the key materials in emission diode. The electronic structure and structural stability of these materials show a significant dependence on chemical composition. Therefore the emission properties and durability of the halide perovskite can be tuned by changing the combination of composition. In this study, using density functional theory (DFT) and molecular dynamics, we theoretically investigated a crystal structure and electronic structure of the partially substituted cubic (A)2PbX3 (A = butylammonium (BA), octylammonium (OA), X = halide). Our calculation results indicate that a bandgap is associated with Pb-X distance in the lattice, although the contribution of A-site ions is little. The relation of bandgap with Pb-X length is further confirmed and refined by expanding the investigated composition based on the 2D perovskite database reported by Marchenko et al. [Chem. Mater. (2020) 32, 7383]. It is found that the structural parameter of Pb-X simply explains the bandgap for different compositions. The relationship of bandgap and emission peaks in photoluminescence (PL) is further investigated with machine learning. Finally, PL emission peaks are predicted for the database and some of them are compared with the experiments for validation. This model explained the trend of the Stokes shift in 2D halide perovskite. The broadness of emission peaks, which may be related to the A site species, is also discussed.

Late News: Strongly Luminescent Hybrid Lead Halides with a Symmetric, Triamine Chromophore Imra Tajuddin, Eugenia S. Vasileiadou, Michael C. De Siena, Ioannis Spanopoulos and Mercouri G. Kanatzidis; Northwestern University, United States

Hybrid lead halide perovskites and their lower dimensional related-structures are rising materials with extensive applications in photovoltaics and light-emitting diodes (LEDs), in part due to their luminescent properties. Herein, we present a family of low-dimensional lead halides with strong photoluminescence, incorporating into their structure the symmetric, triamine chromophore: 1,3,4-tris(1,3,5-tris(4-aminophenyl)benzene, symbolized as T. A zero-dimensional (0D) lead bromide structure is synthesized with the formula: (T)7Pb3Br27.DMF. The novel 0D material contains the triamine molecules with isolated [PbBr6]4- octahedra and (DMF) molecules dispersed throughout.
The distance of the terminal amino-tail of the triamine to the nearest bromine atom is 3.652 Å. As a result of the extended conjugation of the triamine chromophore, (T)7Pb3Br27.DMF displays cation- π interactions, with π- π interactions of 3.498 Å distance between the closest aromatic rings of the

adjacent triamine molecules. The DMF molecules are orientated adjacent to the lead bromide octahedra with an average distance of 3.05 Å of the oxygen atom with the nearest bromine atoms.
The (T)7Pb3Br27.DMF compound exhibits high distortion levels of the [PbBr6]4- octahedra, with an average bond length of 3.01Å, an average bond angle variance of 46.696 deg.2 and an average bond length distortion index of 0.02676. The measured UV absorption spectra of the triamine itself shows two features, one with an absorption edge at 2.85 eV and another absorption edge at 2.58 eV. The (T)7Pb3Br27.DMF compound also displays two features in its absorption spectra with absorption edges at 2.95 eV and 2.00 eV. The studied compounds demonstrate vibrant, strong photoluminescence emission. The triamine chromophore exhibits blueish-white emission with a broad emission peak centered at 428 nm along with a shoulder at 370 nm. The (T)7Pb3Br27.DMF compound demonstrates strong and narrow blue emission at 368 nm with a lifetime of 5 ms due to self-trapped excitons. Additionally, the lead chloride and lead iodide analogues incorporating the triamine molecule have been synthesized. Our work proposes a synthetic strategy in designing hybrid lead halide compounds with symmetric chromophore molecules that exhibit strong photoluminescent emission.

12:15 PM EN08.11.06
Coherent Control of Asymmetric Spintronic Terahertz Emission from Two-Dimensional Hybrid Metal Halides Kankan Cong[1], Eric Vetter[2,2], Liang Yan[3,2], Yi Li[4,1], Qi Zhang[1], Yuzan Xiong[4,4], Hongwei Qu[4,4], Richard Schaller[1], Axel Hoffmann[5,1], Alexander Kemper[2], Yongxin Yao[6], Jigang Wang[6], Wei You[3,2], Haidan Wen[1], Wei Zhang[4] and Dali Sun[2,2]; [1]Argonne National Laboratory, United States; [2]North Carolina State University, United States; [3]University of North Carolina at Chapel Hill, United States; [4]Oakland University, United States; [5]University of Illinois at Urbana-Champaign, United States; [6]Iowa State University, United States

Next-generation terahertz (THz) sources demand light-weight, low-cost, defect-tolerant, and robust components with synergistic, tunable capabilities. However, a paucity of materials systems simultaneously possessing these desirable attributes and functionalities has made device realization difficult. Here we report the observation of asymmetric spintronic-THz radiation in **T**wo-**D**imensional **H**ybrid **M**etal **H**alides (2D-HMH) interfaced with a ferromagnetic metal, produced by ultrafast spin current under femtosecond laser excitation. The generated THz radiation exhibits an asymmetric intensity toward forward and backward emission direction whose directionality can be mutually controlled by the direction of applied magnetic field and linear polarization of the laser pulse. Our work demonstrates the capability for the coherent control of THz emission from 2D-HMHs, enabling their promising applications on the ultrafast timescale as solution-processed material candidates for future THz emitters.

Optically Resonant Halide Perovskite Nanostructures—From Light Control to Lasing Applications Sergey Makarov; ITMO University, Russian Federation

Nanophotonics and meta-optics based on optically resonant all-dielectric structures is a rapidly developing research area driven by its potential applications for low-loss efficient metadevices. Recently, the study of halide perovskites has attracted enormous attention due to their exceptional optical and electrical properties. As a result, this family of materials can provide a prospective platform for modern nanophotonics [1] and meta-optics [2], allowing us to overcome many obstacles associated with the use of conventional semiconductor materials. Here, we overview the recent progress in the field of halide perovskite nanophotonics starting from single-particle light-emitting nanoantennas [3,4], nanolasers [5], microlasers [6,7], and to the large-scale designs working for surface coloration, anti-reflection, and optical information encoding [8-9].

8:30 AM *EN08.12.02
Nanocrystal Heterostructures Involving Halide Perovskites and Other Materials Liberato Manna; Instituto Italiano di Tecnologia, Italy

Halide perovskite semiconductors can merge the highly efficient operational principles of conventional inorganic semiconductors with the low temperature solution processability of emerging organic and hybrid materials, offering a promising route towards cheaply generating electricity as well as light. Following a surge of interest in this class of materials, research on the corresponding halide perovskite nanocrystals (NCs) as well has gathered momentum in the last years.[1] A hot area of research in this field is the fabrication of nano-heterostructures in which the perovskite is one of the domains, which will briefly reviewed, including work from our group. Another class of materials that has been recently investigate by us is that of metal chalcohalides. These

materials offer a broad solid-state chemistry and they been investigated for applications in solar energy conversion, thermoelectrics, hard radiation detection, and superconductivity. Among them, lead chalcohalides have been rarely studied in the past. We have recently reported the synthesis of a series of lead chalcohalides, by means of colloidal approaches, delivering phases and compositions that had not been previously identified in the bulk.[2] These materials present indirect band gaps, they emit in the NIR region of the spectrum at cryogenic temperatures and have unique crystal structures. We will also show our recent results on the synthesis and advanced characterization of heterostructured nanocrystals in which one domain is a lead chalcohalide and the other domain is a cesium lead halide perovskite.[3] The two domains are separated by a flat, atomically defined, epitaxial interface. In these materials, the photogenerated carries are separated at their interface, and as such they might be promising in applications ranging from catalysis to photovoltaics. The talk will also discuss on how the presence of the halide perovskite domain dictates the phase and chemical composition of the metal halide domain.

9:00 AM EN08.12.04
Low Barrier for Exciton Self-Trapping Enables High Photoluminescence Quantum Yield in $Cs_3Cu_2I_5$ Young-Kwang Jung[1] and Aron Walsh[1,2]; [1]Yonsei University, Korea (the Republic of); [2]Imperial College London, United Kingdom

Low-dimensional metal halides have attracted interest from researchers in the field of optoelectronics due to their high photoluminescence quantum yield (PLQY) [1-2]. The fact that these metal halides exhibit a high bulk PLQY, without preparing them in nanocrystal form, makes them an interesting class of optoelectronic materials. One characteristic feature is a large Stokes shift - the difference between absorbed and emitted light wavelength - which is usually attributed to the formation of self-trapped excitons (STEs). STE indicates the state where a photoexcited electron-hole pair is stabilized and trapped at a lattice site. This phenomenon is the result of strong electron-phonon coupling and can be enhanced by a soft crystal host [3]. Although low-dimensional metal halides shows the high PLQY of > 90% via STE emission, the emission processes happening within low-dimensional metal halides is poorly understood at the moment. Indeed, (i) why self-trapping occurs so efficiently; (ii) how self-trapped exciton emission competes against intrinsic band-to-band transitions are not known.

Here, we performed first-principles density-functional theory (DFT) calculations to explain why this class of materials exhibit such a high PLQY. We selected $Cs_3Cu_2I_5$ as the model system for this work as the material is a well-known example of STE emission [4]. Optical properties originate from its intrinsic bulk electronic structure (e.g. high-frequency dielectric function and absorption coefficient) will be firstly assess. Then explicit modelling of STE formation will be carried out to calculate the STE emission energy and self-trapping barrier in $Cs_3Cu_2I_5$. Based on these quantities, we will evaluate the rates of band-to-band recombination and STE emission, and consequently, we predict the quantum yield of blue emission as a function of the excited carrier concentration.

Transport in 2D Layered Lead-Halide Perovskite Films Doaa Shamalia and Nir Tessler; Technion, Israel

Organic-inorganic hybrid perovskites emerged as a very promising material for many applications such as photovoltaics, LEDs, and transistors. These materials have the composition of ABX_3 where A is a small organic cation such as MA^+, FA^+, B is Pb^- or Sn^- and X is a halide anion such as I^-, Br^- and Cl^-. Partial substitution of organic cations in the 3D structure with hydrophobic organic cations can lead to the formation of lower-dimensional perovskites. This led to methods of forming 2D/3D bilayered perovskite, whereby a single-step fabrication process a phase separation is driven by self-assembly is obtained forming an upper 2D layer that serves as a capping layer and a bottom 3D layer.
In our research, we present the influence of the deposition method, the stoichiometry of the precursors’ solution, and the surface energy of the substrate on the quality of the perovskite layers in terms of grain size and crystallinity as well as on the composition of the 2D/3D structure in terms of n=1,2,...
This film optimization allowed us to fabricate field-effect transistors that are based on layered perovskite and use the transistor as a tool to evaluate the material’s properties. We’ll describe the performance of the transistors in terms of device J-V characteristics as well as extraction of residual doping and mobility, as a function of the processing methods. These parameters would assist in designing efficient and stable photovoltaic devices.

Dominance of Ion-Migration in Controlling the Hysteresis in Perovskite Solar Cells Spandankumar H. Ranpariya and Dhirendra K. Sinha; Indian Institute of Information Technology Vadodara, India

In recent years, the organic-inorganic hybrid lead-halide perovskite solar cells (PSCs) have attracted attention due to the record-breaking rise in power conversion efficiency (PCE) from 3.8% in 2009 to 25.5% in 2021. This attractiveness is mainly due to its high optical absorption coefficient with sharp absorption onset, long charge-carrier lifetime, tunable band-gap, and low-cost fabrication. However, the correctness of the reported efficiencies is suspected due to hysteresis in the current density (*J*) versus voltage (*V*) characteristics. In literature, there are mainly two physical reasons widely debated for hysteresis in *J-V* characteristics. The first is the ion migration from the perovskite layer towards the interfaces forming vacancies and thus creating trapping centers for the charge-carriers. The second one is trap-assisted recombination via the defect states, which trap the charge-carriers at the grain boundaries and the interface of charge-transporting layers. In this work, the underlying interest is to comprehend the hysteresis behavior by deriving the hysteresis index (HI) from the simulated power density-voltage characteristic. The value of HI reflects the extent of hysteresis observed in the current-voltage characteristics. We consider a perovskite solar cell in a *p-i-n* structure with $CH_3NH_3PbI_3$ as an active layer. The Spiro and TiO_2 are taken as a hole- and electron- transporting layers, respectively. We utilized a one-dimensional drift-diffusion equation to simulate the current density vs. voltage characteristics by varying the active layer thickness from 100 nm to 500 nm. In addition, the interfacial thickness between the active layer and electron (hole) transporting layers were also varied from 10 nm to 80 nm keeping the active layer thickness intact. The value of HI is observed to be increasing from 0.1 to 0.6 with increasing the thickness of the active layer. It is also observed to be saturated in devices whose active layer thickness is beyond 400 nm. On the other hand, the value of HI was observed to be nearly constant, i.e., roughly 0.5, with a wide variation of interfacial thickness. The observations indicate that the value of HI is dependent on the variation in the active layer thickness, thereby indicating the role of ion-migration is dominant in controlling the hysteresis.

SESSION EN08.13: Photophysics of Low Dimensional Perovskites II

Carrier Cooling in Low-Dimentional Perovskites Artem Bakulin; Imperial College London, United Kingdom

The rapid relaxation of above-gap 'hot' carriers in absorber layer materials currently places a limit on the open-circuit voltage achievable in perovskite photovoltaic devices. The dimentions and dimentionality of perovsikte materials is expected to affect carrier cooling on account of changin coupling between electronic states as well as coupling electronic system to lattice phonon energy levels. Here, ultrafast pump-push-probe spectroscopy is used to compare hot carrier cooling dynamics in 3D perovskites, 8 and 5 nm cuboidal nanocrystals,
3.5 nm nanoplatelets and bulk 2D perovskites prepared using different techniques. Carrier cooling rates are shown to be similar to bulk materials in all but 2D-confined perovskite nanosystems. Surprisingly, cooling rates are observed to increase in such systems, while hot phonon bottleneck phenomena become much less pronounced. This work offers further insight into fundamental physical processes occurring in nanoscale materials and aid in the design of future solar cell absorber systems.

11:00 AM *EN08.13.02
What Do Dephasing Dynamics Teach Us About Exciton Polarons in Hybrid Ruddlesden Popper Metal Halides? Ajay Ram Srimath Kandada[1] and Carlos Silva[2]; [1]Wake Forest University, United States; [2]Georgia Institute of Technology, United States

It is common in the context of hybrid metal halide perovskites and its derivatives to use temperature dependence of photoluminescence linewidths to estimate electron-phonon coupling parameters. However, due to comparable contributions from homogeneous and inhomogeneous mechanisms to the spectral broadening, linear spectroscopies like photoluminescence are incapable of isolating the pure dephasing rates and thus are not representative of the system-bath interactions. In these circumstances, nonlinear coherent optical spectroscopy offers insights into the nature of many-body interactions that are entirely inaccessible to temperature-dependent linear spectroscopies. When applied to Ruddlesden-Popper metal halides, these techniques have indeed enabled us to quantify the elastic scattering effects on the exciton dephasing rates. Here, we will discuss the mechanistic nature of exciton-phonon, exciton-exciton and phonon-phonon interactions in prototypical Ruddlesden Popper metal halides based on such experimental observations. We will discuss our perspective on how the coherent lineshapes of Ruddlesden-Popper metal halides can be effectively rationalized within an exciton polaron framework. We will also discuss the critical role of the metal cation in the observed coherent exciton dynamics.

11:30 AM EN08.13.03
Room-Temperature Continuous-Wave Lasing from 2D Layered Organic-Inorganic Hybrid Perovskites Embedded Microcavities Hongbo Zhang, Yuzhong Hu, Ting Yu and Hong Jin Fan; Nanyang Technological University, Singapore

Two dimensional (2D) layered lead halide perovskites with large exciton binding energies, efficient radiative recombination, and outstanding environmental stability are regarded as supreme candidates for realizing highly compact and ultralow threshold lasers. However, continuous-wave (CW) pumped lasing of 2D Lead halide perovskites, as the precondition for the electrically pumped lasing, is still challenging. Here, the phenylethylammonium lead iodide [$(PEA)_2PbI_4$] thin flakes, exfoliated from the solution-processed millimeter-sized single crystal, were utilized as gain media to construct a vertical-cavity surface-emitting laser (VCSEL), which presents the robust single-mode CW lasing operation with an ultra-low threshold of 5.7 W cm^{-2} at room temperature, attributed to strong optical confinement in the high-Q cavity. Moreover, the multi-mode emission has been synchronously discussed through experiements and simulations. This work opens up a new window for developing novel 2D VCSELs based on the layered lead halide perovskites.

11:45 AM EN08.13.04
Anisotropic Charge Carrier Dynamics in Layered Hybrid Perovskites Probed by Oblique Incidence Ultrafast Terahertz Spectroscopy Kyle Virgil, William Goddard, Geoffrey Blake and Harry A. Atwater; California Institute of Technology, United States

Understanding the transport properties of layered perovskite optoelectronics requires the characterization of carrier dynamics both in the plane of and transverse to the layer structure. We explore carrier transport using polarization-dependent terahertz (THz) conductivity measurements in layered (2D) hybrid perovskites. We have synthesized ~300 nm thick films of n = 1 butylammonium and phenethylammonium lead iodide layered perovskite semiconductors, with layers oriented parallel to sapphire substrates and with crystalline domain sizes of approximately 1 micron diameter. In the measurements, around 110 femtosecond pump pulses from a Ti:sapphire laser source were converted to THz radiation with picosecond pulse duration via an electro-optic crystal. Transmission measurements at normal incidence yielded values of complex transmission coefficients which enable determination of the complex dielectric function in the 0.3 - 2 THz range, corresponding to the in-plane complex conductivities of these materials. We will also discuss results of non-normally incident transmission measurements varying s and p THz polarization to probe the differences in ligand-mediated out-of-plane transport between these layered perovskites, as well as results of density functional theory calculations. This work expands on the utility of oblique incidence terahertz experiments which are rarely implemented for complex parameter extraction in uniaxial thin films. Furthermore, these results underscore the potential for THz spectroscopy to probe fundamental charge transport phenomena in complex photovoltaic materials with layered structures.

Controlling Halide Anion Diffusion in Perovskite Heterojunction with the Dimension of Vacuum Evaporated Perovskites Sang-Hyun Chin, Lorenzo Mardegan, Francisco Palazon, Michele Sessolo and Henk J. Bolink; University of Valencia, Spain

Halide perovskite has been investigated intensively as an attractive candidate for some optoelectronic applications such as solar cells, light-emitting diodes, lasers and photodetectors. Especially, the sharp and easily changeable emission with halide anion exchange make this material group even more attractive for the light-emitting applications. Among this material group, inorganic 3D $CsPbX_3$ (X: Cl^-, Br^-, I^-) semiconductors produce 0D Cs_4PbX_6 insulators in specific conditions. This can be easily done with vacuum co-evaporation with excess CsX. In this regard, we investigate the anion diffusion and emission property of the halide perovskite. These heterojunctions are electrically excited between two electrodes as the light-emitting electrochemical cells (LECs), as a proof-of-concept application. With this simplified structure, the optoelectronic property can be explored without the effects from any charge transport layer. Herein we demonstrate different behavior of anion diffusion depending on the dimension of vacuum co-evaporated cesium lead chloride.

12:15 PM EN08.13.07
Evaluation of Structure and Optoelectrical Properties of Copper Halide Perovskite Films Yuki Matsui, Keitaro Kikuchi, Tomohiro Watanuki and Hironori Ogata; Hosei university, Japan

In recent years, lead halide perovskite solar cells(PSCs) have been attracting attention as the next generation of solar cells because they can be fabricated by the solution process and their high energy conversion efficiency. On the other hand, the lead halide perovskite compounds that constitutes PSCs have problems of instability and toxicity under various conditions. In recent years, researches on solar cells using a copper halide perovskite compounds as a photoactive layer in which Pb is replaced with Cu, which has low toxicity, have been reported. It has been reported that copper halide perovskite compounds have a high absorption coefficient and high charge mobility depending on the compound. However, a solar cell using them has a conversion efficiency of about 2%, and it has been pointed out that further improvement including selection of the compound is necessary.
We have systematically investigated the effects of cation and halide ion types of copper halide perovskite compound films on the stability, morphology and optical properties under various conditions. In this presentation, we will report the detailed experimental results on the electronic characteristics of these thin films and the characteristics of solar cells.
In order to solve these problems, research has been conducted on perovskite compounds in which the Pb at the B site is replaced by Cu, which is less toxic. The Cu-based perovskites have been reported to have high absorption coefficient and charge mobility depending on the compound. However, the conversion efficiency of solar cells using Cu-based perovskite compounds as the photoactive layer is only about 2 %, indicating the need for further improvement, including the selection of compounds.
In this study, we prepared thin films of (C6H5CH2NH3)2CuX4 by changing the X site of the perovskite layer and investigated the application of the compound. The optical band gap energies obtained from the optical absorption spectra are 2.03 eV for (C6H5CH2NH3)2Cu Br4 and 2.05 eV for (C6H5CH2NH3)2Cu Cl4. Both compounds were found to be highly stable in air. The detailed physical properties of the films will be reported in the day.

SESSION EN08.14: Heterostructures, Properties and Applications of Low Dimensional Perovskites

1:00 PM *EN08.14.01
Luminescence from Low-Dimensional Perovskites—From Photophysics to Devices Samuel D. Stranks; University of Cambridge, United Kingdom

Halide perovskites have opened up a new world of semiconductors that can be processed crudely yet exhibit exceptional optoelectronic performance. Their performance has continued to improve not just in photovoltaic configurations, but also in light-emitting diodes (LEDs) and quantum technologies. While the bulk majority of work over the last decade has focused on 3D halide perovskite materials, there is a vast family of perovskites of different dimensions, for example 2D and quasi-2D layered structures in both bulk and nanostructured forms, which can show modular, tunable and high-quality performance.

Here I will present recent progress on synthesis, understanding and device development of several low-dimensional halide perovskite systems. First, I will show results using local time-resolved luminescence measurements to track exciton diffusion in low-dimensional 2D halide perovskite flakes, revealing how the local energy landscape can drive long-range exciton diffusion on the order of hundreds of nanometres. I will show how we can controllably monitor the growth of 2D/3D lead-tin bulk films, and control energy transfer between the different species in the subsequently tailored films. Finally, I will demonstrate the use of low-dimensional perovskites in efficient light emission systems towards white light applications, including in LED device configurations.

1:30 PM EN08.14.04
A Study on the Phase Formation Behavior of 2D Layered Perovskites and Low-Dimensional Hybrids Containing Oligothiophene Derivatives Wouter Van Gompel[1], Paul-Henry Denis[1], Martijn Mertens[1], Kristof Van Hecke[2], Laurence Lutsen[3,1] and Dirk Vanderzande[1,3]; [1]Universiteit Hasselt, Belgium; [2]Ghent University, Belgium; [3]imec, Belgium

2D layered hybrid perovskites are receiving increased attention as active materials for use in various optoelectronic applications, including solar cells, light-emitting diodes, photodetectors, and transistors. Understanding the phase formation behavior of these materials is crucial for their use in optoelectronic devices since different crystal phases possess different optical and electronic properties. The design rules to obtain the desired 2D layered perovskite crystal phase have not been fully determined yet.

For this study, we explored the formation of 2D layered perovskites and low-dimensional hybrids containing oligothiophene derivatives in the organic layer. On the one hand, we varied the number of thiophene rings in the oligothiophene. On the other hand, we varied the halide that is used. We studied the formation of the hybrids in thin films as well as through crystal growth methods.

For the series of lead iodide hybrids, we show that the use of two different processing methods (spin-coating or drop-casting) leads to the formation of two different crystal phases for bithiophene, terthiophene, and quaterthiophene propylammonium cations. One of these phases corresponds to the typical 2D layered perovskite, while the other phase has optical properties corresponding to a dimensionality intermediate between typical 2D and 1D hybrids.

For the bithiophene propylammonium cation, we varied the halide that is used. The crystal structure and phase behavior of the 2D layered perovskites were studied in detail. It is suggested that *via* halide substitution from iodide to bromide to chloride, the molecular degrees of freedom of the bithiophene cations are reduced by spatial confinement due to a smaller inorganic framework. In this way, the formation of lower-dimensional hybrids besides the targeted 2D layered perovskite is limited.

1:45 PM EN08.14.06
Plasmonic Nanocavity Enhanced Luminescence of 2D Ruddlesden Popper Perovskite Thin Film Yashika Gupta, Anuj K. Singh, Abhay A. VS and Anshuman Kumar; Indian Institute of Technology Bombay, India

2D Ruddlesden Popper perovskites are considered potential candidates for next generation optoelectronic devices due to their favourable properties like large excitonic binding energy, superior stability and structural tunability as compared to 3D perovskites[1,2]. The strong quantum and dielectric effects

arising due to the layered structure of these materials offer easy modulation of band-gap in the entire visible spectra, establishing great prospects in laser and light emitting applications. While the quantum confinement effects are stronger in lower dimensional Ruddlesden Popper perovskites resulting in narrow emission linewidth, these perovskites suffer from low intrinsic photoluminescence quantum yield (PLQY), which is found to be less than 1% for completely 2D perovskite thin films[3], thus hampering their optoelectronic performance. Since PL intensity has direct correlation with their emission characteristics, it is important to engineer the device to compensate for the low PLQY of perovskite emitter layer. In this work, we demonstrate a significant fluorescence enhancement can be obtained using a plasmonic nanocavity. Optical simulations based on Lumerical FDTD show a strong near field enhancement coupled with radiative decay enhancement due to Purcell factor results in around ***5-fold enhancement in PL intensity*** for a 2D BA2PbI4 perovskite thin film sandwiched between a metal layer and nanoparticle cavity.

Chirality-Induced Pseudo-Magnetization in 2D Chiral Hybrid Perovskites Eric Vetter[1], Liang Yan[2], Yuzan Xiong[3,3], Steven S.-L. Zhang[4], Zhizhi Zhang[5], Yi Li[5], Hongwei Qu[3], Manoj Jana[6], David B. Mitzi[6], Valentine Novosad[5], Axel Hoffmann[5,7], Wei Zhang[3], Wei You[2,1] and Dali Sun[1,1]; [1]North Carolina State University, United States; [2]University of North Carolina at Chapel Hill, United States; [3]Oakland University, United States; [4]Case Western Reserve University, United States; [5]Argonne National Laboratory, United States; [6]Duke University, United States; [7]University of Illinois at Urbana-Champaign, United States

The ability to generate and manipulate spin information underpins the field of spintronics, which utilizes the electron's spin degree of freedom to transfer and process information. Identifying new 2D magnetic materials empowers the direct control of spin information through the manipulation of magnetization at a low-dimensional limit. However, the Mermin–Wagner restriction induced by thermal fluctuations presents a significant barrier to this pursuit. Here, we report the observation of chirality-induced pseudo-magnetization native to a non-magnetic 2D chiral hybrid organic-inorganic perovskite (chiral-HOIP) identified by spin Hall magnetoresistance measurements. We find pronounced magnetoresistance signals persisting up to room temperature despite the lack of any magnetic elements in the hybrid structures, as well as tunable magnetic hysteretic behaviors controlled by injected spin currents. Our work paves the way for utilizing solution-processed 2D chiral hybrid perovskites in room temperature spintronic applications.

2:15 PM EN08.14.03
Lead-Free Halometallates—The Next Generation of Hybrid Photovoltaic Absorber Materials Harsh Bhatia, Bob Schroeder and Robert G. Palgrave; University College London, United Kingdom

Photovoltaics (PV) play a very key role in achieving the target of world's economic powers to achieve low or zero carbon emission based economy. The present PV market is dominated by silicon based solar cells, however, the high cost of materials have led the scientific community to look for the alternative ways to harness the sunlight. In the recent years, hybrid perovskites have emerged as a possible solar cell technology to achieve the power conversion efficiency in excess of 20%. Despite the very high efficiency due to the strong absorption coefficient, defect tolerance, and high ambipolar carrier mobility, the hybrid perovskite materials suffer from the problems of device stability, and high content of lead (Pb) which makes the commercialization of these materials a gigantic task.

In the present work we have focused on to develop highly tunable lead-free halometalates for use in hybrid solar cells.[1] The materials developed in this work can be best described as the materials between OPV and perovskites. In the present work we have used the conjugated organic molecules rather than the ammonium ions as the organic component to mimic the perovskite packing.[2] This design principle enables us to avoid lead (Pb) as the metal component in the molecule while the 3-D packing of the molecular system is maintained. The 3-D packing of the organic components lead to high charge transport properties and strong absorption in the visible region. Moreover, the inorganic post-transition metal iodides (BiI_3, SbI_3 and SnI_2)[3] have been chosen to coordinate with the organic part due to the presence of filled metal *s* states and large spin-orbit coupling which leads to small band gaps and high carrier mobility. Such inorganic-organic coordinated system lead to high tunability of optical, electronic and structural properties which can lead to efficient PV absorber materials.

4:00 PM EN08.15.01
***In Situ* Ultrafast and Nanoscale Evolution of Carrier Drift Dynamics in $CsPbI_3$ Nanocrystal Film** Kanishka Kobbekaduwa[1], Qian Zhao[2], Chendi Xie[1], Joseph Luther[2], Matthew C. Beard[2] and Jianbo Gao[1]; [1]Clemson University, United States; [2]National Renewable Energy Laboratory, United States

For solution-processing perovskite nanocrystal photonics and optoelectronics, it remains a challenge to uncover the carrier drift dynamics with an intrinsic phonon-scattering mechanism in *in-situ* devices, and within an ultrafast timescale, since the classic time-resolved photoluminescence and transient absorption spectroscopies mainly capture the carrier diffusion dynamics prior to the defect scattering mechanism. Here, we use ultrafast photocurrent spectroscopy to observe *in-situ* the band-like transport prior to carrier trapping in a $CsPbI_3$ nanocrystal array. We attribute transport to the longitudinal optical phonon scattering, while the coupling between phonon and carriers is predominant among classic polar semiconductors and similar perovskites. At room temperature, the carriers preserve band-like transport for more than 70 nm long range drift length and a mobility of more than 14 cm^2/Vs.

4:15 PM EN08.15.02
Ferroelectric and Charge Transport Properties in Strain-Engineered Two-Dimensional Lead Iodide Perovskites Dohyung Kim[1], Bogdan Dryzhakov[1], Yongtao Liu[2], Anton V. Ievlev[2], Olga Ovchinnikova[2], Bin Hu[1], Sergei V. Kalinin[2] and Mahshid Ahmadi[1]; [1]University of Tennessee, Knoxville, United States; [2]Oak Ridge National Laboratory, United States

Transitions from three-dimensional (3D) hybrid organic-inorganic perovskite (HOIP) structures to lower dimensions including 2D and quasi 2D structures opened new range of functional properties in these materials systems. Yet, the performance of solar cells made from 2D HOIP is below 3D compositions due to the higher band gap energy, low carrier concentration and anisotropy in charge transport. Controlling ferroelectricity in 2D HOIPs is considered as a powerful strategy to drive the spatial separation of photogenerated charge carriers to improve the photovoltaic action in this class of HOIPs. In this study, we reveal the strain-dependent ferroelectricity and charge carrier properties in strain-engineered 2D 4,4-difluoropiperidinium (DFPD) lead iodide or (4,4-DFPD, $C_5H_{10}F_2N)_2PbI_4$ perovskite utilizing advanced scanning probe microscopy (SPM) techniques[1]. We demonstrate crystallization- and strain-dependent thin films with different thickness prepared by drop-casting, spin-coating, and vacuum-poling treatment[1]. Band-excitation piezo-response force microscopy (BE-PFM) and contact mode Kelvin probe force microscopy (cKPFM) reveal ferroelectric domains and switchable dynamics with significantly low switching voltages in the low strain film. Photoluminescence (PL) spectroscopy shows strain-dependent optical properties and non-centrosymmetric structure with strong second harmonic generation (SHG) peaks in in the low strain film. In addition, KPFM results demonstrate a higher surface potential in the low strain films while the photovoltage and local current are the highest on the high strain film. Our study demonstrates the critical role of strain engineering on electromechanical and charge carrier dynamics in 2D HOIPs, being important for development of 2D HOIP devices. Additionally, we will present the underlying physical mechanisms of light-ferroelectricity interaction in 2D MHPs[2]. X-ray diffraction (XRD) patterns exhibit significant change in preferential orientation of individual lattice planes under external stimuli. Particularly, the reduced intensity of the (1 1 1) lattice plane under illumination leads to transitioning from a ferroelectric to paraelectric phase. The instability of organic cations is also observed under illumination by time-of-flight secondary ion mass spectrometry (ToF-SIMs). The combination of lattice variation and chemical changes under illumination clearly contribute to the origin of light-ferroelectricity interaction in 2D (4,4-DFPD, $C_5H_{10}F_2N)_2PbI_4$.

Mechanical Buckling in Thin Layer Perovskite Nanobelts of $CsPbBr_3$ Composition Yehonadav Bekenstein; Technion - Israel Institute of Technology, Israel

Flexible semiconductor materials, where structural fluctuations and transformation are tolerable and have low impact on electronic properties, focus interest for future applications. Two dimensional and thin layer lead halide perovskites are hailed for their unconventional optoelectronic features. We report a surprising structural deformation that appears in thin layer colloidal nanobelts upon their adsorption on hydrophobic carbon substrates. We show that the variations in microstructure we detect, are mechanical buckling of the nanobelts. These are determined using transmission electron microscopy (TEM), including selected orientation dark field imaging (SODFI) and tilting experiments. Atomic force near-field microscopy (SNOM-AFM) was used to correlate structure properties with 10nm resolution. By employing plate buckling theory to the data, we approximate adhesion forces between the buckled nanobelt and the substrate. The effect of the buckled perovskite crystal lattice on optoelectronic and other physical properties is still being unveiled. However, the forces and the capillary action leading to the buckling of metal-halide perovskites at the nanoscale, are critical for the design of future devices and heterostructures based on Nano-perovskites. If time permits we will show also preliminary results of spontaneous self-healing/annealing of structural defect in perovskite nanocrystals.

4:45 PM EN08.15.04
Strong Circular Dichroism in the Low-Dimensional Hybrid Perovskite $DMAPbI_3$ from Chiral Amino Acid Incorporation Markus W. Heindl[1], Natalie Fehn[1], Shangpu Liu[1], Lissa Eyre[1], Maged Abdelsamie[2], Tim Kodalle[2], Gregor Kieslich[1], Ian Sharp[1], Aras Kartouzian[1], Carolin M. Sutter-Fella[2] and Felix Deschler[1]; [1]Technische Universität München, Germany; [2]Lawrence Berkeley National Laboratory, United States

Chirality in semiconductor materials enables a number of powerful applications, reaching from consumer electronics and 3D displays to drug screening and encryption [1-3]. Recently, chiral hybrid perovskites have emerged as a promising class of materials for optoelectronic applications based on their ability to preferably absorb and emit one type of circularly polarized light. However, so far, the chiral organics used to introduce chirality into lead halide perovskites almost exclusively consist of a small group of commercially available, primary amines [1].

A textbook example for chiral molecules are the naturally occurring amino acids. These represent a diverse group of organic compounds whose application for industrial production is highly desirable as they are non-toxic, biodegradable and are available in large quantities at relatively low cost. In this work, we now introduce the chiral small organic 3-aminobutyric acid into the 1D perovskite dimethylammonium lead iodide ($DMAPbI_3$) using a simple spin-coating based approach. We find that the resulting material displays strong circular dichroism up to 400 mdeg ($g_{abs} = 17.5 \times 10^{-3}$) in the blue spectral region that is tunable in strength by adjusting the amount of amino acid introduced. We resolve the detailed structural origin of the chirality from XRD experiments of the crystal structure. We employ transient optical spectroscopy to investigate the dynamics of excited state polarization and recombination.

Our findings expand the pool of chiral hybrid materials and provide fresh impulses for future maximization of chiral effects in hybrid perovskite materials.

Equilibrium Between Bright Excitons and Polaron Plasma in 2D and 3D Metal-Halide Perovskites Angelica Simbula[1], Riccardo Pau[1,2], Fang Liu[1], Stefano Lai[1], Daniela Marongiu[1], Francesco Quochi[1], Michele Saba[1], Andrea Mura[1] and Giovanni Bongiovanni[1]; [1]Università di Cagliari, Italy; [2]University

of Groningen, Netherlands

One of the main reasons for the success of perovskite photovoltaics is the presence of free carriers as majority optical excitations in 3D materials at room temperature. To get efficient solar cells, stability and duration improving can be achieved thanks to variations in materials composition, including the use of layered 2D perovskites. However, the current understanding is that in 2D perovskites or at cryogenic temperatures insulating bound excitons form, which need to be split are not beneficial to photoconversion. Here we present a tandem spectroscopy technique, applied to several 3D and 2D hybrid perovskite thin films, that combines ultrafast time-resolved photoluminescence and differential transmission (pump and probe). Our results demonstrate a chemical equilibrium between a majority of non-emitting large polarons and a minority phase of bright excitons, even in 2D perovskites and at low temperatures. The presence of a conductive polaron plasma foresees novel mechanisms for LEDs and lasers, as well as new perspectives for 2D perovskites in photovoltaics.

SESSION EN08.16: Electronic and Optical Properties of Low Dimensional Perovskites

Defect Self-Healing in 2D and 2D-3D Lead Halide Perovskites David Cahen[1,2], Gary Hodes[1] and Sigalit Aharon[1]; [1]Weizmann Institute, Israel; [2]Bar-Ilan University, Israel

Experiments show low to ultra-low densities of optoelectronically active, static, defects in Lead Halide Perovskites, HaPs. We first present a simple logic argument that this must be because of an active reaction to damage, rather than to tolerance to damage. For 3D HaPs we and others presented evidence for self-healing,* a process that, in inanimate matter, is explained by equilibrium thermodynamics. Indeed, we argued that the main cause for such healing and the resulting low (static) defect densities is the small free energy of reaction that just stabilizes the materials against decomposition.*
Here we will show the effect of kinetics, by reporting and discussing results of studying ***single crystals*** of **2D** and **2D-3D** HaPs, and compare these to those obtained on 3D single crystals, in terms of their recovery from photodamage.

8:30 AM *EN08.16.02
Materials Engineering of Halide Perovskites—A Computational Materials Science Point of View Shuxia Tao; Eindhoven University of Technology, Netherlands

Metal halide perovskites have attracted enormous attention in the scientific community in recent years. This attention has been drawn by breakthroughs in perovskite optoelectronics, mainly in photovoltaics and LEDs. Although there has been great progress in their use in optoelectronics, fundamentally understanding this class of materials is still challenging, in particular the interplay of several physical and chemical processes. Many fundamental questions are left unanswered, such as what makes them unique/excellent semiconductors; how to tune their optoelectronic properties; why some compositions are more stable than others; the consequence of their chemical instability on their optoelectronic properties; and how to stabilize them.

My research group focuses on addressing such questions using computer simulations, combining DFT calculations and MD simulations to go from the atomistic scale to molecular scale. In this talk, I will highlight our recent progress on improving the stability of this class of materials by composition engineering, the use of additives, ect. I will also give an outlook of our materials engineering strategies for going from 3D systems to systems with lower dimensions.

9:00 AM EN08.16.03
Structural Dynamics of the 2D-on-3D Pb Halide Perovskite Interface Revealed by Ultra-Low Fluence STEM Sujit Kumar[1,2], Lothar Houben[2], Katya Rechav[2] and David Cahen[1,2]; [1]Bar-Ilan University, Israel; [2]Weizmann Inst. of Science, Israel

To minimize surface reactivity, defects and the possibility of water and O_2 absorption of/by 3D metal Halide Perovskites (HaPs), covering them with an ultra-thin layer of hydrophobic 2D HaP has been reported to be beneficial. At the same time the stability of a 2D-on-3D HaP composite has been questioned, especially based on results from GI-XRD and PL studies. The question of what is happening on an atomic scale is a vexing one, if higher stability is the goal. It is also a fascinating one because of the dynamic nature of the lattices, which, for 3D HaPs at times seems to approach, from the literature, "*panta rhei*" i.e., everything flows. We studied the 2D-on-3D HaP composite by TEM-based methods, using FIB-prepared cross-sections of films; the films were prepared by a new controlled gas-phase cation exchange process of the top layer of a spin-coated 3D $MAPbI_3$ film and characterized by GI-XRD and PL. The 2D HaP was the n=1 Ruddlesden-Popper (F)PEA_2PbI_4, where PEA = phenyl-ethylamine and F-PEA, its mono-fluorinated derivative. All through the study we strove to minimize electron and ion fluences, often below what could be deduced from fluences reported in other works. The results allow us to follow the effects of beam damage and thus to determine conditions of measurement before that stage. We used 4D-STEM and scanning nanobeam electron diffraction (NBED), on relatively fresh and aged (all in inert atmosphere) samples. We find direct evidence for the 2D n=1 phase appearing inside the 3D matrix and also for the formation of quasi-2D phases near the interface with the carbon coat. The results imply 2D/3D perovskite heterointerface lattice rearrangements involving migration of not only (the smaller) MA^+, but also of (the larger) $FPEA^+$ cation. As PEA was found too labile for controlled measurements F-PEA was used to be able to get clear "before" and "after" results and measure actual structural evolution under the beam, which primarily shows the loss of long-range periodicity as well structural rearrangements, leading to quasi-2D phase formation. Our results complement extensive empirical and semi-empirical data to engineer stable 2D-on-3D composites and define conditions for atomic resolution studies of real 2D/3D samples in device-relevant configurations.

Post-Synthetic Transformation of Zero-Dimensional Perovskite Nanocrystals Hanjun Yang, Tong Cai, Lacie Dube, Katie Hills-Kimball and Ou Chen; Brown University, United States

The synthesis of perovskite nanocrystals (NCs) and the control of their composition and morphology is critical to tuning their optical and electronic properties. Beyond direct synthesis methods, in recent years the indirect synthesis of perovskite NCs based on the post-synthetic transformation reactions

of zero-dimensional perovskite NCs has been developed to fine-tune the nucleation and growth of NCs. Herein, we report two examples of the transformation reaction of 0D perovskite NCs to obtain perovskite NCs with uniform morphology, and well-defined crystal structure. Firstly we present the synthesis of ultra-thin $CsPbBr_3$ NWs through the reaction between $PbBr_2$ and Cs_4PbBr_6 0D perovskite NCs. The synthesized $CsPbBr_3$ NWs averaged 2.5 nm in width and tens of micrometers in length, and show blue photoluminescence (PL) with a quantum yield of 15%. We tentative attribute the formation mechanism of $CsPbBr_3$ NWs to the formation of the $PbBr_2$-ligand intermediates, whose structure and be controlled by the length of organic ligands. We further expand this reaction scheme to the synthesis of $CsPbI_3$ NCs with a low-dimensional morphology. Secondly, we present a versatile synthesis technique of bismuth-based perovskites based on the Cs_3BiX_6 (X = Cl, Br) NCs. Both Cs_2AgBiX_6 double perovskite nanocubes and $Cs_4MBi_2Cl_{12}$ (M = Cl, Br) layered double perovskite NCs were obtained in this manner. Furthermore, we found the intermediates during the transformation of Cs_3BiCl_6 to $Cs_2AgBiCl_6$ double perovskite NCs showed a red-shifted PL at 770 nm with enhanced PL intensity, which was tentatively attributed to the passivation of Cs cation in the $Cs_2(Cs_{1-xAgx})BiCl_6$ NC and the large lattice deformation leading to the formation of self-trapped exciton with large trapping energy. Our works provide methods to tune the morphology and composition of perovskite NCs and give insights into the chemical activity of 0D perovskite NCs.

9:30 AM EN08.16.05
Accessing Oriented, Phase-Pure Ruddlesden-Popper Perovskite Films Through Additive-Assisted Processing Shripathi Ramakrishnan, Hao Li, Yuanze Xu, Dongyoon Shin and Qiuming Yu; Cornell University, United States

Low-dimensional Ruddlesden-Popper (RP) perovskites have steadily risen to prominence as stable and efficient photovoltaic materials for solar cell applications due to enhanced structure stability and reduced moisture intrusion in comparison to standard 3D perovskites. However, thin-films processed from stoichiometric 2D precursor solutions tend to possess polydisperse distribution of different number of inorganic layers with the organic dielectric layers behaving as charge transport inhibitors with large binding energies, crippling device performance. Precise processing and composition engineering is necessary to accurately control nucleation and crystallization events to fabricate 2D RP perovskite films of high phase purity devoid of 3D mixtures. Perpendicular crystallographic growth is equally desirable to achieve fluent charge transport along charge collection direction.
In this work, we fabricated 2D RP perovskites $(PEA)_2(MA)_4Pb_5I_{16}$ (Nominal *n*-value = 5) using anti-solvent and hot-casting methods with different combinations of processing additives to improve the vertical orientation and reduce polydispersity of low *n* 2D RP phases and 3D phase. The critical influence of drip-time on phase-distribution and crystal growth was revealed during the application of toluene as anti-solvent with methylammonium chloride (MACl, MACl/MAI = 0.5 mol ratio) as additive. Earlier drip times during spin-coating resulted in greater density of 2D and 3D-like phases, while later times yielded a narrow distribution of vertically oriented polydisperse high *n*-value 2D phases (*n* = 3, 4, and 5) and no 3D phase, confirmed by UV-Vis absorption spectral and XRD study of thin films and EQE measurements of devices. Fine-tuning the anti-solvent discharge time and phase control afforded inverted solar cells of ITO/PEDOT:PSS/$(PEA)_2(MA)_4Pb_5I_{16}$/$PC_{61}BM$/BCP/Ag with PCEs up to 8.51%.
Hot-casting was found to yield RP perovskite films (MACl/MAI = 0.5 mol ratio) with dramatically increased crystallinity and “perfect” perpendicular orientation compared to anti-solvent method. Substrate temperature was found to have a strong impact on the phase distribution and orientation, with sub-optimal heating resulting in high degree of polydispersity and poor crystallinity. Hot-cast films exhibited higher PCE values up to 10.7% owing to improved FF and V_{oc} whilst maintaining an identical EQE profile to anti-solvent treated devices having pure 2D phases.
Thin-films of $(PEA)_2(MA)_4Pb_5I_{16}$ with different concentrations of MACl and NH_4Cl additives were fabricated to understand whether the absence of 3D-character was due to the crystallisation rate, presence of excess $[MA^+]$ or Cl^-. It was found that NH_4Cl additive induced drastically enhanced crystal growth along [111] and [202] planes and formed smooth films with low pinhole density upon hot-casting compared to the MACl additive. However, thin films prepared with NH_4Cl additive displayed a broader distribution of 2D phases with *n* ranging from 1 to 5 and 3D character. Furthermore, devices with the thin films prepared by adding NH_4Cl additive exhibited lower PCEs of 6.1% upon hot-casting, despite favourable orientation, thus demonstrating the benefit of phase purity with large n values. These results will be augmented with Transient Absorption Spectroscopy (TAS) to probe the energy transfer mechanism of graded structure of the polydisperse perovskite and Grazing-Incidence Wide Angle Scattering (GIWAXS) to underpin the time-resolved structural evolution of 2D RP perovskites and quantify individual phases.
This mechanisms on orientational control and fine-tuning the phase distribution of 2D RP phases via adding additives and controlling nucleation and crystallization kinetics as well as how these effects are reflected by photophysical properties of solar cells will be discussed.

SESSION EN08.17: Optoelectronic Applications of Low Dimensional Perovskites

Hybrid Perovskite Quantum Dots for High Efficiency Solar Cells Lianzhou Wang; University of Queensland, Australia

Perovskite quantum dots (QDs) have the advantages of quantum confinement effect, defect-tolerant nature, and the capability of developing lightweight and flexible films, thus attracting much recent research for a variety of functional device developments including QD solar cells and LEDs. Here we report our recent progress on a novel surface ligand engineering strategy in designing new hybrid perovskite QDs, which leads to not only fundamental understanding on the optoelectronic working mechanism of the QDs, but also remarkably improve the optoelectronic quality of the perovskite QDs. The new classes of perovskite quantum dots have been used as building blocks in Quantum Dot Solar Cells with a certified record efficiency of 16.6% with excellent long-term operation stability. By using QDs as light absorbing materials, the QD based photocatalysts also exhibited good performance in photocatalytic gaseous hydrogen production.

Understanding the Synthesis, Structure and Physics of Hybrid 2D Perovskites for Efficient Optoelectronics Jean-Christophe Blancon; Rice University, United States

Organic-inorganic two-dimensional halide perovskites (2DPKs) are soft semiconductors formed by combining organic and inorganic moieties, which self-assemble in solution to form highly ordered periodic stacks. They exhibit a large compositional and structural phase space, which has led to novel and emergent physical properties offering potential for applications in optoelectronics, energy conversion, photonics, spintronics, and quantum devices. To achieve this paradigm, there is a need to understand both the fundamental physics and the growth of both 2DPK crystals and thin films used for integration in devices. In this presentation, I will describe three exciting results.
First we overcome a long-standing challenge in 2D perovskites of realizing phase pure thin-films. Briefly, we demonstrate a scalable approach involving dissolution of single-phase crystalline powders with homogeneous perovskite layer thickness in desired solvents, to fabricate 2D perovskite thin-films with

high phase purity. In-situ characterizations reveal the presence of sub-micron-sized seeds in solution that preserve the memory of the dissolved single-crystals, and dictates nucleation and growth of grains with identical layer thickness of the perovskite layers in thin-films. Photovoltaic devices fabricated with such films yield an efficiency of 17.1% and 1.20V open-circuit voltage, while preserving 97.5% of their peak-performance after 800 hours under illumination without any external thermal management.
Second, we report sunlight-activated anisotropic lattice contraction in 2DPKs, which is reversible and strongly dependent on both the nature of the interlayer organics and the details of the structure. Our theory suggests that light-generated charge accumulation results in the build-up of a bulk compressive strain, which induces a continuous lattice contraction over minutes. In-situ structural measurements on photovoltaic devices directly correlate the light-induced lattice contraction to an increase in the photovoltaic efficiency of Dion-Jacobson 2DPK solar cells from 15.6% to 18.3%. We found that compressive strain enhances inter-layer electronic interactions in 2DPKs leading to three-fold increase in carrier mobility and conductivity in 2DPK thin films.
Third, we employed ultrafast electron diffraction (UED) to capture at the picosecond time scale how light generated hot carriers dissipate their energy to the lattice and affect the 2DPK structure. The carrier cooling dynamic in 2DPKs yields a fast lattice re-ordering that is distinct from 3DPKs, followed by classic slow thermal dissipation of carriers excess energy to the lattice. The former process suggests the light-induced activation of an incipient phase transition, toward a hypothetical undistorted phase due charge-lattice interactions. The effect of anisotropy and the nature of the bulky organic cations were also confirmed to play a role in tailoring carrier-phonon interactions.

11:30 AM EN08.17.03
SnPb Perovskite Solar Cell Exceeding 18% Efficiency with a 1-cm^2 Cell Fabricated Using a One-Step Meniscus Coating Method at a Speed of over 5 m/min Shunsuke Shimo[1], Shigehiko Mori[1], Haruhi Oooka[1], Akio Amano[1], Gaurav Kapil[2], Shuzi Hayase[2] and Kenji Todori[1]; [1]Toshiba Corporation, Japan; [2]The University of Electro-Communications, Japan

Perovskite solar cells (PSCs) are one of the most promising candidates for the next generation of solar cells because they have high power conversion efficiency (PCE) exceeding 20% and they can be manufactured by a high-productivity fabrication process involving low-temperature processing and a roll-to-roll coating method. To meet the growing demand for renewable energy generation, it is necessary to mass-produce solar cells with high PCE at low cost. The PCE limit of $MAPbI_3$ (MA: methylammonium), which is a typical perovskite material, is 31% based on the Shockley-Queisser (S-Q) limit due to its band gap of 1.55 eV. It is thought that the maximum theoretical PCE of a material can be achieved at a band gap of around 1.1-1.4 eV and that a SnPb iodide perovskite compound is a suitable candidate for realizing the maximum PCE value of 33% based on its S-Q limit. In addition, SnPb PSCs are relatively environmentally friendly because they require far less Pb compared with Pb-based PSCs. Studies of SnPb PSCs have been increasing and PCEs exceeding 20% have been reported recently [1]. However, many of these SnPb PSCs are millimeter-scale cells fabricated using spin-coating method. Thus, it is necessary to find a way to manufacture SnPb PSCs with larger areas in a more highly productive manner.
To realize large-area coating, we have been developing the “meniscus coating method” [2,3], which is capable of producing uniform layers with low variations in thickness over a large area. By using this coating method in $MAPbI_3$-based PSCs, we have achieved a PCE of 14.1% in a polymer film module with an active area of 703 cm^2, and 16.1% with an active area of 781 cm^2 in a glass-based module [4]. Accordingly, we expect to realize high-productivity fabrication of SnPb PSCs by utilizing a roll-to-roll process and applying the meniscus coating method.
In this study, we developed the meniscus coating method for a SnPb perovskite layer. This coating realizes high productivity via the 1-step process at a speed of over 5 m/min. In addition, by employing the equimolar constitution of Sn and Pb (Sn:Pb = 1:1), a band gap of around 1.2 eV was realized in the SnPb perovskite layer. We also examined the surface passivation of the SnPb perovskite layer and found a PCE of 18.3% in a 1-cm^2 cell of the SnPb PSC having an inverted structure (ITO/hole transport layer/SnPb perovskite layer/PCBM/BCP/Ag).

Paetzold[1,1]; [1]Karlsruhe Institute of Technology, Germany; [2]Max Planck Institute for Polymer Research, Germany; [3]Technical University of Darmstadt, Germany; [4]The Australian National University, Australia; [5]Universitat Jaume I, Spain

While power conversion efficiencies of perovskite solar cells using the standard (n-i-p) mesoporous and planar architecture have surpassed 24% some time ago, inverted (p-i-n) planar PSCs lag behind considerably. Severe non-radiative interfacial recombination at the perovskite/electron transport layer and at the grain boundaries still limits their open-circuit voltage (V_{OC}) and fill factor (FF) as compared to their n-i-p counterparts. Particularly for next generation monolithic perovskite/Si tandem photovoltaics, which commonly apply a p-i-n perovskite top solar cell, these recombination processes introduce a conceptual hurdle.
To address this challenge, we introduce a novel dual 2D/3D perovskite heterostructure passivation approach by adding phenethylammonium chloride (PEACl) to our methylammonium-free double cation p-i-n perovskite solar cell. Using PEACl:$PbCl_2$ as the additive and PEACl for surface treatment, our approach simultaneously passivates recombination centers at the grain boundaries in the bulk of the perovskite film and recombination centers at the perovskite/C_{60} interface, respectively. The dual 2D/3D heterostructure passivation results in one of the highest reported PCEs for *p-i-n* PSCs of 22.7% with a remarkable V_{OC} and FF of 1.162 V (E_g = 1.57 eV) and 83.2%, respectively. Furthermore, a remarkable stabilized efficiency of 22.3% is demonstrated (5 min at maximum power point tracking), one of the highest reported for MA-free p-i-n PSCs.

Our study researches the advanced use of dual passivation as a key mechanism to manage the detrimental defects both in the grain boundaries and at the perovskite/ETL interface to achieve highly efficient p-i-n PSCs. By means of time resolved photoluminescence and photoluminescence quantum yield, we show that the charge carrier lifetime and quasi-Fermi level splitting are significantly enhanced compared to reference devices. We attribute the improvements to the formation of a 2D Ruddlesden Popper perovskite phase at the film surface and GBs, which leads to efficient chemical passivation of GB and surface defects as well as additional electronic passivation at the perovskite/C_{60} interface. At the same time, the activation energy for ion migration is significantly increased, resulting in enhanced stability of the PSCs under light, humidity, and thermal stress.

Efficient and Stable Two-Dimensional Ruddlesden–Popper Tin Perovskite Solar Cells via Anion Engineering Hao Li, Shripathi Ramakrishnan, Yuanze Xu, Tony L. Xu and Qiuming Yu; Cornell University, United States

Two-dimensional (2D) Ruddlesden–Popper (RP) phase hybrid perovskites have since received a lot of attention as one of the most promising materials for making long-term, stable, high-performance perovskite solar cells (PSCs). The presence of big ammonium cations, such as butylammonium (BA) and phenylethylammonium (PEA), in a 2D or mixed 2D and three-dimensional (3D) structure has recently been shown to limit moisture infiltration at the boundaries of Sn-based perovskites, resulting in exceptional high film and device stability.[1] However, even when synthesized with stoichiometric concentrations of precursors, solution processed 2D tin perovskites still exhibit a mixed 2D phase with varying number of inorganic frameworks that is a signal for spreading of the quantum well (QW) width, inhibiting charge transport, increasing interfacial charge accumulation and affecting final device performance.[2,3] Therefore, it is highly desired to control the QW width into an extremely small distribution and optimize the charge-transport characteristic. In this study, we fabricated 2D RP phase tin perovskite $PEA_2FA_{n-1}Sn_nI_{3n+1}$ thin films with targeted $n = 5$, because of their suitable bandgaps for solar cells, using phenylethylammonium acetate (PEAAc) instead of commonly used PEAI. It is highly expected that compounds with a uniformly distributed intermediate phase in precursors will result in narrower distributed QW width and higher film and device stability due to the strong coordination effect between Ac^- group and Sn^{2+}. The precursor solution prepared from PEAAc has a narrower size distribution and better stability than the solution prepared from PEAI, ensuring the uniform and narrower distribution of QW width and better stability of the thin films prepared via one-step plus anti-solvent solution process. Fourier transform infrared (FTIR) spectra reveal the coordination interaction between Ac^- group and Sn^{2+} via the C=O bond vibration shift in the thin film. In addition, X-ray diffraction (XRD) patterns and UV-vis absorption spectra demonstrate that the films have reduced the amount of small *n* number of 2D perovskites, which is preferred for device charge transport. The orientation of 2D perovskites and QW distribution are studied by grazing incidence wide-angle X-ray scattering (GIWAXS) and femtosecond transient absorption (TA) measurements. In comparison to standard organic spacers PEAI, the photovoltaic performance for the devices made under optimal conditions using PEAAc has a best power conversion efficiency (PCE) of over 9% with no hysteresis using a device structure of ITO/PEDOT:PSS/2D tin perovskite/ICBA/Ag. This is among the highest efficiency for 2D tin perovskite solar cells. This work demonstrates that anion in large organic spacers could play a critical role in forming a narrower distribution of QW, enhancing phase and device stability, and improving device performance. Therefore, anion engineering has the potential to aid in the further development of solar cells, photodetectors, and LEDs utilizing 2D perovskites.

Ion-Assisted Ligand Exchange for Enhanced Electronic Coupling in $FAPbI_3$ Perovskite Quantum Dot Solar Cells Yuanze Xu, Hao Li, Shripathi Ramakrishnan and Qiuming Yu; Cornell University, United States

Colloidal lead halide perovskite quantum dot (QD) has emerged as a promising material for next generation optoelectronic devices due to its unique properties, such as quantum confinement effect, high photoluminescence quantum yield, defect tolerance, and multiexciton generation. For photovoltaic applications, native insulating ligands on QD surfaces need to be removed to achieve strong electronic coupling of adjacent QDs. Unlike metal chalcogenide QDs, the ionic crystalline structure of perovskite is susceptible to decomposition under polar solvents and harsh ligand exchange conditions. Therefore, fundamental insights are needed to establish a mild ligand exchange method to gently modify surface ligand density without causing decomposition. Among the choices of solvents, methyl acetate (MeOAc) strikes to have the moderate polarity to remove surface ligands without decomposing the QDs. However, how inter-QD coupling can be improved during ligand exchange has not been well understood and developed. Here, we report an ion-assisted ligand exchange strategy that enhances the electronic coupling and prevents defect formation in $FAPbI_3$ QD films for perovskite QD solar cells. We synthesized $FAPbI_3$ QDs with hot injection method, followed by a series of purification steps. An average QD size of 12 nm with narrow size distribution was measured from TEM images. UV-Vis absorption spectra of QD solutions show an absorption edge of 775 nm and photoluminescence emission spectra show a peak at 785 nm. Iterative spin coating steps were applied to stack QD films to reach ~300 nm thickness. To conduct the solid-state ligand exchange, spin coated QD films after each spin coating step were dipped into MeOAc solutions, in which acetate salts with different cations (FA^+, GA^+, PEA^+, Pb^{2+}) were added to manipulate ligand exchange capability and suppress defect formation. Acetate, with a higher affinity to Pb^{2+} than oleate, can accelerate the removal of oleate. In addition, it can fill the X-site vacancy and therefore prevent the migration of iodide ions. The cations can fill the vacancies cause by removal of oleylammonium (A-site) and Pb-oleate complex (B-site). The ligand exchange reaction rates with different acetate salts were estimated from the intensity change of the vibrational mode in FTIR spectra and compared. SEM images show that the packing of QDs become more compact after ligand exchange while smooth film surfaces are retained. A slight redshift was observed from photoluminescence emission spectra, verifying successful inter-QD coupling. XRD confirms that no phase transitions happened during ligand exchange, indicating the preservation of nanocrystalline structure. The coupled film exhibits a long PL lifetime because of suppressed trap formation. We fabricated QD solar cells with the structure of ITO/PEDOT:PSS/$FAPbI_3$ QD/PCBM/BCP/Ag. Consequently, all the acetate salts contributed to a significant improvement of J_{SC}, and fill factors were maintained above 75%. The improved J_{SC} was attributed to a net reduction of insulating ligands due to stronger ligand exchange effect of acetate. Except FAOAc-MeOAc, all other acetate salts MeOAc treatments led to increased V_{OC} because of suppressed trap formation. Charge carrier mobilities were measured with electron-/hole-only devices. Light intensity dependent J-V measurements were conducted to investigate the charge recombination mechanisms. This work demonstrates a more reliable solid-state ligand exchange strategy, which enhances the electronic coupling and prevents defect formation in $FAPbI_3$ QD films, and sheds light on the roles of ions in solid-state ligand exchange.

1:00 PM EN08.18.01
Photoinduced Iodide Repulsion and Halides-Demixing in Layered Perovskites Yongtao Liu[1], Miaosheng Wang[2], Anton V. Ievlev[1], Mahshid Ahmadi[2], Bin Hu[2] and Olga Ovchinnikova[1]; [1]Oak Ridge National Laboratory, United States; [2]The University of Tennessee, Knoxville, United States

Mixing halides in metal halide perovskites (MHPs) is an effective approach to adjust MHPs bandgap for applications in tandem solar cells. However, mixed-halide (MH-) MHPs undergo light-induced-phase-segregation (LIPS) under continuous illumination. Therefore, understanding the mechanism of LIPS is necessary for developing stable MH-MHPs. In this work, we investigated LIPS in layered (L)-MHPs, unveiling that spacer cation plays a crucial effect on LIPS. Our chemical characterization of LIPS in L-MHPs revealed an iodide-repulsion effect and consequently the formation of pure-Br-phase or extremely Br-rich phase in the illuminated region, where iodide repulsion is dependent on light intensity and chemical environment (e.g., oxygen penetration into MHPs affect iodide repulsion process). By further probing chemical changes in a MAPb(Br0.5I0.5)3 film under illumination, we observed, in addition to the formation of I-rich and Br-rich domains (that is a generally believed mechanism of LIPS), LIPS also leads to a significant vertical chemical redistribution, which is critical to charge carrier transport and extraction in MHPs devices. Moreover, we discovered that LIPS is more significant in the bulk of the MHP film, which is probably due to a large population of photogenerated charge carriers in the bulk. Overall, by directly characterizing chemical changes due to LIPS, we revealed the chemical changes associated with LIPS in MHPs, which is the key for understanding LIPS mechanism and developing stable mixed-halides MHPs. Our studies about the role of spacer cation in LIPS and extrinsic ion penetration also offers insight into improving the stability of MHPs.

Thermodynamically Stable Colloidal Solids—Interface Energetics from Particle Size Distributions Andrew Nelson and Lawrence Friedman; National Institute of Standards and Technology, United States

The thermodynamics of interfaces, encapsulated in the parameter of the work of interface formation, dictate the stability and evolution of suspensions, gels, emulsions, and many other dispersed systems. In particular, it is one of the main axes along which workers engineer the properties, especially size and shape, of colloidal nanoparticles. A widespread assumption is that such colloidal solutions are never thermodynamically stable: they will tend to aggregate, ripen, or coarsen, limiting their performance and long-term usefulness. This need not be the case, however, and truly stable solid colloidal systems have been contemplated or even proposed for many decades. We build on this work using the framework of classical nucleation theory for colloidal solids, from which a simple expression for the size distribution depending on the concentration of the particle components and the interface energy can be obtained. The need for a statistical-mechanical model describing the particle degrees of freedom hints that colloidal solutions could serve as tests of this contentious part of nucleation theory. Conversely, an experimentally measurable size distribution corresponds directly to a size-dependent interface energy, and thus thermodynamically stable colloids are probes of solid-solution interactions at nanoscopic dimensions. We invert this relation to examine previous data sets from colloidal nanoparticles, and suggest that, from the apparent dependence of interface energy on size, the mechanism of colloid stabilization may be more complex than one of those already proposed, e.g. interface bending energy or dielectric charging. We conclude with a note of caution, however, that so far it remains to be demonstrated conclusively that the systems considered in our work are really thermodynamically stable with a definite place in a multicomponent phase diagram.

Imaging Organic Cations Interfacial Passivation of Inverted Perovskite Solar Cells Stefania Cacovich[1], Guillaume Vidon[2], Laxman Gouda[3], Matteo Degani[3], Jean Rousset[4], Jean-Baptiste Puel[4], Marie Legrand[4], Jean-François Guillemoles[1], Daniel Ory[4] and Giulia Grancini[3]; [1]CNRS IPVF UMR 9006, France; [2]IPVF (Institut Photovoltaïque d'Île-de-France), France; [3]University of Pavia, Italy; [4]Électricité de France (EDF), R&D, France

Inverted perovskite solar cells passivated *via* organic cations exhibit superior power conversion efficiency compared to unpassivated ones. These record efficiencies have been reached thanks to the use of large organic cations to passivate the interface between the perovskite absorber and the transport layers. However, the passivation mechanism of 2D perovskites on top of the 3D bulk absorber layer is still under intense debate in the community. In particular, issues regarding the complete coverage of the passivating layer, the full formation of a 2D layer on top of the 3D bulk perovskite and the possible effects on carrier extractions still need to be clarified. Here, we study the optoelectronic properties and chemical structure of interface doped perovskite solar cells where large cations, namely Cl-PEAI and F-PEAI, were incorporated at both front and rear interfaces of the absorber. The effect of the cation addition led to an increase of all the main PV characteristic, reaching PCE values up to 23.7%. We combined steady-state and time-resolved multidimensional photoluminescence imaging techniques to probe the main optoelectronic and transport properties of such devices. We thus obtained quantitative maps for physical parameters such as Quasi Fermi Level Splitting (QFLS), Urbach Energy and surface recombination rate, which proved a homogenous passivation by Cl-PEAI and F-PEAI cations over the 3D surface. Moreover, we identified interfacial passivation as the main mechanism leading to a clear improvement of the Voc which increases from 1.10 to 1.16 eV on full devices, whereas the addition of the cations on bare perovskite thin films resulted into an increase of the QLFS in the range of 0.01 -0.02 eV. Complementary Raman analyses proved that passivation effect and deeper interaction of delocalised $\prod$ - electron from the F-PEAI and Cl-PEAI with the Pb-I perovskite octahedral are cause for the enhanced thermal fluctuation and formation of large polaron in the perovskite lattice. These passivation effect induces structural deformation which are the main responsible phenomena for the observed delayed carrier recombination and increased photovoltaic performance. By linking optical and electrical measurements we highlight the benefits of this passivation method in maximising all the main photovoltaic characteristics and in approaching inverted perovskite solar cell theoretical limit.

Structural Control and Evaluation of Bismuth-Based Mixed Perovskite Films for Optoelectronic Applications Keitaro Kikuchi, Yuki Matsui, Tomohiro Watanuki and Hironori Ogata; Hosei University, Japan

In recent years, lead halide perovskite solar cells, which have been attracting attention as next-generation solar cells, have an energy conversion efficiency of over 25% and are expected to be practical use in the near future. However, the lead halide perovskite compounds contains lead, which is harmful to the human body and the environment, and is an issue for practical use.
Many studies have been reported on solar cells using perovskite compounds based on tin, germanium, bismuth, etc., which are less toxic than lead. Among them, research on solar cells using bismuth halide perovskite($Ca_3Bi_2I_9$) has been actively conducted and it has been reported that the energy conversion efficiency(PCE) is 3.20 %.
In this study, for the purpose of developing high-quality films applicable to optoelectric applications with adjusted band gap energy in $A_3Bi_2X_9$ compound semiconductors, we fabricated mixed bismuth halide perovskite films with various chemical compositions. Crystal morphology, crystal structure and

physical properties were evaluated using SEM, powder XRD measurement, and light absorption spectrum measurements. In this presentation, we will report these detailed results and the characteristics of solar cells using mixed bismuth halids perovskites.

2:00 PM EN08.18.07
White-Light Emitting Ruddlesden-Popper Perovskites Ashanti Bergonzoni[1], Sébastien Pillet[2], Kamel Boukheddaden[3], Aymen Yangui[4], Pedesseau Laurent[1], Boubacar Traore[5], Claudine Katan[5] and Jacky Even[1]; [1]INSA, iFOTON - CNRS, France; [2]CRMM (Cristallographie, Résonance Magnétique et Modélisation) laboratory - CNRS, France; [3]University Paris Saclay, France; [4]Lund University, Sweden; [5]ISCR (Institut des Sciences Chimiques de Rennes), France

Recently, owing to their excellent optoelectronic properties combined with an enhanced material stability, two-dimensional (2D) organic halide perovskites have emerged as an attractive alternative to 3D perovskites for photovoltaics[1,2]. More, their ability to emit white-light at room temperature with a good color rendering projected this family of materials into the spotlight of potential future low-cost white LED components[3]. However, the underlying physical mechanisms behind these emissive properties are not fully understood. Herein we propose to investigate the origin of the broad-band emission observed at different temperatures in a series of $(C_6H_{11}NH_3)_2PbX_4$ 2D Ruddlesden Popper perovskites (X= Br or I) [4,5] by coupling advanced structural measurements with an atomistic approach based on the density functional theory (DFT). Indeed, as the temperature is decreased, phase transitions between undistorted and distorted structures were observed for the two compounds of the series by means of temperature dependent X-ray diffraction. While this crystallographic phase transition goes along with a measured polarization-electric field hysteresis for the bromide compound, apparition of satellite incommensurate reflections was instead obtained for the Iodine one. We believe that these satellite reflections might also be connected to a low temperature ferroelectric ordering. In order to set a clear interplay between the structural distortions and the observed optoelectronic properties, theoretical studies intend to provide insights of the electronic band structures and polarization characteristics for these compounds.

2D Phase Purity Determines Charge Transfer Yield at 3D/2D Lead Halide Perovskite Heterojunctions Robert J. Westbrook[1,2], Weidong Xu[1], Xinxing Liang[1], Thomas Webb[3], Tracey M. Clarke[2] and Saif A. Haque[1]; [1]Imperial College London, United Kingdom; [2]University College London, United Kingdom; [3]University of Surrey, United Kingdom

Targeted functionalisation of 3D perovskite with a 2D passivation layer via $R\text{-}NH_3I$ treatment has emerged as an effective strategy for enhancing both the efficiency [1,2] and chemical stability [3] of ABX_3 perovskite solar cells, but the underlying mechanisms behind these improvements remain unclear. Here, we correlate the chemical evolution of the 3D/2D|charge transport layer (CTL) interface with the injection yield to the CTL through a mixture of surface sensitive structural and time-resolved optical techniques.
We assign a passivation mechanism where $R\text{-}NH_3I$ reacts with excess PbI_2 in the $MAPbI_3$ film and unsaturated PbI_6 octahedra to form $(R\text{-}NH_3)_2(MA)_{1-n}Pb_nI_{3n+1}$. Crucially, we show that precise control of the 2D $(R\text{-}NH_3)_2(MA)_{1-n}Pb_nI_{3n+1}$ layer underpins performance improvements: n = 1 yields over a two-fold improvement in hole injection to the HTL; n > 1 deteriorates hole injection. Ultrafast transient absorption spectroscopy suggests that this n-dependence is rooted in the fact that fast (< 6ns) hole injection does not occur between the 3D perovskite and 2D layer. Finally, we correlate these improvements in hole transfer with a 30% enhancement in device efficiency. [4] These results help explain contemporary empirical findings in the field and set out an important design rule for the further optimisation of multidimensional perovskite optoelectronics.

SESSION EN08.19: On-Demand
Sunday Morning, December 5, 2021
On-Demand

8:00 AM EN08.04.02
Dark and Bright Excitons in Halide Perovskite Nanoplatelets Moritz Gramlich[1], Michael W. Swift[2], Carola Lampe[1], John L. Lyons[2], Markus Döblinger[1], Alexander Efros[2], Peter Sercel[3] and Alexander S. Urban[1]; [1]Ludwig-Maximilians-Universität München, Germany; [2]U.S. Naval Research Laboratory, United States; [3]California Institute of Technology, United States

Halide perovskite nanocrystals have emerged as excellent light sources for light-emitting devices and lasers due to quantum yields approaching unity and an emission wavelength tunable throughout the visible range. As recently shown, it is the only material currently known that could possess a lowest-lying bright exciton state, greatly enhancing radiative efficiency. This last feature, known as bright-dark exciton inversion, is induced through the Rashba effect, resulting from breaking the nanocrystal inversion symmetry. Nanoplatelets, colloidal semiconductor quantum wells, have additional advantages for light emission, as their radiative rates and outcoupling efficiencies are strongly enhanced through quantum confinement and dielectric confinement effects. Here, we investigate the excitonic fine structure of thickness tunable halide perovskite nanoplatelets by merging time- and temperature-resolved photoluminescence spectroscopy with an effective mass model. We find a thickness-dependent bright-dark exciton splitting reaching up to 33 meV, the

largest ever reported value. Additionally, we find that the bright exciton is further split by up to 16 meV for the in-plane and out-of-plane polarized states. Due to these immense splitting energies, the radiative properties of the nanoplatelets will also be affected at room temperature. The experimental results obtained in this paper are in excellent agreement with the novel theory, which takes quantum confinement and dielectric confinement anisotropy into account. Notably, the model we develop can be directly applied to any semiconductor nanoplatelet and generalized for any nanostructure.

Ionic Transport, Stability and Interfacial Reactivity of Metal Sulfides Solid Electrolytes Gerbrand Ceder; University of California, Berkeley, United States

In this presentation I will give an overview of the mechanism by which Li ions achieve fast ion conductivity in sulfides and contrast it to oxide solid electrolytes. While screening of the electrostatic interaction through the large sulfur ion is very effective in providing a flat energy landscape for lithium, oxygen anions do not provide effective screening, rationalizing why sulfides and oxides require different structure types and compositions to achieve high ionic conductivity. I will also discuss claimed mechanisms for high conductivity such as paddle wheels etc. Finally, I will review the limitations on the anodic and cathodic stability of sulfide-based conductors and discuss their breakdown products.

11:00 AM EN09.01.02
Preparation and Defect Control of Transition Metal Sulfides for Lithium Sulfur Batteries via Chemical and Electrochemical Synthesis Approaches Amy Marschilok[1,2], Esther S. Takeuchi[1,2], Lei Wang[2] and Kenneth Takeuchi[1,2]; [1]Stony Brook University, United States; [2]Brookhaven National Laboratory, United States

Transition metal sulfides are appealing for next generation electrochemical energy storage as they can serve multiple roles as sulfur-equivalent electroactive materials and species promoting effective polysulfide trapping. Chemically and electrochemically based synthesis approaches providing control of sulfide composition and defect structure will be described in this presentation. Materials to mesoscale characterization and correlation with electrochemical function will also be reviewed.

Understanding the Role of Electronic and Interfacial Properties During Li Plating and Stripping Yue Qi; Brown University, United States

The key challenge for the Li-metal electrode is to maintain the smooth surface at the microscopic scale during cycling. The same crystalline structure of Li_2O and Li_2S but different chemistry serve as model systems for the fundamental understanding of the difference of oxides and sulfides during Li stripping and plating processes. To simulate the vacancy formation and accumulation at the Li-metal surface, a combined density functional theory (DFT)

and kinetic Monte Carlo (KMC) simulation was developed. It was found that the lithiophilic interface repels vacancies into the bulk Li, so Li atoms can quickly fill the Li vacancies near the interface and maintain a smooth Li surface. In contrast, the lithiophobic interface traps Li vacancies toward the interface, and the accumulated Li vacancies form voids and roughen the surface. While Li/Li_2O interface adhesion is larger than the Li/Li2S interface, it is predicted that it is easier to maintain a smooth Li surface during delithiation at Li/Li_2O interface. During lithiation platting, it was found the bandgap, tunneling barriers, and electron localization on internal defects, such as pores and crack surfaces and grain boundaries play a more important role for Li-dendrite nucleation and growth. A combined DFT and phase-field method was developed to demonstrate these effects. Several oxides (cubic Li7La3Zr2O12 (c-LLZO), Li1.17Al0.17Ti1.83(PO4)3 (LATP), and Li2PO2N) and sulfide (β-Li3PS4) solid electrolytes and interlayer materials (LiF, Li_2O, and Li_2S) were compared. All of them showed smaller bandgaps on the surface and grain boundaries than the corresponding bulk materials. While LLZO showed the most significant excess electrons on the surface and grain boundaries, β-Li3PS4 showed no such behavior. This is consistent with the observed trend and morphology of Li dendrite growth in different solid electrolyte materials.

2:00 PM *EN09.02.02
Development of Thiophosphate Solid-State Electrolytes for All-Solid-State Lithium Metal Batteries Donghai Wang; The Pennsylvania State University, United States

The family of thiophosphate solid-state electrolytes (SSEs) is one of the most promising candidates for future all-solid-state lithium metal batteries due to their high ionic conductivity at room temperature (>1 mS cm^{-1}), even exceeding conventional liquid electrolytes. However, high-ionic-conductive solid electrolytes such as $Li_{10}GePS_{12}$ are not stable against lithium metal, leading to fast failure of the cell. This talk will first present the synthesis of a new Li_2S-P_2S_5-Li_3N-Al_2S_3 glass-ceramic SSE system through a solid-state reaction approach. The synthesized SSE demonstrated a high ionic conductivity of ~ 5.19 mS cm^{-1} at room temperature and superior stability against lithium metal anode. And stable Li electrodeposition over 1000 h was achieved at a high current rate of 0.6 mA cm^{-2} and a high areal capacity of 0.6 mAh cm^{-2}. Second, a solution synthesis of argyrodite-type SSEs with low annealing temperatures below 200 ºC will be present. The synthesized SSE demonstrated a high ionic conductivity of ~ 4.01 mS cm^{-1} at room temperature and superior stability against lithium metal anode. At room temperature, Li|SSE|Li symmetric cell demonstrated a high critical current density of 1 mA cm^{-2} and low areal interfacial resistance of 6 ~ 7 Ω cm^2. Last, I will present the use of highly conductive SSEs in fabrications of all-solid-state Li-S batteries to achieve high utilization of sulfur and high energy density.

2:30 PM *EN09.02.03
Ultra Stable Sodium-Sulfur Electrochemistry Enabled by Phosphorus-Based Complexation Weiyang Li; Dartmouth College, United States

Beyond the current lithium ion technologies, sodium-sulfur batteries stand out because of the high theoretical specific energy attributed to the multi-electron redox reaction, which overcomes the capacity limitation of intercalation-based chemistry. Major challenges in realizing the full potential of a sodium-sulfur battery are associated with the formation of undesirable intermediates and irreversible precipitation of solid products. This work presents a new series of sodium phosphorothioate complexes that offer superior battery performance across a wide temperature range from -60°C to ambient temperature, showing great promise for enabling next-generation high energy and low cost energy storage systems. The complexes are designed by taking advantage of the chemical affinity of phosphorus with both sulfur and sodium. The complex structures and the electrochemical reaction mechanisms are revealed through coupled experimental characterization and theoretical calculations. The desirable electrochemical properties are attributed to the ability of the complexes to prevent the formation of undesirable precipitates over a fairly wide range of voltages.

3:00 PM EN09.02.04
***In Situ* TEM Investigation of the Effects of Sodium on the Thermal Stability of TiS_2 Nanowires** Rose H. Pham[1], Rory Weeks[2], Edwin Miller[2], Partha Mukherjee[3], Luisa L. Whittaker-Brooks[2] and Beth Guiton[1]; [1]University of Kentucky, United States; [2]The University of Utah, United States; [3]Purdue University, United States

Understanding the thermal stability of nanowires is of key importance for the performance and longevity of nanowire-containing devices, particularly where resistive heating may occur. With growing interest in sodium-ion batteries (NIBs) as a more economical and lower environmental impact alternative to lithium-ion batteries (LIBs), and layered transition-metal dichalcogenides (TMDs) as energy storage materials, it is important to determine both the advantages and limitations of replacing lithium-ion conductors with their sodium analogs. Here, we report an *in situ* heating study to investigate the thermal stability of sodium-intercalated titanium (IV) sulfide (TiS_2) nanowires, performed in the transmission electron microscope (TEM). Both sodiated (Na_xTiS_2) and non-sodiated nanowires were studied using a specialized heating holder, heating between room temperature and 700 °C. Control areas were also investigated to distinguish between heating and electron-beam effects. We observed chemical, morphological, and crystalline changes with increased temperature, solely in the sodiated-TiS_2 samples, demonstrating that sodiation profoundly affects the thermal stability of TiS_2 nanowires.

3:15 PM EN09.02.05
Stable Sodium Alloy Anodes for All-Solid-State Sodium-Sulfur Batteries Li-Ji Jhang, Daiwei Wang and Donghai Wang; The Pennsylvania State University, United States

Sodium-Sulfur (Na-S) batteries are considered a promising candidate for stationary energy storage techniques due to their low cost, long cycle life, and high energy density. For example, Na/*β*"-alumina/S battery has already been developed as stationary energy storage systems. However, the requirement of high temperature (>300 °C) to maintain the molten state of Na anode and S cathode causes extra power consumption and potential safety issues, restricting its broader applications. All-solid-state Na-S batteries operating at a lower temperature (e.g., < 100 °C) have attracted significant attention because of potentially improved safety features while maintaining long cycling life due to no generation of soluble polysulfide. One of the main challenges in developing such all-solid-state Na-S batteries operating at lower temperatures is its poor interfacial stability between Na metal anode and solid electrolyte, resulting in increased impedance, dendrite formation/penetration, and poor cycling life. Herein, we investigated Na alloy anodes and their applications in Na-S batteries. The alloy anode materials (e.g., Na-Sn and Na-Sb alloys) were synthesized by a high-energy ball-milling procedure. Electrochemical performance of the alloy anodes was evaluated, including comparing overpotential and critical current densities in Na-alloy symmetric cells, studying effects of different mass loading and N/P ratios in Na-S batteries. It is found that Na-Sb alloy is a more stable alloy anode with low overpotentials at a wide range of current densities. By pairing with TiS_2 cathode, Na-Sb alloy anode exhibits stable cycle life than Na-Sn alloy anode. All-solid-state Na-S battery cells were also fabricated with high mass loading of the sulfur cathode. The all-solid-state Na-S battery cell can deliver a high initial discharge capacity and maintain a specific capacity above 1000 mAh/g after long-term cycling operating at 60 °C. This finding shows a promising stable Na alloy anode for all-solid-state Na metal batteries to achieve long cycle life at a lower temperature for practical applications in stationary energy storage.

3:30 PM EN09.02.07
Covalent Sulfur Confined in Tunable Mesoporous Hollow Carbon Spheres Enabling High-Rate and Long-Cycling Room-Temperature Sodium-Sulfur Batteries Jianmin Luo[1], Wenkui Zhang[2], Xinyong Tao[2], Weiyang Li[1] and Yiwen Zhang[1]; [1]Dartmouth College, United States; [2]Zhejiang University of Technology, China

Although room temperature sodium-sulfur (Na-S) batteries have attracted huge attention due to its promise for large-scale applications, severe shuttle effect of polysulfide and the sluggish reaction kinetics of non-conductive sulfur in sulfur cathodes, as well as dendritic Na growth in Na metal anodes are the main challenges of this technology. **Notably, most of the previous published works usually devote to solving the issues related to sulfur cathode or sodium metal anode separately. There are rare works of simultaneously enhancing the electrochemical performance of both cathode and anode with two-in-one materials.** Herein, high-rate and long-cycling room-temperature Na-S batteries are achieved by employing covalent sulfur confined in mesoporous hollow carbon spheres (S@MHCS) as stable sulfur cathodes and solid additives for metallic sodium anode **in a carbonate electrolyte** to overcome the above obstacles simultaneously. As the cathode, MHCS can not only provide sufficient electrical contact and accessible Na^+ diffusion to the encapsulated sulfur copolymers for fast kinetics and high capacity, but effectively confine formed short-chain sodium polysulfides for prolonged cycle life. Additionally, the direct addition of the S@MHCS into bulk Na contributes to the homogenous Na plating by inducing Na nucleation and growth within the inner cavity of carbon spheres, and minimizes volume change during cycling, enabling extremely stable Na metal anodes at a ultrahigh current density (**up to 40 mA/cm^2**) along with an ultrahigh capacity (**up to 40 mAh/cm^2**). As a result, a Na-S full cell constructed with S@MHCS exhibits excellent rate capability and outstanding cycling performance.

SESSION EN09.04: Poster Session: Metal Sulfides in Batteries

Three-Dimensional Interconnected Binder-Free Mn–Ni–S Nanosheets for High-Performance Asymmetric Energy Storage Devices with Exceptional Cyclic Stability Nageh K. Allam; American University in Cairo, Egypt

A facile one-step method was demonstrated for the electrodeposition of manganese–nickel sulfide (Mn–Ni–S) 3D interconnected sheets on nickel foam substrates. The as-synthesized materials were characterized using field-emission scanning electron microscopy (FESEM), X-ray diffraction (XRD), energy-dispersive X-ray spectroscopy (EDS), and X-ray photoelectron spectroscopy (XPS) techniques. Upon their use as supercapacitor electrodes, the electrodeposited Mn–Ni–S showed exceptionally high specific capacitance (2849 and 1986 F/g at 1 and 5 A/g, respectively) and an excellent rate capability. Using Fe_3O_4-GR as the negative electrode and the Mn–Ni–S 3D interconnected sheets as the positive electrode to assemble an asymmetric supercapacitor device revealed high power density (800 W kg^{-1}) and energy density (40.44 Wh kg^{-1}) with 90% capacitance retention and a Columbic efficiency of 100% after 11 000 cycles, indicating the high potential of the fabricated materials for practical energy storage devices.

EN09.04.02
Understanding Solid-State Synthesis of Sodium Chalcogenide Superionic Conductors Selim Halacoglu[1], Yang Li[1], Sabina Chertmanova[1], Yan Chen[2], Badri Narayanan[1] and Hui Wang[1]; [1]University of Louisville, United States; [2]Oak Ridge National Laboratory, United States

Sulfide-based superionic sodium (Na) conductors show promising applications as solid electrolytes (SEs) in solid-state Na batteries to achieve the high energy dense, safe, and economic features. For solid-state ionic conductors, the synthesis process strongly influences their crystal structures/phase purity, and thus affect their ionically conductive properties. In situ neutron diffraction (ND) is a powerful tool to track the structural changes during solid-state synthesis process. Among sulfide-based SEs, Na_3SbS_4 family conductors have attractive intense attentions due to their high ionic conductivity (10^{-4}~10^{-3} S cm^{-1}) at room temperature and impressive chemical stability in ambient environment. In this work, we performed in situ neutron diffraction on pristine Na_3SbS_4 without and with doping (i.e. Se) to track the phase change and structural evolution during the synthesis and heat treatment (heating or cooling). The solid-state reaction mechanism during the synthesis process was revealed. In addition, the doping effects on the solid-state reactions, lattice parameters and structure stability were studied. This work presents a detailed structural study using in situ NDs for the synthesis of sulfide-based Na conductors, which provide useful information for the design and synthesis of new solid-state conductors.

8:00 AM *EN09.05.01
Air-Stable Sulfide-Based Electrolytes and Interfaces for All-Solid-State Li Batteries Xueliang A. Sun; University of Western Ontario, Canada

All-solid-state Lithium metal batteries (ASSLMBs) cannot only maximize the energy density, but also show improved safety compared with the conventional liquid electrolyte-based Li-ion batteries. Solid-state electrolytes (SSEs), as the most important component in the ASSLMBs, can determine the electrochemical performance. High ionic conductivity is one of the most basic requirements for an excellent SSE. Sulfide-based SSEs exhibit ultrahigh ionic conductivity (> 10^{-2} S cm^{-1} at room temperature) that can be comparable to the liquid electrolytes, making this kind of SSEs popular and promising. However, air sensitivity and Li metal incompatibility are two major obstacles, which are together with the problematic cathode interface, hindering the development of sulfide SSEs for practical ASSLMBs.[1, 2]
In our work, we employed the strategy of element substitution to design F-substituted Li_6PS_5Cl, Sn-substituted Li_6PS_5I, and Sn-substituted Li_3PS_4 as high-performance Li-metal compatible sulfide SSEs.[4-6] Using these element doping SSEs can derive functional interphases that contain LiF, LiI, and Li-Sn alloy, respectively. These interfacial contents were demonstrated as important to achieve stable Li plating/stripping. Importantly, we found that replacing P with Sn could significantly improve the air stability and ionic conductivity at the same time. The high reaction energy between the Sn-substituted PS_4 tetrahedra and moisture was regarded as the main reason for the improved air stability, while the expanded unit cell and increased Li^+ concentration led to superior ionic conductivity. Our modifications on various common-used sulfide SSEs with multi-function elements provide more choices of sulfide SSEs for practical ASSLMBs. At the cathode side,[7-11] we used interface modification (coating strategy) to improve the interfacial Li^+ transport and

chemical inertness. The electrode and electrochemical performance will be discussed. [12]

Structural and Ion Conduction Properties of Sulfide-Based Solid Electrolyte Materials Saiful Islam; University of Bath, United Kingdom

It is clear that a deeper understanding of metal sulfide materials for solid state batteries requires greater insights into their underlying structure-property relationships. This talk will highlight recent studies in two related areas: (i) Na_3PS_4 is one of the most promising Na-ion conductors, and our studies indicate a new high temperature polymorph showing fast-ion conduction associated with rotational motion of the thiophosphate polyanions; (ii) nanoscale effects on sulfide-based lithium-ion conductors are investigated with the results indicating enhancement in ion conductivity due to changes in local structure and ion diffusion pathways. A combination of materials modelling and experimental methods has helped us gain new insights into sulfide materials, which are valuable in developing strategies to optimize their solid electrolyte properties.

With a Little Help from ^{31}P: Localized Hopping and Long-Range Li^+ Transport in Argyrodite-Type Li_6PS_5I and Related Compounds Katharina Hogrefe and H. Martin R. Wilkening; Graz University of Technology, Austria

Site-disordered thiophosphates of the formula Li_6PS_5X (X = Br, Cl) are considered as the most promising solid electrolytes for all-solid-state lithium batteries with respect to their superior Li^+ diffusion properties [1]. Also for Li_6PS_5I, with its ordered anion and cation sublattice, ^{7}Li (and ^{31}P) nuclear magnetic resonance (NMR) measurements suggest rapid localized Li^+ exchange processes. However, the missing site disorder of Li_6PS_5I does only result in poor long-range ion transport as verified by conductivity spectroscopy [1]. Here, we compare results from ^{31}P spin-lock NMR measurements with recent results from $1/T_{1\rho}$ ^{7}Li NMR experiments [1] to shed light on the pronounced bimodal diffusion behaviour seen in Li_6PS_5I. The observation of ^{31}P via spin-lock NMR offers a another perspective to look at ion diffusion within solids. The influence of rotational jump processes of the PS_4^{3-} polyanions on Li^+ dynamics (and *vice versa*) is discussed as well [2,3]. In conclusion, site disorder in the Li_6PS_5X family is the key property to understand the extraordinarily high Li^+ self-diffusivities seen by NMR for the samples with X = Br, Cl [4]. In addition, we will discuss the influence of nanostructuring on Li diffusion in high-energy ball milled Li_6PS_5I [5] and $Li_{10}GeP_2S_{12}$ (LGPS). In structurally disordered Li_6PS_5I an increase in ion conductivity by 2 orders of magnitude is observed. Hence, Li_6PS_5I turned out to be a suitable model system to study the influence of local disorder by both broadband conductivity spectroscopy and NMR relaxation techniques [5].

Deconvoluting Structural and Dynamic Contributions to the Activation Barrier in Solid State Electrolytes Paul Till[1], Matthias Agne[2] and Wolfgang Zeier[1]; [1]University of Münster, Germany; [2]Research-Center Jülich, Germany

Highly conductive solid electrolytes are necessary to build well performing All Solid-State Batteries with high energy densities.[1,2] However, the discovery and optimization of suitable solid electrolyte materials has been limited, in part due to the lack of a fundamental understanding of the connection between the crystal structure, lattice dynamics and the diffusion process.[3] Many of the established connections have been investigated through one-dimensional solid-solution type substitution experiments, where one atom is exchanged for another and corresponding changes in ionic transport are monitored.[4-6] However, the simultaneous alterations of the crystal structure and lattice dynamics in these substitution series makes it extremely challenging to discern different influences on the transport properties. Herein we utilize a two-dimensional solid solution approach to show that the correlation of structure-based metrics with ionic transport can be misleading, whereas dynamical descriptors (e.g. bond strengths) may be more pertinent to the activation barrier in some fast ionic conductors. Specifically, we use the model $Na_3P_{1-x}Sb_xS_{4-y}Se_y$ system, comprised of the four substitution series $Na_3P_{1-x}Sb_xS_4$, $Na_3P_{1-x}Sb_xSe_4$, $Na_3PS_{4-y}Se_y$ and $Na_3SbS_{4-y}Se_y$ to systematically decouple static and dynamic contributions to the activation barrier. This study indicates that lattice dynamical properties cannot be overlooked in assessing trends of the activation barrier in solid electrolyte substitution series.

High Capacity Retention in Lithium Batteries Utilizing Nano Iron Sulfide Particles Noah B. Schorr, Igor Kolesnichenko, Laura Merrill, Katharine L. Harrison and Timothy N. Lambert; Sandia National Laboratories, United States

The high theoretical specific capacity of 893 mAh/g and energy density of 1273 Wh/kg of FeS_2 make it an attractive choice to pair with a lithium anode for next generation batteries. Development and implementation of secondary FeS_2/Li batteries has been hampered for a variety of reasons including soluble polysulfide formation which causes capacity loss and cell death. Another factor has been a lack of suitable electrolyte for cycling both the FeS_2 cathode and Li anode, with high coulombic efficiency. This talk will focus on the synthesis of FeS_2 nanoparticles, choice of a suitable electrolyte, and cycling protocol to enabling stable cycling of a FeS_2/Li cell. By cycling the nano FeS_2 in a concentrated bisalt electrolyte with a charging voltage cutoff of 2.4 V we have achieved 80 cycles (at the time of this submission) with an average discharge capacity of 421 mAh/g, well above 80% capacity retention under this condition. Using Cu/Li cells we show the plating/stripping of Li in the bisalt electrolyte has an average coulombic efficiency of 98.8% over 50 cycles and 99.1% for the last 40 cycles. Furthermore, we show that the high performance cycling of the cathode and anode is attributed not only to use of a bisalt electrolyte, but also by ensuring a submicron domain size of the FeS_2 particles to mitigate polysulfide generation.

Phase Control and Microstructure Engineering in Thioposphate Solid Electrolytes Bettina V. Lotsch[1,2]; [1]Max Planck Institute, Germany; [2]University of Munich (LMU), Germany

Solid electrolytes (SEs) are at the heart of all-solid-state batteries (ASSBs), which promise higher energy density along with safer operation compared to commercial Li ion batteries. As the ASSB technology matures, research in the field needs to respond to questions pertaining to the upscaling of solid electrolytes, their stability, and the integration of the individual components into ASSBs with extended cycle life. As a consequence, new research areas have been emerging lately, including interfacial engineering and microstructure design, and questions such as the role of stack pressure on battery performance increasingly enter the focus of ASSB design.
This presentation will discuss the development and optimization of lithium[1,2] and sodium[3] thiophosphate SEs based on three complementary approaches, which address both the atomistic level and microstructure of SEs:
(i) We highlight the importance of phase engineering and hybridization in thiophosphate solid electrolytes, exemplified by the discovery of two new polymorphs of $Na_4P_2S_6$ and the formation of composite thiophosphate SEs.[4] Our results showcase how synthetic control and post-synthetic treatment of solid electrolytes can significantly impact the materials properties, even though structural differences may be minute or even hidden by the glassy ceramic character of many thiophosphates.[5]
(ii) The development of solution processing routes for the thiophosphate Li_7SiPS_8 is demonstrated, revealing that aprotic solvents with donor numbers smaller than 15 $kcalmol^{-1}$ are suitable for wet processing, since both crystal structure of the SE and high ionic conductivities (> 1 $mScm^{-1}$) are retained.[6]
(iii) Finally, we pinpoint the role of moderate pressure on the microstructure of SEs and demonstrate its complex impact on the Li ion conductivity of LGPS-type SEs.
Taken together, our findings reinforce the notion that a holistic picture of a SE – including its atomistic structure, defect- and disorder-related phenomena, as well as its microstructure – is needed to understand and accurately predict its function in a realistic ASSB environment.

11:00 AM *EN09.06.03
Fast Sodium Diffusion and Anharmonic Phonons Olivier Delaire[1], Mayanak K. Gupta[1,2], Jingxuan Ding[1], Naresh Osti[3], Doug L. Abernathy[3], William Arnold[4], Hui Wang[4] and Zachary Hood[5]; [1]Duke University, United States; [2]Bhabha Atomic Research Centre, India; [3]Oak Ridge National Laboratory, United States; [4]University of Louisville, United States; [5]Argonne National Laboratory, United States

Solid electrolytes (SEs) exhibit complex atomic dynamics, featuring simultaneous facile hopping of mobile species and soft lattice dynamics of the host lattice. Importantly, fast diffusion involves large-amplitude motions on strongly anharmonic potential energy surfaces, and such anharmonic effects need to be assessed when investigating phonons and their coupling with the stochastic hopping underlying the diffusion process. Phonons describe the atomic dynamics in crystalline materials and provide a basis to encode possible minimum energy pathways for ion migration. Identifying and controlling the pertinent phonon modes coupled most strongly with ionic conductivity could pave the way for discovering and designing new SEs via phonon engineering. This talk will report on investigations of phonons in Na3PX4 and Na3SbX4 (X=S, Se), highlighting strong anharmonic effects and their coupling to fast Na diffusion, using a combination of neutron scattering, ab-initio molecular dynamics (AIMD) and machine-learning accelerated MD. We identify specific anharmonic soft-modes that strongly couple with the Na diffusion process, and show how these modes enable Na-ions to hop along the minimum energy pathways. Further, our quasi-elastic neutron scattering (QENS) measurements, supplemented with large-scale molecular dynamics simulation, provide the Na diffusion constant and the diffusion characteristics. These results offer detailed microscopic insights into the dynamic mechanism of fast Na diffusion and provide an avenue to search for further Na solid electrolytes.

11:30 AM EN09.06.04
Don't Trust Fool's When Looking for Gold—Iron Sulfide as Cathode Material for Mg-Batteries Michael Wilhelm, Veronika Brune, Fabian Hartl and Sanjay Mathur; University of Cologne, Germany

The big market of energy storage systems is mainly dominated by the widely available and conventional lithium-ion batteries (LiBs). Low earth-abundance of lithium and the use of not sustainable cathode materials, like lithium cobalt oxide's, are currently bottlenecks of the commercially available LiBs. In quest of new cathode materials, metal sulfide getting more and more attention to be next-generation cathode materials. Nevertheless, achieving high capacity and good cycling stability are remaining challenges. Especially, pyrite (FeS_2), also known as fools' gold, is a promising candidate to overcome the issues of availability (iron = 5.6 %; sulfur = 0.035 %) and specific capacity (894 mAh g^{-1}). Moreover, by changing the battery setup from lithium to magnesium the energy storage technology can be even more sustainable (Li = 0.002 %; Mg = 2.4 %). Crucial to achieving good energy storage performance of the metal sulfides is the size and shape of the particles in the electrode which affects the thermodynamic properties.
Different analogs of iron sulfides (FeS, Fe_3S_4, and Fe_7S_8) were investigated as cathode material in combination with a magnesium metal anode and characterized by XPS, SEM, and Raman spectroscopy. The influences of the particle size and additives were studied, and demonstrators were successfully manufactured. Additionally, the effect of carbon additives, like CNF and rGO, on the performance of the battery was investigated.

11:45 AM EN09.06.05
Redox Mediated Li-S Flow Battery for Grid-Scale Energy Storage Applications Melissa Meyerson and Leo J. Small; Sandia National Laboratories, United States

There is a need for safe, reliable, and inexpensive batteries with high capacity for grid storage applications. The high capacity (1675 mAh/g) and low cost (~0.1 $/kg) of sulfur make Li-S batteries an excellent candidate for this; however, S has poor electrical conductivity and the proximity of Li to the cathode in conventional batteries can present a safety hazard at grid scale. We address these problems by designing a highly scalable, membrane free redox-mediated Li-S flow battery. Benefits of this design include: 1) The presence of soluble redox mediators enable the reduction/oxidation of the S without the need for conductive carbon additives. 2) The physical separation of the Li anode from the cathode reduces the risk of short circuiting and propagating battery fires. 3) The use of electrolyte additives enables stable Li plating on the anode which improves the cell efficiency, extends the cycle life, and removes the need for expensive solid state separators. We chose decamethyl ferrocene (DmFc, 2.86 V vs Li/Li^+) and cobaltocene ($CoCp_2$, 2.06 V vs Li/Li^+) as redox mediators for their proximity to the redox potential of the Li-S reaction. During cycling, these mediators help chemically oxidize or reduce the S without the need for electrical contact between the S and the electrode. Instead, the soluble mediators are electrochemically oxidized or reduced at the electrode. In order to address the non-uniform deposition of Li on Li metal anodes, we presoaked the Li metal in a LiI solution to form a more stable solid electrolyte interphase (SEI) and used $LiNO_3$ in the electrolyte to improve the stability of the Li deposition. To examine the Li surface chemistry and explain the cycling performance, we conducted pre- and post-cycling characterization of the system. Characterization with x-ray photoelectron spectroscopy and energy dispersive x-ray spectroscopy revealed the presence of uniformly dispersed LiI in the SEI on the Li before cycling, which improves the uniformity of Li deposition on the anode. Scanning electron microscopy revealed globular, rather than filament-like, Li deposition, which is attributed to the presence of $LiNO_3$ in the electrolyte and explains the high coulombic efficiency and cycle life. UV-vis spectroscopy revealed a decrease in the amount of polysulfides present in the electrolyte between 50 and 200 cycles, indicating that the observed capacity loss is likely due to the loss of available sulfur. The combination of the redox mediators and additives enabled our cells to cycle stably for 200 cycles with an average coulombic efficiency of 99.0% and a voltage efficiency of 82.0%.

1:00 PM *EN09.07.01
Computation Guided Design of All-Around Solid Electrolytes for Solid-State Batteries Yifei Mo; University of Maryland, United States

All-solid-state batteries using ceramic solid electrolyte is promising next-generation battery technology. To enable a high-performance solid-state battery, the solid electrolytes need to exhibit high ionic conductivity, wide electrochemical window, interfacial compatibility with anode and cathode, multiple mechanical properties, and air/moisture stability. However, no single solid electrolyte material can satisfy all these desired attributes. For example, sulfides have the highest ionic conductivity but exhibit narrow electrochemical windows and notoriously poor air stability, whereas oxides generally exhibit better

stability but lower ionic conductivity. In order to develop all-around solid electrolytes, our first-principles computation will provide guiding principles and design strategies for improving ionic conductivity, electrochemical window, air stability in solid electrolyte materials. We will also show new solid electrolyte materials systems discovered and designed by computation through an accelerated fashion.

1:30 PM *EN09.07.02
Interplay of Structural Disorder, Site-Disorder and Ionic Conductivity of Superionic Conductors—Insights from Atomistic Computer Simulations Marcel Sadowski and Karsten Albe; TU Darmstadt, Germany

Glassy, glass–ceramic, and crystalline lithium thiophosphates have attracted interest in their use as solid electrolytes in all-solid-state batteries. Despite similar structural motifs, including PS_4^{3-}, $P_2S_6^{4-}$, and $P_2S_7^{4-}$ polyhedra, these materials exhibit a wide range of possible compositions, crystal and amorphous structures, as well as ionic conductivities. Calculations based on density functional theory can be a helpful tool for understanding diffusion pathways and Li^+ ionic conductivity and interface stabilities.
In this contribution I will first discuss recent results on the defect chemistry and conductivity of the solid electrolyte $Li_4P_2S_6$ as well as its interfacial instability with respect to Li. Then, molecular dynamics simulations of crystalline and amorphous Li_4PS_4I will be shown, which unravel the diffusion mechanism and can be explained by a rate-equation model based on superbasins. Finally, results on the Lithium argyrodites of the type Li_6PS_5X (X = Cl, Br, I) are presented, where the influence of S_2-/Br- site-disorder was studied. The simulations reveal that local "Li cages" trap Li ions in the ordered material. At higher degrees of site-disorder the cage structures dissolve and long-range low energy pathways are established. The analysis of pair distribution functions (PDF) and Li-density maps elucidates the correlation between structural disorder and ionic conductivity.

Discovery of New Compounds as Li-Ion and Na-Ion Conductors for All-Solid-State-Batteries Hailong Chen; Georgia Institute of Technology, United States

High performance solid state ionic conductors are much desired as the solid electrolyte for all-solid-state-batteries. The solid electrolyte materials are required to have high room temperature ionic conductivity, low electronic conductivity, good chemical and electrochemical stabilities, and good mechanical properties, and low cost. With these expectations, in recent years we have design and discovered a number of new compounds with promising Li-ion and Na-ion conduction properties, including oxide, sulfide and halide compounds. In this MRS conference we will report some of our recent findings, including sulfide Li-ion conductors with argyrodite structure, halides with layered structures, and Na-ion conductors with modified cubic structures. These compounds all show very high room temperature ionic conductivities and good performance in the cycling test of all solid state batteries. High resolution synchrotron X-ray and neutron scattering techniques, solid state NMR and electron microscopy were complementarily used to reveal the structure-property relationships in these compounds. The impacts of synthesis condition, chemical composition and processing to the ionic conductivity and battery performances will be discussed.

2:30 PM EN09.07.04
Lithiation Mechanism and Structure-Performance Properties of SnS and SnS_2 Anode Active Materials for Lithium–Ion Batteries Damian M. Cupid[1], Albina Glibo[1,2], Nicolas Eshraghi[1], Hans Flandorfer[2] and Marcus Jahn[1]; [1]AIT Austrian Institute of Technology GmbH, Austria; [2]University of Vienna, Austria

Metal chalcogenides such as SnS_2 and SnS are promising anode materials for lithium-ion batteries as their theoretical reversible capacities (644 mAh/g for SnS_2 and 755 mAh/g for SnS) are significantly higher than that of graphite (372 mAh/g). SnS_2 exhibits a layered, hexagonal CdI_2-type crystal structure, in which each Sn^{4+} ion is octahedrally coordinated by S ions with S–Sn–S stacking across the crystallographic *c*-direction. On the other hand, α-SnS can be considered as a "pseudo-2D" orthorhombic structure in which each Sn^{2+} ion is coordinated to three S ions within the layer. The complete lithiation of SnS takes place via successive conversion and alloying reactions. In the conversion reaction, an electrochemically inactive but ionically conductive Li_2S matrix is formed, which buffers the volume change of Sn (~ 300% for formation of $Li_{17}Sn_4$) during the alloying reaction. On the other hand, due to the higher +4 oxidation state of the Sn ions in SnS_2 as well as the presence of vacant interstitial sites in the crystal lattice, the lithiation of SnS_2 starts with the intercalation of lithium ions into the octahedral sites between the S–Sn–S layers. This is followed by the conversion and alloying reactions as for SnS.
In the literature, the electrochemical performance properties of SnS_2 and SnS have been investigated separately from each other, so that there is a lack of comparative data for SnS and SnS_2 anodes with comparable particle morphologies and subjected to the same electrochemical test conditions. Therefore, the motivation of this work is to establish the structure–processing–property relations of SnS_2 and SnS anode active materials with similar particle morphologies, understand the fundamental lithiation mechanisms of both, and elucidate their degradation mechanisms under long-term cycling. In all our experiments, a single, commercially available SnS_2 powder with ~ 10 µm particle size was used as the starting material.
In the first step, XRD, SEM and laser diffraction were performed on the pristine SnS_2 micro-powder to characterize its crystal structure, particle morphology and particle size distribution. Differential thermal analysis, thermogravimetric analysis and heat-treatment experiments in flowing argon followed by XRD with Rietveld refinement of the measured diffraction patterns were conducted to understand the phase transformation kinetics of pristine SnS_2 to SnS. Based on these results, phase pure SnS was synthesized from pristine SnS_2 by subjecting it to heat treatments at T > 700°C in Argon atmosphere.
To produce the anode active materials, pristine SnS_2 and SnS synthesized by the thermal decomposition of SnS_2 were subjected to high-energy ball-milling in ZrO_2 bowls at 200 rpm in an argon atmosphere. This processing yields SnS_2 and SnS nanoparticles with similar morphologies. The anode active materials were subjected to electrochemical testing including galvanostatic cycling, cyclic-voltammetry, impedance spectroscopy, galvanostatic titration and in-situ dilatometry to quantify their structure–performance properties. Furthermore, ex-situ XRD was performed on electrodes at different states of charge to characterize the discharge reaction mechanism, and SEM and XRD were performed on electrodes after 100 discharge/charge cycles to assess the change in structure of the active anode materials after cycling.
Our results show that although the theoretic reversible capacity of SnS is larger than that of SnS_2, SnS_2 performs better during long term cycling. This is attributed to the intercalation of lithium into the SnS_2 crystal structure before the conversion mechanism. This crucial step generates a finer distribution of Li_2S, which is better suited to buffer the volume changes of the Sn particles during successive lithiation/de-lithiation steps.

Novel Metal/Sulfur High-Loading Cathodes in Low-Electrolyte Lithium-Sulfur Batteries Sheng-Heng Chung and Cun-Sheng Cheng; National Cheng Kung University, Taiwan

The lithium–sulfur battery is a promising candidate for next-generation electrical energy storage. The inexpensive, naturally abundant, and environmentally benign sulfur cathode offers an order of magnitude higher theoretical charge-storage capacity (1,672 mAh g^{-1}) than the those of currently used insertion-compound cathodes. However, as a new energy-storage battery system, the lithium-sulfur battery cathodes suffer both material and electrochemical challenges. The sulfur cathode and its end-discharge sulfide products are both good insulators. The high cathode resistance causes a low and irreversible electrochemical utilization of the cell. The conversion between sulfur and sulfides generates liquid polysulfides, which readily diffuse out of the cathode and migrate in the cell. The irreversible migration of polysulfides within the cells results in the fast capacity fade and poor discharge/charge efficiency. Moreover, the low electrochemical utilization and stability challenge the design and fabrication of a high-performance sulfur cathode with a necessary high amount of sulfur and a desired low amount of electrolyte in a cell. The inappropriate cathode design impacts the sulfur cathode electrochemistry, which impedes the development of sulfur cathodes with high energy density and the commercialization of the lithium–sulfur technology.

In our presentation, we present innovations on metal-sulfur nanocomposite possessing a conductive metal nanoshell coated on sulfur particles to improve the conductivity of sulfur cathode, the stabilization of polysulfides, and the reaction kinetics of lithium-sulfur batteries. We adopt the electroless-nickel plating method to synthesize the nickel/sulfur nanocomposite features a multi-functional nickel nanoshell. The metallic coating provides the metal/sulfur nanocomposite with high conductivity. Moreover, nickel has the high polysulfide trapping capability and strong electrocatalytic capability. As a result of these critical advantages in sulfur cathode, the metal/sulfur nanocomposite exhibits excellent lithium-sulfur battery performance, showing high electrochemical utilization and kinetics with high discharge capacity of above 1,000 mAh g^{-1} and excellent rate capability of C/20–C/2 rates with stable cyclability for 200 cycles. These improved electrochemical performances are realized by the high-loading cathode with a high sulfur content of 74 wt% and a high sulfur loading of 14 mg cm^{-2} in a lean-electrolyte lithium-sulfur battery with a low electrolyte-to-sulfur ratio of 7 µL mg^{-1}. The simultaneous improvement in the outstanding material and electrochemical characteristics results in high areal and gravimetric capacities along with a high energy density of 28 mWh cm^{-2}. In conclusion, the superior material design and electrochemical characteristics obtained by our nickel/sulfur nanocomposite as the high-loading sulfur cathode in a lean-electrolyte lithium-sulfur cells make its advanced cathode designs for the development of high-energy-density lithium-sulfur batteries.

Metal-Sulfur Batteries with Stabilized Sulfur Cathodes and Metal Anodes Arumugam Manthiram; The University of Texas at Austin, United States

Metal-sulfur batteries offer tremendous advantages compared to lithium-ion batteries in terms of cost and energy density as sulfur is abundant, inexpensive, and environmentally benign, and both sulfur cathode and metal anodes offer much higher capacities. However, the practical viability of metal-sulfur batteries is hampered by the low energy density and poor cycle life in practical cells. These challenges originate from the poor electronic and ionic conduction in sulfur and its discharged products, polysulfide shuttle, and poor cyclability of metal anodes. To overcome some of these difficulties, generally a large amount of conductive carbon and liquid electrolyte are added to the cell; they enhance the cycle life, but drastically lower the practical energy density and make the metal-sulfur batteries uncompetitive with lithium-ion batteries. On the other hand, it is challenging to manufacture and handle thin lithium-metal or sodium-metal foils, drastically increasing their cost.

To overcome the above challenges, this presentation will first focus on anode-free cells, in which lithium sulfide (Li_2S) cathode is paired with an anode current collector without any free lithium at the anode. The anode-free cells eliminate the handing and manufacturing issues associated with thin lithium-metal foils, increase the cell energy density, and suppress self-discharge before deploying the cells as the cells are assembled in the discharged state similar to the currently used lithium-ion cells. To stabilize lithium-metal plating and stripping, a small amount of additive is incorporated into the Li_2S cathode. The presentation will first present the effect of the incorporation of a small amount of tellurium as a case study. Being in the same group as sulfur in the periodic table, but with a metalloid behavior, tellurium substitutes into polysulfides to form polytellurosulfides, which migrate to the anode and get reduced to form Li_2TeS_3 as a thin, lithium-ion conducting solid-electrolyte interphase (SEI) layer on the plated lithium metal. This enables a uniform deposition of lithium and mitigates the severe electrolyte decomposition, enabling the assembly of cells with less amount of electrolyte. As a result, remarkable improvement in cyclability and capacity is achieved in energy-dense, anode-free full cells and lean-electrolyte pouch cells with high sulfur loading. The mechanisms involved in the drastic improvement in the performance is elucidated with in-depth characterization methodologies, such as time-of-flight secondary ion spectrometry (TOF-SIMS), x-ray photoelectron spectroscopy (XPS), nuclear magnetic resonance (NMR) spectroscopy, *etc*. The speciation with TOF-SIMS is particularly valuable to delineate the dynamics involved in lithium plating and stripping as well as to understand the chemistry involved.

The presentation will then focus on the incorporation of other additives to engineer the behavior of dissolved polysulfides in order to stabilize both the sulfur cathode and lithium-metal plating and stripping. The role of additives on the electrochemical performances will be illustrated with pouch cells fabricated with high sulfur loading and low electryte/sulfur ratio to be practically viable. Then, the presentation will transition to employ some of the understanding gained with lithium-sulfur batteries to sodium-sulfur batteries. Long-life, dendrite free sodium-sulfur cells will be presented, including pouch cell performances, with appropriate engineering of the cell chemistry.

4:30 PM *EN09.08.03
Design of Stable Cathodes for Solid State Li-S Batteries Ping Liu; University of California, San Diego, United States

Solid state Li-S battery promises high energy density and low cost. Multiple challenges remain for the sulfur cathode. S is insulating and experiences large volume changes during cycling. In this talk, we will report our recent effort in developing polymer-S composite materials to address these challenges. The first class of material is based on sulfurized polyacrylonitrile (SPAN). SPAN contains ~ 45% of S and demonstrates excellent cycling stability due to small volume change. Its capacity is limited to ~ 600 mAh/g with a discharge voltage of 1.8 V. In order to further improve materials energy density, we have investigated polymer-S materials with higher S content. SPAN has an approximate formula of C3NS. The carbon content can be reduced to a unit formula of CNS in poly (SCN). The material can be synthesized with free radical oxidation of SCN salts. The material demonstrates an average voltage of 2.1 V with a capacity of 700 mAh/g, thus a much higher energy density than SPAN. Further optimization of materials morphology and cell fabrication will pave the way towards a long-life solid state Li-S battery.

5:00 PM *EN09.08.04
Highly Ion-conductive, Ultrathin, and Robust Sulfide Solid Electrolyte Membrane Daxian Cao, Qiang Li, Xiao Sun and Hongli Zhu; Northeastern University, United States

Sulfide solid-state electrolytes (SEs) featured with nonflammability and superior ionic conductivity (>10^{-3} S cm^{-1}) enable all-solid-state lithium batteries (ASLBs) to deliver safer and more reliable energy storage. However, current sulfides-based ASLBs exhibit far below expected energy densities at the cell level (<50 Wh kg^{-1}, <100 Wh L^{-1}), due to the employment of SE membranes with extreme high thickness (>500 μm), large weight (>150 mg cm^{-2}), and high areal resistance (>100 Ω cm^2). The binder-assisted solution method is a promising strategy to fabricate a thin and robust sulfide SE membrane. However, the high sensitivity to polar solvents and natural brittleness of sulfide SE challenge the fabrication of thin, light-weight SE membranes with no sacrifice in ionic conductivity. To successfully fabricate a thin SE membrane with high ionic conductivity and mechanical strength, a critical step is to select a binder satisfying the following requirements: 1) excellent solubility and stability in the nonpolar solvent; 2) high stability with sulfide SE; 3) high thermal stability; 4) high binding strength. This work will report an advanced binder and a freestanding SE membrane with an ultralow thickness of 47 μm, ultralow areal resistance of 5.10 Ω cm2, and superior ionic conductivity of 1.08 mS cm^{-1}, and the ultrahigh ion conductance of 190.11 mS. The ASLB utilizing this advanced SE membrane delivered cell-level high gravimetric and volumetric energy densities of 175 Wh kg^{-1} and 675 Wh L^{-1}, individually.

SESSION EN09.09: Metal Sulfides in Batteries VII

Monday Afternoon, December 6, 2021
EN09-Virtual

6:30 PM *EN09.09.01
Superionic Lithium Argyrodite Sulfide Electrolytes with Enhanced Air-Stability Yongheum Lee[1,2], Jiwon Jeong[1,3], Hun-Gi Jung[1,2], Seungho Yu[1,2] and Kyung Yoon Chung[1,2]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]KIST School, Korea University of Science and Technology, Korea (the Republic of); [3]Korea University, Korea (the Republic of)

Under the carbon reduction policy, the use of internal combustion engines and fossil fuels has been reduced and electric vehicles and renewable energy have begun to be widely distributed. Batteries are drawing attention as a means of using electric vehicles as electricity and storing renewable energy. However, due to the limitations of the capacity and stability of existing lithium-ion batteries, research is underway on next-generation batteries that can replace the above-mentioned applications.
One of the next-generation batteries that has close performance with existing lithium-ion batteries is sulfide based All Solid State Batteries (ASSBs). In general, the higher the ionic conductivity of used solid electrolytes, the greater the capacity. Sulfide solid electrolyte has relatively higher ionic conductivity than other solid electrolytes. In addition, sulfide solid electrolytes have soft property, making it easy to manufacture batteries with smooth inter-material contacts. It reduce internal resistance of batteries and improves batter performance. For this reason, many developments are underway for sulfide solid electrolytes with high ionic conductivity and soft properties. However, sulfide solid electrolyte is reactive because materials used in sulfide solid electrolyte is P_2S_5 precursor and P-S bond is relatively weak. Therefore the phosphorus in sulfide solid electrolyte react with water, making the electrolyte vulnerable to moisture. Recent studies have been developing chemically stable and high ionic conductive solid electrolytes by replacing or doping the solid electrolyte.
In this study, argyrodite structure sulfide solid electrolyte is synthesized using mechanical milling method. In addition, to improve moisture-weak properties and ionic conductivity, argyrodite sulfide solid electrolytes with other composition are synthesized using antimony and halogen elements. The electrochemical analysis was performed using synthesized solid electrolytes.

7:00 PM *EN09.09.02
Analyzing the Internal Resistance of a Sulfide-Based Solid-State Battery Wonsung Choi, Hyeokjo Gwon, Jun Hwan Ku, Heung Chan Lee, Gabin Yoon and Dongmin Im; Samsung Advanced Institute of Technology, Korea (the Republic of)

The expectations on the solid-state batteries are growing fast. The employment of solid electrolyte instead of liquid not only provides a much better safety, but also enables the use of lithium metal anode, leading to a higher cell energy density [1]. Although it is widely accepted that Li dendrite can penetrate through the solid electrolyte layer causing internal short circuits [2], we have demonstrated that lithium metal anode can be successfully cycled with a proper design of the interfacial layer on the solid electrolyte [3].
High internal resistance is one of the remaining challenges that has to be addressed in the development of solid-state batteries. The ionic conductivity of some sulfide-based solid electrolytes (1 ~ 10 mS/cm) is comparable to that of liquid electrolytes with counting the cation transference number near unity. Nevertheless, the internal resistance of solid-state batteries is considered high due mainly to the interfacial behaviors between solid phases [4, 5]. The charge transfer resistances at the both electrodes and the bulk and grain boundary resistances of the electrolyte are the factors that contribute to the overall cell impedance.
In this work, the internal resistance of a sulfide-based solid-state battery is analyzed component by component. For example, the bulk resistance and the grain boundary resistance for the electrolyte inside the cathode are extracted separately with an AC method employing a transmission line model [6]. In addition, the influences of cell design and process will be discussed.

High Donor Electrolyte Designs for Lithium-Sulfur Batteries with Lean Electrolyte Conditions Jang Wook Choi; Seoul National University, Korea (the Republic of)

Li-S batteries have witnessed considerable progress in the past decades, mainly in terms of cycle life. The shuttling process, the main capacity fading mechanism, was addressed by a variety of approaches targeting all of sulfur cathode, separator, and electrolyte. Nevertheless, the main progress was based

on ether-based electrolytes with compatibility with Li metal counter electrode. To achieve more competitive energy density, electrolyte amount should be minimized thus satisfying the necessity of lean electrolyte conditions. In this talk, I will introduce recent progress in my lab in identifying high donor electrolytes. High solubility of polysulfides results directly in boosting the volumetric energy density. I will also discuss how to secure the compatibility with Li metal anode so that high donor electrolytes can be adopted in practically viable conditions.

8:00 PM EN09.09.05
New Halide Na^+ Conductors Using Earth Abundant Elements for All-Solid-State Na^+ Batteries Hiram Kwak[1], Jeyne Lyoo[2], Juhyoun Park[1], Yoonjae Han[1], Seung-Tae Hong[2] and Yoon Seok Jung[1]; [1]Yonsei University, Korea (the Republic of); [2]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

The application of lithium-ion batteries (LIBs) has been expanded from portable electronic devices to battery-driven electric vehicles and grid-scale energy storage systems. Accordingly, considerations about safety and cost issues have become a top priority. Specifically, the safety concerns originating from the use of flammable organic liquid electrolytes and the cost issues related to Li are serious obstacles. In this regard, the replacement of flammable liquid electrolytes with inorganic Na^+ superionic conductors are considered as an ideal solution. Among various materials for Na^+-conducting solid electrolytes (SEs), sulfide materials have drawn significant attraction with their high ionic conductivities and mechanical deformability, which enables scalable cold-pressing-based fabrication protocols. Unfortunately, due to the intrinsically narrow electrochemical windows, the sulfide SE materials undergo severe side reactions. They do not exhibit sufficient stability with the 3 V-class oxide cathode materials, such as $NaCrO_2$.
Recently, through the reinvestigations on halide SEs, Asano and coworkers reported that trigonal Li_3YCl_6 and monoclinic Li_3YBr_6 showed high Li^+ conductivities of 0.51 and 1.7 mS cm^{-1}, respectively. More importantly, halide SEs, especially chloride compounds, exhibit the combined advantages of sulfide and oxide SEs: deformability and excellent (electro)chemical oxidation stability. Despite these advances in Li^+-conducting halide SEs, reports on Na^+-conducting halide SEs have been scarce.
In this presentation, our recent results on the development of new Na^+-conducting halide SE, Na_2ZrCl_6, and their application to all-solid-state batteries will be presented.

SESSION EN09.10: Metal Sulfides in Batteries VIII

Transition Metal Sulfides for High-Energy-Density Lithium Metal Battery Cathodes Liping Wang[1] and Hong Li[2,3]; [1]University of Electronic Science and Technology of China, China; [2]Institute of Physics, Chinese Academy of Sciences, China; [3]Tianmulake Institute for Energy Storage, China

Li-free cathodes (e.g. FeS*x*, FeF*x*) demonstrate high operational voltages and high specific capacities, offering high energy densities for rechargeable lithium metal batteries. However, they suffer from severe capacity decay. Here, in this work, we synthesized a series of transition metal sulfides (M = Ti, V, Cr, Mn, Fe, Co, Ni, and Cu). We find that FeSx demonstrates the best cycling stability and rate performances. Its electrochemical reaction mechanism is correspondingly revealed. Pouch cell using FeS*x* as cathodes demonstrates a specific energy density of higher than 350 Wh kg^{-1}. This study reveals that Li-free cathodes will receive broad attentions, especially with the mature of Li metal and electrolyte.

9:30 PM *EN09.10.02
Design Strategies for the Development of Efficient Metal-S Batteries Aninda J. Bhattacharyya; Indian Institute of Science, India

An important strategy for beyond Li-ion rechargeable battery chemistries has been to use cheaper earth-abundant and sustainable electroactive materials. In this line of thought, sulfur is an important example as it is available in considerable abundance and is non-toxic. Sulfur delivers a high theoretical capacity of 1672 mAh g^{-1}, nearly one order higher compared to the best of the intercalation cathodes (IOCs) used in Li/Na-ion batteries. Metal sulfur-based batteries function based on conversion reactions with the possibility of two exchangeable Li-ions per S-atom as compared to approximately one Li-ion/formula unit of IOC. The underlying electrochemistry in a liquid electrolyte-based metal-S battery poses several challenges. The formation of intermediate polysulfides during the reversible conversion of elemental S_8 to metal-sulfide is a major challenge. The majority of the published work focuses on the design of suitable conducting matrices targeted towards high S-loading and efficient entrapment of polysulfides. The initial part of the lecture will discuss a few of our contributions from this perspective for Li/Na/Mg-S batteries. Our work highlights the critical role of materials design and *in operando* studies for the development of highly stable metal-S batteries (Gomes et al. *ACS Sustainable Chem. Eng.* 2020; Bhardwaj et al *ACS Appl. Materials Interfaces. Eng.* 2020; *ACS Appl. Energy Mater.* 2018). The studies reveal several interesting fundamental insights related to the mechanism of storage which eventually has a strong bearing on the metal-sulfur battery performance. For the success of metal-sulfur batteries at the commercial level, drastic new and alternate strategies are necessary. The subsequent part of the talk focuses on this aspect and discusses alternative configurations of metal-sulfur batteries. An important example in this regard is our recent demonstration of a Li-metal free sulfur battery employing a lithiated anatase TiO_2 anode and free-standing Li_2S-carbon cathode (Bhardwaj et al, 2021).

10:00 PM EN09.10.03
A Development of Low-Electrolyte Lithium-Sulfur Cells with High-Loading Sulfur Cathodes Sheng-Heng Chung and Yin-Ju Yen; National Cheng Kung University, Taiwan

The increasing demand for advanced rechargeable batteries featuring a high energy density and high electrochemical efficiency has driven the development of new electrode materials with a higher charge-storage capacity than those of traditional intercalation cathodes. In this regard, the conversion lithium-sulfur battery is the most promising inexpensive, high-capacity novel rechargeable battery system because of the low cost, wide availability, low environmental impact, and high energy density of sulfur. However, the fast progress in the lithium-sulfur technology has encountered the inability to develop a high-loading sulfur cathode with a promising electrochemical performance in a lean-electrolyte lithium-sulfur battery. A result of the insulating nature of solid active materials and the diffusion problem of the liquid active materials, the lithium-sulfur literature usually reports performance of devices by utilizing a sulfur loading and sulfur content of less than 4 mg cm^{-2} and 60 wt%, respectively, in a cell using an excess amount of liquid electrolyte with a high electrolyte-to-sulfur ratio of over 11–20 μL mg^{-1}. Unfortunately, this might result in a challenge in the development and investigation of the lean-electrolyte lithium-sulfur cell with high-loading sulfur cathode and with high electrochemical utilization of sulfur.

In our presentation, we present the development of a lean-electrolyte lithium-sulfur with low electrolyte-to-sulfur ratios of 4–7 μL mg^{-1}. In the lean-electrolyte lithium-sulfur, a high-loading sulfur cathode with a high sulfur content of 68 wt% and a high sulfur loading of 8.64 mg cm^{-2} demonstrates high electrochemical utilization, excellent reaction kinetics, and stable cyclability. The cells exhibit discharge capacities of 630–870 mAh g^{-1} and 580–631 mAh g^{-1} at C/10 and C/5 cycling rates for 200 cycles. The corresponding energy density values attain 11–16 mWh cm^{-2}. Moreover, we investigate the possible failure mechanism of a lean-electrolyte lithium-sulfur cell with a high-loading sulfur cathode. Our study indicates that the consumption of electrolyte during cycling leads to the slow ion diffusion and the deposition of insulating solid active material on the electrode, which causes the decreased Coulombic efficiency and irreversible capacity loss. Therefore, it would be necessary studies of the lithium-sulfur battery cathode at a slow rate for a long cycle life to guarantee the electrochemical stability and with the Coulombic efficiency to ensure the cyclability and the electrochemical efficiency during long cycles.

In conclusion, our cathode and cell design exhibit an outstanding cathode performance featuring high energy density and long cyclability with a high amount of sulfur at a lean electrolyte condition. Moreover, we explore the challenges that might be encountered by other high-loading cathodes under research at a low electrolyte-to-sulfur ratio, and propose the possible analytical tools and solutions to address the issues found.

10:05 PM EN09.10.04
Ni-Rich Layered Oxide Cathodes Using Mixed Catholytes of Sulfide and Halide for All-Solid-State Batteries Jong Seok Kim, Yoonjae Han and Yoon Seok Jung; Yonsei University, Korea (the Republic of)

Owing to the high energy density, lithium-ion batteries (LIBs) have expanded their applications from mobile electronic devices to electric vehicles and energy storage systems. In terms of high energy density and safety, all-solid-state lithium batteries (ASLBs) are promising next-generation batteries. Ni-rich layered lithium metal oxides, $LiMO_2$ (M = Co, Ni, Mn, Al), and inorganic solid electrolytes are considered as the crucial components for high-performance ASLBs. Especially, sulfide SEs (e.g., $Li_{10}GeP_2S_{12}$, $Li_{5.5}PS_4Cl_{1.5}$) that exhibit the maximum Li^+ conductivity of 10^{-2} S cm^{-1} and mechanical deformability that enables simple cold-pressing-based fabrication of ASLBs, are expected to achieve commercialization of ASLBs.
However, sulfide SEs suffer from serious interfacial degradation between $LiMO_2$ and SEs, which originates from their low electrochemical oxidation stability (< 3 V *vs.* Li/Li^+). Specifically, the high reactivity of Ni^{4+} of $LiMO_2$ induces high interfacial resistances of cathodes. Despite unsatisfactory ionic conductivity (max. 10^{-3} S cm^{-1}), halide SEs have been newly emerging due to their excellent electrochemical oxidation stability (> 4 V *vs.* Li/Li^+) and thus good compatibility with $LiMO_2$[1][2].
In this work, we propose a multi-use of sulfide and halide SEs to compromise their drawbacks for the application to $LiMO_2$ cathodes in ASLBs. The partial replacement of catholytes with Li_3YCl_6 in $LiNi_{0.88}Co_{0.11}Al_{0.01}O_2$ electrodes using Li_6PS_5Cl, which leads to the improved electrochemical performances, will be presented.

10:10 PM EN09.10.05
Stable and High Energy All–Solid–State Lithium Metal Battery by Li Metal Modification Haechannara Lim[1], Seunggoo Jun[1], Yong Bae Song[1], HongYeol Bae[2], Jin-Hong Kim[2] and Yoon Seok Jung[1]; [1]Yonsei University, Korea (the Republic of); [2]RIST, Korea (the Republic of)

Electrification of vehicles boosted research regarding Li ion batteries (LIBs) with higher energy. However, energy density of conventional LIBs has approached its theoretical limit. Applying alternative electrode such as Li metal anode is one promising strategy. Unfortunately, it is hindered by internal short circuit and severe reaction with liquid electrolyte. All-solid-state Li metal batteries (ASLMBs) using non-flammable inorganic solid electrolytes have thus emerged to resolve the problems related with liquid electrolytes and the safety concerns as well. Especially, sulfide solid electrolytes have been one of the most promising candidates thanks to their high ionic conductivities comparable to that of liquid electrolyte (~ 2.0×10^{-2} S cm^{-1}) and mechanically ductile property. However, sulfide SEs also do not fully stabilize Li metal anodes. They are reductively decomposed to form byproducts, such as Li_2S and Li_3P, in contact with Li metal. Moreover, cycling upon high current density leads to the void formation which promotes the dendritic Li growth, which calls for the need to pressurize the ASLMBs. Thus far, in most previous reports, ASLMB cells have been tested using thick Li metal foils (~1 mm). Herein, we report on our recent results of ASLMB cells employing thin (~20 um) Li metal anodes that are prepared by scalable electroplating process. Furthermore, cycling performances affected by the application of protective layers will be presented.

10:15 PM EN09.10.07
Origin of Polysulfide Shuttling in Li-FeS_2 Batteries Aliya S. Lapp[1], Grace Whang[2], Austin Bhandarkar[1], Bruce S. Dunn[2] and A. A. Talin[1]; [1]Sandia National Laboratories, United States; [2]University of California, Los Angeles, United States

FeS_2 is a promising conversion cathode material, due to its earth abundance, low toxicity, and high energy density. Despite these advantages, commercialization of rechargeable Li-FeS_2 batteries has been inhibited by rapid capacity fade. One factor believed to play a critical role in the origin of this capacity fade is polysulfide shuttling. However, mechanistic understanding of polysulfide shuttling in Li-FeS_2 batteries is lacking. Herein, we use in-situ UV-vis spectroscopy to study the formation and shuttling of polysulfides in Li-FeS_2 batteries. We find two key results. First, both our chemical and electrochemical lithiation studies show that polysulfides form during the initial lithiation step. This surprising finding is in contrast with the previously proposed mechanism for Li-FeS_2 batteries. Second, polysulfide shuttling decreases by a factor of 2-4x when an ionic liquid electrolyte is used in place of a conventional organic electrolyte. Furthermore, we show that careful choice of the electrolyte anion can lead to nearly complete polysulfide mitigation. Overall, our results provide important insights for understanding and thus prevention of polysulfide shuttling in Li-FeS_2 batteries.

Bimetallic Co–W–S Chalcogenides Confined in N, S-Codoped Porous Carbon Matrix Derived from Metal-Organic Frameworks for Highly Stable Electrochemical Energy Storage Devices Nageh K. Allam; American University in Cairo, Egypt

Transition-metal dichalcogenides are gaining much interest in the energy storage sector due to the two-dimensional (2D) nature and conductivity of the materials. However, single transition-metal dichalcogenides are not stable, preventing their practical use in real devices. Herein, we demonstrate the

synthesis of binary metal dichalcogenides (Co–W–S) via carbonization of zeolitic imidazolate framework (ZIF-67), a subclass of metal-organic frameworks, encapsulated with phosphotungstic acid (PTA@ZIF-67). The morphology and surface functional groups of the as-synthesized Co–W–S composite are characterized via field-emission scanning electron microscopy (FESEM), high-resolution transmission electron microscopy (HRTEM), and Fourier transform infrared (FTIR) spectroscopy. Furthermore, the crystal structure and elemental composition of the fabricated Co–W–S composite are elucidated by X-ray diffraction (XRD) and X-ray photoelectron spectroscopy (XPS) analyses. Upon testing its electrochemical performance as a supercapacitor electrode, the fabricated Co–W–S@N, S-codoped porous carbon (N, S-PC) shows exceptional specific capacitance (1929 F g^{-1} at 5 mV s^{-1}). Furthermore, the constructed asymmetric supercapacitor device using Co–W–S@N, S-PC, and activated carbon as positive and negative poles, respectively, displays superior energy density and power density of 32.9 Wh kg^{-1} and 700.2 W kg^{-1}, respectively, with high Columbic efficiency over 10 000 charge/discharge cycles at 10 A g^{-1}.

Role of Spin Interactions in Thermoelectric Properties of Fe-Rich Magnetic FeTe Md Mobarak Hossain Polash and Daryoosh Vashaee; North Carolina State University, United States

The anomalous thermoelectric transport properties of iron-telluride (FeTe) near magneto-structural transition temperature (~70K) have been reported earlier with little insight. The coexistence of magnetism and quantum effects can be the probable origin of these anomalies, requiring detailed investigations of the magnetic, galvanomagnetic, and thermoelectric transport properties. The magnetic susceptibility shows a bicollinear stripe type spin ordering in the antiferromagnetic domain and short-range ferromagnetic ordering at the beginning of the paramagnetic domain. The galvanomagnetic properties reveal a multicarrier transport impacted by spin fluctuations. Further, phonon- and magnon-drag contributions are evaluated related to the origin of the anomalous thermoelectric properties. The small entropy contribution from the magnonic heat capacity supports the phonon-drag as the origin of a thermopower peak at ~50K, while the field-dependent reduction of the thermopower is associated with the field-dependent modification of the spin-phonon interaction. The field-dependent change of the paramagnetic thermopower is attributed to the spin-fluctuation suppression or the paramagnons. The sharp drop in thermal conductivity above ~70K is related to the structural change modifying the phonon modes. The knowledge gained from studying the spin and quantum effects on transport properties of FeTe is instrumental for designing high-performance spin-driven thermoelectrics.

4:15 PM EN10.14.03
Characterization of Intra- and Inter-Valley Scattering in Thermoelectric Materials—A First-Principles Investigation Vahid Askarpour and Jesse Maassen; Dalhousie University, Canada

A major goal of thermoelectric (TE) research is to find or develop materials with improved efficiencies. One strategy towards higher-performance TEs is band convergence, which seeks to align multiple electronic valleys within a narrow energy range. This approach can boost the power factor, a component of TE efficiency, compared to a single valley by simultaneously increasing the Seebeck coefficient and the electrical conductivity – two competing quantities. While band convergence has been demonstrated experimentally and is the source of many theoretical studies, rigorous scattering calculations indicate that the benefits of this strategy depend sensitively on the strength of inter-valley collision processes. Unlike intra-valley scattering with both initial and final states residing within the same valley, inter-valley processes scatter carriers from one valley to another. The latter can increase significantly when aligning multiple valleys, and potentially offset the gains from band convergence.

In this talk, we present results of a first-principles investigation to characterize, and to understand what controls, intra- and inter-valley electron-phonon scattering in TE materials. For this study we selected six materials, including three lead chalcogenides (PbS, PbSe, PbTe) and three half-Heuslers (ScNiBi, ScPbSb, ZrNiSn), which possess multiple equivalent conduction valleys. Density functional theory (DFT) was utilized to rigorously compute the electron-

phonon scattering and TE characteristics. The intra- and inter-valley scattering rates are analyzed by separating the contributions originating from the electron dispersion and from the electron-phonon coupling, and by elucidating what controls each component. We find that increasing the energy of the zone-edge phonons is effective at reducing inter-valley scattering and enhancing the power factor by >50%. Finally, since DFT electron-phonon calculations can be very demanding, we propose a simple approach to estimate the inter-valley coupling strength, which is found to agree qualitatively with the rigorous results. These findings provide insights into what controls the scattering characteristics to help to guide our search and design of new TE materials with reduced inter-valley scattering and enhanced power factors.

Grain Size Dependence of Thermoelectric and Thermomagnetic Transport in the Weyl Semimetal NbP Eleanor Scott[1], Katherine Schlaak[1], Chenguang Fu[2], Satya N. Guin[3], Safa Khodabakhsh[1], Ashley Paz y Puente[1], Claudia Felser[3] and Sarah J. Watzman[1]; [1]University of Cincinnati, United States; [2]Zhejiang University, China; [3]Max Planck Institute for Chemical Physics of Solids, Germany

Weyl semimetals combine both topological and semimetallic effects in their transport of fermions through both bulk and surface states, making them excellent candidates for transverse thermoelectric transport via the Nernst effect. The Nernst effect is a transverse thermoelectric effect in which an applied magnetic field and perpendicular temperature gradient produce a mutually perpendicular voltage. The applied field creates a skew force separating charge carriers. Contributions from both polarities of charge carriers add together, so two-carrier systems such as NbP and other Weyl semimetals are advantageous. Single crystalline NbP has shown an unprecedentedly large Nernst thermopower, exceeding 800 microV K-1 at 109 K and 9 T [1]. Bulk polycrystalline NbP maintains a large Nernst thermopower, although its magnitude is decreased by approximately a factor of 8 under similar circumstances [2]. Here, we explore both transverse and longitudinal thermoelectric and thermomagnetic transport as a function of grain size in bulk polycrystalline samples of NbP, where different annealing times result in different grain sizes. The polycrystalline samples show a significantly larger Seebeck coefficient in comparison to results in single-crystalline NbP, however this decreases with increasing grain size. The Nernst thermopower is much smaller when compared to single-crystalline NbP, however the Nernst effect is still very pronounced in polycrystalline NbP, even as the Nernst thermopower decreases with increasing grain size. Polycrystalline NbP also exhibits a large isothermal magneto-Seebeck effect, which was rigorously not the case in isothermal measurements of single-crystalline NbP. The polycrystalline samples' deviation in transport from results on single-crystalline NbP are hypothesized to be due to increasing the number of grains and thus interfaces of the topological material, which can then cause topological states to potentially dominate transport. The field dependence of electrical resistivity, thermal conductivity, and the Hall effect in each sample have also been determined. Chemical analysis has been completed using ICP-OES in order to determine the effect of annealing on composition and ensure it remained consistent for each sample. Via microstructural characterization and thermoelectric transport measurements, we can begin to determine the effects of grain size on transport in Weyl semimetals.

***In Situ* Performance of a Nanostructured Bulk Thermoelectric Generator in the Core of a Nuclear Reactor** Nicholas Kempf[1], Mortaza Saeidi-Javash[1], Haowei Xu[2], Ju Li[2] and Yanliang Zhang[1]; [1]University of Notre Dame, United States; [2]Massachusetts Institute of Technology, United States

Thermoelectric devices placed in the core of a nuclear reactor can generate electricity from thermal energy to enable self-powered sensors for in-situ monitoring of critical parameters of the nuclear fuel assembly, increasing power plant safety. The in-situ performance of a Thermoelectric Generator (TEG) has never been tested in the extreme environment of a nuclear reactor core. A TEG made from state-of-the-art nanostructured bulk half-Heusler materials was inserted into the core of a nuclear reactor and irradiated for 30 days to an exposure of 153 megawatt-days. The TEG electrical resistance, voltage, and power output were measured continuously while it generated electricity using radiation as a heat source. Despite a sharp drop in TEG power when operating at relatively lower temperature, the TEG showed a 1900% increase in power output due to in-situ annealing and a significant recovery of both the Seebeck coefficient and electrical conductivity when operating at increased temperature and reactor power. Atomic scale modeling indicates the irradiation provided sufficient energy to induce a partial phase transformation, converting the semiconducting half-Heusler structure into a metallic phase stable at low temperatures. However, with sufficient thermal energy, the structure reverts to the original non-irradiated phase and thermoelectric properties quickly recover. The same materials comprising the TEG were separately irradiated with alpha particles and scanning thermal microscopy was used to determine the influence of irradiation dose on thermal conductivity and Seebeck coefficient while microstructural characterization of the irradiated materials confirmed predictions from atomic scale modeling. These results indicate the thermoelectric materials experienced thermally activated healing during which irradiation-induced defects were annihilated and the material microstructure partially recovered along with the thermoelectric properties. These results suggest that with proper control over the TEG operating temperatures, the nanostructured half-Heusler TEG could produce power and operate indefinitely in the core of a nuclear reactor. This work creates opportunities for solid-state power generation utilizing high-efficiency nanostructured thermoelectric materials in the harsh environment of a nuclear reactor.

Grain Size Dependence of Thermoelectric and Thermomagnetic Transport in the Triple Point Topological Metal MoP Abhishek Saini[1], Chenguang Fu[2,3], Safa Khodabakhsh[1], Ashley Paz y Puente[1], Claudia Felser[3] and Sarah J. Watzman[1]; [1]University of Cincinnati, United States; [2]Zhejiang University, China; [3]Max Planck Institute for Chemical Physics of Solids, Germany

MoP (Molybdenum Phosphide) is a topological metal which has been shown to host a triply degenerate point in its electronic structure and a pair of Weyl points in its bulk electronic structure [1]. Its complex band structure makes it unique for electrical and thermal transport, with single-crystalline MoP previously demonstrating an extremely high electrical conductivity and the potential for hydrodynamic charge flow [2]. In this work, both longitudinal thermoelectric (Seebeck effect) and transverse thermomagnetic (Nernst effect) phenomena are investigated for the first time in polycrystalline samples of MoP over a range of temperatures (2 K – 400 K) and externally applied magnetic fields (-9 T to +9 T). Temperature and magnetic field dependent measurements of thermal conductivity, electrical resistivity, and the Hall effect are also investigated. This study is extended to grain-size dependence of the aforementioned physical properties by annealing different samples for varying amounts of time to promote grain growth, with average grain size confirmed via SEM.
Compared to single-crystalline MoP [2], thermal conductivity is found to be approximately 2 orders of magnitude smaller while electrical resistivity is 1-2 orders higher in polycrystalline MoP. The Seebeck coefficient is small, due to a very high carrier density as is the case with most metals, with a maximum value of ~4 $\mu V K^{-1}$ at 380 K. A small magneto-Seebeck effect is seen at temperatures below 200 K with the magnitude of the Seebeck coefficient decreasing in a magnetic field. At temperatures below 100 K, thermal conductivity has also been found to decrease in a magnetic field, with the effect most pronounced at the peak of thermal conductivity in the temperature range of 28-35 K. The magnetoresistance effect is large and increases with decreasing temperatures, showing a similar trend in comparison to single-crystalline MoP [2]. Moreover, a minimal Nernst effect is detected. Furthermore, the effect of grain size is clearly visible in these measured transport properties. Thermal conductivity increases significantly with increasing grain size, while the

electrical resistivity reduced marginally with larger grain size. The magnitude of the Seebeck coefficient also increased in larger grain-sized samples. These changes can be attributed to the reduced number of grain boundaries in the material due to annealing and hence lesser obstruction to charge flow.

5:15 PM EN10.14.07
Measurements of Thermal Conductivity of Porous Media by Time-Domain Thermoreflectance (TDTR) Using Transferred Metal Films Husam Walwil[1], Yunshan Zhao[2,1], John Thong[1,3] and Yee Kan Koh[1]; [1]National University of Singapore, Singapore; [2]Nanjing Normal University of China, China; [3]Singapore Institute of Technology, Singapore

Thermal transport in porous structures is yet to be fully understood. For example, the influence of the microstructure's heterogeneities in porous electrodes of Li ion batteries remain poorly addressed, in part due to challenges in accurate thermal measurement of porous samples. In this talk, we introduce an approach based on time-domain thermoreflectance (TDTR) to accurately measure the thermal conductivity of porous materials, by transferring a metal film to bridge the micro-pores to provide a continuous, flat, and smooth surface for TDTR measurements. We demonstrate our approach by measuring the cross-plane thermal conductivity (k_{PnC}) of a wide range of microscale SiO_2 phononic crystals, with pore diameters of 1 – 3.5 μm and porosity of 13 – 50 %. To achieve accurate TDTR measurements, we ensure that the metal transducer films are sufficiently stiff and thus establish good thermal contact with the necks of the phononic crystals. The good agreement between our k_{PnC} measurements and calculations of effective medium theory validates our approach. We also introduce a guideline that allows the design of the film transfer process onto the porous materials. This approach could be conveniently employed in future studies of heat transport in a wide range of porous materials.

Ultra-Sensitive Thermometry Enables Direct Measurements of Reversible Heat Absorption in Li-Ion Batteries Zhe Cheng and David Cahill; University of Illinois at Urbana-Champaign, United States

The control of temperature in lithium-ion batteries (LIBs) is critically important for the performance, reliability, and safety of LIBs. To design proper thermal management strategies, a greater understanding of thermal effects in LIBs is needed. The reversible heat in LIBs due to entropy change is fundamentally important to understand the chemical reactions in LIBs. However, the reversible heat has not been directly measured previously due to the limited temperature resolution of applied thermometry. We develop an ultra-sensitive thermometry with a noise floor of 32 μK/sqrt(Hz) and a noise equivalent temperature resolution of ± 10 μK, which is several orders of magnitude higher than previous temperature measurements applied on LIBs in the literature. We observe the reversible heat absorption of a LIR2032 coin cell during charging with negligible irreversible heat generations at a charging rate of C/200. The entropy changes of the cell obtained from the directly measured reversible heat agree excellently with the entropy changes obtained by measuring temperature dependent open circuit voltage (OCV). This is the first verification of the way to obtain entropy changes by measuring temperature dependent OCV which is widely used in the literature, while the changes in mechanical stress with temperature could also possibly change OCV. Our work enables a new regime of studying thermal effects in batteries at charging rates orders of magnitude lower than previous works, and significantly contributes to fundamental understanding of the entropy changes of the chemical reactions in LIBs.

Using Frost to Promote Cassie Ice on Hydrophilic Pillars Hyunggon Park[1], Farzad Ahmadi[2] and Jonathan Boreyko[1]; [1]Virginia Tech, United States; [2]University of California, Santa Barbara, United States

Nanostructured superhydrophobic coatings can trap air pockets underneath ice and frost, greatly reducing their adhesion strength to the surface, but these coatings readily degrade in real-life conditions. Here, we develop a novel approach to trapping air pockets between ice and hydrophilic aluminum micropillars that does not require any hydrophobic coatings or nanostructures. First, frost was preferentially grown atop the micropillars by a two-step process: condensation primarily grew on top of the micropillars due to their sharp corners and elevation over the non-condensable gas barrier; as this upper condensate froze, it evaporated any underlying condensate due to the hygroscopic nature of ice. Second, Cassie ice was formed by virtue of the impacting droplets freezing atop the frost-tipped micropillars before impalement could occur. A scaling model reveals that the dynamic pressure of an impacting droplet causes the water to wick inside the frost much faster than the time scale to impale between the pillars. Our findings suggest that frost-tipped structures can suspend freezing droplets in the Cassie state.

Bridging-Droplet Thermal Diodes Mojtaba Edalatpour and Jonathan Boreyko; Virginia Tech, United States

Solid-state thermal diodes are bottlenecked by poor diodicity while phase-change thermal diodes are constrained by either a gravitational dependence, a 1D configuration, or poor durability. Here, we invent a novel bridging-droplet thermal diode which bypasses all of these existing shortcomings. Our diode consists of two opposing copper plates separated by a micrometric-thick insulating gasket; one plate contains a superhydrophilic wick structure while the other contains a smooth hydrophobic coating. In the forward mode of operation, liquid water evaporates from the heated wicked plate and vapor condenses onto the hydrophobic plate. The large contact angle of the dropwise condensate enables droplet bridging across the gap to replenish the wicked evaporator, sustaining the phase-change heat transfer. Conversely, in the reverse mode, our diode is an excellent thermal insulator as the heat source is now on the back face of the hydrophobic plate. A lumped resistance thermal model is developed to quantify the overall heat transfer coefficient across our thermal diode. Results show that the overall heat transfer ratio (i.e. diodicity) can be boosted considerably through careful design of the wick structure and gasket thickness.

Learning Hidden Physics from Reduced-Order Modeling of Bubble Dynamics in Boiling Heat Transfer Arif Rokoni[1], Lige Zhang[1], Tejaswi Soori[1], Han Hu[2] and Ying Sun[1]; [1]Drexel University, United States; [2]University of Arkansas, United States

Boiling heat transfer is a highly effective but stochastic process where the working fluid undergoes vigorous liquid to vapor transition. Physics-based modeling of bubble dynamics during boiling is challenging due to the drastic changes in system parameters, such as nucleation, bubble morphology, temperature, pressure, and velocity. The vast amount of data from both experiments and numerical simulations have led to the use of artificial intelligence (AI)/deep learning (DL) to gain valuable physical understanding of complex phenomena occurring during natural and industrial processes, including reduced order modeling, turbulence closure model, flow control, and extraction of governing equations. Real-time analysis of bubble statistics in pool boiling is challenging at high heat fluxes where vigorous bubble coalescence is observed. Unsupervised deep learning approaches, such as principal component analysis (PCA), clustering, and autoencoders, have the advantage of minimal human intervention unlike supervised learning. The PCA is a versatile data-analysis tool to determine low-dimensional representations of high-dimensional images by extracting dominant variations and patterns in the raw data without any supervision. In nuclear reactors and other boiling heat transfer applications, early forecasting of the boiling crisis can aid in mitigating catastrophic damage of the heater surface. To predict the future states of the boiling phenomena, long short-term memory (LSTM) neural network is a very efficient tool to estimate time-series variations in the input data, such as bubble dynamics.
In the present study, PCA is used to extract hidden physics from boiling heat transfer processes using in-house pool boiling experimental images of the bubble dynamics. The principal component (PC) representations are made in the new low-dimensional coordinate system by determining the dominant correlations within the high-dimensional data. The first few dominating principal components are used to reconstruct the instantaneous bubble shape and size, which drastically reduces the dimensions of boiling images. The results show that the dominant frequency of the first PC increases with heat flux in the discrete bubble regime until it reaches a peak and then decreases with heat flux in the bubble interference and coalescence regime where the former is associated with the increase in bubble nucleation sites and the latter is associated with the bubble coalescence during pool boiling. Image segmentation is also performed to capture bubble statistics, such as size and numbers to verify the findings of PCA analysis. The temporal variations of the PCs are then used as training data for long short-term memory (LSTM) which predicts the future variations of the PCs. Future predictions of PCs are used to reconstruct the bubble images demonstrating the capability of deep learning (DL) model to predict bubble dynamics. Both steady state and transient pool boiling cases are studied using PCA-LSTM DL algorithm and trained DL model can predict bubble dynamics well.

Design of a Multiscale Ceramic Heat Exchanger for High-Temperature, High-Pressure Applications Chad Wilson[1], Xiangyu Li[1], Evelyn N. Wang[1], Olivia Brandt[2], Rodrigo Orta Guerra[2], Rodney W. Trice[2] and Jeffrey P. Youngblood[2]; [1]Massachusetts Institute of Technology, United States; [2]Purdue University, United States

By operating in a high-temperature, high-pressure environment, the efficiency of a thermodynamic cycle can be significantly improved. However, extreme operating conditions require material and design innovations on the classic heat exchanger component. Previous work has attempted to develop heat exchangers for extreme environments by employing superalloy materials in traditional architectures, leading to costly fabrication and limited power density improvement. In this work, we present the design of a multiscale silicon carbide heat exchanger capable of operating in extreme conditions (1300 °C, 250 bar). Enabled by ceramic co-extrusion and geometrically optimized for both high thermal performance and mechanical strength during steady state operation, our heat exchanger offers a scalable and effective solution to address traditional material limitations while offering promising efficiency and performance improvements compared to current state-of-the-art heat exchangers.

SESSION EN10.02: Thermoelectrics I

1:30 PM EN10.02.01
Re_4Si_7-Based Transverse Thermoelectric Generator with No Hot-Side Contacts Michael R. Scudder[1], Bin He[1], Yaxian Wang[1], Aksah Rai[2], David Cahill[2], Wolfgang Windl[1], Joseph Heremans[1,1,1] and Joshua E. Goldberger[1]; [1]The Ohio State University, United States; [2]University of Illinois at Urbana-Champaign, United States

Making diffusion-resistant and thermally stable electrical and thermal contacts to the hot side of a thermocouple-based thermoelectric generator (TEG) is a major technological challenge. Such contacts are not needed in transverse thermoelectric devices, in which a thermal gradient in a single material with two cold end contacts induces a perpendicular voltage. Furthermore, the contact resistances of multi-thermocouple (thermopile) generators contribute irreversible losses, to the extent that the device figure of merit ZT of such a thermopile-based TEG is often much lower than the materials zT of the n-type and p-type legs. In a transverse TEG, only two voltage contacts are needed, reducing the irreversible losses in the contacts and bringing ZT much closer to the material transverse thermoelectric figure of merit, zxy¬T. Until now material zxyT values have always been too low for practical applications. When cut at a particular angle, single-crystals of Re4Si7 have a zxyT of 0.7±0.15 at 980 K. A combination of thermal and electronic measurements of multiple single crystals with different doping levels, density functional theory calculations, and analytical models establish that these large zxy¬T values come from anisotropic thermopowers that arise from thermal population of the highly anisotropic valence band and isotropic conduction band. A transverse Re4Si7 TEG was constructed with no contacts on the hot side, and the ZT derived from measurements of its thermal efficiency near 600 K fits the values of zxy¬T well. This proves experimentally that contact losses are minimized in this geometry as well. Hopefully, thus, transverse TEGs open a new approach to circumventing two of the major technological problems that stand in the way of making practical TEGs.

1:45 PM EN10.02.02
Exploring the Effects of Counter Ion Chemistry in Doped Thermoelectric Carbon Nanotube Networks Tucker L. Murrey[1], Taylor Aubry[2], Jeffrey Blackburn[2] and Andrew Ferguson[2]; [1]University of California, Davis, United States; [2]National Renewable Energy Laboratory, United States

Semiconducting single walled carbon nanotubes (s-SWCNTs) have demonstrated promising performance in low temperature thermoelectric thin films. Like polymer-based organic electronic materials, charge carrier density and in-turn thermoelectric properties, can be tuned using molecular charge-transfer dopants. In this work, we build upon previous demonstrations of p-type doping by employing a series of novel molecular dopants based on dodecaborane (DDB) clusters. The unique chemical and electronic structure of these DDB clusters, compared to oxidants like triethyloxonium hexachloroantimonate (OA) and 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F4TCNQ), increases the spatial separation between the negative DDB counter ion and the hole carriers injected into the nanotubes. Thereby increasing the mobility of the charge carriers and yielding an increase in the thermopower (Seebeck coefficient) for a given electrical conductivity. This enhanced transport ultimately increases the thermoelectric power factor to surpass the previous best-in-class for enriched s-SWCNT thin film networks.

2:00 PM EN10.02.03
Hybrid Ionic-Electronic Thermoelectric Converters to Harvest Heat from Temperature Gradient and Temperature Fluctuation Jianyong Ouyang; National University of Singapore, Singapore

Although great progress has been made in thermoelectric conversion, the performance of thermoelectric generators is still not good enough for large-scale practical application. The conventional thermoelectric generators utilize heat only from the temperature gradient through the Seebeck effect. Apart from the temperature gradient, the temperature related to waste heat always fluctuates. Here, I will report our work on developing hybrid ionic-electronic thermoelectric converters that can harvest generate electricity from both temperature gradient and temperature fluctuation. As a result, they can generate output power at least 4 times of the conventional thermoelectric generators.

2:15 PM EN10.02.04
Towards Tellurium-Free Thermoelectric Modules for Power Generation from Low-Grade Heat Pingjun Ying[1], Ran He[1], Jun Mao[2], Qihao Zhang[1], Heiko Reith[1], Jiehe Sui[3], Zhifeng Ren[2], Gabi Schierning[1,4] and Kornelius Nielsch[1,5,5]; [1]IFW Dresden, Germany; [2]University of Houston, United States; [3]National Key Laboratory for Precision Hot Processing of Metals, China; [4]University of Bielefeld, Germany; [5]Technische Universität Dresden, Germany

Thermoelectric technology converts heat into electricity directly and is a promising source of clean electricity. Commercial thermoelectric modules have relied on Bi_2Te_3-based compounds because of their unparalleled thermoelectric properties at temperatures associated with low-grade heat up to 550 K. However, the scarcity of elemental Te greatly limits the applicability of such modules. Here we report the performance of thermoelectric modules assembled from Bi_2Te_3-substitute compounds, including p-type MgAgSb and n-type $Mg_3(Sb,Bi)_2$, by using a simple, versatile, and thus scalable processing routine. For a temperature difference of 250 K, whereas a single-stage module displayed a conversion efficiency of 6.5 $^0/_0$, a module using segmented n-type legs displayed a record efficiency of 7.0 $^0/_0$ that is comparable to the state-of-the-art Bi_2Te_3-based thermoelectric modules. Our work demonstrates the feasibility and scalability of high-performance thermoelectric modules based on sustainable elements for recovering low-grade heat.

Silicon—A Revenant Thermoelectric Material for Micropower Applications Mark Lee[1], Ruchika Dhawan[1], Hari P. Panthi[1] and Hal Edwards[2]; [1]The University of Texas at Dallas, United States; [2]Texas Instruments, United States

The development of miniature (~ 0.1 cm^2 area) silicon integrated circuit (IC) sensors and networking devices for internet-of-things (IoT) and biomedical electronics has spurred the question of how to make such devices energy autonomous, i.e., how to reliably and sustainably energize such devices when they are embedded in remote environments that are often dark, have no access to wall plug power, and are not routinely accessible for battery replacement. Recently, interest has developed in small microelectronic thermoelectric generators (μTEGs) as one method to give IoT and biomedical devices energy autonomy wherever a reliable thermal gradient exists. Most current research on TE technology concentrates on developing new materials having a high TE figure-of-merit $ZT = (S^2\sigma/\kappa)T$, where S, σ, and κ are the material's thermopower, electrical conductivity, and thermal conductivity, and T is the mean operating temperature. Doped Si is known to have a poor $ZT \sim 0.01$ due to its high κ. The focus on complex materials having high $ZT \sim 1$ is because a TEG's ideal thermodynamic efficiency increases with the ZT of the materials used to form the thermopile. However, high ZT materials can be expensive to synthesize, often contain toxic or non-earth-abundant elements, and are generally incompatible with Si IC processing, all of which can substantially increase the cost of integration with standard IC devices.

We report on small area (<< 1 mm^2) μTEGs using doped Si and $Si_{0.97}Ge_{0.03}$ as the TE material, all fabricated on a standard industrial Si IC process line following the same protocols and process flows used to make commercial IC devices. These μTEGs can generate specific power densities (per unit area for heat flow per square of temperature difference, ΔT) greater than 80 $\mu Wcm^{-2}K^{-2}$, which is comparable to or better than most existing bulk TEGs using high ZT materials. Moreover, these small area Si μTEGs can generate voltages exceeding 1.5 V with several μA of current using commonly encountered ΔTs ~ 20 to 25 °C. This voltage and current level is sufficient to properly energize some existing commercially available IoT ICs using only a warm copper rod as the energy source. Because these μTEGs can be directly integrated on-chip in the same process flow with the circuits they support, they provide one solution to energy autonomy at extremely low marginal cost.

These Si-based μTEGs build on an alternative approach to μTEG device design that emphasizes application of device physics and circuit engineering principles to optimize a μTEG's generated power per unit area at any given ΔT, rather than narrowly focusing on thermodynamic efficiency. This strategy exploits the ability of industrial Si processing to fabricate thermopiles consisting of a very large number of TE elements in a small area, thereby producing a high total power and voltage density despite relatively low efficiency per TE element. Modern Si processing is also very good at controlling parasitic thermal and electrical resistances, thus minimizing extrinsic degradation of overall TEG performance. Experimental results on power and voltage generation as well as Peltier cooling will be presented. Physics-based models for optimizing performance will also be discussed at both the material level (e.g., effects of dopant concentration and small percentage Ge alloying) and the device design level (e.g., effects of parasitic electrical and thermal resistances and proper design of thermopile packing fraction).

2:45 PM EN10.02.06
High-Throughput Printing and Doping Engineering of High-Performance and Flexible Thermoelectric Devices Using Colloidal Nanocrystal Inks Yanliang Zhang; University of Notre Dame, United States

The flexible thermoelectric generator (f-TEG) is a very promising technology for energy harvesting to enable self-powered wireless sensors and wearable devices, an area of exponential growth. Here, we present high-throughput and scalable additive manufacturing methods to fabricate f-TEGs using colloidal nanocrystals, and rapid screening and optimization of doping to achieve unprecedented thermoelectric performances. Flexible TE films with gradient doping concentrations were printed using a high-throughput aerosol jet printing method. A scanning probe method is applied to quickly identify the optimal doping concentrations. Highly scalable extrusion printing (or screen printing) method is applied to print relatively thick films to achieve high thermoelectric efficiency and enable practical device applications. Along with the nanoparticle ink printing, we developed innovative interface engineering and sintering method in order to improve the density and charge carrier mobility of the printed films.
The p-type and n-type printed films demonstrate peak ZTs of 1 and 0.8 near room temperature along with superior flexibility, which is among the highest reported ZT values in flexible thermoelectric materials. A flexible thermoelectric device fabricated using the printed films produces a high power density above 19 mW/cm^2 with 80 K temperature difference between the hot side and cold side. The high-throughput and scalable printing methods can efficient and low-cost manufacturing process to transform high-efficiency colloidal nanocrystals into high-performance and flexible TEG devices for broad range of applications.

Engineering Thermal Conductivity in Thermoelectric Materials G. J. Snyder and Ramya Gurunathan; Northwestern University, United States

Reducing phonon or lattice thermal conductivity is one of the most straightforward ways to improve thermoelectric performance of a material. Introducing phonon scattering easily lowers lattice thermal conductivity but in order to improve thermoelectric performance it must reduce electron mobility to much a lesser extent. While this has been quantified for some point defect scattering examples, it is rarely considered for other scattering mechanisms. Interfaces such as grain boundaries and precipitates are well known to reduce thermal conductivity but their effect on mobility is poorly studied both experimentally and theoretically. Dirty high-angle grain boundaries are known to dramatically reduce mobility in Mg2Si and Mg3Sb2 making some samples unusable as thermoelectrics while clean, low angle grain boundaries can be as good as single crystals. There are many ways to engineer various types of clean, epitaxy-like interfaces in bulk materials.
It has recently become apparent that the low thermal conductivity in PbTe that enables $zT \sim 2$ is largely due to the lattice softening correlated to defects that produce internal strain rather than directly scattering phonons. New revelations about heat transport further indicate that heat is transported diffusively and not even by phonons in many good thermoelectric materials. The detailed understanding of nanoscale microstructure will usher in a new era of nanostructured thermoelectric materials.

Designing Porous Polymers for Passive Daytime Radiative Cooling Yuan Yang; Columbia University, United States

Cooling plays an important role in the human society. It consumes significant amount of electricity and generates 8% of CO2 by human activities. Passive Daytime Radiative Cooling (PDRC) is an electricity-free method for cooling terrestrial entities, which has potential to remarkably reduce electricity consumption. In PDRC, a surface has a solar reflectance of nearly 1 to avoid solar heating, and high emittance close to 1 in the long wavelength infrared (LWIR) transparent window of the atmosphere (wavelength λ = 8- 13 mm) for radiating heat to the cold sky. This allows the surface to passively achieve sub-ambient cooling. In the talk I will present our recent studies on developing porous polymers with excellent PDRC performance. The high density of nano/micropores in polymer leads to efficient light scattering at the interface between the polymer and air, which effectively enhance solar reflectance and thermal emittance. High solar reflectance above 0.96 and high thermal emittance of 0.97 are achieved simultaneously. This talk will emphasize on 1) How to achieve high performance by simple and environmental benign aqueous processing, and 2) Modeling to understand optimal pore distribution in porous radiative cooling polymers.

4:15 PM EN10.03.02
Quantification of the Radiative Contribution to Transient Thermal Grating Decay Alexei Maznev, Sean Robertson, Michael Short and Keith Nelson; Massachusetts Institute of Technology, United States

Thermal conductivity measurements at elevated temperatures are complicated by the contribution of radiative heat transport. Accounting for the radiative contribution is difficult as it often depends on the configuration of the measurement apparatus and the dimensions of the sample. Furthermore, the Radiation Transfer Equation (RTE), which is essentially the Boltzmann transport equation for photons, is difficult to solve even for simple geometries. The laser-induced transient thermal grating (TTG) technique has an advantage in that heat transport takes place entirely within the sample, with no other parts of the apparatus involved, and the simplicity of the sinusoidal spatial temperature profile makes the heat transfer problem amenable to analytical treatment.

In this report, we present a rigorous analysis of the thermal grating decay in a non-scattering absorbing medium in the presence of both radiative transport which is described by the RTE and non-radiative (intrinsic) transport described by the conventional heat diffusion equation. We provide an analytical solution to the coupled equations and quantify the radiative contribution to the effective thermal conductivity. We analyze the limiting cases of diffusive and ballistic radiative transport and show that the radiative contribution is maximized in the intermediate case when the absorption length of thermal radiation is comparable to the heat transfer distance, namely, at $a/L \sim 1/4$, where a is the absorption length and L is the TTG period. We present calculations for specific materials focusing on molten salts that have been proposed as thermal energy transport and storage media. We also calculate the upper bound for the radiative contribution, which does not require the knowledge of the absorption coefficient.

We find that while the radiative contribution to the effective thermal conductivity may be significant for L in the millimeter or centimeter range, in a typical transient grating measurement with $L \leq 20$ μm it will be in most cases negligible. Thus the TTG technique yields the intrinsic thermal conductivity unaffected by radiative transport. In addition to this practical conclusion, our analysis provides a Fourier-domain Green's function that can be used to calculate the temperature field in the presence of radiative transport for an arbitrary initial temperature distribution or an arbitrary distribution of heat sources in an unbounded medium.

A High-Performance Solar-Thermal Regulation Through Switchable Transmittance Window Xuanjie Wang and Shankar Narayanan; Rensselaer Polytechnic Institute, United States

With industrialization and population growth, the rise in energy consumption has become a critical global issue. A significant portion of the energy in buildings is due to heating, ventilation, and air conditioning (HVAC). The major source of the consumption is the heat transfer to building envelopes. Recently, smart windows have been investigated extensively to reduce energy consumption while maintaining thermal comfort for indoor environment. Smart windows are glazed units coated with special materials to have dynamic control on the transmittance of solar irradiation into buildings under different ambient environments. In our study, a high-performance solar-thermal regulation is achieved through switchable transmittance window. Specifically, the surface turns reflective (lessen the cooling demand) and absorbing (lessen the heating demand) under different modes. The difference of solar transmittance ($\Delta\tau$) is 0.59, accordingly. The device level testing shows a good ability of large range thermal regulation under the illuminance of 1 sun.

Nanophotonic Control of Thermal Emission: From Broadband Directionality to Radiative Cooling Aaswath Raman; University of California, Los Angeles, United States

Thermally generated light is a fundamental feature of nature. Its ubiquity makes its control and harnessing both of intrinsic scientific interest and of great importance for energy and heat transfer applications. In this talk, we will discuss our results in nanophotonic approaches to controlling thermal emission, particularly using epsilon-near-zero (ENZ) materials. We will introduce gradient epsilon-near-zero materials that can support leaky electromagnetic modes that couple to free-space waves at fixed angles of incidence over a broad bandwidth. We will then present experimental demonstrations of broadband directional thermal emitters using a range of oxides, designed to operate over long-wave infrared wavelengths. We will furthermore demonstrate implementations of gradient ENZ using doped semiconductors that allow for arbitrary control of spectral bandwidths and directional response as a function of doping gradient, highlighting a new degree of freedom enabled by configuring ENZ response spatially in a layered photonic structure. Finally, we will also illustrate the benefits of directional and spectral control of thermal emission in the context of radiative cooling applications.

$Y_2Ti_2O_5S_2$ - A Quasi-layered Oxysulphide for Thermoelectric Applications Katarina Brlec and David O. Scanlon; University College London, United Kingdom

One of the many pathways to decreasing the impact of climate change is to increase the efficiency of current fossil fuel based systems. Even the best internal combustion engines suffer from thermal losses where up to 70% of energy is lost as exhaust heat. These losses can be offset to an extent by thermoelectric devices which convert waste heat into useful electrical energy via the Seebeck effect. The efficiency of thermoelectric materials is typically evaluated using the figure of merit (ZT), with some of the best performing materials reaching ZTs of over 2 at low temperatures.[1] However, current state-of-the-art thermoelectric materials contain rare or toxic materials, making them commercially unappealing.

The quest for high ZT materials at low temperatures is complicated by the interdependence of the properties that determine ZT, so maximising the factor is challenging. High Seebeck coefficient and low lattice thermal conductivity favour good thermoelectric performance. Generally, anions of differing mass also help to scatter phonons which decreases the lattice thermal conductivity meaning that mixed anion materials are particularly good candidates for the discovery of novel thermoelectrics.

$Y_2Ti_2O_5S_2$ has been studied as a potential battery anode, with both experimental and computational studies agreeing on the presence of fast Li-ion diffusion through the material.[2,3] The unique cation deficient Ruddlesden-Poppler structure opening type I Wadsley-Roth intercalation windows in the distorted perovskite-like TiO5S layer was found to govern the diffusion of species. The relative stability to Li, Na, K and Mg intercalation also points to the the dopability of the material, which is important for thermoelectric purposes.

In this study we use hybrid density functional theory to computationally predict the thermoelectric properties of $Y_2Ti_2O_5S_2$. Analysis of the electronic conductivity and Seebeck coefficient using the state-of-the-art AMSET code, which factors in realistic scattering processes, demonstrates that $Y_2Ti_2O_5S_2$ shows promise for low temperature thermoelectric applications.

EN10.04.04
A Novel Class of Rigid and Structured Capillary Materials by Femto-Laser Etching for Passive Devices—Towards the Water-Energy Nexus Matteo Alberghini[1,2], Matteo Morciano[1,2], Paolo Sirianni[3], Eliodoro Chiavazzo[1], Luciano Scaltrito[1,3], Matteo Fasano[1,2] and Pietro Asinari[1,4]; [1]Politecnico di Torino, Italy; [2]Clean Water Center, Italy; [3]Microla Optoelectronics, Italy; [4]Istituto Italiano di Ricerca Metrologica, Italy

Passive devices based on water absorption and evaporation offer a robust, cost-effective, off-grid and sustainable alternative for a wide variety of applications, ranging from personal thermal management to water treatment, filtration and sustainable cooling technologies. These devices do not require high quality energy inputs and, due to the absence of moving mechanical parts, require low maintenance, are cost-effective and usually made from off-the-shelf materials. Moreover, they are optimal for off-grid installations and, in general, promote the sustainable transition to the water-energy nexus. These devices generally exploit porous capillary media to overcome small hydraulic heads and supply the working fluids throughout the system without the need for active mechanical or electrical components. Clearly, maximizing the capillary properties of the porous materials used is crucial to enhance their overall performance: poor capillary properties leads to dry-out and would significantly limit the maximum achievable device size. Thus, neglecting the capillary properties of the porous materials employed would significantly hinder the productivity and scalability of the proposed technology.

This work proposes a paradigm shift in the design of passive devices by replacing the traditional porous materials with a rigid layer, etched with optimized grooves. The concept was tested on aluminum sheets, which were machined by femto-laser to promote wicking on an otherwise flat surface. The technique guarantees an optimal control of the resulting geometrical parameters of the channel, which, through its interplay with the material surface chemistry, allows fine-tuning of the resulting capillary properties. The wicking properties of the obtained sample were compared with those of other engineered porous layers, used as components of passive devices previously reported in the literature. The experimental results were interpreted by a novel theoretical model for mass transfer in open microchannels, which was then used to estimate the effects of the geometry and hydrophilicity of the grooves on their resulting capillary action. Finally, the perspective application of the proposed material in passive desalination devices was investigated both theoretically and experimentally. First, the validated capillary model was coupled with a lumped-parameters heat and mass transfer model for vapor transport in hydrophobic membranes, aiming to evaluate how the capillary properties of porous materials affect the optimal size and maximum productivity of such devices. Then, the salt-rejection capabilities and the durability of the proposed material were evaluated.

The developed theoretical model might serve as a tool to investigate the combined effects of capillary and geometric properties and working conditions on the design constraints of a passive devices component and identify its optimal configuration. Furthermore, the experimental investigation demonstrates the potential of the proposed material for novel components of passive devices for the energy and water sector, paving the way to a new class of rigid materials capable of significant scalability and, thus, their range of use.

EN10.04.05
Scalable and Robust Silica Aerogel Materials from Ambient Pressure Drying Massimigliano Di Luigi and Shenqiang Ren; University at Buffalo, United States

Aerogels constitute one of the best thermal insulating materials, typically featuring remarkably low values of thermal conductivity due to their extremely high porosity above 95% comprised mostly of mesopores with an average size of approximately 10 nm, as well as considerably high values of specific surface area (> 500 m^2/g), all properties that result in an outstanding option for applications related to energy saving purposes. However, two of their main disadvantages are associated to (a) a relatively high cost at industrial level, and (b) their brittleness and lack of good mechanical properties as a consequence. By leveraging the benefits of ion-exchange sodium silicate solution as silica source, as well as the use of surfactants, we report an ambient pressure drying silica aerogel nanocomposite material that yields superior thermal insulation and mechanical properties. Such combination of components and process parameters provide an exceptionally overall low-cost alternative for the production of aerogel-based, eco-friendly solutions that are suitable for energy efficient applications.

EN10.04.06
Heterogeneous Nucleation of Gallium with Lattice-Matched Cubic Carbides and Nitrides Phases Sourav Chakravarty[1], Darin Sharar[2] and Patrick Shamberger[1]; [1]Texas A&M University, United States; [2]CCDC Army Research Laboratory, United States

Latent thermal energy systems (LTES) store/discharge energy at nearly constant temperatures using melting/solidification of phase change materials (PCMs). However, energy barriers associated with the nucleation of a solid can cause the liquid state to remain in a metastable state below the equilibrium melting temperature, requiring additional undercooling to initiate solidification. Thus, the existence of undercooling tends to reduce reversibility and overall efficiency of LTES, and to introducing an element of stochastic variability in the solidification process that makes accurate prediction of the state of the system challenging. Among PCMs, metallic PCMs are of particular interest because of their high volumetric energy density and ability to rapidly absorb heat, which is critical in thermal management of electronics, optical, and photovoltaic systems. Gallium is a low melting metal (T_{fusion} = 30 °C) with a high volumetric energy density (400 MJ/m^3) and high thermal conductivity (29.4 W/m°C), making it an ideal candidate for room temperature thermal management applications, where rapid absorption of heat is a key performance indicator. However, the application of Ga as a PCM is severely limited due to the large degree of undercooling, which can exceed 60 °C in small volumes (10 ml) as measured by DSC in aluminum containers at relatively rapid cooling rates (10 °C/min). Here, we exploit epitaxial relationships to identify several cubic carbide and nitride phases that reduce the undercooling of Ga. Among these, HfC and ZrN result in maximum reduction undercooling, with undercooling in the range of <20° C and <10° C for volumes of 10 ml. The observed relationship between lattice mismatch and measured undercooling conform to the relationship predicted by heterogeneous nucleation theory. Thus, this study supports parallel efforts in other classes of materials systems (organic compounds, inorganic salts and salt hydrates), which suggest that epitaxial relationships offer an efficient and valid approach for identify candidate nucleation agents, and predicting the activity of those phases across a broad class of phase change material systems. Among other applications, Ga and Ga based eutectics are of interest for thermal management in electronics packaging and photovoltaics. The carbides and nitrides used in this work are commonly used as coatings and diffusion barriers, thereby suggesting the usage of these carbides and nitrides as thin film barriers to protect the underlying components in addition to serving as nucleation agents for Ga.

EN10.04.08
Engineering Antiphase Boundaries in Fe_2VAl Towards Cost-Effective, High Performance Thermoelectrics Cory T. Cline, Weiling Dong, Ian Baker and Jifeng Liu; Dartmouth College, United States

The Heusler alloy Fe_2VAl shows great promise as an ecofriendly and low cost replacement to conventional low temperature (250-500 K) thermoelectric materials. Current thermoelectrics use toxic and expensive elements like Te and Sb, whereas Fe_2VAl offers a larger power factor at a lower cost and is non-toxic. Fe_2VAl also allows for mechanical robustness leading to formable thermoelectric modules than can wrap a concave surface rather than typical flat modules that are commercially made for cold temperature applications. The key issue with Fe_2VAl is it's a relatively large thermal conductivity compared to its semiconductor competitors. The aim of this project is to examine multiple routes to reduce thermal conductivity by enhancing phonon scattering by:

1. Partial lattice substitutions/doping with heavier atomic mass elements (1D phonon scattering sites)
2. Microstructural engineering through anneal/quench treatments (3D phonon scattering)

Arc-melted Fe_2VAl alloy shows a thermal conductivity around 10 W/m*K measured at 300 K. Replacing some of the V with Sn or Ti has been shown to reduce the thermal conductivity by 20% and produce a good n-type or p-type material, respectively. Thermal conductivity, Seebeck coefficient and electrical conductivity have been measured for the dopant additions of 1-5 at.% for Sn, Ti, W, Ta, Ge and Si. Ge shows the most notable performance improvement with both a reduction in thermal conductivity and an enhancement in the Seebeck coefficient. However, Sn additions produce very similar performance improvements with the added benefit of better ductility.

Using water-quench treatments, we have also seen a significant drop in thermal conductivity in Ge-doped Fe_2VAl. X-ray diffraction (XRD) showed that annealing at 1273 K for 48 h produces an ordered L_{21} phase. Differential scanning calorimetry + XRD have shown that a stable B2-phase is achievable if the material is held above 1393 K for 2 h. Once the material achieves the B2 phase, where the V and Al atoms are random in the lattice, the material is water-quenched to preserve the B2 phase as the bulk phase. Dark-field transmission electron microscopy using superlattice reflections showed the presence of numerous thermal anti-phase boundaries (APBs). The room temperature thermal conductivity of $Fe_2VAl_{0.9}Ge_{0.1}$ annealed at 1273 K for 48 h is 9.3 W/m*K whereas the thermal conductivity of the same alloy annealed at 1393 K for 2 h and water-quenched is 4.5 W/m*K mainly due the presence of APBs in the material. Various anneals have been used to produce changes in the density of the APB domains and the resulting effect on both the thermal and electrical conductivity has been determined. Overall, through a combination of partial lattice doping and microstructural phase engineering, the zT of the Fe_2VAl Heusler alloy has been increased from 0.07 to 0.18 at 300 K.

EN10.04.09
Late News: Synergetic Enhancement of Thermoelectric Performance in Coated Grain Nanocomposite by Wave-Like Phonon Scattering and Carrier Filtering Junphil Hwang[1], Minju Lee[1], Jungwon Kim[2], Sujin Kim[1], Woochul Kim[3] and Sung-Jin Kim[1]; [1]Ewha Womans University, Korea (the Republic of); [2]KIST, Korea (the Republic of); [3]Yonsei Univ, Korea (the Republic of)

Thermoelectric energy conversion has a lot of attention because of its simple and convenient energy conversion of heat to electricity. In this work, thermoelectric nanocomposite with coating layer at the grain boundary was synthesized using chemical synthesis. Coated grain nanostructure has significant advantages for thermoelectricity because of energy filtering and effective coherent phonon scattering by coated grain boundary. Our newly developed phonon scattering model has proved phonon scattering by coated grain boundary is caused by interference of wave-like phonons. The coherent phonon scattering in coated grain boundaries is more powerful than particle-like phonon scattering by other kinds of impurities. The chemical synthesis strategy for coating process is conducted by cation exchange reaction of SnTe powder considering HSAB theory, thermodynamic factors. The thermoelectric figure of merit(zT) was 1.90 at 923 K for the CdTe/SnTe and 1.68 at 823 K for the eco-friendly $CuInTe_2$/SnTe nanocomposite.

EN10.04.11

Exploiting Bi-Modulated Magnetic Field and Drive Current Modulation to Achieve High-Sensitivity Hall Measurements on Thermoelectric Samples Gabor Parada[1], Ferenc Korsos[1], Christophe Defranoux[1], Jan-Willem G. Bos[2], Eric Don[3], Jake Bowers[4] and Mustafa Togay[4]; [1]Semilab Semiconductor Physics Laboratory Co. Ltd., Hungary; [2]Heriot-Watt University, United Kingdom; [3]Semimetrics Ltd, United Kingdom; [4]Loughborough University, United Kingdom

Hall mobility measurements of samples with high carrier density is challenging due to the low Hall voltage. Although an increase of the drive current enhances the Hall voltage, over a certain level, Joule heating at the contacts results in unreliable measurements, due to changes in the resistivity around the contact and/or the generation of thermoelectric voltage at the contacts. Localised heating may even damage the sample.
Therefore, suppressing measurement noise is essential to obtain valid Hall mobility results from low resistivity samples, which can be achieved using modulation methods, varying periodically either the magnetic field or the drive current during the Hall measurement.
The Parallel dipole line (PDL) AC Hall measurement technique is a very practical way to realize pure harmonic magnetic field modulation in a very compact design using rotating permanent magnets . The frequency selective “lock-in” evaluation of the resulting sinusoidal Hall voltages significantly reduces measurement noise and makes it possible to determine the Hall-mobility in highly conductive materials, up to a certain limit.
However, in metals or in thermoelectric materials featuring very high free carrier density (over 1 E21 cm^{-3}) the signal-to-noise ratio is still not sufficient to get a valid result.
In this work, we combine magnetic field modulation with alternating polarity drive current, i.e. using a simultaneous two-parameter modulation at very different frequencies to gain further noise reduction.
The reliability of the bi-modulated PDL Hall method was investigated by comparing the results with the standard AC field PDL Hall measurement from several moderately conductive materials. Hall mobility results from Si and SiAs samples using the two methods were within 1% and were in good agreement to typical values in the literature.
Then, Sn doped NbCoSb thermoelectric samples were tested ,featuring very high carrier density, above the specification of the standard PDL Hall measurement.
While the standard PDL Hall measurement provided inconsistent and highly fluctuating results depending on the drive current as well, the bi-modulated method resulted in very stable Hall voltage reading and repeatable mobility values. The Hall mobility values measured from the highly conductive samples (1-3 E21 cm^{-3} carrier density) are in the 2-11 $cm^2/V^{-1}s^{-1}$ range in good agreement with results of material simulations.
Analysing the frequency dependence of the AC drive current using a series of resistors defined the applicability range of the drive current modulation which turned to be limited by the “RC” time constant of the sample resistance (R) and the cable capacitances (C). Since higher resistance samples can be tested reliably without alternating the drive current, these tests confirmed the applicability of bi-modulated PDL Hall method for the high carrier density range in interest.
In conclusion, the combination of the AC magnetic field and alternating drive current in PDL Hall systems provides an astonishing Hall voltage sensitivity which results in accurate Hall mobility results even in thermoelectric samples featuring carrier concentration above 1 E21 cm^{-3}.

SESSION EN10.05: Measurement

Measuring the Gradients in Thermal Properties Due to Ion Bombardment Thomas W. Pfeifer[1], Ethan A. Scott[2], Khalid Hattar[2], John A. Tomko[1], Patrick E. Hopkins[1], Kenny Huynh[3], Michael Liao[3] and Mark Goorsky[3]; [1]University of Virginia, United States; [2]Sandia National Laboratories, United States; [3]University of California, Los Angeles, United States

The thermal properties of semiconductors following exposure to ion irradiation are of great interest as pertaining to the cooling of electronic devices, however the spatially-varying structural and compositional changes inherent to ion bombardment often make measurement difficult. We present an advance to the Time Domain Thermoreflectance (TDTR) technique, and a study in which we demonstrate the measurement of Silicon bombarded with Krypton ions, throughout the stopping region. We also use Transmission Electron Microscopy (TEM) to validate our findings and further explore the structural effects of bombardment.
TDTR is a pump-probe technique that measures the change in thermoreflectance on the surface of a sample as a function of pump-probe delay time from picoseconds to nanoseconds. This change in thermoreflectance is related to both the temporal temperature decay from impulse heating driven by the sub-picosecond pump pulse and the frequency-dependent temperature rise induced from the modulated pump pulse train. The thermal decay response is then fitted to a multi-layer model in order to extract the thermal properties of interest. Ordinarily, TDTR is well-suited to the measure thermal properties even beneath the surface of the sample, which in our case, allows for the measure of properties within the ion-stopping region. We modify the traditional analysis by discretizing a layer and instead fitting for a function of thermal conductivity. This allows the measure of the depth-dependent thermal conductivity due to ion bombardment, and we find a thermal conductivity profile with an excellent match to the predicted and observed damage profiles from SRIM and TEM. This is beneficial for thermal characterization of materials, and as a tool for profiling bombardment-induced damage.
Our technique, in combination with TEM, is able to show a measured thermal conductivity of as low as 2.34 W/m/K for regions of defected crystalline silicon containing 5-15nm amorphous pockets. We explain this measured thermal conductivity as being a product of both porosity / nanocomposite interface scattering effects, and greatly reduced thermal conductivity of the crystalline regions as a product of purely structural disorder. We also note that the measure of the thermal conductivity of the defected crystalline regions between the amorphous pockets is among the lowest ever measured.

10:45 AM *EN10.05.02

Thermal Conductivity, Li Stoichiometry and Three-Dimensional Thermometry of Solid Electrolytes for Li–Ion Batteries David Cahill; University

of Illinois, United States

Thermal management in Li-ion batteries is critical for their safety, reliability, and performance. I will discuss three aspects of our current work on the physical properties of solid electrolytes (SEs) for solid-state batteries. 1) Measurements of the thermal conductivity of air and moisture sensitive halide and sulfide SEs are enabled by depositing the Al transducer film for time-domain thermoreflectance (TDTR) measurements with a compact sputter deposition chamber mounted inside a glove box. Thermal conductivities of halide and sulfide SEs are in the range 0.45–0.70 W m^{-1} K^{-1}, a factor of 2-3 smaller than the thermal conductivities of oxide SEs. The thermal conductivity has a glass-like temperature dependence that presumably arises from the strong atomic scale disorder that is necessary for high ionic conductivities. 2) Characterization of the Li composition of solid-electrolytes and electrodes is a ubiquitous challenge in battery research because analytical techniques based on core-level excitations are not applicable to Li. We recently implemented nuclear reaction analysis using a 1.8 MeV proton beam and spectrometry of 4-8 MeV alpha particles that are generated by the $^{7}Li(p,\alpha)^{4}He$ reaction. This ion-beam analysis technique achieves a Li composition accuracy of a few percent across a depth of several microns with a depth resolution of 100 nm. 3) While knowledge of boundary conditions and thermal properties of materials is sufficient to calculate the temperature field within a battery, direct measurements of temperature fields in three-dimensions would be valuable in situations where the heat sources and thermal properties are not well known. As a first step in this direction, we have characterized the temperature dependence of the nuclear magnetic resonance linewidths of ^{7}Li in common solid electrolytes. The linewidth has a strong temperature dependence when the hopping rate of the ^{7}Li ion overlaps with the natural linewidth created by dipolar coupling and may provide an approach for 3D thermometry by magnetic resonance imaging.

11:15 AM *EN10.05.03
Ultrafast Infrared Pump-probe Measurements for Time Domain Measurements of Electron, Phonon and Polariton (Plasmon and Phonon) Relaxation Patrick E. Hopkins; University of Virginia, United States

The fundamental interactions among photons, electrons and phonons at interfaces dictate heat transport in a wide array of materials and interfaces used in energy conversion and storage technologies. Characterization of these electron and phonon thermal properties are commonly studied with pump-probe methods. In standard implementations of these techniques, visible light laser sources are used to excite and probe electronic transitions on the surface of samples, and thus relate the temporal decay of these electronic states to temperature and resulting material properties. At these photon energies, the nature of the probe response is electronic, in that electronic interband transitions dominate the optical response.

In this presentation, we demonstrate the use of sub-picosecond infrared laser pulses as a means of more direct resolving the thermal response of nonequilibrium carriers. The low energy nature of these laser pulses with respect to electronic interband transition energies in metals and semiconductors allows for direct probing of free electron responses in metals and semiconductors and resonating with coupled nonequilibrium polaritonic carriers in non-metals. We will show the ability to: i) probe the purely free electron response in Au and recover the predicted thermal electron-phonon coupling factor; ii) probe the time domain relaxation of phonons in semiconductors based on optical interactions with optical phonon modes; and iii) monitor the ultrafast thermal decay of coupled plasmon-polariton modes in doped CdO and phonon-poliarton modes in hexagonal boron nitride.

11:45 AM EN10.05.04
Thermally Conductive Carbon Fiber-Phase Change Material Composite for Thermal Runaway Prevention Jose A. Martinez and Randall M. Erb; Northeastern University, United States

The increasing prevalence and efficiency of electric vehicles have continuously driven the need for high-energy-density lithium-ion battery packs. Within these battery packs, the exothermic reactions of the cell cause an increase in temperature and thus require efficient thermal management systems to prevent thermal runaway events and catastrophic failure. Current solutions include polymer PCMs, which absorb heat as they melt. Their low thermal conductivity limits the heat transfer rate through the PCM, making them inefficient for thermal runaway scenarios. We tackle this problem by incorporating aligned carbon fibers into a polymer PCM. Our material shows a five times increase in through-plane thermal conductivity and more efficient thermal energy absorption. We demonstrate this through thermal characterization, computational modeling, and simulated thermal runaway on a benchtop scale testbed.

Progress in Measuring, Modeling and Manipulating Thermal BoundaryConductance Pamela M. Norris, LeighAnne Larkin, Nam Q. Le, Carlos Polanco, Justin Smoyer and Jingjie Zhang; University of Virginia, United States

The ability to predict, understand, and control thermal transport in materials and at interfaces remains a critical challenge and goal of nanoscale thermal transport research. In nanostructures where phonons are the primary thermal energy carriers, interfaces between dissimilar materials represent the dominant thermal resistance. An increased understanding of phonon-mediated transport across interfaces is critically needed, so that nanostructured devices can be more effectively designed and implemented.

Over the past several decades, the nanoscale heat transfer community has identified and investigated many factors that influence phonon transport across solid-solid interfaces. Experimental data, simulation results and theoretical analysis have all elucidated the collective effects of vibrational spectra, harmonic and anharmonic processes, defects, and mixing on the ability to transport heat across a solid-solid interface. As the community continues to study these phenomena many challenges arise. In the regime of simulations, it is difficult to develop a computational model that captures all the properties of a physical material and the interactions between materials. From the standpoint of the experimentalist, there is no perfect system or set of systems that allows factors influencing thermal transport to be decoupled. In all areas of thermal transport research, the challenge is either decoupling or understanding the

interplay of complex effects that manifest differently in various materials and experimental/computational environments.

At the Nanoscale Energy Transport Laboratory at the University of Virginia, our research efforts combine computational and experimental techniques to model, measure, and predict phonon dynamics, and the resulting thermal properties, for a wide range of technologically relevant systems. We have approached this problem experimentally, measuring nanoscale systems with time-domain thermoreflectance (TDTR), and computationally, tracking atomic thermal motion in non-equilibrium molecular dynamics (NEMD) simulations, and investigating quantum mechanical effects using the non-equilibrium Green's functions (NEGF) approach This work is complicated by the wide spectra of phonon mean free paths, ranging from a single atomic spacing to the size of the material system.

Here we review approaches for measuring, modeling and manipulating thermal boundary conductance across solid-solid interfaces in hopes of developing avenues to control the heat transport at the atomistic length scale. For example, we have demonstrated that insertion of a layer with intermediatevibrational properties of the two contacts joining at an interface can enhance the interfacial thermal conduction under certain conditions. By utilizing an exponentially mass-graded interface, even further increases in enhancement are possible, attributed to the strength of anharmonicity in addition to matching of vibrational spectra. The ultimate goal is to drive the discussion of thermal management from a design afterthought down to intentional design at the nanoscale where the heat is generated, completing the journey from TIM to transistor.

Observation of Solid-State Bidirectional Thermal Conductivity Switching in Antiferroelectric Lead Zirconate ($PbZrO_3$) Kiumars Aryana[1], John A. Tomko[1], Ran Gao[2], Md Shafkat Bin Hoque[1], Thomas W. Pfeifer[1], Alejandro Salanova[1], David H. Olson[1], Jeffery Braun[1], Eric R. Hoglund[1], Joyeeta Nag[3], John Read[3], Michael Grobis[3], Elizabeth Opila[1], Lane W. Martin[2], Jon Ihlefeld[1] and Patrick E. Hopkins[1]; [1]University of Virginia, United States; [2]University of California, Berkeley, United States; [3]Western Digital Corporation, United States

Thermal regulators that enable controlling temperature on demand is a key component in the development of solid-state thermal circuits. A highly efficient thermal regulator should operate near or above room temperature and offer a quick and large on/off switching ratio. Switching the thermal conductivity of a material can be achieved upon repeatable transformations in the electronic or phononic structure. However, reliable high-performance thermal regulators are still missing from the literature. A promising class of material candidates for dynamic thermal conductivity switching that have recently received considerable attention due to their fast, repeatable, and well-integrated trigger mechanism are ferroelectric perovskites such as lead zirconate titanate $PbZr_{1-x}Ti_xO_3$ (PZT_x) and lead titanate $PbTiO_3$(PTO). Despite the large focus on investigating the thermal conductivity of PZT and PTO with varying conditions, their antiferroelectric end-member, lead zirconate $PbZrO_3$(PZO), has received much less attention. In this material, a sufficient electric field will transition the antiferroelectric phase to a ferroelectric phase where there is a volume expansion, reduction in the unit cell size from 8 formula units to 6, and the possibility of altering the populations of ferroelastic domains. Furthermore, there are ferroelastic domains within antiferroelectric PZO and they too may impact phonon scattering rates. In addition to AFE to FE phase transition, PZO undergoes another phase transition upon heating where the lattice structure goes from 8 formula units to 1, and is expected to reduce the phonon scattering rate and lead to higher thermal conductivities. In this study, we experimentally demonstrate how thermal conductivity of antiferroelectric $PbZrO_3$ can be bidirectionally switched by -10% and +15% upon applying electric field and thermal excitation, respectively. Our approach takes advantage of two separate phase transformation mechanisms in $PbZrO_3$ that influence the phonon scattering rate in different manners. This is the first experimental realization of a fast (<1 second) and high-performance thermal regulator with a net switching ratio of 25% from 1.2 to 1.5 W/m/K.

Nanoscale Si Fishbone Structures For Manipulating Heat Transport Using Phononic Resonators for Thermoelectric Applications James Lees, Ben Durham, Christopher Reardon, Martha Anderson-Taylor, Philip J. Hasnip, Thomas Krauss and Sarah Thompson; University of York, United Kingdom

Thermoelectric devices have significant potential for energy management, but current materials struggle with efficiency, usually captured using the Figure of Merit (zT):

$zT=S^2\sigma T/\kappa$

where S is Seebeck coefficient, T is Temperature, κ is thermal conductivity and σ is electrical conductivity. The goal is to create a material with a low κ but a high σ. In Silicon (Si) the electrical energy is carried by electrons (or holes) but the thermal energy is mostly carried by phonons. This means that it is possible in principle to affect only phonons and so decrease κ without affecting σ.

There has been much work on modifying the κ value of semiconductors by increasing the phonon scattering, but this tends to also increase scattering of the charge carriers.[1] In this work we take a different approach in which metamaterials are designed to exhibit resonances which lie within the range of thermal phonons. These resonant phonons are predicted to hybridise with the thermal phonons causing standing waves, decreasing their group velocity and hence κ, these structures are known as nanophononic metamaterials (NPM).[2] Molecular dynamics simulations of Si NPMs suggest that the κ value may be reduced by up to two orders of magnitude in comparison to Si membranes, where the effect is largest for NPMs with high aspect-ratio nanoresonators.

The majority of previous attempts to experimentally test these predictions have relied on the growth of nanopillars of Si where it is difficult to control the critical model parameters such as aspect ratio and density of the pillars. Here, we present an all-planar design similar to the work of J.Marie et al[3] in which these parameters can be individually varied. In this work, the thermal transport properties are spatially resolved using Scanning Thermal Microscopy (SThM) which enables the correlation of the thermal properties with the geometry.

For this new device a freestanding Si membrane is constructed and patterned using E-beam lithography to produce a series of lateral resonant nanostructures off a central shaft which leaves the top surface of the shaft exposed for direct measurement using SThM. These naturally resonant nanostructures can be individually controlled across a number of the critical model parameters such as length and width (thus aspect ratio) as well as position, number of and spacing between the structures. This enables direct measurement of the impact of the various parameters on the resultant κ. The Si nanostructures have been fabricated at a variety of sizes to a minimum width of 115 nm and a maximum length of 30 µm. Workable structures up to a maximum aspect ratio of 26:1 have been tested.

SThM, in both air and vacuum, is used to take simultaneous localised topography and thermal measurements across the device with a spatial resolution of 100 nm. Two methods were used to measure the local κ of the structures enabling correlation between the dimensions and the thermal properties. In the first method, the SThM tip becomes a heat source, whose measured temperature is a function of the local κ. In the second method, an external temperature gradient of up to 2.8mK/µm across the sample was established using a fabricated micro heater; the SThM tip is used to measure the variations in the temperature gradient along the shaft correlated with dimensional variations. Using this gradient

changes of as low as ~10% can be determined. The κ values were extracted using COMSOL to model the thermal profiles which enabled the effects of the sample topography to be accounted for.

Discovery of the Novel Sustainable *n*-Type Thermoelectrics Zn_2NX (X = Cl, Br, I) by Anion Mutation of ZnO Kieran B. Spooner[1,2] and David O. Scanlon[1,2,3]; [1]University College London, United Kingdom; [2]Thomas Young Centre, United Kingdom; [3]Diamond Light Source, United Kingdom

Thermoelectrics transform heat into electricity and vice versa, making them valuable tools for the generation and recycling of clean, renewable energy. While progress has been made increasing the efficiency of thermoelectrics, measured by the dimensionless figure of merit, ZT, the best systems often contain rare or toxic elements, such as PbTe and Bi_2Te_3, which reduces their sustainability. Furthermore, ZTs of *n*-type thermoelectrics have lagged behind those of their *p*-type counterparts. Conductive oxides have shown promise as potential thermoelectrics[1] due to their strong electrical conductivity and high temperature stability, particularly ZnO, which has reached a ZT of 0.65 at 1000 K.[2] As they are often hindered by their high thermal conductivity, nanostructuring has been extensively tested for overcoming this problem,[3] but limits the electrical conductivity as well as the thermal conductivity, reducing the potential ZT increases.

Here we use hybrid density functional theory (DFT) to screen the anion mutated ZnO derivatives Zn_2NX (X = Cl, Br, I)[4] for thermoelectric properties. We analyse their thermal and electronic transport beyond the constant relaxation time approximation (CRT) using Phono3py[5] and AMSET[6] respectively. We show that anion mutation is a highly effective means to reduce the lattice thermal conductivity, and analyse the combined effect of the various other changes this makes to the materials, comparing to each other, ZnO and thermoelectric materials in general. We then use these insights to assess the potential of the anion mutation method.

Hydrogel-Based Materials with Fast Kinetics for Water-Harvesting and Thermal Management of Electronics Jian Zeng, Ka Man Chung, Xintong Zhang and Renkun Chen; University of California, San Diego, United States

Efficient harnessing and management of thermal energy attracts widespread interest in the context of water-energy nexus. Recently, hydrogels have shown great promises for water-based heat and mass transfer processes such as thermally driven water harvesting, desalination and thermal management of electronics due to the high capacity of water adsorption by hydrogel (could store water up to > 100 times of dry gel mass) and high osmotic pressure for salt rejection. Despite extensive studies on the high adsorption capacity, much less efforts have been paid to improve the kinetics of the heat and mass transfer processes, which are important performance metrics such as the water production yield in water harvesting from air, water flux in desalination and thermal conductance of electronic cooling. In this talk, we present the structural engineering of hydrogels for significantly enhanced kinetics. The general strategy is based on thin polyelectrolyte hydrogel coating on the surface of a metal scaffold with large effective surface area. Due to small thickness of the hydrogel coating and high thermal conductivity of the metallic scaffold, the heat and mass transfer rate are significantly improved, leading to high adsorption/desorption kinetics. As an example, porous aluminum foam was coated with ~ 100 μm thick hydrogel to provide 10-fold increase in the surface area, leading to a short adsorption time constant of < 15 mins and short desorption time constant of 10 mins. In an optimized adsorption/desorption cycle, we can obtain water yield > 20 kg_{water} kg_{gel}^{-1} day^{-1} and > 10 kg_{water} m^{-2} day^{-1} by using the thermo-responsive polyelectrolyte hydrogel. We also apply an aluminum fin heat sink coated with thin hydrogel for passive evaporative cooling of electronics. Taking advantage of the high latent heat of water during evaporation, small thermal resistance across the thin gel and high adsorption capacity of gel, we achieve high thermal conductance ~ 200 W m^{-2} K^{-1}, high cooling power of > 1.5 kW m^{-2} and long operational time of ~ 6 hours in the peak-hours. The gel can also be fully regenerated during the off-peak hours at night. Our studies show the potential of structural engineering of hydrogel-based materials to enhance heat and mass transfer kinetics.

The Orbital Chemistry of High Valence Band Convergence and Low-Dimensional Topology in PbTe Madison Brod and G. J. Snyder; Northwestern University, United States

PbTe, one of the most highly performing thermoelectric materials, and similar GeTe- and SnTe- based alloys have been used in the power sources for NASA space missions for several decades. The exceptional thermoelectric performance of PbTe and its alloys is partially attributed to the high valley degeneracy of its valence band edges, which leads to an enhnaced thermoelectric quality factor, and hence, maximum attainable efficiency. The high valley degeneracy of the valence bands is due to the convergence of multiple valence band maxima at low-symmetry points in the first Brillouin zone. In fact, prior studies using first-principles calculations suggest that as the valence band edges become more highly converged, the valence band Fermi surface undergoes a topological transition from a valence band edge described by a 3D density of states to a thread-like Fermi surface described by a 2D density of states. Transport modeling with the Boltzmann transport equation (BTE) predicts significant gains in thermoelectric performance upon this transition to

lower-dimensional bands in bulk 3D materials. In the work presented here, we study the chemical origins of this favorable valence band behavior in PbTe by considering both numerical and analytical solutions to a tight-binding model with nearest and next-nearest neighbors. The tight-binding method offers the advantages of extremely short computational times and of employing a chemically intuitive basis comprised of recognizable atomic orbitals. We develop simple atomic orbital pictures and molecular orbital energy level diagrams for high symmetry *k*-points in the Brillouin zone to describe a tight-binding wavefunction corresponding to the valence band edge in PbTe. Furthermore, we find that in a theoretical tight-binding electronic structure of a model IV-VI rock salt compound where four different valence band extrema are effectively converged, a 1D Fermi surface can be obtained. Using the BTE, we predict further gains in thermoelectric performance from this 1D Fermi surface topology relative to the 2D and 3D cases. We use the results of this analysis to predict and to understand potential alloying strategies to further optimize the electronic structure of PbTe and its analogues. This work can be directly extended to the other IV-VI rock salt compounds (IV = Ge, Sn, Pb; VI = S, Se, Te), and the orbital chemistry framework applied here can be more generally applied to new materials systems in order to guide the understanding and discovery of materials with optimal electronic structures for thermoelectric performance.

4:30 PM EN10.07.03
Programming Exothermic Phase Change Material Crystallization and Downstream Thermoresponsive Processes in Hydrogels Thomas B. Schroeder and Joanna Aizenberg; Harvard University, United States

The on-demand exothermic crystallization of stably supercooled phase change materials, which have long been used in the context of hand warmers and heat pads, shows promise as a component of engineered energy transduction cascades. These processes amplify a small nucleation trigger to release large quantities of thermal energy that can be used to activate downstream processes that respond to changes in temperature.

Our group has developed a strategy for controlling the spatiotemporal evolution of crystal growth and heat release in metastable phase change materials. In this work, we synthesize polymer networks from acrylamide monomers in supersaturated aqueous solutions of sodium acetate using ultraviolet light and a photoinitiator. Photomasks are used to create metastable hydrogels with patterned domains that remain unpolymerized. Upon nucleation with seed crystals of sodium acetate trihydrate, long needle-like crystals grow through unpolymerized regions; the growth front in these areas is up to seven times faster than in polymerized domains, where a polycrystalline composite forms. Crystal growth is accompanied by a wavelike temperature profile with a peak at the solid/liquid interface. In one set of conditions, the peak temperature during fast crystallization through unpolymerized solutions was 45 °C, whereas the slower crystal growth process through a polymer network peaked at 30 °C. These profiles are well-described by a one-dimensional analytical model; the discrepancy between peak temperatures can be fully explained by the velocity difference.

We demonstrate the utility of this technique by using it to pattern thermoresponsive processes, which can be induced to proceed in a wavelike fashion following the peak temperatures of the crystal growth fronts. We use the temperature difference between polymerized and unpolymerized regions to selectively activate processes that proceed at threshold temperatures above 30 °C, such as wax melting or hydrogel contraction, within predefined areas to form complex patterns such as text.

Can Dynamic Covalent Networks Be Used as Thermal Conductivity Switches? Joshua M. Rinehart, John R. Reynolds and Shannon K. Yee; Georgia Institute of Technology, United States

The ability to dynamically control heat flow in materials (i.e. thermal conductivity switches) would enable the development of more efficient energy systems, ranging from controlling heat flow in computer chips to allowing phase change materials to be more efficient in buildings. However, developing polymer systems that exhibit dynamic thermal conductivity changes remains a challenge due to the difficulty in using external stimulus to significantly alter a polymer's ability to conduct heat. It has been previously shown that a mixture of polymers that interact via hydrogen bonding can form a network with a drastic increase in thermal conductivity compared to their pure components. One potential mechanism is to reversibly switch the strength of interactions between chains by using dynamic covalent crosslinks. It has been hypothesized that Diels-Alder reactions are one such way to dynamically control crosslinking and thereby the utilization of the Diels-Alder reaction could result in dynamic thermal switching. In this work, a series of precursor uncrosslinked statistical copolymers with varying mole fractions of furan functional groups were synthesized via RAFT polymerization. The precursor polymers were crosslinked using a reversible Diels-Alder cycloaddition to form dynamic covalent networks of varying crosslink densities. Two separate crosslinkers were used to investigate how the molecular weight and length of the crosslinker influence the thermal and mechanical properties of the network. It was found that the thermal conductivity was largely unaffected by the extent of crosslinking and the structure of the crosslinker counter to previous motivating studies. Additionally, the elastic modulus was measured and gives insight into why thermal conductivity did not significantly change. For this system, the Diels-Alder reaction was also found to be slow in the solid-state, possibly further limiting its utility as a thermal conductivity switch due to slow switching speeds.

5:00 PM EN10.07.05
Chemically Tuning Non-Parabolic Electronic Structures in Rock-Salt IV-VI Compounds Michael Toriyama, Madison Brod and G. J. Snyder; Northwestern University, United States

Non-parabolic electronic structures oftentimes reinforce the thermoelectric performance of a material, due to a larger effective valley degeneracy. While materials with inverted bands sometimes exhibit high valley degeneracy, for example rock-salt SnSe, the beneficial feature is not guaranteed for all materials with such unique inverted electronic structure topology. We survey the electronic structures of rock-salt IV-VI compounds, which demonstrates that band inversion is a necessary, but not sufficient, condition for high valley degeneracy in inverted band compounds. Using a combination of $k \bullet p$ theory, tight binding theory, and Density Functional Theory calculations, we show that the degree to which the bands are inverted is a chemically-tunable parameter that is partly responsible for inducing multiple carrier pockets in IV-VI compounds.

5:15 PM EN10.07.06
Thermal Evolution of Internal Strain in Doped PbTe James P. Male[1], Riley Hanus[1,2], G. J. Snyder[1] and Raphael P. Hermann[2]; [1]Northwestern University, United States; [2]Oak Ridge National Laboratory, United States

Recent improvements in the efficiency of heat-to-electricity energy conversion in lead chalcogenide thermoelectrics involve reducing the thermal conductivity by incorporating large amounts of internal strain. The extent to which typical lead chalcogenide processing techniques (such as doping, ball milling, and densification) increase internal strain and dislocation density must be quantified to improve materials design. In this study, neutron powder diffraction is leveraged to evaluate the internal strain introduced by ball milling in doped and undoped powders. Doping with Na and/or Eu increases internal strain beyond ball milling alone with the greatest increase from combining the two dopants. Strain recovery occurs in each powder above 400 K but can be suppressed by co-doping – indicating a strong dopant-dislocation interaction in this system. Therefore, high temperature processing of PbTe powders should be avoided if high internal strain is desired. Low temperature densification and/or rapid pressing techniques may be key to maintaining

internal strain in the final pressed pellet. This work provides key guidance for defect engineering to maximize internal strain and thermoelectric performance in PbTe thermoelectrics.

SESSION EN10.08: Water

Atmospheric Water Harvesting Using Organic-Inorganic Hybrids and Isoenthalpic Thermodynamic Cycle Vincenzo Gentile[1], Michael Bozlar[2,3], Marco Simonetti[1] and Forrest Meggers[3]; [1]Politecnico di Torino, Italy; [2]The University of Texas at Arlington, United States; [3]Princeton University, United States

Over the last five years, atmospheric water harvesting has gained significant interest as a promising alternative to address the growing water scarcity problems across the globe. In this work, we synthesized a hygroscopic, organic-inorganic hybrid material and combined it with an efficient thermodynamics cycle to convert atmospheric water vapor to liquid water. We demonstrate the potential of the novel hygroscopic materials under extreme (arid) climate conditions: ambient temperature higher than 30°C and dew point lower than 5°C. The hybrid hydrogel material is obtained through the crosslinking reaction of polyelectrolytes with counter ions. We used sodium alginate and calcium alginate as the precursors to form the hygroscopic material into any desired geometries (spherical particles, rectangular structure, etc). The water vapor capture and subsequent release and conversion to liquid water is achieved through a co-located heat/mass transfer. During the water uptake step (adsorption), the stream of humid air flows through the sorbent, and the water vapor is stored in the hydrogel through a combination of endothermic and exothermic reactions. During the regeneration step, the air flow running through the device is inverted to allow a stream of hot air to contact the hydrogel. The hot air combined with high relative humidity allows for high dew points operations, such that spontaneous water condensation can take place at ambient temperatures. In addition, our experiments show that our setup can operate under dry climate conditions (ambient dew points lower than 5°C), and only use solar thermal energy to drive the regeneration cycle (water release). Finally, we demonstrate that the whole process can be scaled-up to enable the production of liter-scale freshwater on a day-night cycle.

10:45 AM EN10.08.03
High Performance Solar Evaporator with Salt Rejecting Capability Xiangyu Li, Lenan Zhang, Yang Zhong, Arny Leroy and Evelyn N. Wang; Massachusetts Institute of Technology, United States

Thermally localized solar evaporation provides a sustainable solution to address the water-energy nexus, which is promising for the applications in vapor generation, seawater desalination, wastewater treatment, and medical sterilization. However, salt accumulation has been identified as one of main practical challenges, which induces undesired fouling and reduces device lifetime. Here, we develop a novel confined water layer structure enabling a simultaneously highly efficient and salt rejecting solar evaporation. With high-fidelity modeling and experimental characterization of salt transport, we optimize the fluidic flow in the confined water layer. With the optimized flow field, our design is capable of salt transport without sacrificing energy efficiency. In addition, we further applied our design to the contactless solar evaporator and report a record-high efficiency. The fundamental understanding of salt transport shown in this work paves a new avenue toward the high-performance and reliable solar evaporation with low-cost and high material flexibility.

11:00 AM EN10.08.04
Modeling the Adsorption Kinetics of Salt-Embedded Hygroscopic Hydrogels Lenan Zhang, Carlos D. Diaz, Zhengmao Lu, Jeffrey C. Grossman and Evelyn N. Wang; Massachusetts Institute of Technology, United States

Water adsorption has attracted particular attention owing to its broad applications in atmospheric water harvesting, energy storage, and thermal management. Hygroscopic hydrogel has been recognized as a promising material due to the large total uptake, fast kinetics, and low material cost. Although high-performance water adsorption with hydrogel has been experimentally demonstrated by several recent works, the fundamental understanding of the adsorption kinetics remains elusive because of the complex transport mechanics inside the hydrogel. In this work, we develop a two-concentration model to predict the adsorption kinetics of hydrogel, where two coupled diffusion equations are introduced to describe the vapor and liquid transport, respectively. Taking the $CaCl_2$ embedded hydrogel as an example, we calculated the adsorption kinetics at various relative humidity and showed good agreement with experiments. More importantly, we show that liquid transport, driven by the gradient of water chemical potential, plays a significant role in the rapid kinetics of hydrogel. Liquid transport induces the redistribution of water in the polymer matrix the therefore leads to the volumetric expansion of the hydrogel. With a parametric study, we identified the key parameters responsible to the kinetics of adsorption, where an optimal initial porosity is predicted. Furthermore, the kinetics can be largely engineered by changing the elastic modulus of the hydrogel. This work provides the first modeling framework for the adsorption kinetics of hydrogel, which can serve as a design guideline in applications of the atmospheric water harvesting, energy conversion, and thermal management.

11:15 AM *EN10.08.05
A Few Recipes to Move the Leidenfrost Point David Quéré[1,2]; [1]ESPCI, France; [2]École Polytechnique, France

The levitation of water drops can be triggered by augmenting the temperature of the solid on which they sit. Above a threshold (typically 200°C on regular solids), water detaches from its substrate, owing to the presence of a continuous vapor film, which makes the liquid extremely mobile. We discuss how to decrease and increase the Leidenfrost point (LFP), which can be exploited in different applications: on the one hand, a smaller LFP allows us to make water mobile with a much smaller quantity of energy; on the other hand, a larger LFP makes it possible to maintain heat exchange at high temperature, a valuable property for heat pipes.

1:30 PM EN10.09.01
Understanding the Defect Chemistry of the Mixed-Anion Thermoelectric, LaZnOP Maud Einhorn, Benjamin A. Williamson and David O. Scanlon; University College London, United Kingdom

The ever increasing societal demand for clean energy, coupled with the impending global climate emergency has driven an influx of research into renewable energy. To attempt to mitigate the most catastrophic effects of climate change, it has been proposed that greenhouse gas emissions must be reduced by 20%, alongside a significant increase in the energy efficiency of existing processes. Wasted thermal energy is generated by processes across the energy sector, transportation, and the human body itself. Thermoelectric devices, can be used to convert thermal energy into a clean source of electricity, generating no emissions and without the need for moving parts. Importantly, these materials can provide a route to significantly increase the overall energy efficiency of existing process across a range of sectors via waste-heat harvesting.[1]

The effectiveness of a thermoelectric material is measured using the dimensionless figure of merit *ZT*, with the world record set at 2.6 for single-crystal SnSe along the through-plane direction.[2] Realising reasonable conversion efficiencies generally requires high electrical conductivity and low thermal conductivity, with the maximum *ZT* of a material often limited by the strong correlation between these properties. The parameters that contribute to the overall *ZT* of a material are also highly dependent on the concentration of charge carriers in the system, and therefore it is important to gain a comprehensive understanding of the defect chemistry of thermoelectric materials to maximise efficiency.

In this study, we predict the maximum theoretical *ZT* of LaZnOP, a mixed-anion compound which has promising thermoelectric properties, using density functional theory. The performance of oxide thermoelectrics generally lagging behind the efficiencies achieved by chalcogenide-based materials such as Bi_2Te_3, with poor carrier mobilities and high intrinsic thermal conductivities hampering progress.[3] Mixed-anion materials have been looked to in an attempt to tackle these issues, with the more complex crystal structures reducing the lattice component of thermal conductivity. Many high-mobility mixed-anion compounds have also been reported on recently. The charge transport properties will be calculated using state-of-the-art methods based on hybrid-density functional theory, employing the AMSET approach to calculate electron-scattering rates going beyond the constant relaxation time approximation.[4]

We show that LaZnOP has the potential to be an extremely promising earth-abundant thermoelectric material, with a ZT exceeding that of most oxide materials, provided it is dopable to 10^{19}-10^{20} carriers cm^{-3}.[5] Electronic-structure and band-alignment calculations suggest p-type dopability, according to the doping limit rules, and predict high hole mobilities. A full study of the defect chemistry of LaZnOP was also performed using hybrid-DFT, to assess the doping potential of LaZnOP, and guide future synthesis.

Photonic Flash Sintering of High-Performance and Flexible Silver Selenide Thermoelectric Films Mortaza Saeidi-Javash, Minxiang Zeng and Yanliang Zhang; University of Notre Dame, United States

Flexible thermoelectric generators have the ability to harvest thermal energy from a variety of heat sources (e.g. human skin) and directly convert it into electricity to work as a sustainable power source for sensors and wearable devices. Due to the limited thermoelectric (TE) performance of conducting polymers and rigidity of inorganic materials (e.g., Bi_2Te_3 and Sb_2Te_3), it remains a challenge to prepare low-cost, highly flexible, and high-performance TE materials. An efficient thermoelectric generator is composed of materials with a high thermoelectric power factor $S^2\sigma$ (S is the Seebeck coefficient and σ is the electrical conductivity), and low thermal conductivity κ. Herein, we fabricated n-type silver selenide films on flexible porous nylon membrane using vacuum-assisted filtration, followed by photonic flash (i.e., intense pulsed light) sintering. In contrast to conventional thermal sintering, rapid and versatile photonic sintering using intense pulsed light offers great advantages as it can sinter the silver selenide films at elevated temperatures without overheating/damaging the underneath polymeric substrate. Moreover, silver selenide shows an excellent absorptivity throughout the ultraviolet-vis (UV-vis) spectra with perfect overlap with the wavelength range of the emitted light during flash sintering. Silver selenide with exceptional thermoelectric power factor of ~ 2200 $\mu W/mK^2$ can be achieved within an extremely short sintering period of 2 ms. The flexible silver selenide materials with high thermoelectric performance near ambient temperatures can be considered an ideal candidate for low-grade waste-heat-recovery applications. This work introduced a promising pathway to realize high-performance and flexible TE devices with a broad range of applications in harvesting and managing thermal energy.

2:00 PM EN10.09.04
Full Experimental Seebeck Tensor Characterization for (p × n)-Type Transverse Thermoelectrics Juncen Li, Matthew Grayson and Mercouri G. Kanatzidis; Northwestern University, United States

(p × n)-Type transverse thermoelectrics were proposed as a potential thermoelectric material for Peltier cooling at cryogenic temperature and integrated thermoelectric devices. In transverse thermoelectric materials, highly anisotropic ambipolar conduction gives rise to an off-diagonal Seebeck coefficient, generating a voltage drop perpendicular to an applied temperature gradient [1]. Some anisotropic thermoelectric materials are found to have an ambipolar Seebeck effect, with a negative Seebeck coefficient along one direction and positive orthogonal Seebeck, hence the name (p × n)-type. However, standard experiments only measured Seebeck coefficients along specific crystal axes, which is, in principle, insufficient to map the full Seebeck tensor of a low symmetry crystal. And due to the lack of Onsager symmetry, the Seebeck tensor, unlike transport coefficients like electrical conductivity, can have up to 9 independent components for the lowest symmetry case (triclinic) [2]. It is also advantageous to use a single sample to measure all Seebeck components since multiple samples might have slightly different doping [3]. Here, we report results for an all-in-one measurement set-up for measuring the full Seebeck

tensor on one sample with custom-made apparatus. Experiments on pre-characterized isotropic material confirm this apparatus can accurately determine the 9 Seebeck components. Anisotropic van der Pauw measurement can also be integrated into the apparatus to measure the full in-plane anisotropic resistivity tensor on the same sample, hence giving the anisotropic in-plane power factor [4]. Results of Seebeck tensor measurements in known anisotropic materials such as bismuth single crystals will also be presented.
The apparatus is an insulated aluminum sandwich-structure with contacts and thermocouples built in. First, two aluminum plates ($25\times25\times4mm^3$) are machined with aligned thru-holes and tapped holes for the respective plates. Second, grooves for contacts and thermocouples are laser cut on the inner surface of machined aluminum blocks with accurate positioning. Then, the aluminum plates are anodized to create an electrically insulated surface. After that, indium contacts and thermocouples are placed into the grooves. Finally, samples ($8\times8\times2mm^3$) are sandwiched between the two aluminum plates, with thermal epoxy/paste to ensure good thermal contact. A temperature gradient along 3 orthogonal directions can be achieved by placing the sandwiched blocks between the heater and heat sink in different orientations. The temperature gradients are measured by the built-in thermocouples while voltages along different directions are measured by the electrical contacts, thus giving the full Seebeck tensor. We used pre-characterized isotropic thermoelectric material PbTe as a reference sample to test the accuracy of the method. The diagonal Seebeck coefficients agree with results from the standard measurement method within 10%, and the error introduced in the 6 off-diagonal terms are smaller than 5% of the diagonal values.

Thermoelectric Properties and Scattering Mechanisms in Lead Ruthenate Derivatives Sepideh AkhbariFar, Werner Lutze and Ian L. Pegg; The Catholic University of America, United States

We synthesized several derivatives of lead ruthenate pyrochlore ($Pb_{(2+x)}Ru_{(2-x)}O_{(6.5\pm z)}$) by varying the Pb/Ru ratio, thereby introducing changes of lattice site occupancy, vacancies and valences. Reducing the number of Pb^{2+} ions create more vacancies in the A_2O' sublattice and change the properties of the already existing oxygen vacancies, which are occupied by Pb $6s^2$ electron lone pairs in pure lead ruthenate ($Pb_2Ru_2O_{6.5}$). Less than two Pb^{2+} ions mean less electrons for the vacancies. Decreasing the concentration of Ru^{4+} affects electrical conductivity, which is mainly governed by the RuO_6 backbone structure of ruthenate pyrochlores. We applied solid state synthesis and measured the thermoelectric properties of the ceramic compounds between 298 and 573 K. All compounds were isomorphic, like pure $Pb_2Ru_2O_{6.5.}$ We analyzed our results for underlying scattering mechanisms of electrical (σ) and thermal conductivity (κ), the Seebeck coefficients (S) in terms of carrier concentrations, using existing quantum physical models. All ceramics were *p*-type and showed metal-like electrical conductivity and glass-like thermal conductivity. Therefore, the same scattering mechanisms were seen for all pyrochlores. Electrical conductivity $\sigma(T)$ and electronic thermal conductivity $\kappa_e(T)$ were governed by 'electron impurity scattering'. The 3-phonon resistive process (Umklapp scattering) controlled the lattice thermal conductivity $\kappa_L(T)$, which supports the electron-impurity scattering mechanism. In all compounds, the Seebeck coefficients were inversely proportional to the carrier concentration.

2:30 PM EN10.09.06
Modelling Thermoelectric Properties in a Multicomponent Alloy Space Ramya Gurunathan[1], Suchismita Sarker[2], Logan Ward[3], James Saal[4], Apurva Mehta[2] and G. J. Snyder[1]; [1]Northwestern University, United States; [2]SLAC National Accelerator Laboratory, United States; [3]Argonne National Laboratory, United States; [4]Citrine Informatics, United States

Alloy systems with multiple principal elements are considered attractive for thermoelectric materials because the mass and strain fluctuations introduced into the lattice can effectively scatter phonons and suppress the lattice thermal conductivity. However, both charge carriers and heat-carrying phonons are known to experience scattering due to alloying effects. We apply analytic transport models, based on perturbation and effective medium theories, to predict how alloy scattering will affect the thermal and electronic transport across the full compositional range of several pseudo-ternary and pseudo-quaternary alloy systems. For carrier mobility, the work of Makowski and Glicksman[1] provides a straightforward expression for alloy effects in a binary system, however, an extension to higher-order systems has not been presented. We develop a multicomponent extension to the alloy mobility model by applying computational thermodynamics techniques used to calculate excess Gibbs energy, namely the Redlich-Kister polynomial and Muggianu model. In the case of thermal transport, a recent reformulation of the Klemens alloy model[2] provides a straightforward route to compute the thermal conductivity of multicomponent alloys. From our calculations, we find that the thermal conductivity is lowest along the binary system with the largest mass contrast such that adding additional alloying elements is not necessarily beneficial from the standpoint of alloy scattering.

The alloy scattering analytic methods will predict smooth variations of transport properties with increasing disorder. However, through experiment, we can occasionally observe discontinuous changes in properties, resulting from abrupt transitions due to electronic band convergence or phase separation. In order to retain these experimental insights, we combine the physical models described above with the statistical Gaussian Process Regression (GPR) method. In this physics-informed GPR, the transport models are used to specify the prior means of the Gaussian process. Bayesian inference is then used to simultaneously update the prediction mean and variance using all the available experimental data. As a result, we can acquire both predicted values and their associated uncertainties, informed both by the physics-based functional form of alloy scattering and the full corpus of experimental data available.

Thermal Batteries as a Solution to the Grid Storage Problem Asegun Henry; Massachusetts Institute of Technology, United States

Energy storage is arguably the most important single technology we have to develop in order to mitigate climate change. We have to store an overabundance of renewable energy, when the weather is favorable, and discharge it back to grid when there is demand. Commercially available technologies are unable to meet the future needs of the grid, and the most critical property is the cost per unit energy (CPE). Towards solving this problem, the Atomistic Simulation & Energy (ASE) group at MIT is developing an extremely low-cost (< $10/kWh) technology termed thermal batteries. This talk will review how the technology works and progress to date.

4:30 PM EN10.10.02
Energy-Efficient Adaptive Personal Thermal Management Po-Chun Hsu; Duke University, United States

Energy-Efficient Adaptive Personal Thermal Management
Thermal homeostasis is one of the most vital factors for humans. Small deviations from thermal comfort zones can reduce work productivity, while sudden or large changes in thermal environments can lead to serious health issues such as cardiovascular diseases, influenza, and stroke. The indispensable nature of thermal comfort leads to enormous energy consumption for indoor temperature control, which constitutes 15% of the total US energy consumption and is responsible for considerable amounts of carbon footprint and climate change. To mitigate the issue and find the balance between thermal comfort and energy-efficient, personal thermal management has been demonstrated to be a powerful solution. By developing new wearable technologies with thermal engineering functionalities, we can provide the optimal local thermal environment to the users rather than the entire building. As our environments and physiological conditions change frequently, there is a pressing need to develop dynamic personal thermal management techniques that can essentially act as artificial thermoregulation. Nevertheless, the limited portable power source has again become a harsh constriction. There is still room to improve in terms of wearability, tunability, and energy efficiency.
In this talk, I will introduce our recent research progress of wearable varied emittance (WeaVE) devices that modulate the human body radiative heat transfer to accomplish thermoregulation with ultralow energy consumption. Compared with active generating/pumping heat, WeaVE devices are non-volatile and do not consume energy to maintain heating/cooling. I will explain three different versions of WeaVE devices, each of which with different application scenarios. (i) Electrochromic WeaVE vary the emissivity with only 0.5 V and are stretchable to fit the human body contour. (ii) Sweat-actuated WeaVE combines radiative and convective heat transfer to achieve large-range autonomous thermoregulation. (iii) Mechanical triple-mode WeaVE can vary between transmittance, emittance, and reflectance modes to expand from human skin to other objects with various emissivities.

Nano-to-Microsphere Polycrystalline Opals Using Slope Self-Assembly for Advanced Thermal Management Carlos D. Diaz, Rishabh M. Shetty, Samantha Cheung, Geoffrey Vaartstra, Ashwin Gopinath and Evelyn N. Wang; Massachusetts Institute of Technology, United States

Inverse opals have attracted significant interest over the last decade as a templated microporous architecture with great potential for high-performance phase-change heat transfer devices. However, commonly used fabrication methods for the initial opal template yield structures with limited permeability due to small achievable feature sizes and the presence of defects in the crystalline array, hindering the use and performance of inverse opals in thermo-fluidic applications. In this work, we show how slope self-assembly method is a promising approach for phase-change thermal management. We developed a model, which was validated by experiments, to achieve high throughput and controllable opal self-assembly method with the potential of overcoming limitations in previous fabrication methods. We demonstrated the ability to fabricate millimeter-scale polycrystalline opal monolayers with sphere sizes ranging from 500 nm up to 10 μm, while centimeter-scale opals, comparable with wafer-scale state-of-the-art demonstrations, were also possible with some sparse sphere stacking or small uncovered areas. Due to the large achievable pore sizes, which exceed by an order of magnitude the sizes possible with the vertical deposition method, these structures have the potential to yield inverse opals capable of withstanding heat fluxes up to two orders of magnitude higher than those made with other fabrication methods. In addition, due to the simplicity, high throughput, and large range of achievable feature sizes of the method, these structures can also be used in a broad range of applications such as molecule printing and high-performance electrochemical systems.

SESSION EN10.11: Thermal Management II
Session Chairs: Samuel Graham and Junichiro Shiomi
Monday Morning, December 6, 2021
EN10-Virtual

8:00 AM *EN10.11.01
New Insight and Route for Developing Isotropic Heat Spreader with Small Thermal Boundary Resistance Junichiro Shiomi; The University of Tokyo, Japan

The topic of developing high-performance heat spreader has been around for a long time and there has been great advancement thanks to the community, but the demand for better heat spreader is getting larger than ever for thermal management of high-speed telecommunication and electric vehicles. In those application of important for sustainability and resilience, the large heat flux generated during the operation would overly elevate the temperature of devices, which can degrade the device and limit the performance. What is required is to effectively spread the condensed heat in three-dimensions using materials with (effectively) isotropically high thermal conductivity. In this talk, we will introduce two approaches; copper-diamond composite and graphite-copper composite. In both cases, the key is to bond materials with small thermal boundary resistance or large thermal boundary conductance (TBC).

As for the copper-diamond composite, an unconventional approach applying self-assembled monolayer (SAM) prior to the high-temperature sintering of copper/diamond composite was utilized to enhance the TBC between copper and diamond. The enhancement was first systematically confirmed on a model interface system consisting of deposited-copper-layer/SAM/diamond-substrate by detailed SAM morphology characterization and TBC measurements. TBC significantly depends on the SAM coverage and ordering, and the formation of high-quality SAM promoted the TBC. There, by systematically varying the end groups of SAM and the kind of substrate, some interesting insight was found. Although, TBC is typically positively correlated with interfacial adhesion at an interface, the experiments showed that a weak van der Waals interface can give a higher TBC than a strong covalently bonded

interface. This occurs in a system with highly mismatched vibrational frequencies (copper/diamond) modified by SAM. Further analyses revealed that this is attributed to the trade-off between the bridging (of vibrational spectra) and binding effects [1]. Then, applying the knowledge to the copper diamond composite, the diamond particles were simultaneously functionalized by SAM with the condition giving the highest TBC in the model system and sintered together with the copper to fabricate isotropically high thermal conductivity composite [2].

For the graphite-copper composite, although graphite is a promising candidate owing to its high basal-plane thermal conductivity, its application has been restricted by its low c-axis thermal conductivity. Here, this issue is resolved by transforming graphite into an isotropic thermal conductor by building a structure that can effectively route heat in all three dimensions. We developed a double-decker structure with differently oriented graphite layers to realize high heat dissipation from a local heat source. The critical issue of bonding the graphite layers was overcome by a high-temperature process using copper as the binding layer. As a result, graphite/copper composite efficiently dissipates heat nearly isotropically and performs even better than the above copper-diamond composite [3]. The detailed experimental analysis and demonstration of the heat transfer will be presented at the talk.

8:30 AM *EN10.11.04
Dynamic Droplet Events on Heat Transfer Surfaces Ryan Enright; Nokia Bell Labs., United States

Dynamic droplet events on heat transfer surfaces give rise to interesting and surprising behaviours that are relevant to advancing our understanding of thermal energy transfer across interfaces. Here, we discuss two particularly interesting cases; jumping droplet condensation on superhydrophobic surfaces and the impact of a volatile droplet on a superheated wetting surface.

In the first part of this talk we address the heat transfer performance of superhydrophobic surfaces limited by the low individual droplet growth rates associated with extreme droplet apparent advancing contact angles ($\theta_{app} \rightarrow 180°$) and the fundamental size limits of coalescence-induced droplet jumping. Our detailed condensation heat transfer modelling coupled with numerical simulations of binary ($N = 2$) and coordinated ($N > 2$) droplet coalescence, show that biphilic surfaces with smooth, low surface energy spots on a superhydrophobic background exhibit an unprecedented 10X higher jumping droplet condensation heat transfer coefficient when compared to homogenous superhydrophobic surfaces. Model predicted design optimization of the biphilic surface is validated against condensation experiments. Our findings clarify the role of droplet jumping dynamics and distribution densities by revealing optimum design guidelines for biphilic surface development for maximum condensation heat flux. Contrary to current understanding, we observe that spot wettability should not be optimized towards minimizing droplet nucleation energy barrier, rather it should minimize droplet adhesion while maximizing individual droplet growth rate.

We then describe the crucial impact thermal capillary waves and ambient gas rarefaction have on enhancing/limiting the jumping speeds of coalescing nanodroplets on low adhesion surfaces. By using high-fidelity non-equilibrium molecular dynamics simulations in conjunction with well-resolved volume-of-fluid continuum calculations, we are able to quantify the different dissipation mechanisms that govern nanodroplet jumping at length scales that are currently difficult to access experimentally. We find that interfacial thermal capillary waves contribute to a large statistical spread of nanodroplet jumping speeds. As the gas surrounding these liquid droplets is no longer in thermodynamic equilibrium, we also show how the reduced external drag leads to increased jumping speeds. This work demonstrates that, in the viscous-dominated regime, the Ohnesorge number and viscosity ratio between the two phases alone are not sufficient, but that the thermal fluctuation number (Th) and the Knudsen Number (Kn) are both needed to recover the relevant molecular physics at nanoscales. Our results and analysis suggest that these dimensionless parameters would be relevant for many other free-surface flow processes and applications that operate at the nanoscale.

In the second part of this talk, we present preliminary results on the Leidenfrost (critical heat flux) limit for dynamic droplet interactions with superheated surfaces. We identify a scientifically and practically relevant wetting behaviour in the Leidenfrost transition regime. We provide experimental observation of an inverted phase fingering instability demonstrating fractal-like wetting structures at the Leidenfrost transition indicating a rich interplay of fluid flow undergoing a change of phase and surface forces that is not currently well understood.

Thermal Management Strategies to Enable Ga_2O_3 and AlGaN-Based Electronics Samuel Graham[1,2], Mark Goorsky[3], Asif Khan[4] and James Speck[5]; [1]Georgia Institute of Technology, United States; [2]University of Maryland, United States; [3]University of California, Los Angeles, United States; [4]University of South Carolina, United States; [5]University of California, Santa Barbara, United States

Ultrawide bandgap semiconductors made from high Al content AlGaN alloys and Ga_2O_3 have promise for future rf electronics and power switches. One of the key issues that arises from using these ternary alloys is the intrinsic low thermal conductivity of AlGaN and Ga_2O_3 and the low thermal boundary conductance at contacts with these alloys. This requires careful design of the device architecture and layout in order to yield effective heat dissipation pathways for AlGaN systems. In this talk, we will present modeling results which demonstrated specific regimes where cooling from the backside or topside of the ultrawide bandgap devices provide the most efficient pathway for heat dissipation. We will also present modeling and experimental results that demonstrate the effectiveness of the integration of high thermal conductivity dielectrics on the heat dissipation efficiency in these devices. Limitations on the integration of these layers through direct growth or bonding will be discussed. Finally, the impact of the reaction between metal contacts and UWBG materials like Ga_2O_3 will be discussed and its role on thermal transport from the devices analyzed through device modeling.

9:30 AM *EN10.11.03
Co-Designing Electronics with Direct Monolithic Integration of Metals for More Sustainable Thermal Management Nenad Miljkovic; University of Illinois at Urbana-Champaign, United States

Power densification of electronics is greatly shaped by their co-design with emerging thermal management technologies. Heat spreaders represent a thermal routing technique implemented to reduce thermal resistance and limit electronic device temperature fluctuation. Here, we demonstrate the co-design of electronic systems through the monolithic integration of copper (Cu) directly on electronic devices to serve as heat spreaders and temperature stabilizers. We developed a fabrication recipe to electrically insulate the electronics with Parylene C and conformally coat them with Cu, demonstrating greater proximity to heat generating elements, elimination of thermal interface materials, and unprecedented cooling performance compared to existing cooling technologies. Our sustainable cooling method with 8 µm thick Parylene C can handle up to 600 V, providing exceptionally low device-to-ambient specific thermal resistances approaching 2.5 (cm2K)/W in quiescent air and 0.8 (cm2K)/W in quiescent water, with time constants of 110 s in air and 5.61 s

in water. Our cooling technology has the potential to enable the continued realization of very compact and highly power dense electronics and reduction in the cooling energy consumption.

Organopolysilazane Polymer as High Emissive Coating for Passive Daytime Radiative Cooling Applications Udayan Banik, Hosni Meddeb, Maximilian Götz-Köhler, Ashutosh Agrawal, Nies Reininghaus, Kai Gehrke, Oleg Sergeev, Jonas Stührenberg, Maciej Sznajder, Martin Vehse and Carsten Agert; German Aerospace Center, Germany

Passive Daytime Radiative cooling (PDRC) technology has the potential to significantly reduce our energy dependency for cooling buildings. It is an emerging, innovative green technology which uses the deep space as a cold sink to emit excess heat from an object through earth's atmosphere mitigating the heat island effect in urban areas. Achieving an efficient PDRC cooler requires high emission through the spectral range (8-13 µm) where the atmosphere is transparent, while reflecting the incoming solar spectra[1,2]. IR emissive polymers present a simple yet promising approach that enables controlling emission through molecular bonding[3]. However, relatively thick polymer coatings (20-200µm) are required to achieve sufficient high emissivity. To realize high cooling performance, an emitter with low absorption of the downward heat radiation from the atmosphere is desired. Aforementioned spectral selectivity on the other hand, generally requires complex nano-engineered structures to achieve restricted emission in the spectral range of 8-13µm. We have recently demonstrated for the first time a PDRC structure based on a spectrally selective organopolysilazane planar emitter which is simple to manufacture [4].
Organopolysilazane are silicon-based polymers where alternating silicon and nitrogen atoms form the backbone of the polymeric structure along with methyl and vinyl group attached to it. Polysilazane (PSZ) barrier coatings have been studied widely for their chemical resistance, stability, corrosion protection properties and easy applicability. The exceptional high transmissivity in the UV-Vis region and flexibility of polysilazane based coatings enable versatile application of these coatings[5,6]. We present here the optical properties and cooling performance of a simple dual layer spectrally selective PDRC structure with PSZ coating as a thermal emitter on a thin film silver reflector. Due to the high transparency of the polymer coating the structure allows for 97% reflection of the solar spectrum. We demonstrate the characteristic bond vibrations from the functional groups of the polymeric structure which coincides very well with the atmospheric transmittance window of 8-13µm resulting in the high emissivity of 0.9 in the 8-13µm wavelength range. The structure with a 5 µm thin coating can cool down to 6.8°C below ambient owing to a cooling power of 93.7 W/m^2. Based on long term outdoor performance tests and degradation tests under different environment, the changes in optical response and reliability of the PDRC structure was evaluated. We believe that polysilazane emitter coatings due to its simplicity and tenability will open new research possibilities for PDRC applications.

Improve Effective Thermal Conductivity in N-Type Copper-Nickel Alloy for Active Cooling Application Shuai Li[1], Sabbir Akhanda[1], Kyle Synder[2] and Mona Zebarjadi[1]; [1]University of Virginia, United States; [2]CCAM - Commonwealth Center for Advanced Manufacturing, United States

The conventional thermoelectric (TE) cooling modules are optimized for refrigeration to pump heat from the cold end to a heat sink. To achieve the best energy conversion efficiency, it requires a combination of a large thermoelectric power factor and low thermal conductivity to reach a high figure of merit. Whereas active cooling aims at draining heat from the heat source to a heat sink, which makes the low thermal conductivity of the commercial TE cooling disadvantageous. The metallic thermoelectric modules, on the contrary, combine large thermoelectric power factor and large thermal conductivity, allowing a more efficient drain of heat via both active Peltier cooling and passive cooling than the passive or the TE refrigeration ones. The fact that the active Peltier cooling can be adjusted by applying current to the modules also provides a more controllable way of heat management. In this study, we show that a Cu-Ni alloy with both a high power factor and a reasonable thermal conductivity can be synthesized with cheap industrial level ingredients and via the simple ball-mill and hot-press process in the lab. A power factor of $42 \mu W/(cm^1K^2)$ can be reached at room temperature with the proper Cu-Ni composition and annealing process, which is surpassed the state-of-art study on Cu-Ni thermoelectric materials synthesized with expensive high purity elements. The effective thermal conductivity of the Cu-Ni alloy with proper composition can surpass the passive thermal conductivity of pure copper at raised temperature (>400K). The deposition parameters of Directed Energy Deposition (DED) have been optimized for the specific Cu-Ni composition. Dense samples with properties comparable with samples from the laboratory have been made and characterized. Our study shows the potential of Cu-Ni alloys as an active cooling material and the compatibility of Cu-Ni Alloy with additive manufacturing, which enables the TE active cooling modules to adopt the optimal geometry to minimize the interfacial thermal resistance between the heat source and the heat sink, as well as scale down for the heat management of integrated circuits.

11:00 AM EN10.12.03
Broadband Light Absorber with Au-Coated Hierarchical Nanoturf Structures for Solar-Thermal Conversion Jong Uk Kim, Seung Ji Kang, Seok Joon Kwon and Tae-il Kim; Sungkyunkwan University, Korea (the Republic of)

Although much attention has been paid to the development of photothermal materials and designs that can convert solar irradiation into exploitable thermal energy, it remains some obstacles such as limited light absorbing band and narrow incident angle. This study proposes a black gold-coated hierarchical nanoturf (Au/h-nanoturf) membrane incorporated with randomly distributed high aspect ratio (AR)
nanostructures and micro-through holes. Thanks to structural advantages, this large area membrane exhibited good absorption of the broadband solar light

spectrum. The h-nanoturf is further combined with a microcone array to enhance solar absorption extended to the near-infrared range as well as the omnidirectional incident direction of the light. The fundamental mechanism of the strong omnidirectional broadband absorption performance of the h-nanoturf was thoroughly analyzed with computational electrodynamics simulations. Consequently, we employed the Au/3D h-nanoturf with microscale hole (μ-hole) membrane to fabricate an advanced solar-vapor generator.

11:15 AM EN10.12.04
Radiative Heat Transfer Between Superconducting Films Raul Esquivel-Sirvent, Shunashi Castillo-López, Giuseppe Pirruccio and Carlos Villarreal; Universidad Nacional Autonoma de Mexico, Mexico

We present a theoretical study of the near-field radiative heat transfer between high-Tc superconducting thin films made of optimally doped YBa2Cu3O7−δ. The critical temperature for these ceramics is Tc = 93 K. We show that thin films significantly enhance the radiative heat transfer by efficiently coupling each interface's optical modes. The heat transfer between thin films turns out to be up to one order of magnitude higher than that for bulk plates in normal and superconducting states. The change of the optical response above and below Tc also plays an important role since the superconducting phase transition leads to an abrupt suppression of the total heat flux. A detailed study of the different modes and the heat transfer is also presented, showing that for these materials, the mir infrared damping of the dielectric function determines to a significant extent role in the magnitude of the heat flux.

11:30 AM EN10.12.05
Large Change of Thermal Conductivity Induced by Temperature and Light in Azobenzene-Based Mesophases Noa Varela-Dominguez[1], Carlos López-Bueno[1], Alejandro López-Moreno[1,2], Gustavo Rama[1], Maria Giménez-López[1] and Francisco Rivadulla[1]; [1]Centro Singular de Investigación en Química Biolóxica e Materiais Moleculares (CiQUS), Universidade de Santiago de Compostela, Spain; [2]IMDEA Nanociencia, Spain

Achieving an efficient management of the heat dissipated in a variety of devices, is important for their proper functioning, and to prevent their uncontrolled failure. Research in the field of thermal regulation has mainly focused on the development of complex fluids through the dispersion of nanoparticles in different solvents (Keblinski et al., Materials Today, 8, 36, 2005) and on the manufacture of 'defective' solid materials, in which the thermal conductivity is limited by the introduction of impurities or interfaces at the atomic scale. However, these materials have several drawbacks: in the case of nanofluids, the high concentrations of dispersed particles needed to achieve a substantial change in thermal conductivity often result in rheological problems, preventing their application; in the case of 'defective' solids, the artificial impurities cannot be modified once the material has been manufactured, so that the modulation of thermal conductivity by an external stimulus is impossible. Thus, the development of efficient and tunable thermal regulators is one of the challenges in materials science.
'Soft matter' thermal devices based on liquids, gels or mesophases, are promising candidates in this direction. Shin et al. reported a reversible threefold change in the thermal conductivity of an azobenzene polymer induced by light (Shin et al., PNAS, 116, 8629, 2019).
Here we report the synthesis and thermal conductivity of 4,4'-dialkyloxy-3-methylazobenzene derivatives, with different alkyl chain lengths (between 3 and 10 carbon atoms). These systems show a rich thermal phase diagram, with different crystalline, anisotropic mesophases, and isotropic liquid configurations, as a function of temperature. The reversible changes in the alignment of the alkyl chains along these phases results in reversible variations of the thermal conductivity up to 26%. Moreover, the conformational transition between trans and cis azobenzene groups under UV-Vis illumination leads to reversible crystal-to-liquid transition, changing the thermal conductivity up to 40%.
We discuss the effect of chain length and temperature on the kinetics of the transformation, and on the stability of the different phases formed.
The large variety of light-responsive chemical groups, combined with the powerful strategies developed by organic and polymer chemists over the last decades, suggest that this could be a successful approach to develop effective thermal switches.

11:45 AM *EN10.12.06
Thermodynamics of Light Management in Near-Field Thermophotovoltaics Georgia T. Papadakis[1] and Shanhui Fan[2]; [1]ICFO – Institute of Photonic Sciences, United States; [2]Stanford University, United States

We analyze near-field thermophotovoltaic systems in terms of their open-circuit voltage (Voc). Unlike previous numerical results with fluctuational electrodynamics, we introduce a simple analytic model that captures the physics of near-field thermophotovoltaic systems and predicts their performance metrics in terms of both current and voltage. We show that (i) operating in the near-field naturally enhances radiative recombination, and that (ii) owing to photon recycling and minimal radiation leakage, near-field thermophotovoltaic systems can be much thinner compared to typical PV cells, thus reducing non-radiative losses. Combination of these effects leads to values of Voc that can approach the radiative limit.

SESSION EN10.13: Simulation and Machine Learning
Session Chair: Yuan Yang
Monday Afternoon, December 6, 2021

1:00 PM EN10.13.01
Discovery of Materials for Thermionic Energy Conversion by High-Throughput Density Functional Theory and Machine Learning Peter Schindler[1,2], Evan Antoniuk[1], Gowoon Cheon[1], Yanbing Zhu[1] and Evan Reed[1]; [1]Stanford University, United States; [2]University of Vienna, Austria

The work function is the key surface property that determines how much energy is required for an electron to escape the surface of a material. This property is crucial for thermionic energy conversion, band alignment in heterostructures, and electron emission devices. The discovery of thermally stable, ultra-low work function materials (less than 1.5 eV) would allow thermionic conversion of heat (>1500 °C) directly to electricity with efficiencies exceeding 30% (typical thermionic and thermoelectric converters have efficiencies around 10%). In recent years, data-driven approaches based on high-throughput *ab-initio* calculations have emerged as a new paradigm to facilitate the search through vast chemical spaces for new materials with tuned properties or novel behavior. The rapid increase in available computational data structured in open source material databases such as Materials Project, AFLOW, and NOMAD has opened an avenue towards material discovery using data-mining and statistically driven machine learning approaches. However, most big material databases largely lack to report surface properties like the work function as each bulk material typically has dozens of distinct low-index crystalline surfaces and terminations. Here, we report a high-throughput workflow using density functional theory (DFT) to calculate the work functions of 29,270 surfaces (23,603 slab calculations) that we created from 2,492 bulk materials, including up to ternary compounds. On the low tail end of the work function distribution, we discover 162 surfaces with an ultra-low (<2.5 eV) work function. Based on this database we develop a physics-based

approach to featurize surfaces and use supervised machine learning to predict the work function. We find that physical choice of features improves prediction performance far more than choice of model. Our random forest model achieves a mean absolute test error of 0.19 eV when predicting the work function, which is more than 4 times better than the baseline and comparable to the accuracy of DFT. This surrogate model enables rapid predictions of the work function (~10^5 faster than DFT) across a vast chemical space and facilitates the discovery of material surfaces with extremely low work functions for energy conversion and electronic applications.

Study of Thermoelectric Performance of Polymer Nanocomposites by Applying Generalized Effective Medium Theory Shivani Shisodia[1], Abdelhak H. Sahraoui[1], Dharmendra P. Singh[1], Benoit Escorne[2] and Michael Depriester[1]; [1]Université du Littoral Côte d'Opale, France; [2]Université du Littoral Côté d'Opale, France

Thermoelectric (TE) materials grabbed much interest in various applications such as cooling, power generation, sensors, aircraft, etc. due to their ability to convert waste thermal energy into electric energy[1–3]. The interdependency among thermal conductivity, electrical conductivity, and Seebeck coefficient acts as a barrier to enhance thermoelectric performance. However, thanks to nanotechnology, it is possible to break this interdependency by employing interface phonon scattering approach to enhance the TE efficiency. Introducing lattice mismatch concept at nanoscale can decrease the lattice thermal conductivity more effectively than electrical conductivity[4]. Also, Seebeck coefficient can increase due to the quantum confinement effect at nanoscale, without decreasing the electrical conductivity[5].
The current work is the continuation of our previous work based on the synthesis and characterization of poly (3,4-ethylene dioxythiophene): polystyrene sulfonate (PEDOT: PSS) filled with different wt. fractions (0.001-0.05) of inorganic graphene oxide-titanium dioxide (GO-TiO_2). Here, we succeed to break the interdependency of thermoelectric parameters by enhancing electrical conductivity and Seebeck coefficient whilst deducing thermal conductivity as a function of filler wt. fraction.
The present work is more focused on in-depth analysis of the obtained experimental results by using theoretical predictions. Firstly, the electrical conductivities, the thermal conductivities, and the Seebeck coefficients of aforementioned composites were measured experimentally. Secondly, the experimentally obtained results were fitted by using Effective medium theory (EMT) and Generalized effective medium theory (GEMT) based on Landauer and Sonntag's equations. The obtained best-fit parameters demonstrate the individual TE properties of the matrix and the filler.
EMT and GEMT have been directly applied to understand the evolution of electrical and thermal conductivities of the composites as a function of filler wt. fraction. However, for the Seebeck coefficient, we have utilized the Sonntag's extended model for degenerate semiconductors where the heat flux was replaced by the entropy flux. Therefore, the ratio of thermal conductivity to Seebeck coefficient is considered as a transport parameter and has been utilized to understand the evolution as a function of filler wt. fraction instead of Seebeck coefficient alone. The obtained best-fit parameters for the matrix and the filler were found to be in good agreement with the literature.

Keywords: Thermoelectricity, thermal conductivity, Electrical conductivity, Seebeck coefficient, Generalized effective medium theory.

Machine Vision and Learning Models for Materials Design Youngjoon Suh, Chuanning Zhao, Ramin Bostanabad and Yoonjin Won; University of California, Irvine, United States

Advances in thermal and energy sciences bring transformational efficiency enhancements in energy, water, manufacturing processes, and electronics cooling by fundamentally manipulating energy processes across multiple length and time scales. Herein, the energy processes are naturally complex, and create dynamic changes in thermofluidic features, which are represented as bubbles or droplets. Furthermore, the improvements in the energy process critically depend on our ability to design and realize materials with optimal properties, adding another level of complexity. Unveiling energy processes integrated with materials design can be possible by collecting interpretable and rich physical descriptors from bubbles or droplets. These challenges for extracting physics from complex, dynamic, and fast-moving objects may be addressed using revolutionary intelligent machine vision. Therefore, one of my research interests is to build a data-driven framework based on live images by converging the recent advancements in artificial intelligence (AI)-enabled machine vision, data processing, and deep learning models, to push the boundaries of knowledge about thermofluidic physics.

In this talk, I will discuss AI-enabled innovations, data-centric thinking, and opportunities, by showcasing a few examples. 1) I will first introduce the modular framework that can produce high-throughput fast data acquisition, streamline automatic data processing, and create a spatiotemporal thermal mapping at extreme resolutions. 2) I will explore input space (e.g., material or surface parameters) by generating imaging data on dynamic bubble/droplet topologies along with heat transfer data where the experimental design and heat transfer performance will be fully connected with physical descriptions. Therefore, the rational design of material or surface parameters can engineer solid-liquid-vapor contact lines that result in favorable phase change curves. 3) Then, I will discuss avenues to design functional thermal architectures that are widely employed as high-surface conduits for thermofluidic applications.

Late News: Spark Plasma Sintering of $SrVO_{3-\delta}$ and Mixed Perovskites for Thermal Energy Management Liam E. Fisher, Xiaochuan Tang and Kaka Ma; Colorado State University, United States

Previous density functional theory work suggested that $SrVO_{3-\delta}$ is a promising candidate as electron emissive material for thermionic energy conversion because of the predicted ultralow work function (1.86eV). Additionally, A- and B-site doping in ABO_3 perovskites can increase power factors and decrease thermal conductivity compared to traditional oxide perovskites for thermoelectric energy conversion. To experimentally explore the potential of using $SrVO_{3-\delta}$ and its mixed perovskites for thermal energy management via thermionic or thermoelectric conversion, bulk polycrystalline $SrVO_{3-\delta}$ samples were synthesized via spark plasma sintering. The effects of Ba- and Ti- doping on the microstructure, electrical conductivity, and thermal stability of $SrVO_{3-\delta}$ were investigated. Results revealed that the microstructure consists of predominant $SrVO_{3-\delta}$ phase with minor $SrTiO_{3-\delta}$ phase, with grain size of approximately 15 μm. The thermionic emission behavior tested in an Ar plasma will be discussed as well.

Improvement of Thermoelectric Power Generation Performance in Silicide-Based Thermoelectric Modules Using Higher Manganese Silicide $MnSi_{\gamma}$ Naoto Fukatani[1], Masakuni Okamoto[1], Yosuke Kurosaki[1], Shin Yabuuchi[1], Tomohisa Takamatsu[2], Yuzuru Miyazaki[2] and Jun Hayakawa[1]; [1]Hitachi Ltd, Japan; [2]Tohoku University, Japan

A lot of energy is lost as waste heat in the process of producing and consuming electricity. Utilizing a vast amount of heat energy is essential for realizing a sustainable society. Thermoelectric conversion technology is one of the solutions for utilizing waste heat effectively because it enables a direct conversion of heat into electricity without any moving parts. The higher manganese silicide of $MnSi_{\gamma}$ is a promising thermoelectric material composed of less-toxic elements with a material figure of merit *ZT* reaching up to 1.0. We have previously reported that it is possible to reduce the thermal conductivity and improve *ZT* by co-doing Re and Ge to the matrix of $MnSi_{\gamma}$. In this study, silicide thermoelectric modules using p-type $(MnRe)(SiGe)_{\gamma}$ were prepared and its power generation characteristics were evaluated.
An alloy powder of p-type $(MnRe)(SiGe)_{\gamma}$ was prepared by a mechanical alloying method, and then sintered using a spark plasma sintering method. For the n type, a Mg_2Si-based material, which was developed by Yasunaga Co., was used. To join the p-type, n-type elements and Cu electrodes, the modules were sintered at 550 – 750°C with a pressure of 10 MPa.
We investigated the dependence of thermoelectric properties on the Re and Ge amount in $(MnRe)(SiGe)_{\gamma}$. The ratio between sublattices of $MnSi_{\gamma}$, γ, was clarified to be reduced with increasing Re and Ge amount. Both Seebeck coefficient and electrical resistivity decreased, and the power factor increased, owing to the generated carriers by the reduced γ. On the other hand, the lattice thermal conductivity decreased with increasing Re and Ge amount due to the mass-difference and strain-field-difference phonon scattering. As a result, *ZT* increased up to 0.70 at 500°C when the substitution amount of Re was 0.10 and that of Ge was 0.03. The power generation characteristics of the 1-pair and 9-pair thermoelectric modules composed of $(MnRe)(SiGe)_{\gamma}$ and Mg_2Si were evaluated by changing the elements heights h = 1.0, 2.0, 3.0, 3.5 mm when the hot side and cold side are 500°C and 20°C, respectively. The output power density increased as the element height decreased and showed the similar tendency as the results of the power generation characteristic simulation. As the element height decreased, the temperature difference applied to the element decreased and the open voltage also decreased, but the electrical resistance value also decreased significantly. As a result, output power density took the maximum value with respect to the element height. The maximum output power density of 14.3 kW/m^2 at 500°C was obtained when h = 2.0 mm. On the other hand, module resistance analysis revealed that interfacial resistance was present in about 20 – 30% of the total due to non-uniform bonding between the thermoelectric elements and the electrode. To improve the binding condition, sintering temperature of the modules were varied in the temperature range of 550 – 750°C. As increasing sintering temperatures, the module resistance decreased due to the improvement of the bonding between the elements and electrode. At high sintering temperatures above 650°C, although the module resistance decreased, the open voltages of the modules decreased due to the diffusion of Cu from the electrode to the elements, and the output power also decreased. As a result, maximum output power density of 17 kW/m^2 was obtained at the sintering temperature of 600°C, which is the highest level in the reported thermoelectric module using $MnSi_{\gamma}$ and Mg_2Si. The power generation simulation suggests that the maximum output power increases up to 22 kW/m^2 if the interfacial resistance in the module were completely removed.
This study is based on results obtained from the Future Pioneering Program “Research and Development of Thermal Management and Technology” commissioned by the New Energy and Industrial Technology Development Organization (NEDO). This work is also supported by TherMAT.

High-Resolution Elemental and Strain Study of High Entropy Thermoelectric Materials Yong Yu[1,2], Stephen Pennycook[1], Bosman Michel[1] and Jiaqing He[2]; [1]National University of Singapore, Singapore; [2]Southern University of Science and Technology, China

Thermoelectric materials directly convert thermal energy to electrical energy and *vice versa*. To improve the energy conversion efficiency, accurate characterization of the atomic structure is critical, as this defines the charge- and phonon-transport. Scanning transmission electron microscopy (STEM) is widely used for defect characterization in thermoelectric materials, as structural defects and lattice strain often play a critical role in phonon scattering. However, the recently emerging high entropy thermoelectric materials are challenging objects for this characterization due to their very small strain and atomic-scale elemental mixture.
Here we show that these challenges can be solved by careful sample preparation, microscope fine-tuning, and the application of new experimental methods. Three STEM-based techniques are applied: atomic resolution energy-dispersive X-ray spectroscopy (EDS), geometric phase analysis (GPA), and nanobeam diffraction analysis (NBED) to understand the elemental positions and subtle lattice distortion, which are important for understanding the structure-property relationship.
Our high entropy material has a composition of $Pb_{0.89}Sb_{0.012}Sn_{0.1}Se_{0.5}Te_{0.25}S_{0.25}$ and was compared to the low entropy PbSe control material. The atomic positions of Pb, Sn, Te, Se were found by atomic resolution EDS mapping. Pb and Sn occupy the ‘Na’ position, while Te and Se occupy the ‘Cl’ position of the NaCl crystal structure, demonstrating that the elements were mixed homogenously at the atomic level.[1]
GPA can quantify the local strain distribution. However, weak strain fields require careful attention since the inevitable sample drift and scan noise will induce artifacts. To optimize this, we first wait a long time to minimize the sample drift, then we adopt fast scanning and take a stack of 30 frames, and finally, we use the ‘Smart Align’ software plugin to align the stacks together. This can simultaneously reduce the artifacts from sample drift and from scan noise, to give a strain analysis with 0.3% accuracy. With this, we find that the strain distribution in our high entropy alloy is much wider than that of low entropy alloy. The histogram shows that the statistical distribution in the high entropy alloy is much wider along with the normal <002> and shear <220> directions than in the low entropy alloy. This is important information, as the normal and shear strains are directly linked to the lattice thermal conductivity.[1]
As GPA requires atomic resolution images, the observational area cannot be very large and NBED is used to overcome this shortage. We use a 4 nm parallel probe to scan a much larger area of 400 nm by 400 nm to obtain a series of electron diffraction patterns. With careful analysis, we are able to map the strain with an accuracy of 0.06%. The results of NBED indeed confirm that the strain distribution of the high entropy alloy is much wider than the low entropy alloy. However, the absolute values in the strain field by NBED are lower than what was obtained with GPA. This shows the strength of GPA at a very small scale: in this high entropy alloy, the local strain varies in areas smaller than 2 nm and the strain measured with NBED only gives an average of the probed 4 nm area. In the case of our high entropy alloy, a full picture of the strain fields will therefore only be obtained by a combination of the GPA and NBED results.[1]

Improvement of Thermoelectric Performance *via* Hierarchical Defect Engineering Using Nanoparticles as Building Blocks Mari Takahashi[1], Kimihiro Numano[1], Wei Zhou[1], Masanobu Miyata[1], Michihiro Ohta[2] and Shinya Maenosono[1]; [1]Japan Advanced Institute of Science and Technology, Japan; [2]National Institute of Advanced Industrial Science and Technology (AIST), Japan

Sustainable development goals (SDGs) have recently been considered across the world. Keeping requirements of sustainable and clean energy in mind, energy harvesting is one of the important technologies, since this technology can convert waste heat into electricity. The thermoelectric (TE) figure of merit ZT is expressed by $\sigma S^2T/\kappa$, where σ is electrical conductivity, S is Seebeck coefficient, T is absolute temperature and κ is thermal conductivity. For the practical applications, TE materials with $ZT > 1$ have been desired. On the other hand, over 80% of the waste heat generated in industry is in the ranges of 373−575 K.[1)] Therefore, sustainable TE materials consisting of earth abundant and relatively non-toxic elements whose ZT value is higher than 1 at such low temperature range have been desired for many years.
There are several methods to improve ZT of TE materials. Among them, the fabrication of TE materials by sintering chemically-synthesized nanoparticles (NPs) has attracted much attention, mainly because κ can be significantly reduced through phonon scattering at the interfaces of well-defined nanograins. Comparing to the conventional ball milling technique, the use of chemical-synthesis of NPs as building blocks has several advantages.[2,3)] For example, the fabrication time required to obtain a pellet is shorter; the size of well-defined nanograins in the pellet can be easily controlled; various kinds of nanoinclusions can be introduced in the material just by mixing two or more different types of NPs; mesoscale defects can be created by controlling the size of domain of nanoinclusions; atomic defects can readily introduced in NPs. In other words, it offers unprecedented opportunities for the hierarchical defect engineering.
Previously, we synthesized Zn doped Cu_2SnS_3 NPs (Zn-CTS) with changing Zn content. The results showed that the pellet fabricated by either $Cu_2Sn_{0.85}Zn_{0.15}S_3$ or $Cu_2Sn_{0.95}Zn_{0.05}S_3$ NPs showed relatively high ZT value of 0.37 at 670 K than that of pristine CTS fabricated by the conventional method.[4)] Basically, Zn incorporation causes hole doping, and thus, as Zn content increased, σ of Zn-CTS increased. However, when the material became metallic, κ increased according to the Wiedemann–Franz law. In order to decrease carrier thermal conductivity κ_{car}, $Cu_2Sn_{0.9}Zn_{0.1}S_3$ NPs, which has the lower κ, were mixed with $Cu_2Sn_{0.85}Zn_{0.15}S_3$ NPs, which has the higher σ, in the ratio of 1:9. Owing to the sea-island structure composed of $Cu_2Sn_{0.9}Zn_{0.1}S_3$ NPs (island) and $Cu_2Sn_{0.85}Zn_{0.15}S_3$ (sea), the pellet could maintain high σ while κ showed lower value than that of pure $Cu_2Sn_{0.85}Zn_{0.15}S_3$ because of the efficient phonon scattering at the interfaces between sea and islands. As a result, the highest ZT value of 0.64 was achieved at 670K.[5)]
As this example shows, there is plenty of room for improvement of ZT by the hierarchical defect engineering using NPs as building blocks. In this talk, we will show you our recent results about the hierarchical defect engineering for discussion.

Ultra-Light-Mass Band Engineering in N-Type Mg_3Bi_2-Based Materials Ryosuke Yamamura, Yuriko Kaneko, Tsutomu Kanno and Hiromasa Tamaki; Panasonic Corporation, Japan

N-type Mg_3Sb_2-based compounds, discovered by our group in 2016, are one of the potential candidates for low-cost and high-performance thermoelectric materials comparable to the commercial Bi_2Te_3 [1]. A Bi-rich side of N-type Mg_3Sb_2-Mg_3Bi_2 solid solution has recently attracted attention by its excellent low-temperature thermoelectric performance [2]. One possible, yet controversial, mechanism is the band convergence between the six-valley carrier pocket (CB_1 band) and the single-valley band at Γ-point (Γ band) with increasing the Mg_3Bi_2 content [3, 4]. This motivates us to perform DFT-based modelling of electronic structure and thermoelectric properties for Mg_3Sb_2-Mg_3Bi_2 solid solution.
Our analysis reveals that the band convergence does not occur even for Mg_3Bi_2 end, but ultra-light Γ band slightly above the CB_1 minima enhances its power factor. We find that, by increasing Bi content, the band effective mass of the Kane-type Γ band becomes one order of magnitude lighter than that of the parabolic CB_1 band, where the energy gap is nearly closed. Despite the single-valley and not converged character, the contribution of the ultra-light Γ band to the transport properties is as significant as the six-valley CB_1 band, leading to the enhanced power factor greater than $30\mu W/cmK^2$ for Mg_3Bi_2 end. In this talk, we also compare our computational modeling with experimental results. Discovery of the ultralight Γ band in Mg_3Bi_2-based materials will open the possibility of ultra-light-mass band engineering to design high-performance thermoelectric materials.

7:30 PM EN10.15.05
Double Charge Polarity Conversion by Sb Doping in Layered SnSe with Switchable Substitution Sites Xinyi He[1], Chihiro Yamamoto[1], Takayoshi Katase[1], Keisuke Ide[1], Hidenori Hiramatsu[1,2], Hideo Hosono[2] and Toshio Kamiya[1,2]; [1]Laboratory for Materials and Structures, Tokyo Institute of Technology, Japan; [2]Materials Research Center for Element Strategy, Tokyo Institute of Technology, Japan

Due to the current growing energy issues, the importance of thermoelectric energy conversion has been increasing. Recently, tin selenide (SnSe) with a layered crystal structure has extensively been studied as it exhibits a high figure-of-merit $ZT > 2$ [1]. However, SnSe has a serious issue; i.e., the carrier polarity control is still difficult, which is critical to realize p-n homojunction devices. Pure SnSe is a native p-type semiconductor, and p-type conductivity is enhanced by impurity doping, e.g., by alkali ion-doping [2]. Bi and halogen ions have been employed for electron doping at the Sn and the Se sites, respectively [3-5]. However, the maximum carrier concentration has been limited to 10^{17} cm^{-3} because of the low activation efficiency (less than 0.1%) of the Bi^{3+} donor. Antimony ion (Sb^{3+}) doping at Sn^{2+} site is expected to produce n-type SnSe, and the Sb-doped SnSe is reported to show high thermoelectric efficiency with $ZT = 1.1$ even in practical polycrystalline form. However, there are contradicting reports on the charge polarity (n-type or p-type); i.e., some papers report n-type and the others p-type [6-8].
In this work, we have discovered an unusual phenomenon, the double inversion of the charge polarity, in $(Sn_{1-x}Sb_x)Se$ by varying only the Sb concentration (x), and elucidated the doping mechanism. Pure SnSe shows p-type conduction, while $(Sn_{1-x}Sb_x)Se$ shows n-type conduction for $0.005 < x < 0.05$, and finally re-inverts to p-type conduction for $x > 0.05$. The substitution sites of Sb distributes for the Sn sites and the Se sites, and the major substitution site

switches from the Se (Sb_{Se}) to the Sn site (Sb_{Sn}) with increasing *x*. This means the charge state of Sb changes from -3 to +3 with increasing *x*. We explain the mechanism of the double polarity inversion from the band alignment and the first-principles calculations; pure SnSe shows p-type conduction due to the formation of Sn vacancy, and $(Sn_{1-x}Sb_x)Se$ exhibits the apparent n-type behavior due to conduction through additional Sb_{Se} impurity band, and then finally re-inverts to weak p-type, where the Fermi level approaches the midgap level located between the additional Sb_{Se} band and conduction band minimum. The clarification of Sb doping mechanism would give a crucial guide to develop more sophisticated doping route for SnSe and high-performance energy-related devices.

Wearable Flexible Thermoelectric Generator System for Self-Powered Temperature Sensor Jeong Hun Kim, Jong-Pil Im, Yeriaron Kim and Seung Eon Moon; Electronics and Telecommunications Research Institute, Korea (the Republic of)

Thermoelectric power generators that can produce electrical energy from the temperature difference between the two ends are attracting attention as a next-generation clean power generation system because they can be applied to various places where heat sources exist and do not generate by-products during the power generation process. Recently, results of operating application systems such as simple acceleration sensors or electrocardiograms by attaching them to the human body have been published. As such, thermoelectric generators are easy to apply with a small volume of independent power source. It is also receiving attention as a power source for wearable devices that can be monitored at all times.

In this study, a flexible thermoelectric element capable of uniform contact with human arm was fabricated through a printing process-based thermoelectric element manufacturing method that applied a BiTe-based inorganic material and a flexible silver electrode on the sacrificial layer. In particular, by using Polyurethane foam as a polymer filler material to support the structure and lowering the thermal conductivity, it was possible to confirm more than twice the power compared to the case of using Poly(dimethylsiloxane) (PDMS). In addition, on a curved surface with a radius of curvature of 4 cm, the output was 5 times higher than that of a flat metal substrate, and through this, a method for effectively collecting heat from the human body was presented.

In the case of a cooling unit to maintain a temperature difference, a fin-type heatsink that is generally used has a relatively large volume and uses a hard material, so it is difficult to apply it to a flexible thermoelectric device. To solve this, UV curability hydrogel that can absorb water was used as a flexible and stretchable heat sink. Effective cooling properties were obtained from the evaporation of water contained in the hydrogel heatsink, and as a result of testing the performance of the manufactured thermoelectric generator system in the form of a band that can be worn on the human body, the power generation amount of more than 30 $\mu W/cm^2$ under the convection condition of 1.5 m/s was able to confirm. It was confirmed that the capacitor could be charged and the temperature sensor could be driven. As an eco-friendly independent power system technology, it is expected that it can contribute as an energy device for various wearable applications that require continuous measurement and communication, such as an attachable biometric sensor.

7:40 PM EN10.15.07

Prediction of High Thermoelectric Performance in the Low-Dimensional Metal Halide $Cs_3Cu_2I_5$ Young-Kwang Jung[1] and Aron Walsh[1,2]; [1]Yonsei University, Korea (the Republic of); [2]Imperial College London, United Kingdom

Metal halides have been intensively studied for their optoelectronic applications e.g. solar cells and light emitting deivces. Recently, their potential as thermoelectric materials has emerged where unique vibrational properties of metal halides -- such as localised phonons and ultra-low lattice thermal conductivity -- plays important roles. Up to date, the highest thermoelectric figure of merit ZT reported among metal halides is ~0.15, which is well short of the champion ZT of 2.6 achieved in SnSe. $Cs_3Cu_2I_5$ is an alternative metal halide with an low-dimensional crystal structure where $[Cu_2I_5]^{3-}$ clusters are surrounded and isolated by Cs^+ cations and there is no direct connectivity between neighboring anionic clusters [1]. Its unique optoelectronic properties related with the low-dimensional structure have been studied, but its charge and heat transport properties have not been indenified yet.

In this study, we assess the thermoelectric potential of $Cs_3Cu_2I_5$ combining state-of-art first-principles simulation techniques. Thermal transport properties were calculated using anharmonic lattice dynamics [2] where an ultra-low conductivity for the perfect crystal that is found. By employing an *ab initio* description of carrier scattering [3], we further investigate electron transport properties of the material. Efficient electron transport throughout the crytal is confirmed, which is attributed to an unexpectedly low effective mass for the electron in the low dimensional structure. As a result of imbalanced electron and heat transport, $Cs_3Cu_2I_5$ is predicted as an ideal thermoelectric semiconductor that exhibits the characteristics of "phonon-glass electron-crystal" with an accessible *ZT* of greater than 2 [4].

7:45 PM EN10.15.08

Large Phonon Drag Thermopower Enhancement by Epitaxial Strain and Phonon Leaking in $LaAlO_3$ / $LaNiO_3$ / $LaAlO_3$ Heterostructure Masatoshi Kimura, Xinyi He, Takayoshi Katase, Keisuke Ide, Hidenori Hiramatsu, Hideo Hosono and Toshio Kamiya; Tokyo Institute of Technology, Japan

Phonon drag thermopower (S_g) has received great attention because total *S* is enhanced compared to the conventional carrier-diffusion thermopower (S_d) by $S = S_d + S_g$, and thus the energy conversion efficiency is enhanced [1]. S_g is expressed as $S_g = (m^* v_s l_\lambda) / (\tau_e e T)$ in the non-degenerated regime [2]. Therefore, the conventional approach to observe S_g is to utilize ballistic phonon with long mean free paths (l_λ) in high quality semiconductors [3] or large electron effective mass (m^*) in strongly correlated electron systems [4]. However, S_g is observed only in limited materials at low temperatures and its peak value is small. Here, we report an unusually large S_g enhancement in the thin-film heterostructure of a strongly correlated electron oxide $LaNiO_3$ (LNO). We investigated the effects of layer thickness and surface termination on *S* of LNO epitaxial films grown on $LaAlO_3$ (LAO) substrates with the in-plane lattice mismatch of -1.5%. The 50 – 3 unit cells (u.c.) thick LNO epitaxial films with step & terrace surfaces were grown by pulsed laser deposition on (001) LAO single crystal. LAO-capped LNO films were fabricated by first depositing a 3 u.c. LNO film, followed by growing a 10 u.c. LAO capping layer. The LNO film grows coherently with strain up to thickness 50 u.c. on the LAO substrate. The pseudo-cubic lattice parameters for out-of-plane (*c*) and in-plane (*a*) are 3.88 Å and 3.78 Å, respectively. The *c*/*a* is 1.026, indicating the in-plane compressive strain in the LNO films. For the LAO-capped 3 u.c. LNO film, the tri-layer structure of LAO/LNO/LAO grows coherently with strain. By reducing the LNO layer thickness, the film showed the metal-insulator transition at a critical thickness of 5 u.c. On the other hand, the surface termination by 10 u.c. LAO capping layer changed the 3 u.c. LNO film

more conductive again, which shows a metal-insulator transition at T = 77 K.
The phonon-drag S_g is not observed in the bulk LNO, whereas it appeared at T = 25-33 K for the LNO epitaxial films with compressive strain by the LAO substrate. By reducing LNO layer thickness down to 3 u.c. and subsequent LAO surface termination, S was enhanced 10 times from that of bulk LNO due to the large phonon drag S_g, and the S_g contribution to the total S spreads in much wider temperature range, reaching up to 220 K. We clarified that the S_g enhancement originates from a coupling of lattice vibrational phonons to the Ni 3*d*-electrons whose effective mass becomes larger in the strained ultra-thin LNO film and also from the strong electron-phonon scattering enhanced by the phonon leakage from the LAO substrate and the capping layer. The present results demonstrate a new approach to manipulate both electronic and phononic properties in atomic-scale controlled transition metal oxide (TMO) heterostructures for high-performance thermoelectrics.

Enhanced Thermoelectric Response in Sb_2Te_3 Thin Film by Incorporation of Size-Selected Gold Nanoparticles Abhishek Ghosh and Bodh Raj Mehta; Indian Institute of Technology, India

Enhancement in the thermoelectric (TE) properties through carrier filtering in polycrystalline Sb_2Te_3 thin film is realized by incorporating size-selected Au nanoparticles grown by an integrated gas-phase synthesis method. Crystalline Singlet nanoparticles of Au having a narrow size distribution are embedded between two Sb_2Te_3 layers. Thermoelectric properties have been investigated by varying the concentration of nanoparticles, which reveal a significant increase in the Seebeck coefficient and power factor with a slight deterioration in electrical conductivity. Samples containing non-size selected Au particles with broad size distribution are also synthesized to understand the effect of non-uniformity in size distribution on TE properties and compared with the samples containing size-selected particles. In addition, scanning probe techniques were employed to understand the nature of the interface formed between Sb_2Te_3 and Au nanoparticles which reveals the formation of a Schottky barrier in the interface. The study provides an opportunity to manipulate the TE properties in Sb_2Te_3 thin films by constructing a metal-semiconductor heterostructure by controlling the concentration and randomness to achieve a high TE performance.

Capillary-Driven Condensation for Enhanced Energy Efficiency Samuel Cruz, Yajing Zhao, Kyle Wilke, Hyeongyun Cha, Daniel J. Preston and Evelyn N. Wang; Massachusetts Institute of Technology, United States

Significant interests in enhancing the efficiency of condenser designs and reducing water consumption have emerged for thermoelectric power plants. While substantial efforts have focused on methods to enhance heat transfer performance in condensers, ongoing challenges remain including maintaining robust non-wetting behavior for enhanced heat transfer enhancement during dropwise condensation. In our work, we present a new mode of condensation termed capillary-driven condensation. In this approach, a porous hydrophobic membrane atop a wicking structure on the condensing surface helps generate a capillary pressure gradient to drive liquid transport through the wick to an exit port for condensate removal. The wick both sets the thickness of the condensate-wick layer and increases its effective thermal conductivity, reducing the overall thermal resistance. Meanwhile, the hydrophobic porous membrane helps generate the capillary driving pressure via its microscale pores to transport the condensing fluid out of the wick and significantly increase the heat transfer performance. With well-controlled microfabricated structures, i.e., a silicon nitride membrane suspended on a micropillar wick, we show a successful proof-of-concept. The wick fills completely upon nucleation, and small droplets on top of the membrane are continually absorbed into the wick through the membrane pores. The visualizations suggest promising heat transfer enhancements and are corroborated by our developed models. Simultaneously, we have been pursuing scalable approaches to achieve capillary-driven condenser designs, including diffusion-bonded, hydrophobized hierarchical copper meshes, and electro-spun membrane covered metal wicks. This work suggests a promising path for incorporating capillary-based condenser designs to enhance the efficiency of power plants, thermal management strategies, and water desalination systems, among others.

Monitoring and Quantifying Condensation Frosting on Lubricant-Impregnated Surface Doris Vollmer, Lukas Hauer, Katharina Hegner and William S. Wong; Max Planck Institute for Polymer Research, Germany

Despite the widespread occurrence of frost, understanding and controlling condensation-frosting still poses several challenges. Control of condensation-frosting is relevant for a range of industries: In the energy, transportation or telecommunication sectors, frost constitutes serious hazards when it forms on critical components of machines and devices, causing them to fail.

Amongst anti-frosting and anti-icing surfaces, slippery lubricant-impregnated porous surfaces (SLIPS) are discussed due to frosting-retardant and ultra-low ice adhesion properties [1]. However, the understanding of its formation and growth − particularly on SLIPS − remains elusive. The reasons are multi-fold: Insights into frosting are hampered by poor optical contrast between water, frost and lubricant and by the non-equilibrium nature of frost formation, that involves multiple time and length scales.

To reach better insight, we have developed a novel setup that enables the *in-situ* monitoring of lubricant reorganization, condensation and freezing of water drops using Laser Scanning Confocal Microscopy. Such a setup descriminates between condensation and freezing of water, reorganization of lubricant accompanied by growth of dendrites. In particular, our setup provides spatially and temporally resolved data of the formation and growth of frost, accompanied by quantifiable lubricant reorganization.

As model system, we utilize surfaces with micro- and nanostructures. The coatings are lubricated with silicone oil. Condensation frosting starts with

nucleation and growth of water droplets. The condensation and continued growth of droplets on lubricant impregnated surfaces is largely influenced by the structure geometry and wetting property of the lubricated solid surface [2].

Lowering the temperature results in droplet freezing and frost formation. Frosting results in lubricant depletion in the array. Although detrimental at first sight, we note that frost induced lubricant depletion is reversible when the frost is melted in situ. We determined the suction pressure induced by frost dendrites, which wicks lubricant into the frost structure [3].

Formation of frost dendrites result in a particularly harsh depletion mechanism. Notably lubricant depletion can be prevented. Therefore, the interstitial spacing of the lubricant impregnated surface needs to be kept lower than that found in frost dendrites (≥ 100 nm). To prove this concept, we used densely packed nanoparticles. The nano-interstices are kept between 10 to 50 nm. The capillary pressure keeping lubricants in the nano-interstices exceeds the capillary suction pressure by frost dendrites. We term this the design concept "*capillary-balancing*". Notably, the facile and scalable coating shows passive anti-icing [4].

Hierarchical Microtube Structures for Pool Boiling Heat Transfer Enhancement Youngsup Song, Carlos D. Diaz, Hyeongyun Cha, Lenan Zhang, Yajing Zhao and Evelyn N. Wang; Massachusetts Institute of Technology, United States

Boiling is an essential process in a variety of applications such as power plants, water purification, and steam generation. The boiling performance can be described by two major parameters: heat transfer coefficient (HTC) and critical heat flux (CHF), which dictate the efficiency and operational heat flux limit during the nucleate boiling, respectively. The previous study has shown that simultaneous enhancements of HTC and CHF values can be achieved with hemi-wicking surfaces consist of micropillar and microtube structures. There has been a trade-off, however, between the two parameters associated with the competition between nucleation site density and complete utilization of capillary wicking. In this work, we mitigate the trade-off by incorporating nanostructures on top of microtube and micropillar structures and demonstrate the extreme pool boiling performance for both HTC and CHF. Specifically, we controlled vapor nucleation for HTC enhancement with surface structures in millimeter, micrometer, and nanometer scales by the separation of microtube clusters, microtube cavities, and nanostructures, respectively. At the same time, the augmented capillary wicking on hierarchical structures achieved significant CHF enhancement. The visualization of bubble dynamics with a high-speed camera supports our findings that HTC and CHF enhancements can be achieved by multi-scale control of vapor nucleation on hemi-wicking surfaces. The extreme boiling performance achieved in this work is not only promising for various boiling applications but also providing important implications for fundamental aspects of boiling heat transfer mechanisms.

11:45 AM EN10.16.04
Real-Time Manipulation of Liquid Droplets on SLIPS Using Photo-Responsive Surfactants Xichen Liang[1], Lei Zhao[2], Serena Seshadri[2,1], Sophia Bailey[2], Michael Haggmark[1], Farzad Ahmadi[2], Michael Gordon[1], Javier Read de Alaniz[2], Paolo Luzzatto-Fegiz[2] and Yangying Zhu[2]; [1]University of California, Santa Barbara, United States; [2]UCSB, United States

Fast and programmable transport of liquid droplets on a solid substrate is desirable in microfluidic devices, condensation in power plants, microchips cooling, and even water collection in the space. Past research has focused on designing substrates with asymmetric structures or surface modifications where droplets behaviors are passively controlled, or by applying external stimuli such as electrowetting where patterning of intricate electrodes is required. In this work, we demonstrate tunable and programmable droplet motion on a slippery liquid-infused porous surface (SLIPS) using light and photo-responsive surfactants. When illuminated by the light of appropriate wavelengths, these surfactants can reversibly change interfacial tensions in a multi-phase fluid system, which generates Marangoni flow that drives droplet motions. Experimental results demonstrate that a 70 μL static droplet can move 9 mm in one minute upon irradiation of a UV laser and the merging time of two droplets can be manipulated by adjusting light projection positions. We also model the photo-Marangoni flow inside the droplet and calculate the net driving force. The method demonstrated in this study serves as a simple and exciting new approach for dynamic manipulation of droplets for microfluidic, thermal and water harvesting devices.

12:00 PM EN10.16.05
Bulk Lubricant Infusion in Soft Substrates Enhances Condensate Removal Cheuk Wing Edmond Lam[1], Chander S. Sharma[2], A. Milionis[1], Abhinav Naga[3], Gabriel Rodriguez[1], Marco F. Del Ponte[1], Valentina Negri[1], Hopf Raoul[1], Maria D'Acunzi[3], Doris Vollmer[3], Hans-Jürgen Butt[3] and Dimos Poulikakos[1]; [1]ETH Zürich, Switzerland; [2]Indian Institute of Technology Ropar, India; [3]Max Planck Institute for Polymer Research, Germany

Heterogeneous condensation on soft substrates benefits from higher nucleation density. However, compared to rigid substrates, condensate droplets on such surfaces suffer from viscoelastic dissipation at the three-phase contact line as they slide, inhibiting their removal. These droplets manifest as thermal resistance to condensation heat transfer between the cooled substrate and the ambient vapour. The presence of these pinned droplets also limits the available area for fresh nucleation sites as well, thus lowering overall heat transfer efficiency.

In this work, we explore the effects of infusing a lubricant into the bulk of polydimethylsiloxane (PDMS, Sylgard 184) on the material properties relevant to wetting phenomena. By varying the proportion of the base, curing agent and the lubricant, we identify the resulting amount of uncrosslinked chains by a swelling-and-deswelling process and their molecular distribution with gel permeation chromatography (GPC). Elasticity of the different substrates is measured with micro-indentation tests which we correlate with measured wetting ridge heights at the contact line. Viscoelastic dissipation at the contact line is characterised by measuring droplet sliding velocities. Cloaking of the water droplets is studied with laser scanning confocal microscopy followed by a transient measurement of the resulting change in droplet surface tension. We conclude the study with microscale observation of condensation for nucleation densities and droplet growth rate, and a dew collection experiment for overall performance improvement in condensate removal. We correlate the measured condensation characteristics with the material properties of the substrate.

We find that 5 wt. % of bulk lubricant infusion, despite resulting in a substrate of lower bulk elasticity, significantly reduces viscoelastic dissipation at the contact line as indicated by an increase in droplet sliding velocity. Additionally, the nucleation density is more than doubled compared to PDMS substrates without bulk lubricant infusion. We also observe that further increase above 5 wt. % bulk lubricant concentration has an insignificant effect on the

condensation dynamics over the substrate. Moreover, there is a small reduction in droplet growth rate for lubricated substrates. This reduction can be attributed to the cloaking of droplets by uncrosslinked chains due to the presence of a lubricant layer on the substrate top surface. Overall, these factors combine to result in an increase of ~40% in dew water collection for lubricated substrates compared to non-lubricated ones.

Understanding the Temperature Dependence of Carrier Mobility Alex M. Ganose[1,2], Junsoo Park[1] and Anubhav Jain[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]Imperial College London, United Kingdom

The temperature dependence of experimental mobility is commonly used as a predictor of the dominant scattering mechanism in thermoelectric materials. Knowledge of the dominant scattering mechanism is employed to fit models of charge transport including deformation potentials and effective masses, and to obtain estimates of the optimal doping concentration and temperatures that maximise thermoelectric performance. However, if the scattering mechanism is determined incorrectly, this can lead to wildly inaccurate predictions of materials properties and optimal conditions, frustrating efforts to optimise devices. By reviewing the temperature dependence of 24,000 mobility calculations, I demonstrate that the temperature-dependence of mobility is not a reliable indicator of the dominant scattering mechanism. Furthermore, I reveal that many materials long considered to be dominated by deformation-potential scattering are instead controlled by polar optical phonons. I conclude with the pitfalls of predicting the major scattering type based on the experimental mobility trend alone.

Soft Anharmonic Phonons and Ultralow Thermal Conductivity in $Mg_3(Sb,Bi)_2$ Jingxuan Ding[1], Tyson Lanigan-Atkins[1], Mario R. Calderon Cueva[2], Arnab Banerjee[3,4], Doug L. Abernathy[4], Ayman Said[5], Alexandra Zevalkink[2] and Olivier Delaire[1,1,1]; [1]Duke University, United States; [2]Michigan State University, United States; [3]Purdue University, United States; [4]Oak Ridge National Laboratory, United States; [5]Argonne National Laboratory, United States

Thermoelectric materials enable direct conversion of waste heat into electrical energy. The conversion efficiency is inversely proportional to the thermal conductivity, which is generally dominated by phonons in semiconductors. Zintl compounds AMg_2X_2 (A=Mg,Ca,Yb; X=Sb,Bi) constitute a class of new thermoelectric compounds with excellent thermoelectric performance in n-type $Mg_3(Sb,Bi)_2$ alloys, with zT values up to 1.6 reported so far. Mg_3Sb_2 exhibits very low lattice thermal conductivity (~1-1.5 W/m/K at 300K), comparable with PbTe and Bi_2Te_3 with only half of their mass densities. Meanwhile, contrary to common mass-trend expectations, replacing Mg with heavier Ca or Yb yields a threefold increase in k_L in $CaMg_2X_2$ or $YbMg_2X_2$. We report on neutron scattering and first-principles studies of the lattice dynamics of AMg_2X_2. Inelastic neutron scattering measurements founds a large phonon softening and flattening of low-energy transverse acoustic phonons in Mg_3Sb_2 and Mg_3Bi_2 compared to $CaMg_2X_2$ or $YbMg_2X_2$. Combined with simulations, we highlight the importance of a specific soft Mg-X chemical bond that suppresses phonon group velocities and drastically enlarges the scattering phase-space, enabling the threefold suppression in thermal conductivity. These results provide key insights for manipulating phonon scattering without the traditional reliance on heavy elements and disorder.

Probing Local Vibrational Modes at Crystal Defects in 3D and 2D Systems by Space- and Angle-Resolved Vibrational Spectroscopy Xingxu Yan, Chaitanya A. Gadre, Toshihiro Aoki, Ruqian Wu and Xiaoqing Pan; University of California, Irvine, United States

Imperfections such as stacking faults and interfaces are recognized as critical factors in modifying thermal properties and heat transport in crystal materials by scattering phonon and changing vibrational structure. They play an even more decisive role when the material's dimension is reduced to the nanoscale. Although diverse modelling tools have been deployed to understand the interaction between heat and imperfections in solids, the effect of crystal defects on thermal conductivity is being treated without considering the local change of phonon dispersion relation. In contrast, some studies have predicted the existence of extra vibrational modes due to dislocations or interfaces [1, 2]. However, the experimental evidence of those local modes is fundamentally elusive from either thermal conductivity measurements or conventional vibrational spectroscopies such as Raman and inelastic neutron scattering spectroscopies due to their inefficient spatial resolution [3]. Recently, the energy resolution of monochromated electron energy-loss spectroscopy (EELS) has been dramatically improved to a few millielectronvolts, which opens a new era of probing nanoscale feature of vibrational modes in materials using the aberration-corrected scanning transmission electron microscope (STEM) [3]. By balancing spatial, energy, and momentum resolutions, we can obtain a powerful space- and angle-resolved vibrational EELS method [4]. Here we show three cases to demonstrate how to utilize this emerging tool to reveal the local vibrational modes at (1) a stacking fault in cubic silicon carbide, (2) an interface in a Si–Ge heterojunction, and (3) an interface in a two-dimensional (2D) MoS_2-WSe_2 lateral heterojunction.

Stacking faults are common imperfections in SiC, and remarkably affect the bulk thermal conductivity. We acquired the angle-resolved vibrational spectra from both the stacking-fault-containing region and defect-free region. At the defect, the acoustic phonons at X point of the first Brillouin zone undergo an energy red shift of 3.8 meV and major intensity modulations. These striking features arise from the symmetry breaking and variation of interatomic force constants and are assigned to the local defect phonon modes. Both the reduced phonon energy and flattened dispersion curves of defect phonon modes help understand the defect-induced reduction of thermal conductivity [4]. In the second case, we employed a similar strategy to probe the interface phonon modes at a Si-Ge epitaxial interface, which is believed to facilitate the heat transport across interface [2]. The interfacial vibrational EEL spectrum contains extra vibrational signals at 48 meV (11.6 THz), which are absent in the phonon structure of either Si or Ge [5]. The exotic vibrational feature is also unveiled at the interface of monolayer MoS_2-WSe_2 heterojunctions [6]. Our work opens the door to investigating phonon propagation around crystal defects and provides guidance to the engineering of desired heat management for semiconductors and power electronic devices [7].

Direct Measurement of Electrocaloric Temperature Changes in Ferroelectric Relaxor Polymers for Thermal Management Applications Yusra Hambal[1], Vladimir Shvartsman[1], Qiming Zhang[2] and Doru C. Lupascu[1]; [1]University of Duisburg-Essen, Essen, Germany; [2]The Pennsylvania State University, United States

Alternative concepts of electric mobility, miniaturization in the electronics industry and the quest for environmentally friendly air-conditioning and refrigeration technology have opened many doors for advancements in the area of new materials for thermal management. The electrocaloric effect can be an alternative technology in this regard. The electrocaloric effect is a phenomenon observed in dielectric materials, as they undergo an adiabatic temperature change or an isothermal entropy change upon the application/removal of an electric field. Ferroelectric relaxor polymers are attractive, as they show slim hysteresis loops close to room temperature, which is favorable for the electrocaloric performance.
In the present work, we measure the electrocaloric temperature change in Polyvinylidene fluoride – trifluoroethylene – chlorofluoroethylene P(VDF-TrFE-CFE). The solution casting method was employed to prepare free-standing polymer films of P(VDF-TrFE-CFE). The free-standing polymer films are about 20 µm thick. The sputter coating technique was used to deposit silver electrodes onto the free-standing film. The dielectric permittivity curves measured against temperature show typical broad frequency dependent maxima which is typical for relaxors. The $P - E$ hysteresis loops were measured as a function of temperature. A slim hysteresis loop is observed confirming the relaxor behavior of P(VDF-TrFE-CFE). The direct electrocaloric effect was measured as a function of temperature and electric field using a custom-designed quasi-adiabatic calorimeter. A maximum electrocaloric temperature change of ~ 2 K is observed in 20 µm thick P(VDF-TrFE-CFE) films.

1:45 PM EN10.17.04
Passive Solar Desalination Systems Using Membranes Farzad Ahmadi and Yangying Zhu; University of California, Santa Barbara, United States

Over two-third of the world's population will lack sufficient access to fresh water by 2025. As water scarcity increases, desalination plants are on the rise as over 98% of the earth's water is brackish and sea. The current large-scale desalination plants mainly utilize thermal evaporation or reverse osmosis to increasing the supply of fresh water. However, these techniques are energy-intensive and require large infrastructures. Along this line of thought, solar desalination systems could be great candidate choice as a reliable device. Despite the great attempt to increase the evaporation efficiency of the solar desalination devices, the condensation part of the system is not yet optimized which limits the overall solar-to-water conversion efficiency. Here, we are presenting a passive, reliable, and highly efficient solar desalination system that does not require any energy consumption except one sun power. Our device consists of two parallel puros membranes which are mounted closely together that make our device efficient due to the minimal vapor diffusion resistance. Unlike other methods that use capillary force to transport the sea water, we are using hydrostatic pressure to flow the sea water into our device which is subsequently getting preheated using heat recycling. This study provides insights into improving the overall efficiency of solar desalination devices. Using scaling analysis, the evaporation and condensation flux has been modelled.

Robust Silane Self-Assembled Monolayer Coatings on Plasma-Engineered Copper Surfaces Promoting Dropwise Condensation Ruisong Wang, Jiahui Guo and Dion Antao; Texas A&M University, United States

Vapor condensation is prevalent in various industrial and heat/mass transfer applications, such as power generation and conversion, water harvesting/desalination, and electronics thermal management. Dropwise condensation has been demonstrated to have better heat transfer performance due to faster condensate removal (*i.e.*, droplets shedding), as compared to the traditional filmwise mode, which occurs on typical metal oxide condenser surfaces. The key to enhanced condensation is thin (< 100 nm) coatings with low contact angle hysteresis. Thin low surface energy coatings (*e.g.*, self-assembled monolayers or SAMs) have been utilized to promote dropwise condensation especially on copper surfaces for over half a century. However, all thin coatings (polymer or SAM) degrade within a few hours during condensation of water vapor, and specifically trichlorosilane SAMs fail within 30 mins on metal surfaces. After coating failure/degradation, water vapor condensation transitions from the dropwise mode to the filmwise mode. In this work, we significantly enhance the durability of silane SAMs on copper surfaces *via* plasma modification of the substrate, and the preferential dropwise condensation mode is maintained for hundreds of hours when condensing water vapor. Low surface energy silane SAM coatings deposited on our plasma modified copper substrates demonstrate a low contact angle hysteresis (≈20°), and better bonding between the silane SAM and the copper substrate is achieved for substrates at different roughness levels. Additionally, we elucidated the degradation mechanism of silane SAMs on copper during water vapor condensation and revealed the required surface chemistry to develop robust silane SAM coatings on copper surfaces. Various nano-to-macroscale surface analysis techniques are utilized to characterize the coating, surface and interface properties. This work sheds light on the degradation mechanisms of low surface energy monolayer coatings on copper during water vapor condensation, and provides durable solutions for industrial applications with enhanced heat transfer performance.

2:15 PM EN10.17.06
Tuning the Ferroelectric Response in Blend Film of P(VDF-TrFE) by Direct Measurements via ThermoReflectance Atul S. Tripathi[1], Layla Farhat[1,2], Mathieu Bardoux[1], Stéphane Longuemart[1], Ziad Herro[2] and Abdelhak H. Sahraoui[1]; [1]Université du Littoral Côte d'Opale, France; [2]Université Libanaise, Fanar, Liban, Lebanon

The exploitation of electrocaloric effect (ECE) is an emerging field of research because it provides an energy-efficient and environment–friendly alternative to conventional cooling devices for a broad range of applications, such as on-chip and temperature regulation for sensors and electronic devices. Although ECE has been observed in a variety of ferroelectric ceramics, crystal and polymer and performance were not satisfactory. Recently, a ferroelectric thin film based on P (VDF-TrFE) has been demonstrated a high EC effect. Compared to ferroelectric ceramics, P (VDF-TrFE) has the advantage of low density, good toughness, high electrostriction rate, and environmental protection too. Currently, a number of the existing methods have been developed to characterize the electrocaloric effect in the Direct and Indirect methods. Direct methods, measure the change in EC temperature or heat exchanged in the material in the presence or removal of the electric field. However, the indirect method is based on Maxwell's equation that allows obtaining the variation of entropy and variation of temperature. Detect the temperature variation in the thin film is difficult due to the rapid dissipation of heat in the substrate. In addition mass of the assembly (substrate +measuring device) is greater than that of the thin layer alone, and makes the heat variation is undetectable by direct and indirect method. Therefore, we need to study this material using instruments offering high resolution.

Thermoreflectance is a photothermal technique whose high frequency of operation makes it possible to probe the material on small thicknesses. This method has a function based on temperature dependant reflectivity of a surface which is probed using the intensity variation of a reflected laser beam. In this work, blend film of copolymer P (VDF-TrFE) and relaxor Ter polymer P (VDF-TrFE-CFE) in a different ratio. After optimization, the copolymer crystallinity was improved due to the coupling that was observed from the characterization. This optimized crystalline thin film was further characterized by recently developed direct measurement via thermoreflectance where the pump laser beam was replaced by an alternating electric field that is applied across our electrocaloric material to induce the electrocaloric effect (ECE). To apply this method, variation of deltaT as a function of applied field and frequency was studied in optimized blend film and achieved the delta T(K) >2 at room temperature.

Raising Dielectric Permittivity Mitigates Dopant-Induced Disorder in Conjugated Polymers Meenakshi Upadhyaya, Michael Lu-Díaz, Subhayan Samanta, Muhammad Abdullah, Kevin Kittilstved, Dhandapani Venkataraman and Zlatan Aksamija; University of Massachusetts Amherst, United States

Conjugated polymers need to be doped to increase charge carrier density and reach the electrical conductivity necessary for electronic and energy applications. While doping increases carrier density, Coulomb interactions between the dopant molecules and the localized carriers are poorly screened in organic semiconductors because of their low dielectric permittivity and thus causes an increase in energetic disorder as evident in the broadening and a heavy tail effect in the electronic density-of-states (DOS). We relate the dopant-induced energetic disorder to a reduction in the Seebeck coefficient while deep traps in the heavy tail cause a collapse in the conductivity. We show that increasing the dielectric permittivity (ε) of the polymer mitigates dopant-carrier Coulomb interactions resulting in a simultaneous increase in conductivity and Seebeck coefficient. We simulated electron hopping between localized sites with a modified Gaussian disorder model and included electrostatic interactions between carriers and clustered dopants. We iteratively solved the non-linear Pauli's master equation to compute time-averaged occupational probabilities of the sites from which relevant transport quantities are calculated. Increasing ε from 3 to 12 nearly restores the intrinsic DOS, resulting in a large increase in the power factor. We validated this prediction experimentally in iodine-doped P3HT and P3HT blended with barium titanate nanoparticles. The addition of 2% w/w barium titanate nanoparticles increased conductivity and Seebeck across a broad range of doping, resulting in a four-fold increase in power factor. Beyond improving the thermoelectric performance, we note that most of the improvement we observed in the power factor comes from increases in the conductivity, particularly at low to medium doping concentrations, which is broadly useful in organic electronics. Our method of incorporating additives with a high dielectric constant precludes the need for synthetic modifications and thus can be applied to a wide range of polymers. The vapor doping method followed in our study avoids interfacial effects on the DOS that can arise from modulation doping using field-effect transistors and also wide angle X-ray scattering (WAXS) studies show that the overall film morphology is essentially maintained during the measurement over a wide range of carrier concentration. This synergetic computational and experimental study shows a clear path forward to mitigate dopant-induced energetic disorder and develop high-performance organic electronic materials with improved charge transport through dielectric screening.

6:45 PM EN10.18.02
Negative Thermal Expansion and Ultra-Low Thermal Conductivity of ZrW_2O_8 Sora-At Tanusilp[1], Masaya Kumagai[1,2], Yuji Ohishi[3], Hideki Furusawa[4], Motoomi Suwabe[4] and Ken Kurosaki[1,5]; [1]Institute for Integrated Radiation and Nuclear Science, Kyoto University, Japan; [2]SAKURA Research Center, SAKURA internet Inc., Japan; [3]Osaka University, Japan; [4]Furuuchi Chemical Corporation, Japan; [5]University of Fukui, Japan

For decades, ZrW_2O_8 has been known as a negative coefficient of thermal expansion (CTE) material. The negative CTE is probably due to its unique crystal structure. ZrW_2O_8 has been therefore considered as a promising candidate for thermal management applications, which can be applied to use as a CTE compensating component for controlling thermal expansion of various composites such as ceramics, polymers, and metals. On the other hand, thermal properties other than the CTE of ZrW_2O_8, such as thermal conductivity, are almost unknown. Here, we synthesized a highly dense bulk sample (%T.D. > 95%) of ZrW_2O_8 from a very fine powder (~ 31 nm) using a spark plasma sintering (SPS) technique. It was revealed that ZrW_2O_8 exhibited the lowest level of thermal conductivity among various oxides in a wide temperature range from 300 to 823 K. Furthermore, we investigated various physical properties related to such low thermal conductivity through the anharmonicity such as peculiar CTE, elastic constant, and Grüneisen parameter. Owing to its extremely low thermal conductivity, ZrW_2O_8 can be used as a thermal barrier material, which generally operates at high temperatures.

7:00 PM EN10.18.03
Oxide-Free Copper Nanoparticle Incorporated Gallium-Based Liquid Metal Alloy for High-Performance Thermal Interface Materials Seokkan Ki[1,2], Jaehwan Shim[1,2], Seungtae Oh[1], Seunggeol Ryu[3], Jaechoon Kim[3] and Youngsuk Nam[2]; [1]Kyung Hee University, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [3]Samsung Electronics Co., Ltd, Korea (the Republic of)

Thermal interface materials (TIMs) with high thermal conductivity, surface wettability, and fluidic characteristics are crucial for the thermal management of high-power electronics. Gallium-based liquid metal alloys (LMAs) have been investigated as TIM due to their relatively high thermal conductivity (~23 $Wm^{-1}K^{-1}$), low melting point (<10°C), and low processing temperature. To further increase the thermal conductivity of LMA, a few studies tried to incorporate metallic fillers into the liquid metal matrix. However, these attempts have been limited due to the oxidation of the LMA matrix, which leads to severe solidification of the fabricated composite at a high volume fraction of fillers. In this work, we incorporate copper nanoparticles (Cu NPs) into the eutectic gallium-indium-tin (GaInSn) LMA using an oxide-free ultrasonication-assisted particle internalization method. Developed GaInSn/Cu NPs composite provides over 180% enhancement of thermal conductivity (~65 $Wm^{-1}K^{-1}$) with only 4% volume fraction of fillers. The obtained thermal conductivity is higher than those of the previously-reported Ga-based composites at over 20% volume fraction of fillers. In the liquid metal droplet impacting test, the GaInSn/Cu NPs shows almost identical spreading diameter compared to the untreated GaInSn, which represents the maintained fluidity of the composite. Experimentally measured thermal property is demonstrated based on the nanoparticle clustering phenomenon, in which we microscopically visualize the formation of the copper clusters within the liquid metal matrix to calculate the prediction model. The calculated effective thermal conductivity is well-matched to the experimental data, indicating that the nanoparticle clusters provide additional heat pathways. In terms of surface wetting characteristics, the LMA shows a high-quality interface with silicon substrate due to the formation of ~10nm of Ga_2O_3 adhesion layer confirmed through X-ray photoelectron spectroscopy (XPS). In the heat dissipation performance test, GaInSn/Cu NPs presents over 20% lower hot-spot temperature compared to the one obtained with the thermal grease at high (>150 Wcm^{-2}) heat flux regime and also provides thermal stability over 230 cycles of acceleration test at high-temperature exposure (~100°C), suggesting applicability for high-power density semiconductor packaging applications.

7:15 PM EN10.18.04
Power Generation via Droplet Impact on Superhydrophobic PMN-PT Pyroelectric Surfaces Jeonghoon Han[1], Seungtae Oh[2], Hee Jae Hwang[2], Dukhyun Choi[2], Choongyeop Lee[2] and Youngsuk Nam[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Kyung Hee University, Korea (the Republic of)

Single crystalline pyroelectric materials offers new opportunities for efficient thermal energy harvesting utilizing temperature fluctuation. Recent works have demonstrated the pyroelectric generators utilizing various thermal energy such as body heat and latent heat of fluids. However, the sustainable and high performance pyroelectric thermal harvesting has not been realized yet. In this work, we introduce the pyroelectric generator utilizing the rapid temperature fluctuation during a droplet impact. The thin single-crystalline PMN-PT of 100 μm thickness was incorporated to the generator in order to improve the pyroelectric coefficient with reducing the thermal mass. To further enhance the temperature fluctuation during the drop impact, the top surface of the pyroelectric generator was coated by the silanized titanium oxide nanoparticles. Then a 14 μl water drop of 293K was impacted on the developed pyroelectric generator by varying the surface temperature from 313K to 353K. Based on the measured pyroelectric current and voltage values, the pyroelectric current prediction model was developed utilizing the correlation of the maximum spreading diameter during drop impact. The developed model accurately predicted the pyroelectric electricity generation under a wide range of experimental conditions. The maximum pyroelectric current and power density were measured to be 66 μA and 19.2 μW/cm^2, which surpasses previous pyroelectric thermal harvesting results. We believe this work will help to develop efficient pyroelectric thermal energy harvesters.

7:30 PM EN10.18.05
Erythritol Impregnated within Surface-Roughened Hydrophilic Metal Foam for Medium-Temperature Solar-Thermal Energy Harvesting Xiaoxiang Li; Shanghai Jiao Tong University, China

Erythritol (ET) has received increasing research attention for medium-temperature phase change solar-thermal energy storage. However, ET suffers from serious supercooling, low thermal conductivity, poor solar absorption, and leakage after melting, which lead to low solar-thermal energy harvesting and releasing efficiency. Herein, we simultaneously overcome these inherent shortcomings by impregnating ET within the surface-roughened hydrophilic copper foam, which is prepared by subsequent oxidization of commercial copper foam and thermal reduction under hydrogen and using stably dispersed crumpled graphene particles as the solar-thermal converter. Such oxidization-reduction-treated copper foam not only provides numerous heterogeneous nucleation sites and lowers the nucleation energy barrier for forming ET crystals during the solidification process, but also facilitates rapid charging and discharging along with three-dimensional heat conductive networks, and confines the melted ET. Compared with neat ET, the copper foam-templated composites have reduced the supercooling degree by ~60 °C and improved thermal conductivity by more than 5 times, which in turn lead to a large latent-heat releasing percentage of 85.8% and a high heat-extraction efficiency of 94.2%. We demonstrate that such composites can be used for high-efficiency, medium-temperature, form-stable, direct solar-thermal energy harvesting, and the harvested heat can be readily converted into electricity to power small devices.

7:45 PM EN10.18.06
Reduced Graphene Oxide-Coated Micropillar Structure of Different Aspect Ratio for Boiling Heat Transfer Maroosol Yun[1], Geehong Choi[2], Donghwi Lee[3] and Hyung Hee Cho[1]; [1]Department of Mechanical engineering, Yonsei University, Korea (the Republic of); [2]Hyundai steel, Korea (the Republic of); [3]University of Wisconsin–Madison, United States

Boiling heat transfer is a promising approach for an ever-growing need for higher cooling capacities. To heighten the operating limit of boiling heat transfer, critical heat flux (CHF) should be enhanced. CHF is the maximum heat flux of fully developed nucleate boiling, just before vapor film covers heated surfaces, which results in an abrupt increase of wall temperature. To delay CHF, supplying sufficient working fluid to the heated surface should be ensured, thus research into CHF enhancement had explored various surface modification techniques including nanoparticle coated surface. In general, nanoparticle coatings are known to enhance CHF and heat transfer coefficient (HTC) by efficiently dissipate heat into the working fluid and promoting bubble nucleation by providing porous nucleation sites. And graphene materials could be fitting candidates since they exhibit superb thermal conductivity and graphene platelet could form porous layers on the substrates which promote bubble nucleation. However, gathering an excessive amount of graphene platelet onto the surface could discourage liquid supply due to its hydrophobic nature. This overcrowding graphene problem could be modulated by combining graphene deposition with an appropriately micro-structured surface since the particle deposition takes place at the microlayer region. Here, we propose reduced graphene oxide (rGO)-coated micropillar structure with varying aspect ratios to promote nucleate boiling and save liquid supply paths. The rGO-coated micropillar surfaces were prepared by deep reactive ion etching (DRIE) and following nanofluid boiling step with rGO solution of 0.0005 wt%. Micropillar structures of different aspect ratios (m5, m10, m20) fabricated by DRIE are 4 μm in diameter and 5, 10, 20 μm in height, respectively. Fabricated surfaces were evaluated by a pool boiling setup with deionized(DI) water as a working fluid. The temperature of DI water was maintained at the saturated temperature at atmospheric pressure. The results showed that rGO coated surface shows smoother and faster ONB by providing suitable cavities which promote bubble nucleation for lower wall superheat. And wall superheat was lessened for all rGO-coated cases owing to the high thermal conductivity of rGO particles. For the morphologies of the rGO coating, porous rGO coating embraced the lateral side of micropillar when the aspect ratios of the micropillar arrays were relatively lower (m5, m10), which might result in blockage of water supply, while the rGO layer coated over the tip of the micropillar when the aspect ratio of the micropillar was sufficiently high (m20). This difference came from the location of the microlayer varies with the aspect ratio of the micropillar arrays during the fully developed nucleate boiling regime. Presented surfaces of plain, rGO-coated m5, m10, and m20 recorded 89 W/cm^2, 174 W/cm^2, 177 W/cm^2, and 256 W/cm^2 in CHF, respectively. The maximum heat transfer coefficients were recorded as 20.4 kW/m^{2}K, 50.9 kW/m^{2}K, 45.9 kW/m^{2}K, and 74.3 kW/m^{2}K, respectively. The significant improvement on CHF and HTC in the rGO-coated m20 case indicates that rGO coatings on the m20 were mainly placed over the tip, saving spaces between micropillars and emphasizes the importance of ensuring flow paths to enhance the nucleate boiling. This study will be helpful for enhancing boiling heat transfer for the usage in the field needing extreme cooling capacities such as data storage center, heat exchanger, and fusion reactor.

8:00 PM EN10.18.08
The Effect of Al Doping on Nanoscale Thermal Transport in Swift Heavy Ion Irradiated Polycrystalline β-Si_3N_4 Azat Abdullaev[1], Mostafa Valadkhani[2], Arno Janse van Vuuren[3], Jacques O'Connell[3], Ruslan Rymzhanov[4], Anel Ibrayeva[4,5], Mehdi V. Allaei[2], Vladimir Skuratov[4] and Zhandos Utegulov[1]; [1]Nazarbayev University, Kazakhstan; [2]University of Tehran, Iran (the Islamic Republic of); [3]Nelson Mandela University, South Africa; [4]Joint Institute for Nuclear Research, Russian Federation; [5]Nur-Sultan Branch of Institute of Nuclear Physics, Kazakhstan

Comprehensive understanding on radiation resistance of nuclear fuels and cladding materials during normal reactor operation is very important for the construction of a new generation of safe and energy-efficient nuclear reactors. Particularly, the control of radiation-induced heat transport is a critical issue for nuclear reactor system design and validation.
Swift heavy ion (SHI) irradiation simulates nuclear fission products in terms of the structural damage caused to materials in the actual nuclear reactors [1]. At high energies, typical of SHIs, where the ion penetration depth is of the order of several microns, the projectile energy is deposited in the target through

an inelastic process through which electronic energy loss dominates on nanoscale depths, leading to intense localized *thermal spikes* causing displacement of lattice atoms along nanoscale-thick ion tracks along the ion path in insulating materials [2].
It is well known that nitride ceramics demonstrate a high level of resistance to SHI radiation and no visible tracks have been observed in most ceramics except silicon nitride. This material is considered to be a promising material as inert matrix fuel host and therefore it is vital to understand the parameters of latent track formation and structural change. Several works have shown that the doping of materials and thermal conductivity play an important role in the formation of these tracks [3,4]. Therefore, the main goal of this study is to determine the impact of Al doping on thermal conductivity degradation due to the related nano-structural damage.
We used polycrystalline β-Si_3N_4 ceramic samples with different level of Al doped concentration ranging from 0.05 to 3%. The SHI irradiation was performed at the IC-100 FLNR JINR cyclotron facility in Dubna, Russia where the samples were irradiated by Bi, Xe, Kr and Ar ions at room temperature and fluences ranging from 10^{12} to 10^{14} ions/cm^2. For structural analysis the samples were analyzed in both TEM and STEM modes and complimented with diffraction analysis using a JEOL ARM-200F TEM operating at 200 kV. Cross-plane thermal conductivity measurements were done using picosecond time domain thermoreflectance (TDTR) technique at different modulation frequencies to enable thermal probing at nanoscale depths. Both TEM analysis and thermal conductivity measurements revealed that the high concentration of Al doping lowers the resistance of β-Si_3N_4 to ion track formation resulting in amorphization and substantial decay in thermal conductivity. Depth-resolved TDTR measurements were used to validate models based on semi-analytical Klemens phonon transport and non-equilibrium molecular dynamics to analyze SHI-induced nanoscale damage.

Innovative Surface Engineering for Transformative, Hybrid Energy Management and Exploitation (THEME) Zuankai Wang; City University of Hong Kong, China

The progress of human civilization is highly dependent on the capability to harness and deploy energy and water. On one hand, owing to carrying plenty of kinetic and electrostatic energies, water is at the heart of many energy conversion and harvesting devices. On the other hand, the large latent heat of water also endows it as a ubiquitous flowing currency in energy transfer (heat transfer) devices. The close intertwining among water, energy, and heat becomes pronounced with the penetration of miniaturized devices in every corner of our society. Despite inherent coupling and diversity in varying energy processes, there lies in a common need, i.e., achieving high energy efficiency while low water consumption.
This simple need, however, encounters several challenges. First, the miniaturization of electrical devices driven by the Moore's Law poses increased heat flux and difficulty in energy supply, especially for implantable application. Second, scientifically, harnessing the synergy between water, energy and heat to improve energy efficiency calls for the heterogeneous integration of different materials, interfaces, and systems, which poses the daunting complexities in formulating a basic framework, rational design, and scalable fabrication. Third, technically, recent breakthroughs have demonstrated the power of designing surfaces to mediate water transport for efficient thermal cooling and energy harvesting for sustained power supply, however, conventional approaches for surface design are handled separately, which are complicated and inefficient. Without proper design, surfaces are also susceptible to structural and functional instability and compromise overall performances.

Leveraging the dual nature of both water and surfaces as well as drawing inspirations from nature's power in managing the flow of water, energy, heat through the elegant control of surface properties, in this talk, I will discuss an innovative surface engineering-based approach for transformative, hybrid energy management and exploitation (THEME) that results in synergistic effects and novel functionalities that go beyond conventional designs. Examples include how to efficiently promote phase change heat transfer such as condensation, boiling, in particular cooling down large-scale hot surfaces by several hundreds of degrees, how to achieve energy-free cooling and how to efficiently harvest water energy from moisture, encapsulated water and flowing water.

8:30 AM *EN10.19.02
Nanostructured Passive Cooling Based on Evaporation and Radiation Jia Zhu; Nanjing University, China

Nanostructures with carefully tailored properties can be used to manipulate the flow of light, heat and water, to enable high performing passive cooling through evaporation and radiation. I will present our recent progress.

The first example is cooling photovoltaic device through evaporative cooling. We demonstrate a monolithic tandem solar electricity-water generator that synergistically produces electricity and clean water by utilizing the full spectrum of solar irradiance. This design posseses two components: a top infrared-transparent photovoltaic device using above-band-gap photons, and a bottom solar water purifier using the below-band-gap photons. A well-designed water-proof thermal interconnecting layer (WTIL) makes these two components work synergistically: the bottom purifier serves as an evaporative cooler of the top solar cell to increase its efficiency, whereas the thermalization energy of the top cell is reutilized by the bottom purifier for producing more clean water. We experimentally demonstrate that a prototype hybrid tandem solar device with WTIL can generate electricity with a power output of 204 W m-2 and purify water at a rate of 0.80 kg m-2 h-1 under 1-sun illumination.

The second example is about passive cooling. Radiative cooling which sends heat to space through atmospheric transparency window without any energy consumption, is attracting significant attention. For radiative cooling to achieve high cooling performance, it is ideal to have a selective emitter, with an emissivity dominant in the atmospheric transparency window. However, so far scalable production of radiative cooling materials with selective emissivity

has not been realized. Here we will present a hierarchical design for a selective thermal emitter to achieve high performing all-day radiative cooling. Moreover, it is revealed that this hierarchically designed selective thermal emitter shows significant advantage if being applied to alleviate Global Warming or to regulate temperature of the Earth-like planet.

9:00 AM *EN10.19.03
Enhancing Light-Heat-Fluid Transport via Nanofabrication and Micro-3D Printing for Solar Energy-Water Nexus TieJun Zhang; Khalifa University of Science and Technology, United Arab Emirates

Harvesting natural energy and water resources from the earth and beyond is essential for the mankind. Solar energy-water nexus is of paramount importance to achieve sustainable development goals of our world, where effective transport at the light-matter and fluid-solid interfaces is the key. In this talk, I will present recent advances in enhancing interfacial transport by tailoring optical and wetting properties of materials and structures via micro-3D printing and nanofabrication. A new class of spectrally selective nanocomposite solar absorbers is proposed to harness sunlight and minimize thermal emission. Functionalized micro and nanoporous membranes are applied to enhance liquid propagation and vapor generation, meanwhile new physical insights are obtained from infrared imaging and magnetic resonance analyzer. Latest development of micro-3D printing technologies enables the digital fabrication of biomimetic structures for high-performance transport devices in various energy and water applications. These innovations pave the way for accelerating the knowledge discovery of light-heat-fluid transport and developing cost-effective solutions to real-world grand challenges.

9:30 AM *EN10.19.04
Device and Material Innovation for Energy-Neutral Sunlight-Assisted Atmospheric Water Harvesting Dimos Poulikakos, T. Schutzius, I. Haechler, H. Park, G. Schnoering, Cheuk Wing Edmond Lam, M. Donati and A. Milionis; ETH Zurich, Switzerland

Two-thirds of humanity live under conditions where the net fresh water withdrawal is more than twice the natural water availability for at least 1 month per year, and half a billion people suffer from this water stress throughout the entire year. Atmospheric water vapor is ubiquitous and represents a promising alternative to address global clean water scarcity. Sustainably harvesting this resource requires energy neutrality, continuous production, and facility of use. In this talk I will discuss promising approaches from my research group addressing the above challenges, Refs. (1-3), involving the development of innovative materials and systems. These utilize radiative cooling to the outer space with optimized radiation shielding (1), or sorption intermittency guided by the time scales of the designed materials, combined with solar energy (2), to harvest atmospheric water efficiently and continuously (over 24 hours), beyond the capabilities of the state-of-the-art solar energy driven water harvesting systems. Water removal from such systems without expending additional energy is also addressed. This is enabled with a fully passive superhydrophobic condensate harvester, working with a coalescence-induced water removal mechanism from a novel sprayable superhydrophobic coating (3).

Transient Effects Caused by Gas Depletion During Carbon Dioxide Electroreduction Alvaro Moreno Soto[1,2], Jack R. Lake[1] and Kripa K. Varanasi[1]; [1]Massachusetts Institute of Technology, United States; [2]Universidad Carlos III de Madrid, Spain

The novel use of CO_2 electroreduction to produce carbon-based components that do not contribute to the Greenhouse effect has encouraged the vision of carbon dioxide as a renewable feedstock with the goal to reach net zero emissions into the atmosphere.
The variety of useful products that may be obtained from such an electrochemical process strongly depends on the material of selection as electrocatalyst. In this research, we have focused on the `coinage' metals, i.e. copper, silver and gold, due to their accessibility and the vast literature available. Whereas gold and silver are very selective to carbon monoxide, copper produces wide variety of components, covering liquids (such as methanol, formate and ethanol) and gases (such as carbon monoxide, methane and ethylene). However, one aspect that has not been yet addressed in detail and which heavily affects the chemical reaction efficiency is the CO_2 availability to the working electrode. In this aspect, the performance of any chemical reaction is significantly affected by the concentration of reactant gas in the proximity of the reacting site. Therefore, the overall chemical reaction efficiency strongly depends on the mass transfer capabilities of the system. A means of measuring the performance of the carbon dioxide electroreduction process is by comparing the total amount of generated carbon-based products and the amount of produced hydrogen. Hydrogen is originated at the parallel side-reaction occurring at the same time than CO_2 electroreduction. Its formation implies then that not all the current invested in the system is dedicated to consume carbon dioxide. Even though H_2 co-evolution is unavoidable with current techniques, other novel technologies (such as the gas diffusion electrode) are being developed to optimize the partial current exclusively dedicated to reduce CO_2. Here, mass transfer capabilities play a major role: the reaction consumes CO_2 in areas close to the electrode surface and originates a gas depletion environment that needs to be compensated. Therefore, in quiescent electrochemical cells, gas depletion drastically affects the overall chemical efficiency, especially in the long run.
In this research, we present a detailed description of the mass transport limitations originated by diffusion alone compensating for gas depletion in the vicinity of the electrode. This investigation is particularly important and relevant for the cases in which a reaction is maintained over long periods of time, as it would be the case for industrial scale CO_2 electroreduction. More specifically, this work focuses on the evolution of gas depletion over time as the reaction consumes the available CO_2 and provides an indirect accurate means of measuring that evolving gas concentration by pH. Indeed, the level of pH near the electrode's surface is based on two major contributions: the decrease in the CO_2 concentration due to gas depletion and the generation of ions during chemical reaction. We develop a mathematical model that accounts for the evolution of the gas concentration in areas surrounding the electrode and refer it to the experimentally-measured pH.
Finally, we conclude that CO_2 depletion is the cause of the strong decay in the chemical efficiency of a continuous chemical reaction. Pulsed electrochemistry is then proposed as an alternative method to compensate for such an effect. In this scenario, a certain current is cycled on and off periodically, allowing the electrodes to react for a certain period of time, letting the system rest afterwards. This way, gas diffusion through the liquid electrolyte is able to partially compensate for the consumed CO_2 in the vicinity of the electrode. The overall chemical efficiency can be then maintained over longer periods of time. However, the total production is compromised. A discussion over the preferability of efficiency over production rate is then debated at the end and open to discussion.

10:45 AM EN11.01.02
Characterizing Degradation Mechanisms in Gas Diffusion Electrodes for the Electrochemical Reduction of Carbon Dioxide Emiliana Cofell[1], Uzoma Nwabara[1], Saket Bhargava[1], Danielle Henckel[2], Zachary Park[1] and Paul Kenis[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]National Renewable Energy Laboratory, United States

The electrochemical reduction of CO_2 offers the dual benefits of recycling CO_2, thereby mitigating emissions, and producing intermediates for valuable fuels and chemicals such as CO, formic acid, ethylene, and ethanol in a carbon-neutral manner.[1,2] Previous research has focused on the application of gas diffusion electrodes (GDEs) in CO_2 reduction systems, which has enabled the conversion of CO_2 into products at a high rate.[3,4] Despite these GDEs requiring a lifetime of at least 3000 hours for economic feasibility, their durability has not been studied widely.[4,5] In fact, many GDEs studied to date show declining performance over time, the causes of which have not been determined. Progress in this area, in particular with respect to understanding GDE degradation mechanisms, will be crucial for further development of CO_2 reduction technology.
This presentation will discuss post-testing changes in GDE cathode surface morphology and composition as a function of electrolyte composition and applied current density/potential. We investigated these changes *via* a variety of surface and bulk characterization techniques (SEM, EDS, Micro-CT, XRD). This approach identified degradation mechanisms including carbonate deposit formation, surface passivation, and catalyst layer restructuring, leading to loss of catalyst availability. In particular, we determined that a highly alkaline electrolyte, although beneficial for achieving high current densities and efficiency for CO production, causes the rapid formation of carbonate deposits on the GDE surface due to high local pH at the reaction interface.[7] The extent of carbonate deposit formation depends heavily on electrolyte cation identity and concentration. We also explored the impact of potential cycling on the catalyst later, noting significant restructuring and loss of catalyst layer when more positive potentials are repeatedly applied to the cathode. By using a combination of materials characterization techniques and electrochemical methods, we are able to image the evolution of the GDE surface, determine which conditions lead to loss of catalyst surface area, and better understand how to develop long-lasting electrodes for electrochemical reduction of CO_2 to value-added chemicals.

11:00 AM EN11.01.03
Revealing Chemical Processes in CO_2 Reduction with Local pH Imaging Confocal Microscopy Characterization of Gas Diffusion Electrodes Annette Boehme, Alex Welch and Harry A. Atwater; California Institute of Technology, United States

Carbon dioxide reduction in a gas diffusion electrode is a complex chemical process with potential for achieving electrocatalytic product synthesis with high throughput and selectivity. Spatially and time-resolved chemical measurements have the potential to elucidate the kinetic and transport processes in this complex environment. To this end, we report results of *operando* local pH measurements with confocal fluorescence microscopy around an operating CO_2 reduction gas diffusion electrode that enable understanding about CO_2 reduction electrocatalysis. Because the pH varies on the micrometer-scale close to the surface of an electrode, measuring the bulk pH does not provide a sufficiently detailed picture to understand the local reaction conditions. In our first experiments we have compiled three-dimensional pH maps with micron-scale resolution that are indicative of CO_2 flow through the inhomogeneous morphology of a porous gas diffusion electrode permeated by a periodic array of cracks in the microporous layer. These maps provide clear evidence for inhomogeneous CO_2 diffusion in the microporous layer, such that CO_2 diffuses faster through cracks and larger pores in the electrode. As CO_2 travels through a gas diffusion electrode and dissolves in the electrolyte, it lowers the local pH due to carbonate reactions. Therefore, the local pH can provide valuable information about the diffusion of CO_2 though different electrode morphologies. However, when an electrical current is applied, the pH around a

gas diffusion electrode increases because CO_2 reduction reaction and the hydrogen evolution reaction both consume protons. The interplay between these two effects is crucial to understand and tailor the reaction microenvironment around the working electrode surface.
We use the two-color fluorescent pH sensitive dye 8-Aminopyrene-1,3,6-trisulfonic-acid-trisodium-salt (APTS) that is sensitive between pH 11.5 and 14 to spatially resolve the pH close to the surface of an operating gas diffusion electrode. The dye is dissolved with a concentration of 125 µM in 2 M KOH electrolyte and excited by a laser at 458 nm under a confocal microscope. The fluorescence of the dye is collected separately for two wavelength intervals from 480-550 nm and 551-754 nm and the ratio of the emission collected from the two excitations is a measure for the pH. The confocal microscope allows to excite the dye at different heights in z above and in cracks in porous gas diffusion electrodes. Through movement of the stage in x- and y-direction and taking measurements consecutively, we can map the pH time-resolved in all three spatial dimensions. With this setup, we performed time-dependent measurements without any applied current to investigate how the CO_2 flux through different gas diffusion electrode substrates made of porous PTFE and carbon paper influences the pH. We found that CO_2 dissolves faster through gas diffusion electrodes made of PTFE due to its larger pore size. We also investigated how the CO_2 permeates through different cracks 10s of microns wide in the carbon paper support and found that the pH first changes locally within the crack relative to the planar electrode surface. Additionally, cracks promote faster CO_2 transport through the electrode. To investigate if this is advantageous for CO_2 reduction, we will report results of experiments with current densities in the 0-30 mA/cm^2 range. Further, we will discuss the local pH at the electrode surfaces for different gas diffusion electrode structures with the goal to identify ideal gas diffusion electrode designs. For this, we will present three-dimensional pH maps with different applied current densities for PTFE working electrode supports with different pore sizes.
We expect that these results will provide valuable insights into the interplay between local pH and CO_2 reduction mechanisms for differently structured gas diffusion electrodes.

Modifying the Electrolyte in CO_2 Electroreduction with Additives to Influence Product Selectivity Elizabeth J. Biddinger; City College of New York, United States

CO_2 electroreduction offers the opportunity to convert a waste and greenhouse gas into valuable products using renewable electricity. CO_2 electroreduction on copper results in a plethora of carbonaceous products unselectively and generates hydrogen. Methods for tuning the selectivity include controlling the reduction potential, modifying the catalyst morphology, adjusting the electrolyte pH, changing the reactor design, and altering the electrolyte composition. By including additives in the electrolyte, the CO_2 solubility, pH, conductivity and interactions at the electrode interface can be modified, resulting in changes to the product selectivity in CO_2 electroreduction. Salts and ionic liquids, added at low concentrations to aqueous bicarbonate electrolytes, can be promising modifications to the electrolyte while still maintaining the favorable buffering ability that bicarbonates bring. The hydrophilicity of the anion plays a significant role in the product selectivity on copper. For example, when the highly hydrophilic dicyanamide ($[DCA]^-$) – based additives are used, CO_2 electroreduction is effectively shutoff and hydrogen evolution is enhanced. In contrast, highly hydrophobic bis(trifluoromethylsulfonyl)imide ($[NTF_2]^-$)-based additives lower hydrogen evolution activity and increase formate production. XPS, EQCM and FTIR suggest that the surface coverage of the additives significantly influences CO_2 electroreduction.

Exploring How Collective Ionic Assembly Influences Electrochemical Carbon Dioxide Upgrading Matthew A. Gebbie and Beichen Liu; University of Wisconsin–Madison, United States

Electrochemical reduction of CO_2 to CO, CH_4, and other value-added products provides compelling opportunities to realize the sustainable production of commodity chemicals. While increasingly demonstrated in lab-scale systems, a critical roadblock slowing the development of industrial processes is a poor understanding of how molecular assembly at electrode-electrolyte interfaces contributes to catalytic activity. Recently, ionic liquids have emerged as promising CO_2 reduction electrolytes, since low overpotentials and enhanced product selectivity has been observed for several classes of ionic liquids. However, the mechanisms of ionic liquid-mediated catalysis remain subject to ongoing discussion. Here, we present our research on tuning the collective assembly of ionic liquids to understand mechanisms of ionic liquid-mediated CO_2 reduction at silver, copper, and carbon surfaces. By changing ion structures, concentrations, and solvent environments, we reveal unexpected scaling relationships between structure, concentration, and reactivity. Notably, our findings point to collective assembly as a key factor underpinning structure-reactivity relationships for CO_2 electro-reduction. To highlight the impact of this concept, we will show how our findings help resolve mechanistic puzzles in the ionic liquids electrocatalysis community and suggest new strategies for controlling the performance of sustainable CO_2 electrochemical upgrading.

1:45 PM EN11.02.02
Microenvironment Created by Nanoparticle Ligands for Selective CO_2 Electroreduction Sunmoon Yu, Dohyung Kim and Peidong Yang; University of California, Berkeley, United States

Local reaction environments where catalysts operate have been considered as critical as intrinsic active site nature of the catalysts in governing overall catalytic performance. For instance, enzymes are known to attain superior catalytic specificity and activity by creating optimal local reaction environments around their active sites using amino acid side chains. However, creating such ideal microenvironment for synthetic catalysts has been a grand challenge. Recently, we have found that nanoparticle surface ligands (e.g., alkylphosphonic acid), inevitably introduced for colloidal nanoparticle synthesis, in fact can actively create favorable microenvironment under electrochemical bias for selective CO_2-to-CO electroconversion. This microenvironment, so-called nanoparticle/ordered-ligand interlayer (NOLI), is composed of a metal (e.g., silver) nanoparticle and a structurally ordered ligand layer in a detached state. The interlayer created between the nanoparticle surface and the ordered-ligand layer encompasses dehydrated cations, associated with the ligand layer in the vicinity, exhibiting pseudocapacitive characteristics. This microenvironment offers unique active site centers through enhanced electrostatic interactions between the NOLI constituents and adsorbed CO_2 molecules, significantly enhancing catalytic turnover. In this talk, I will present how this catalytic interlayer can be created and its catalytic effect for selective CO_2 electroreduction. We also show the generality of the NOLI catalyst design, which is demonstrated across several transition metal nanoparticles, ultimately achieving up to 99% selectivity towards CO at low overpotentials. Furthermore, the NOLI catalyst is translated to a gas-diffusion environment, retaining nearly unit CO selectivity up to high current densities in neutral media (e.g., 98.1% at 400 mA/cm^2 in 1 M $KHCO_3$). In addition, I will also present our recent spectroscopic results that give insights into how initial nanoparticle assembly on a support, found necessary for the formation of the structurally ordered ligand layer and thus the NOLI, can enhance intermolecular ligand interactions and

promote collective behavior of the ligands. I will conclude by giving a broad perspective on new opportunities in harnessing nanoparticle ligand interactions for developing advanced electrocatalysts.

Direct and Continuous Generation of Pure Liquid Fuels via Electrocatalytic Carbon Dioxide Reduction in Solid Electrolytes Peng Zhu and Haotian Wang; Rice University, United States

With continuously decreased price of renewable electricity, it becomes increasingly attractive to utilize electrical energy for the production of fundamental chemical feedstocks or fuels. Electrochemical CO_2 reduction reaction (CO_2RR) provides a green and sustainable "bottom-up" pathway to generate basic chemical feedstocks ranging from C_1 to C_3 products. Liquid fuels from CO_2RR, such as formic acid, methanol, acetic acid, ethanol, and propanol, are of particular interest due to their high energy densities and ease of storage and distribution**.** However, this route is still retarded by the following two long-standing challenges in the field: there is still a lack of highly selective, active, and stable catalysts for CO_2RR to produce target liquid fuels, especially for high-value products beyond formic acid; another challenge is that the liquid fuels generated from CO_2RR electrolysis are always in a mixture with conventional liquid electrolyte, which subsequently necessitates energy- and cost-intensive downstream separation processes to recover pure liquid fuels. Through integrating rational designs in both catalyst and reactor, here we demonstrate a direct and continuous generation of high-purity and high-concentrated liquid fuels via electrochemical CO_2/CO reduction. By designing a novel porous solid electrolyte (PSE) layer between cathode and anode, other than traditional liquid electrolyte, efficient ionic transport was successfully maintained while no impurity ions (*e.g.* K^+, Na^+, HCO_3^-, OH^-…) were mixed into generated liquid fuel. When employed in this novel PSE reactor, we successfully demonstrated directly producing pure formic acid solutions from CO_2RR on Bi-based catalysts with nearly 100 % purity. Through flexible tuning of the carrier gas stream, we also achieved an ultra-high concentration up to nearly 100 wt.%. Meanwhile, by tuning the edge-to-surface ratio of Cu nanocube catalyst, we demonstrated an unprecedented acetate performance in neutral pH with an ultrahigh relative purity of up to 98% and concentrations up to 2 wt.%, with excellent stability of over 150 h continuous operation.

Engineering Atomically Dispersed Single Metal Active Sites for CO $_2$ Electroreduction Gang Wu; SUNY Buffalo, United States

Atomically dispersed and nitrogen coordinated single metal sties (MN_x: M=Ni, Co, and Fe) embedded in carbon support have exhibited exceptional catalytic activity and selectivity for the electrochemical CO $_2$ reduction reaction (CO2RR) to CO. However, the understanding of the intrinsic and morphological factors contributing to the catalytic properties of MN_x sites is still lacking. Using a Fe-N-C model catalyst derived from the ZIF-8, we deconvoluted three key morphological and structural elements of FeN $_4$ sites, including particle sizes of catalysts, Fe content, and Fe-N bond structures. Their monotonous effects on the CO2RR were comprehensively elucidated. Engineering the particle size and Fe doping is critical to control extrinsic morphological factors of FeN $_4$ sites for optimal porosity, electrochemically active surface areas, and the graphitization of the carbon support. In contrast, the intrinsic activity of FeN $_4$ sites was only tunable by varying thermal activation temperatures during the formation of FeN $_4$ sites, which impacted the length of the Fe-N bonds and the local strains. The structural evolution of Fe-N bonds was characterized at the atomic level. First-principles calculations further elucidated the origin of intrinsic activity improvement associated with the optimal local strain on the Fe-N bond. The obtained understanding can further apply to the design of other singles (e.g., Ni) and dual metal sites (Ni-Fe) catalysts

Towards Electrifying Chemical Manufacturing Through Enhanced Electrode Durability, Process Intensification and Co-Conversion Paul Kenis; University of Illinois at Urbana-Champaign, United States

Today, the chemical industry manufactures most chemicals and fuels using energy-intense thermal / catalytic processes that are responsible for a significant fraction of anthropogenic CO_2 emissions. Impending climate change necessitates a drastic reduction of greenhouse gas emissions over the next few decades. Electrifying manufacturing of some intermediates or products holds promise to significantly reduce the carbon footprint of the chemical industry. While techno-economic (TEA) and life-cycle (LCA) analyses of the electrochemical reduction of CO_2 to products such as CO, formic acid, ethylene, and ethanol indicate their promise, these also highlight the challenge to compete in terms of cost with present-day chemical conversion processes operated at scale [1].

This contribution will elaborate on three approaches to bring economically feasible, (close to) carbon-neutral electrified chemical manufacturing (electrolysis) closer. First, while active and selective catalysts now exist for electroreduction of CO_2 to products such as CO, formic acid, ethanol, and ethylene, the electrode technology enabling electrolysis over 1000s of hours is still lacking. This presentation will summarize the range of encountered electrode degradation mechanisms [2], elaborate on accelerated durability CO_2 electrolysis testing methods, and present a few approaches to mitigate electrode degradation.
Second, the electroreduction of CO_2 is highly dependent on the exact operating conditions of the process. This presentation will summarize system design rules that enhance CO_2 electrolysis performance (Faradaic efficiency, energy efficiency, conversion efficiency) through fine-tuning of a combination of parameters [3]: (i) Electrolyte composition and pH; (ii) Electrolyte flowrate; (iii) CO_2 feed flowrate; (iv) Catalyst loading; and (v) The use of magnetic fields to enhance mass transfer.
Third, this presentation will elaborate on how performing desired chemical conversions on both electrodes will drastically reduce the energy required to drive these electrolysis processes individually. We found, for example, that co-conversion of CO_2 (reduction at the cathode) with organic waste molecules (oxidation at the anode) reduced the overall energy consumption by 40-50%.[4] Identifying suitable anode catalysts and electrodes for selective organic oxidations will be a major materials research challenge for the next decade. Co-conversion electrolysis process technology could be the starting point for a new generation of chemical manufacturing technology that is significantly more energy efficient than the traditional thermochemical processes, while also able to use renewable feedstocks, such as CO_2, water, biomass adducts, or organic waste streams.

The Influence of Magnetic Moment on Chemical Activity for Design of 3D Electrochemical Systems Chloe Groome, Huong Ngo, Jie Li, Ruqian Wu and Regina Ragan; University of California, Irvine, United States

We present results elucidating the role of magnetic moment on catalytic activation energy barriers with a first principles approach. While many structure-activity relationships have been uncovered, further insight is still needed to design new catalysts from the large elemental design space on high surface area supports with performance comparable to platinum group metals. Specifically, single atom transition metal catalysts on graphene defect moieties with different magnetic moments, but similar charge transfer, are found to exhibit differing degrees of asymmetry of spin states near the Fermi energy. The effect of spin-dependent chemical pathways for transition metal SAC supported on graphene defects has been examined only recently. Previously, chemical reactions undergoing spin crossing have been considered to be spin forbidden or too slow to be practical. However, transition metal SAC have been demonstrated to facilitate spin crossing at points of minimal energy difference (<0.1 eV), allowing reactions such as CO oxidation to proceed along pathways with lower energy barriers. We utilize a first principles approach to examine how the spin state of the SAC and reactants can affect catalytic energy barriers of V, Fe, Mo, and Ta on two different graphene defects with differing magnetic moments. Single vacancy and pyridinic N-doped single vacancy defect moieties were investigated since they have similar charge transfer to metal adatoms but differing magnetic moments. Climbing image-nudged elastic band (CI-NEB) calculations of activation energy barriers of CO oxidation on all transition metal SAC in relaxed geometries on both defect moieties show all barrier energies on N-doped single vacancy defects were 0.8 eV or less. These low activation energy barriers suggest that the CO oxidation reaction would proceed at room temperature with pyridinic N-dopants present in the defect environment. Due to the similar charge transfer calculated for both defect moieties, changes in activation barrier energy values were correlated with differences in the spin state of the frontier orbitals. Spin polarized projected density of states calculations demonstrate relatively lower activation energy barriers for systems with higher spin state asymmetry near the Fermi energy; CO oxidation on Ta and V SAC have decreases in activation barrier energies of 27% and 44%, respectively. This motivated additional NEB calculations to compare the activation barrier energies of spin-constrained reaction pathways having differing spin states. By constraining the magnetic moment of the CO oxidation reaction to be either 0 (singlet), 1 (doublet), or 3 (quartet) states, the energy barriers of the doublet and quartet spin states were found to be quite similar with less than 0.05 eV of difference. However, both magnetic states had significantly lower energy barriers compared to the non-magnetic spin state, over 0.5 eV of difference. Since mainly the frontier orbital affects bonding, magnetic moment alone does not explain differences in chemical activity. We will present results suggesting that the magnetic moment of frontier orbitals could play a significant role in enhancing catalytic performance, as well as more traditionally understood mechanisms such as charge transfer and the proximity of frontier d-orbitals to the Fermi level. Computational design of materials is used to define processing conditions for three-dimensional porous graphene structures. Fabrication and characterization of macroscopic graphene structures with high surface area and architectures to facilitate mass transport will also be presented.

4:15 PM EN11.03.02
Potential of Zero Charge Measurement by Second Harmonic Generation Pengtao Xu and Jin Suntivich; Cornell University, United States

The rational design of high-performance electrochemical systems requires a fundamental understanding of the electrode-electrolyte interface. One of the key parameters essential for this understanding is the potential of zero charge (U_{pzc}). We present a methodology for characterizing this parameter. Our approach is based on electric-field induced second-harmonic generation (EFISH), a nonlinear optical method specific to the solid-liquid interface. We will discuss the physics behind this effect and how a potential-dependent EFISH experiment can reveal the electric field inside the electrochemical double layer and consequently U_{pzc}. We will further compare the results to the values obtained from other experimental approaches and discuss the implication from the work function analysis. Our work demonstrates EFISH as a facile method for measuring U_{pzc} and studying how the interfacial electric field influences electrocatalysis.

The Presence and Role of the Intermediary CO Reservoir During the Electroreduction of CO_2 at the Cu Surface Sheena Louisia, Dohyung Kim and Peidong Yang; University of California, Berkeley, United States

The optimization of the electrochemical reduction of CO_2 to value-added products using Cu catalysts requires tailoring past the surface. Although often overlooked in heterogeneous catalysis, the microenvironment confined near the surface has been recognized as a necessary component of catalytic performance. Despite its importance, this regime still remains understudied due to a lack of suitable characterization techniques. A better understanding of the microenvironment formed near the catalyst surface is especially relevant to multistep reactions like the electroconversion of CO_2 to multicarbon (C_{2+}) products during which its formation is likely inherent to the reaction pathway. In this work, we report on-stream substitution of reactant isotope (OSRI), a new method that uses the subsequent introduction CO_2 isotopes and mathematical modeling to shed a new light on the unique microenvironment formed near Cu surfaces during CO_2 electrolysis. This method reveals the presence of an intermediary CO reservoir concentrated near the Cu surface during the reaction that influences C_{2+} formation. Applied to a Cu nanoparticle (NP) ensemble and Cu foil, the OSRI method indicates that more than a monolayer of CO intermediates is necessary to facilitate CO_2-to-C_{2+} conversion. Specifically, the intrinsic C_{2+} activity only increased after reaching a density of ~100 CO molecules per surface Cu atom. The Cu NP ensemble is found to satisfy this criterion at a lower overpotential than the Cu foil thus making it a better candidate for efficient C_{2+} production. Furthermore, given the same reservoir size, the ensemble's intrinsically higher C-C coupling ability is highlighted by the 4-fold higher C_{2+} turnover it achieves at a more positive potential. Applicable to any Cu surfaces, this method offers a novel approach to distinguish the contribution of the microenvironment from the Cu surface's intrinsic C-C coupling ability. OSRI provides new insights on how the presence of CO intermediates in the microenvironment impacts C_{2+} formation during the electroreduction of CO_2 on Cu surfaces and thus, highlights an additional dimension to consider when pushing future CO_2 reducing-catalysts designs beyond the surface.

Regulating Surface Oxide Activity for Decarbonizing Chemicals and Fuels Yang Shao-Horn; Massachusetts Institute of Technology, United States

We will discuss how to tune oxide electronic structure and design oxide surfaces to control the kinetics of key reactions central to making of chemicals and fuels using electrons from renewables (Kuznetsov et al. Joule 2018 and Hwang et al. Science 2017). Increasing metal-oxygen covalency (smaller energy gap between metal d and O 2p states) enhances activity for oxygen evolution upon water splitting but beyond an optimal value reduces oxide stability. Exploiting this concept to examine a series of oxides not only sets record catalytic activity but also establishes a new reaction mechanism for the most active oxides, where both metal and oxygen sites can catalyze oxygen evolution (Grimaud et al. Nature Chemistry 2017) and deprotonation from oxide surface can be rate-limiting (Hong et al. EES 2017) – contrary to long-standing belief. Tuning metal-covalency and activating surface oxygen sites points to a new direction to increase oxide activity and stability (Kuznetsov et al., JPCC 2018). Such concepts have been applied in the design of oxide surfaces to enhance the catalytic activity of NO oxidation to NO_2 (Nature Catalysis 2021) and suppress the dehydrogenation of electrolytes to enhance the lifetime of high-energy Li-ion batteries (Giordano et al. JPCL 2017, and Zhang et al., EES 2020).

The Study of TiO_2 Polymorphs for Solar Fuels Production Francesca S. Freyria[1], Nicola Blangetti[1], Sandra Doria[2,3], Simelys Hernandez[1], Mariangela Di Donato[2,3], Sergio Brovelli[4], Maela Manzoni[5], Serena Esposito[1] and Barbara Bonelli[1]; [1]Politecnico di Torino, Italy; [2]LENS - European Laboratory for Non-Linear Spectroscopy, Italy; [3]Italian National Research Council (CNR), Italy; [4]Università degli Studi di Milano-Bicocca, Italy; [5]University of Torino, Italy

During this century, climate change and energy demand have been becoming one of the major global concerns for the human beings. Taking inspiration from nature, the production of fuels and chemicals through CO_2 conversion or water splitting under the solar light can counteract these challenges.[1] So far, although TiO_2 is one of the most studied and applied photocatalysts due to low toxicity and cost and high biocompatibility and stability, some scientific questions are still unresolved. Several physico-chemical aspects can affect its photocatalytic performance, such as particles morphology, crystalline phases, band gap and specific surface area. Among these, by applying different sol-gel synthesis methods,[2] we study how the presence of polymorphs and Ti^{4+}/Ti^{3+} defects can play a role in the photocatalytic efficiency for solar fuels production when they act alone or coupled with quantum dots (QDs).[3] TiO_2 mainly exists in three different crystalline polymorphs: anatase and rutile (tetragonal structure) and brookite (orthorhombic structure), where the latter two phases have a direct band gap whereas the former phase shows an indirect band gap, with an average value from 3.0 eV up to 3.4 eV. The photogenerated electrons and holes show different behavior among the polymorphs due to different electron-trap depths and possible defects, which influence the final photocatalytic performance.[4] Moreover, to absorb a wider part of the solar spectrum and to fast deliver photons to the photocatalytic centers, copper-based QDs at different wavelength emissions in the visible and NIR range are chosen as harvesting antennas.
To control the presence of the polymorphs and the coupling with QDs, we change the titanium precursors and the type of template, by also adopting a greener template-free procedure in mild calcination conditions. The photocatalysts are characterized by means of X-ray powder diffraction (XRPD), quantitative phase analysis as obtained by Rietveld refinement, diffuse reflectance (DR) UV−Vis spectroscopy, N_2 adsorption/desorption at −196 °C, electrophoretic mobility in water (ζ-potential), X-rays photoelectron spectroscopy (XPS) and electron microscopy. Charge transfer and recombination processes are characterized using transient absorption spectroscopy. The photocatalytic behavior of these nanostructures is assessed under simulated sunlight at 1 Sun (i.e. 100 mW/cm^2 of intensity).

EN11.04.02

Strong Photoreductant Consisting of a Two-Dimensional Electride Electron Donor and a Pt(II) Complex Photoredox Catalyst Seunga Heo[1], Yu Sung Chun[1], Joonho Bang[2], Ho Seong Hwang[3], Eun Jin Cho[3], Sung Wng Kim[2] and Youngmin You[1]; [1]Ewha Womans University, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of); [3]Chung-Ang University, Korea (the Republic of)

Inorganic electrides are solid-state sources of solvated electrons which serve as powerful reducing agents in organic transformations. Since electrons in electrides are strongly confined within the interstitial sites, their effective detrapping is the key to harnessing the strong reducing power of solvated electrons. Recent studies have revealed that two-dimensional (2D) electrides, such as $[Ca_2N]^+e^-$, exhibit superior electron-donating ability beyond the conventional $[Ca_{24}Al_{28}O_{64}]^{4+}4e^-$ electride, because of extremely high densities of anionic electrons that are delocalized over the interlayer space between the cationic layers. However, the inherent instability of $[Ca_2N]^+e^-$ in organic solvents retards utilization of their superior electron-donating ability.
To overcome this limitation, we propose a strategy that uniquely combines a photoredox catalyst molecule and a chemically stable 2D electride. $[Gd_2C]^{2+}2e^-$ was chosen because it exhibits high robustness against air and moisture. The notable stability was ascribed to anionic electrons being weakly localized at the Gd sites between layers of $[Gd_2C]^{2+}$. In addition, $[Gd_2C]^{2+}$ has a rigid layer framework with strong covalent bonding between the Gd and C atoms. $[Gd_2C]^{2+}2e^-$ slowly decomposed in 2,2,2-trifluoroethanol (TFE) to release solvated electrons. The effective diffusion length of the solvated electrons should remain small due to the slow alcoholysis. To utilize the released solvated electrons, we added Pt(II) complexes of cyclometalating ligands, including 2-phenylpyridinate (Ptppy), 2-(4,6-difluorophenyl)pyridinate (Ptdfppy), and 2-(3-methoxyphenyl)pyridinate (PtOMe), into the $[Gd_2C]^{2+}2e^-$ suspension. The planar and electron-rich Pt(II) complex adsorbed onto the surface of the $[Gd_2C]^{2+}2e^-$ electride, and rapidly accepted one electron at a rate of 10^7 s^{-1} upon photoexcitation, which is greater than the diffusion rate in TFE (~10^5 s^{-1}). The one-electron-reduced Pt complexes were electrochemically stable enough to deliver the electron to benzyl bromide substrates in the bulk with very negative reduction potentials (E_{red}, -2.20 ~ - 2.46 V vs standard calomel electrode (SCE)). This electron transfer recovered the neutral Pt(II) complexes. Therefore, the cycle enabled photogated electron transport from the stable

$[Gd_2C]^{2+}2e^-$ electride to substrates. The key benefit of this reducing system was the suppression of undesirable charge recombination. The charge recombination by back electron transfer was prohibited due to the irreversible disruption of the $[Gd_2C]^{2+}2e^-$ electride after the electron ejection. The desirable properties collectively served as the photoredox catalysis principle for the reductive generation of the benzyl radical from benzyl bromide, which is the key intermediate of dehalogenation or homocoupled products. We examined the photoinduced reducing ability of the combined $[Gd_2C]^{2+}2e^-$/Pt complex system for a variety of benzyl bromides. Our optimized reaction conditions included deaerated CH_3CN:TFE (3:1, v/v) containing 0.25 M substrate, $[Gd_2C]^{2+}2e^-$ ($4e^-$ mmol), and Ptdfppy (2 mol %), which was photoirradiated at a wavelength of 365 nm (4 W) at room temperature for 18 h. The conditions yielded dehalogenated and homocoupled products in yields as high as 98%. These results successfully demonstrated the effectiveness of our photoreducing system. We expect that our strategy will stimulate renewed research interest in the synthetic applications of stable yet unreactive 2D electrides.

EN11.04.03
Effect of Substrate-Induced Lattice Strain on the Electrochemical Properties of Pulsed Laser Deposited Nickel Oxide Thin Film Jacob Som[1], Jonghyun Choi[2], Nikhil R. Mucha[1], Panupong Jaipan[1], Svitlana Fialkova[1], Kwadwo Mensah-Darkwa[3], Ram K. Gupta[2] and Dhananjay Kumar[1]; [1]North Carolina Agricultural & Technical State University, United States; [2]Pittsburg State University, United States; [3]Kwame Nkrumah University of Science and Technology, Ghana

For decades, the vast ignition of non-renewable energy sources represents an extreme risk to the world by discharging gases that cause air contamination and global warming. Using a facile pulsed laser deposition process, nickel oxide (NiO) thin films has been deposited on strontium titanate, lanthanum aluminate, and sapphire substrates. The substrate–film lattice mismatch and how it influences the electrochemical properties of NiO thin film electrocatalyst have been studied. X-ray diffraction measurements were carried out to confirm the phases and determine interfacial lattice strain. AFM measurements were used to analyze the surface topography of the catalyst and determine the surface roughness of the film. The electrochemical analysis was performed in one molar potassium hydroxide solution. It was observed that the electrocatalytic activities of the NiO thin films exhibit a strong sensitivity to strain; the NiO thin film samples with the smallest strain recorded the lowest overpotential for the half-cell hydrogen evolution reaction. Additionally, the charge storage capacity of the NiO electrocatalyst has been explored and might be a function of surface roughness. The electrochemical properties and simple synthesis make these NiO-based catalyst thin films helpful in incorporating as high-surface-area electrodes for water electrolysis.

Self-Assembled Monolayer Modulated Ag Catalysts—Enhanced Catalysis of CO_2RR to CO Zhengyang Yang, Fanglin Che and Zhiyong Gu; University of Massachusetts Lowell, United States

The self-assembled monolayer (SAM) has been widely applied to modulate surface science for heterogeneous catalysis. In particular, 4-Mercaptobenzonitrile (4-MBN) SAM features a highly delocalized electron environment along with the benzene-nitrile head group, and its tail group – sulfur strongly bonds to the metal surface, i.e., Ag. Thus, 4-MBN SAM becomes a promising stable modifier to fine-tune the catalytic activity and selectivity of metal surfaces for the chemical process involving electron-transfer step, i.e., electrocatalysis. The electro-reduction reaction of CO_2 to CO (CO_2RR-to-CO) over Ag provides a sustainable approach to utilize renewable energy and generate value-added chemicals. However, there are major limitations of CO_2RR-to-CO over Ag: (1) low stability of Ag surface-active sites under high overpotentials due to the surface reconstruction; (2) high energy requirement of the potential rate-limiting step (RDS) – initial CO_2 activation.
To address the above challenges, we hypothesize that a highly ordered 4-MBN SAM will stabilize the Ag surface-active sites via strong thiol-metal chemisorption and promote initial CO_2 activation via the enhanced electron transfer between $OCOH^*$ and 4-MBN SAM. To examine our hypothesis, we first applied DFT calculations to investigate the stabilities of 4-MBN SAMs modulated Ag catalysts. The DFT results show that 4-MBN SAM strongly bonds to Ag surfaces, with the adsorption energies of ~-2 eV at a low 4-MBN surface coverage (< ¼ monolayer). With an increase of the 4-MBN surface coverage over ¼ monolayer, 4-MBN SAMs stabilize active and less thermo-favored surfaces (i.e., Ag100 and Ag211), and will potentially inhibit the surface reconstruction and stabilize Ag surface active sites. In addition, we examined the potential RDS of CO_2RR-to-CO (i.e., CO_2+H^*à$OCOH^*$) over 4-MBN modulated Ag catalysts. Interestingly, at a high surface coverage of 4-MBN (> ¼ monolayer), the adsorption of $OCOH^*$ is more favorable over the organic active sites – nitrogen of 4-MBN, and the stabilized $OCOH^*$ intermediate results in lower reaction energies of CO_2+H^*à$OCOH^*$, as compared to the pristine Ag scenario. This improvement can be explained via a large ET region at the high surface coverages of 4-MBN, which greatly strengthens the electronic interaction between the nitrogen of 4-MBN and the carbon of $OCOH^*$. In summary, our work provides a systematic understanding of the physical and chemical properties of 4-MBN modulated Ag catalyst and its potential catalytic performance of CO_2RR-to-CO at the atomic scale. This work also guides a new strategy for the (electro)catalyst design with improved stability and activity via the SAMs modification as compared to the conventional metal catalysts.

From Rusting to Solar Power Plants—A Successful Nano-Patterning of Stainless Steel 316L for Visible-Light-Induced Photoelectrocatalytic Water Splitting Nageh K. Allam; American University in Cairo, Egypt

A novel propitious nanoporous anodized stainless steel 316L (NASS316L) photoanode was developed for water splitting. The anodization could successfully produce a uniform nanoporous (~ 90 nm in pore diameter) array (~ 2.0 μm thick) of NASS316L with a high pore density. Several techniques, including FESEM, EDX, XRD, XPS, ICP-OES, and UV–vis-NIR spectrophotometry, were employed to characterize the catalyst and to assess and interpret its activity toward water splitting. Surprisingly, the NASS316L retained almost the same composition of the bare stainless steel 316L, which recommended a symmetric dealloying mechanism during anodization. It also possessed a narrow band gap energy (1.77 eV) and a unique photoelectrocatalytic activity (~ 4.1 mA cm^{-2} at 0.65 V versus Ag/AgCl, 4-fold to that of α-Fe_2O_3) toward water splitting. The onset potential (−0.85 V) in the photocurrent–voltage curve of the NASS316L catalyst demonstrated a negative shift in its Fermi level when compared to α-Fe_2O_3. The high (23% at 0.2 V vs Ag/AgCl) incident-photon-to-current conversion efficiency and the robust durability revealed from the in situ analysis of the produced H_2 gas continued recommending the peerless inexpensive and abundant NASS316L catalyst for potential visible-induced solar applications.

EN11.04.06
Electrochemical Methane Conversion with IrO_2(110) Catalysts Jaehyun Lee, Jiwoo Yang, Jiwon Sul and Jun Hyuk Moon; Sogang University, Korea (the Republic of)

Liquid phase CH4 oxidation under mild conditions is a promising field for energy-efficient conversion. Although highly active electrochemical catalysts have achieved methane-alcohol conversion at room temperature and pressure, high alcohol production remains a challenge. We have confirmed the sustainable electrochemical conversion of methane to alcohol using IrO2 catalyst. IrO2 has an activation energy for C-H bond of 9.5 kJ/mol, which is very low compared to conventional metal oxide catalysts. It is a catalyst known to facilitate methane activation reaction due to strong interaction between Ir_{cus} sites and methane molecules. Nevertheless, IrO2 has not yet been reported as an electrochemical catalyst for methane oxidation. The surface phase of IrO2 is determined by the sintering temperature, and we selectively fabricated the IrO2 (110) surface, which is the most effective surface for CH4

activation. Higher methane oxidation activity was confirmed compared to previously reported studies, and 216.9% higher alcohol production was achieved at room temperature and pressure, and the mechanism of alcohol formation by oxidation of methane by active oxygen in the catalyst was confirmed.

EN11.04.08
First-Principles Studies of Doped SnO_2 for Photocatalytic Applications Yeongrok Jin and Jaekwang Lee; Pusan National University, Korea (the Republic of)

SnO_2 has been identified as one of the promising and suitable oxide-based photocatalytic semiconductors. However, the large bandgap limits its application in the visible region. Doping is an efficient way of optimizing the materials properties and improving the photocatalytic performance. Here, using the first-principles density functional theory calculations, we considered the substitutional and interstitial doping of SnO_2 with Fe and Cr atoms. We find that Fe atoms tend to occupy interstitial sites while Cr atoms prefer to occupy substitutional sites with the different amount of oxygen vacancies. Bandgap narrowing, O-K edge electron energy loss spectra due to the oxygen vacancy, and resulting enhanced photocatalytic behavior of visible light will be discussed and associated underlying mechanism will be introduced along with scanning transmitted electron microscopy measurements.

EN11.04.09
Spontaneously Formed CuS_x Catalysts for Electrochemical Reduction of Industrial CO_2 Gases Jinwook Lim, Wan Jae Dong, Jae Yong Park, Dae Myung Hong and Jong-Lam Lee; Pohang University of Science and Technology (POSTECH), Pohang, Korea (the Republic of)

The development of selective and stable catalysts for electrochemical CO_2 reduction reaction (CO_2RR) in CO_2-purged electrolyte that contains sulfur is essential for practical application because CO_2 gas emitted from industry inevitably contains hundreds ppm-level of H_2S gas. Despite many researchers have been demonstrated selective and stable catalysts for electrochemical reduction of pure CO_2 gas, the conversion of industrial CO_2 gas has been limited. Here, we demonstrated the copper sulfide (CuS_x) catalysts which were spontaneously formed by dipping the Cu foil into laboratory-prepared industrial CO_2-purged in 0.1 M $KHCO_3$ electrolyte. Since the industrial CO_2 contains H_2S gas, sulfur species dissolved in the electrolyte can easily react with Cu foil. As the concentration of dissolved sulfur species increased, the reaction between Cu foil and sulfur enhanced. As a result, the average size and surface density of CuS_x increased to 133.2<!--[if gte msEquation 12]><m:oMath><i style='mso-bidi-font-style:normal'><m:r>±</m:r></m:oMath><![endif]--><!--[if gte vml 1]><v:shapetype id="_x0000_t75" coordsize="21600,21600" o:spt="75" o:preferrelative="t" path="m@4@5l@4@11@9@11@9@5xe" filled="f" stroked="f"> <v:stroke joinstyle="miter"/> <v:formulas> <v:f eqn="if lineDrawn pixelLineWidth 0"/> <v:f eqn="sum @0 1 0"/> <v:f eqn="sum 0 0 @1"/> <v:f eqn="prod @2 1 2"/> <v:f eqn="prod @3 21600 pixelWidth"/> <v:f eqn="prod @3 21600 pixelHeight"/> <v:f eqn="sum @0 0 1"/> <v:f eqn="prod @6 1 2"/> <v:f eqn="prod @7 21600 pixelWidth"/> <v:f eqn="sum @8 21600 0"/> <v:f eqn="prod @7 21600 pixelHeight"/> <v:f eqn="sum @10 21600 0"/> </v:formulas> <v:path o:extrusionok="f" gradientshapeok="t" o:connecttype="rect"/> <o:lock v:ext="edit" aspectratio="t"/> </v:shapetype><v:shape id="_x0000_i1025" type="#_x0000_t75" style='width:9pt; height:14.25pt'> <v:imagedata src="file:///C:/Users/JW/AppData/Local/Temp/msohtmlclip1/01/clip_image001.png" o:title="" chromakey="white"/> </v:shape><![endif]-->33.1 nm and 86.2<!--[if gte msEquation 12]><m:oMath><i style='mso-bidi-font-style: normal'><m:r>±</m:r></m:oMath><![endif]--><!--[if gte vml 1]><v:shape id="_x0000_i1025" type="#_x0000_t75" style='width:9pt;height:14.25pt'> <v:imagedata src="file:///C:/Users/JW/AppData/Local/Temp/msohtmlclip1/01/clip_image001.png" o:title="" chromakey="white"/> </v:shape><![endif]-->3.3%, respectively. Due to the larger amount of sulfur content and the enlarged electrochemical surface area of CuS_x, the faradaic efficiency of formate was improved from 22.7 to 72.0% at -0.6 V_{RHE}. Additionally, CuS_x catalysts showed excellent stability for reducing the industrial CO_2 to formate. Change in faradaic efficiency was hardly observed even after long-term (72 h) operation. This study experimentally demonstrated that spontaneously formed CuS_x catalysts are efficient and stable for reducing the industrial CO_2 gas to formate.

EN11.04.11
Electrochemical Control of Multiscale Morphology in Dendritic Copper Foams Hamed Mehrabi[1], Johanna Nelson Weker[2] and Robert H. Coridan[1]; [1]University of Arkansas, United States; [2]Stanford University, United States

Structured copper substrates have gained scientific attraction as electrodes for catalysis, especially for CO_2 reduction (CO_2RR). Dendritic copper foams offer many of the functional aspects considered to be beneficial for activity and selectivity for CO_2RR, including three-dimensional structure, high surface areas, and a large density of grain boundaries. The typical fabrication method for dendritic copper foams is via high-rate cathodic electrodeposition in acidic solutions of Cu^{2+} ions. The competing hydrogen evolution introduces large voids to the foam structure because of bubbles evolving from the surface, which can add to the hierarchical structure of the electrode, but also provides ready-made bubble nucleation sites for hydrogen evolution during CO_2RR. Here, we consider how to fabricate copper foams with intentional control over these bubble nucleation sites. Namely, we explore high-rate Cu electrodeposition in lactate-stabilized, alkaline copper solutions and its effects on the hierarchical structure on multiple length scales. We will show the control that the electrochemical growth conditions exert on the nanoscale, microscale, and macroscale structure of the Cu foams. The electrochemical nature of the Cu-lactate complex and the significant reduction of hydrogen evolution during deposition result in copper dendrites that are significantly denser and more fine-grained than Cu foams derived from acidic solutions, as indicated by tomographic studies of synchrotron-based, transmission x-ray microscopy computed tomography reconstructions. We will also demonstrate that this morphological control has consequences for both the electrocatalytic and mass transport behavior for the Cu electrocatalysts in both hydrogen evolution and in selectivity in CO_2RR reactions.

EN11.04.13
Enhanced Photoelectrochemical Performance of $Ca_2Fe_2O_5$ Photocathodes via Two-Step Annealing Joon-Soo Yoon, Joo-Won Lee and Yun-Mo Sung; Korea Univ, Korea (the Republic of)

Recently, ternary oxide semiconductors have received increasing attention as a promising photocathode material for photoelectrochemical (PEC) water splitting. There exists large room to tune their electronic structures which can directly affect PEC properties. However, developing a ternary oxide photoelectrode showing improved PEC performance still remains at a challenging stage. Here, we report the success in the synthesis of high-density $Ca_2Fe_2O_5$ (CFO) nanorods on a NiO/FTO layer that is an effective hole transport layer (HTL) using a wet chemical approach. Also, we propose a two-step annealing strategy to further increase the PEC efficiency of $Ca_2Fe_2O_5$ (CFO) photocathode. It was elucidated that two-step annealing was beneficial to their PEC properties in various aspects such as morphologies, chemical states, optical properties, and impedances. In addition, the NiO buffer layer further enhanced their charge transport properties. Enhanced PEC performance was observed by LSV and IPCE measurements. CFO on NiO HTL fabricated via two-step annealing demonstrates a photocurrent density of up to -313.7 $\mu A/cm^2$, which is 76 % higher than that of CFO without HTL fabricated via single-step annealing. The mechanism that the annealing process modifies material characteristics and affects the PEC performance was discussed in detail.

SESSION EN11.05: Catalyst and Electrode Engineering

Ag^{II}-Mediated Electrocatalytic Ambient CH_4 Functionalization Inspired by HSAB Theory Danlei Xiang[1], Jesus A. Iñiguez[1], Jiao Deng[1], Xun Guan[1] and Chong Liu[1,2]; [1]University of California, Los Angeles, United States; [2]California NanoSystems Institute, United States

Developing an efficient chemical transformation pathway of ambient CH_4 functionalization is an ongoing challenge and the key resides on the discovery of new catalytic systems. The hard-soft acid-base (HSAB) theory suggests that high-valent transition metals, as soft class (b) Lewis acids based on Pearson's classification, are suitable candidates for CH_4 activation due to methyl moiety's relatively low value of chemical hardness. While most of class (b) transition metals have been studied, divalent silver (Ag^{II}), possibly due to its reactive nature, is the only class (b) high-valent transition metal center that is yet reported to exhibit reactivities towards CH_4 activation. Inspired by such notion, here we report that electrochemically generated Ag^{II} metalloradical readily functionalizes CH_4 into methyl bisulfate (CH_3OSO_3H) at ambient conditions in 98% H_2SO_4. Mechanistic investigation experimentally unveils a low activation energy of 13.1 kcal mol^{-1}, a high pseudo-first-order rate constant of CH_4 activation up to 2.8×10^3 h^{-1} at room temperature and a CH_4 pressure of 85 psi, and two competing reaction pathways preferable towards CH_4 activation over solvent oxidation. Reaction kinetic data suggest a Faradaic efficiency exceeding 99% beyond 180 psi CH_4 at room temperature for potential chemical production from widely distributed natural gas resources with minimal infrastructure reliance.

10:45 AM EN11.05.02
Molybdenum Chalcogenides as Electrocatalysts for Energy Conversion Jessica Ortiz Rodriguez[1] and Joseph Perryman[1,2]; [1]University of California, Davis, United States; [2]Stanford University, United States

The successful use of electrolysis processes at an industrial scale, such as aluminum electrorefining, brine electrolysis, and water splitting, has increased the interest of using electrochemistry to promote other promising reactions, including hydrogen evolution, CO_2 reduction, and ammonia synthesis. To design electrocatalysts which selectively produce fuel from aqueous media, the tuning of local surface coordination and electronic structure becomes imperative. In this work, we tune the surface electronic structure by changing chalcogen composition in different molybdenum chalcogenides systems to understand proton adsorption interactions. The molybdenum chalcogenides evaluated were synthesized successfully via high-temperature microwave-assisted and template-controlled approaches. Their ability to stabilize proton adsorption was studied under relevant conditions for hydrogen production in acidic media. Electrochemical characterization showed that increasing the electronegativity of the chalcogen increases the hydrogen adsorption strength due to the higher relative basicity of the chalcogen. The results presented here provide guidelines to improve proton adsorption in metal chalcogenide systems and increase selectivity in various electrochemical reactions.

11:00 AM EN11.05.04
A Microbial-Material Hybrid System for Photocatalytic Nitrogen Fixation with High Quantum Efficiency Xun Guan[1], Sevcan Ersan[1], Xiangchen Hu[2], Timothy Atallah[1], Yongchao Xie[1], Shengtao Lv[1], Bocheng Cao[1], Jingwen Sun[1], Ke Wu[1], Xiangfeng Duan[1], Justin Caram[1], Yi Yu[2], Junyoung Park[1] and Chong Liu[1]; [1]University of California, Los Angeles, United States; [2]ShanghaiTech University, China

Nitrogen in biological molecules ultimately comes from the reduction of dinitrogen. Interfacing biological catalysts with inorganic materials is constructive towards efficient and customizable chemical production at ambient temperature and pressure. Here, we demonstrate a microbial-material hybrid system with an appreciable internal quantum efficiency of (19.8 ± 2.6)% for photocatalytic nitrogen fixation. This hybrid system consists of nitrogen-fixing microbes and semiconductor quantum dots with a unique interfacial charge transfer behavior at the microbial-material interface. Metabolomics and proteomics studies reveal a metabolism favoring nitrogen accumulation, pertinent to our observed efficiency of nitrogen fixation.

Rate and Mechanism of Electrochemical Formation of Surface-Bound Hydrogen Ding-Yuan Kuo, Xinyao Lu, Bintao Hu, Hector Abruna and Jin Suntivich; Cornell University, United States

The formation of a surface-bound hydrogen atom from one proton and one electron plays an enabling role in renewable hydrogen production. Quantifying the surface-bound hydrogen kinetics, however, requires decoupling the delicate interplay of numerous processes. In this work, we describe a cyclic-voltammetry method for measuring the rate constant for the formation of surface-bound hydrogen atoms (“hydrogen electro-adsorption”). We find that the hydrogen electro-adsorption on platinum single crystals is ~100x faster in acid than in base. Reaction-order analysis suggests that the electro-adsorption occurs as a proton-coupled electron transfer (PCET) reaction in acid, whereas in base, the electro-adsorption requires the interfacial water reorganization. This work demonstrates a methodology for quantifying the interfacial PCET kinetics and reveals the hydrogen electro-adsorption kinetics as the reason why the hydrogen evolution electrocatalysis on platinum is faster in acid than in base.

11:45 AM EN11.05.06
Late News: Epitaxial Growth of Flower-like MoS2 on One-Dimensional Nickel Titanate Nanofibers as a Sweet Spot for Efficient Photoreduction of Carbon Dioxide Haritham Khan, Hazina Charles and Caroline S. Lee; Hanyang University, Korea (the Republic of)

The ever-increasing human demand for energy and constant depletion of fossil fuels have sparked a global crisis with urgent attention. Global warming has also become an increasingly serious environmental concern due to its excessive emission of carbon dioxide and similar greenhouse gases. Currently, the conversion of CO_2 into renewable energy in the presence of sunlight is considered to be a viable technique to reduce global warming. Photocatalytic reduction of CO_2 has recently attracted substantial interest, but the activity, stability, and stability of products were severely determined by the efficiencies of light-harvesting, charge migration, and surface reactions. The rational design and preparation of dissimilar dimensional materials (1D/2D) have been therefore extensively investigated as heterogeneous photocatalysts. 1D materials possess distinct advantages of efficient electron transport and optical excitation while suffering from the drawback of low surface area. Meanwhile, 2D materials show a large surface area but tend to agglomerate. Interfacial engineering is a promising technique to take full advantage of the unique dimensionality-dependent advantage while mitigating the disadvantage during sustainable energy applications.

Herein, a highly synergized $NiTiO_3/MoS_2$ (1D/2D) heterostructure was synthesized using a two-step process. In the first step, $NiTiO_3$ nanofibers were synthesized through electrospinning which was later combined with 2D flower-like MoS_2 through a hydrothermal process. The morphologies and optical properties of as-synthesized photocatalysts were analyzed by a series of characterizations. The selective growth of highly reactive 1T along honeycomb-

like 2H phases were also observed through XPS and TEM analysis. The hybrid $NiTiO_3/MoS_2$ exhibited a red-shift to the visible light region with an enhanced absorption capacity. At the optimum loading of 2wt.% MoS_2, $NiTiO_3/MoS_2$ exhibited the highest CO_2 reduction producing CO and CH_4 gases of 130 $\mu molg^{-1}h^{-1}$ and 55 $\mu molg^{-1}h^{-1}$ which are 3.8 (34 $\mu molg^{-1}h^{-1}$) and 3.6 (15 $\mu molg^{-1}h^{-1}$)-fold higher than those of pristine $NiTiO_3$ nanofibers respectively, with overall CO_2 selectivity of 84%. The enhanced photoreduction performance could be attributed to the enhanced light absorption, higher surface area and coexistence of 1T and 2H phases of MoS_2 in the hybrid structures. Moreover, the significantly accelerated charge separation and reduced recombination of charge carriers on account of the strong electronic coupling is verified through photoluminescence and EIS analysis. This work contributes to the development of efficient and stable photocatalytic materials which could also be used further in water splitting, H_2 evolution, and other photocatalytic activities as an efficient photocatalyst.

SESSION EN11.06: Electro-Bio Systems

1:30 PM *EN11.06.01
Employing Synthetic Biology to Design Microbial Electrocatalysts for Nitrogen Reduction Shelley Minteer; University of Utah, United States

Ammonia is one of the most widely produced chemical in the world. Most ammonia (over 66%) is now produced through the Haber−Bosch process, consuming approximately 5% of the global natural gas production and contributes to over 3% of global carbon dioxide emissions. In an effort to develop an electrochemical alternative, we have engineered cyanobacterium to perform nitrogen fixation under ambient conditions without consuming natural gas, in stark contrast to the Haber-Bosch process that requires extreme temperatures and pressures to the same end. To realize the heterologous expression of nitrogenase, we transformed the cyanobacterium S. elongatus PCC 7942 with the minimal nitrogen fixation (nif) gene cluster. Biosynthesis of Mo-nitrogenase generally requires a large number of nif genes. However, the transformation and transcription of such a larger set of gene cluster into the cyanobacterium is challenging. In this work, a minimal nif cluster with reduced genetic complexity was chosen to accomplish the transformation of the cyanobacterium S. elongatus PCC 7942. The cyanobacterium S. elongatus PCC 7942 was transformed with nif genes and it was shown to be able to express active nitrogenase. The engineered S. elongatus PCC 7942 was immobilized on an electrode to accelerate the microbial conversion of nitrogen into ammonium
using electrichemical driving forces. Methyl viologen (MV) was added as an electron mediator to shuttle electrons from the electrode to the enzyme active center, since MV can go through the cell membrane and deliver continuous electrons to nitrogenase. In this talk, we will compare and contrast this strategy to other bioelectrocatalytic strategies for nitrogen reduction.

2:00 PM *EN11.06.02
Powering Catalysis in Microorganisms Using Electrochemistry and Synthetic Biology Caroline Ajo-Franklin; Rice University, United States

Microorganisms precisely control biological processes, including biosynthesis and cell growth, by regulating the redox state of different biomolecules. These processes can be modulated by electrochemically coupling intracellular biomolecules to an external electrode, but current approaches afford only limited control and specificity. Here we describe using electrical current to reduce specific biomolecules, allowing control of biosynthesis and cell growth in two industrially relevant microorganisms, *Escherichia coli* and *Lactobacillus plantarum*.
To enable electrochemical control of *E. coli*, we used synthetic biology to introduce a heterologous electron transfer pathway. *E. coli* expressing *mtrCAB* from *Shewanella oneidensis* MR-1 consumed electrons directly from a cathode when fumarate or nitrate, both intracellular electron acceptors, were present. The fumarate-triggered current consumption occurred only when fumarate reductase was present, indicating all the electrons passed through this enzyme. Moreover, MtrCAB-expressing *E. coli* used current to stoichiometrically produce ammonia. Thus, our work introduces a modular genetic tool to reduce a specific intracellular redox molecule with an electrode, opening the possibility of electronically controlling biological processes such as biosynthesis and growth in any microorganism.
Complementing this approach, we discovered that *L. plantarum*, a lactic acid bacteria used industrially to produce fermented foods, can uptake electrons. This electron uptake occurs under anaerobic conditions when a terminal electron acceptor and its corresponding oxidioreductase are present. Unlike other anaerobic respiratory modes in *L. plantarum*, this current consumption does not require addition of co-factors such as heme or riboflavin. Electron uptake promotes cell growth and acidification of the media, both processes essential for food fermentation. We find that the *L. plantarum* metabolism is shifted towards ATP producing pathways in the presence of both a cathode and a suitable electron acceptor. This surprising discovery opens the possibility of using electrical current to drive industrial production of fermented foods using lactic acid bacteria.

2:30 PM *EN11.06.03
Sustainable Bioelectrochemical Conversion of CO_2 and N_2 to High Value Materials Peidong Yang and Stefano Cestellos-Blanco; University of California, Berkeley, United States

Climate change is a pressing global dilemma driven by the combustion of hydrocarbon fuels to CO_2, a potent greenhouse gas. CO_2 reduction has been the focus of intensive research with the goal of closing the carbon loop. A promising avenue to CO_2 conversion encompasses the materials-biology nexus. Microorganisms evolved over millions of years to fix CO_2, H_2O and N_2 with high selectivity and low substrate activation while self-regenerating. We have designed light-active nanomaterials that pair biocompatibly with these microorganisms in order to harness their biocatalytic activity. We demonstrate that by controlling the microenvironment in a silicon nanowire – bacteria ensemble, we can boost the solar-driven turnover rate of CO_2 reduction. Furthermore, adaptation of whole-cell autotrophic biocatalysts to a cytotoxic environment increases their ability to process CO_2. In addition to optimizing the CO_2 conversion rate by improving the material-biology interface and biocatalyst robustness, we establish synergistic co-cultures with guidable dynamics and outputs. We firstly present an integrated process for the production of 3D-printable biopolymer from CO_2. An autotrophic bacteria-mediated process converts CO_2 to acetate which is then directly used as the primary carbon source for biopolymer production by secondary bacteria without any processing of the culture medium between microbial production steps. We also showcase a consortium involving acetogenic *Sporomusa ovata* and diazotrophic *Rhodopseudomonas palustris* for tandem CO_2 and N_2 fixation to tunable value-added products. Co-culture dynamics and products can be directed by substrate availability and electrochemical inputs. Finally, we illustrate an electrochemically catalyzed abiotic pathway for sugar generation from CO_2. The sugars are employed as an *Escherichia coli* feedstock for the production of value-added materials.

Surface and Interface Engineering for High Performing Catalysis Yu Huang; University of California, Los Angeles, United States

The rising demands in providing energy, food, and water for the rapid-growing world population while addressing climate change and environmental pollution requires dramatic acceleration in technical innovations. Green and sustainable production of renewable energy is critical in solving the imminent challenges. Electrocatalysis plays a central role in diverse energy technologies that are of increasing importance for applications in mobile electronics, electric vehicles, as well as renewable energy industry. Despite considerable progresses, many electrocatalytic systems are still plagued by insufficient catalytic efficiency, poor stability or high cost of the precious metal catalysts used. In this talk I will share our research centred around pushing the limits of novel catalysts based on the understanding of the fundamental physical and chemical processes at the catalytic surfaces which can vastly improve the efficiency of diverse electrocatalytic systems, leading to a sustainable ad energy efficient society. In particular, I will discuss our efforts in promoting the mass activity and enhancing the stability of Pt-based cathode catalysts for hydrogen fuel cell applications.

4:30 PM EN11.07.02
Iron Quantum Dots Electro-Assembled on Nanocarbons as Electrocatalyst for the Oxygen Reduction Reaction in Terrestrial and Space Applications Armando Pena-Duarte[1], Timothy D. Hall[2], Santosh Vijapur[2], E J. Taylor[2] and Carlos R. Cabrera-Martinez[1]; [1]University of Puerto Rico, United States; [2]Faraday Technology Inc, United States

Highly dispersed iron-based quantum dots (QDs) onto nanocarbons were successfully electrodeposited by the Rotating Disk Slurry Electrodeposition (RoDSE) technique. Our findings through chemical physics characterization revealed that the continuous electron pathway interaction between the interface metal-carbon was controlled.

The rotating ring-disk electrode (RRDE) and the prototype generation unit (PGU) of *in-situ* H_2O_2 generation in fuel cell experiments revealed a high activity for the oxygen reduction reaction (ORR) via two-electron pathway. These results establish the Fe/C catalyst at a competitive level for space and terrestrial new materials carriers, specifically for the *in-situ* H_2O_2 production. Transmission electron microscopy (TEM) analysis reveals the well-dispersed Fe-based quantum dots with a particle size of 4 nm. The structural and chemical-physical characterization through induced coupled plasma-optical emission spectroscopy (ICP-OES), transmission scanning electron microscopy (STEM), X-ray diffraction (XRD), Raman spectroscopy, X-ray photoelectron spectroscopy (XPS), and X-ray absorption spectroscopy (XAS); reveals that, under atmospheric conditions, our quantum dots system is a $Fe^{2+/3+}/Fe^{3+}$ combination. The QDs oxidation state tunability was showed by the applied potential.

The obtention of H_2O_2 under the compatibility conditions of the drinking water resources available in the International Space Station (ISS) enhances the applicability of this iron- and carbon-based materials for *in-situ* H_2O_2 production in future space scenarios. Terrestrial and space abundance of iron and carbon, combined with its low toxicity and high stability, consolidates this present work to be further extended for the large-scale production of Fe-based nanoparticles for several applications.

Our approach is to switch the nanocarbon source and metal-carbon configurations, to control the two-electrons route in the ORR kinetics for fuel cells in space technologies. This consolidates our present work as a large-scale production process of highly active Fe nanoparticles for *in situ* H_2O_2 generation.

Likewise, the origin of the current transients, generated during the RoDSE technique, are associated with the Fe/C and H_2O/H^+ couple interactions through electrocatalytic amplification. The enhanced current transients open the possibility to design a fluidized bed reactor-like, to study the electrochemical amplification reactions where the electrocatalyst is used as a label to obtain higher yields. Accurately, large-scale production of treasured gases for human space missions via electrochemical amplification of the HER and OER, to produce large quantities of gases such as H_2 and O_2, represents a fascinating research field.

Experimental Sabatier Plot for Predictive Design of Active and Stable Pt-alloy Oxygen Reduction Reaction Catalysts Jin Huang[1], Xiangfeng Duan[1,1], William Goddard[2], Alessandro Fortunelli[3], Qingying Jia[4] and Yu Huang[1,1]; [1]University of California, Los Angeles, United States; [2]California Institute of Technology, United States; [3]Consiglio Nazionale delle Ricerche, Italy; [4]Northeastern University, United States

The broad dissemination of proton-exchange membrane fuel cells (PEMFCs) is largely limited by the high cost of platinum (Pt)-based catalysts that are used to accelerate the sluggish oxygen reduction reaction (ORR) at the cathode. While the theoretical descriptor, $\triangle E_O$ (oxygen binding energy to the catalyst surface), has been widely adopted for predicting the activity, its experimental analogue has met very limited success and the durability of the resulting catalysts is yet difficult to predict. To date, the developments of highly active and stable Pt-alloy nanocatalysts have largely relied on anecdotal discoveries. Therefore, it is essential to develop experimentally tangible descriptors that capture key parameters for efficient and rapid catalyst design. Herein, by combining theoretical modeling and experimental observations, we developed a binary experimental descriptor that directly reflects the calculated $\triangle E_O$ on Pt-alloy catalyst surface, leading to an experimental Sabatier plot that can be used to comprehensively predict both the catalytic activity and stability of a wide range of Pt-alloy ORR catalysts. Furthermore, based on the established Sabatier plot, we demonstrated the design of a PtNiCo catalyst that simultaneously delivers a superior activity and robust stability, approaching the peak of the Sabatier plot.

Direct Electrosynthesis of Pure Aqueous H_2O_2 Solutions with High Production Rates Based on Carbon Catalysts in a Solid Electrolyte Reactor Yang Xia and Haotian Wang; Rice University, United States

Hydrogen peroxide (H_2O_2) is a crucial chemical with a wide range of applications in civil and industrial fields. It is currently produced from the industrial energy- and waste-intensive anthraquinone process. Its centralized feature also makes it rely heavily on the storage and transportation of H_2O_2, which is unstable and hazardous. Electrocatalytic oxygen reduction reaction (ORR) to H_2O_2 provides an alternative to realize green and delocalized production, with the only inputs from renewable electricity, water and air. However, this route still faces two challenges: 1) lack of catalysts which selectively drive the $2e^-$ ORR towards H_2O_2 (instead of H_2O); 2) generated H_2O_2 are typically in mix with solutes in traditional electrolyzers, which necessitates complicated separation processes to recover pure H_2O_2 solutions for applications.

To make the electrochemical route more reliable in the future scaling-up, we reported a direct and continuous production of pure H_2O_2 solutions for the first time, through rational design of both catalyst and reactor. Here, we report a direct electrosynthesis strategy that delivers separate water (H_2O) and oxygen (O_2) streams to an anode and cathode separated by a porous solid electrolyte, wherein the electrochemically generated H^+ and HO_2^- recombine to form pure aqueous H_2O_2 solutions with different concentrations. By optimizing a functionalized carbon black catalyst, we achieved over 90% selectivity for pure H_2O_2 at current densities up to 200 mA cm^{-2}, which represents a H_2O_2 productivity of 3.4 millimoles per square centimeter per hour.

To further improve the activity and lower the overpotential at high current densities for industrial-level applications, we introduced boron-doped carbon catalyst which can achieve better activity under industrial-relevant current densities (saving over 200 mV overpotential at up to 300 mA cm^{-2}) compared to the state-of-the-art oxidize carbon catalyst while maintaining a high selectivity (up to 90%). By incorporating the boron-doped carbon catalyst into our solid electrolyte cell setup, we achieved high partial H_2O_2 current densities (400 mA cm^{-2}) with high selectivity (up to 95%), which represents a H_2O_2 productivity of 7.36 millimoles per square centimeter per hour. The setup can also undergo 200-hour stability test without degradation, making it a good candidate to be further improved in the aspect of potential scaling-up for electrochemical H_2O_2 production in industrial level with long-lasting performance.

5:15 PM EN11.07.05
Understanding the Role of P in Achieving Selective Catalysis for CO_2 Reduction and H_2O_2 Generation by Oxygen Reduction Scott Geyer; Wake Forest University, United States

Development of efficient, selective and cost-effective electrocatalysts is central to the efficient production of sustainable fuels and industrial feedstocks. While significant progress has been made in the hydrogen evolution reaction (HER) for water splitting, the direct synthesis of industrial fuels and feedstocks by the CO2 reduction reaction (CO_2RR) still presents significant challenges related to the limited number of metals that maintain selectivity over many reaction steps while sufficiently inhibiting competing HER. In this presentation we will show our success in promoting CO_2RR over HER as well as H_2O_2 over H_2O in the oxygen reduction reaction (ORR) using metal-phosphorus nanocrystalline catalysts based. Taken together, these three examples show the promise of controlled stoichiometric control in promoting desirable catalytic properties.

Recently (Nature Communications 2019) we demonstrated that CO_2 reduction on AgP_2 NCs shows a 3-fold reduction in Faradaic CO overpotential compared to Ag NCs. The reduced overpotential is consistent with the free-energies of the intermediates calculated with density functional theory in which the calculated free energy for COOH* is roughly three times lower for both the AgP_2 (111) and AgP_2 (211) surfaces compared to Ag (111). Operando X-ray absorption spectroscopy (XAS) gave insight into the role of P in stabilizing positive Ag partial oxidation states under reductive potentials, where at -0.8 V vs. RHE (corresponding to the peak in selectivity for CO2-to-CO), the Ag oxidation state in AgP2 NCs is +1.08 and stable for 2 h. In comparison, AgO and Ag_2O are reduced to Ag0 in less than 50 s at -0.8 V vs. RHE. Consistent with experiment, Bader charge analysis of COOH* on Ag and AgP_2 also shows a higher Ag oxidation state of AgP_2 versus metallic Ag. Notably, the decrease in overpotential was observed for a system that still maintained selectivity for CO_2RR over HER, despite the presence of P atoms on the surface. Free energy calculations for H* on Ag and P suggest Ag remains inactive for HER and that for the Ag(211) surface P over-binds H, consequently limiting HER.

Pushing towards selective C_2 product formation requires efficient C-C bond formation at sufficiently low overpotentials to avoid methane formation. Current work demonstrates a 280 mV reduction in ethylene overpotential on Cu3P compared to Cu nanocrystals, with C_2H_4 selectivity reaching 68%. Encouragingly, HER is again limited. The mechanism behind the observed increase in C_2H_4 selectivity is partially revealed by density functional theory and in situ FTIR, which suggests the reduction in the barrier for formation of CHO* creates a low overpotential regime in which a CO* and CHO* rich surface facilitates the bimolecular C-C bond formation reaction.

The role of P in templating metal atoms to control selectivity is demonstrated in the selective H_2O_2 ORR by PtP_2 NCs (Nature Communications 2020). For Pt-based oxygen reduction, the selectivity for the 2 e- H_2O_2 pathway versus the 4 e- H_2O pathway depends critically on the comparative strength of the Pt-OOH and the O-OH bonds. On pure Pt, strong bridge binding of OOH* decreases the chance of desorption and weakens the OOH bond which increases reactivity in the subsequent 4 e- pathway steps. PtP_2 increases the Pt separation and destabilizes the OOH* bridge bond based on DFT calculated bond distances. The result is a dramatic change in selectivity toward H_2O_2 which reaches 98%. Atomic layer deposition of Al_2O_3 prevents NC aggregation and enables application in a polymer electrolyte membrane fuel cell (PEMFC) with a maximum $r(H_2O_2)$ of 2.26 mmol h^{-1} cm^{-2} and a current efficiency of 78.8% even at a high current density of 150 mA cm^{-2}. Catalyst stability enables an accumulated neutral H_2O_2 concentration in 600 mL of 3.0 wt% (pH = 6.6).

5:30 PM EN11.07.06
H_2O_2 Production using Polymeric Organic Semiconducting Electrocatalysts J. Tyler Mefford, Ana De La Fuente Duran, Allen Yu-Lun Liang, Stephen D. Kang, William C. Chueh, Alberto Salleo and Alexander Giovannitti; Stanford University, United States

Decarbonization of the chemical industry requires transitioning from thermochemical transformations towards electrochemical pathways that use “green” electricity generated from renewables. These electrochemical processes focus on converting abundant natural chemical resources, such as the atmospheric gases O_2, N_2, CO_2, and H_2O, into fuels and valuable commodity chemicals, such as H_2, H_2O_2, NH_3, and multi-carbon products. But these processes are kinetically unfavorable and require the use of electrocatalysts for reasonable efficiencies. An ideal electrocatalyst should be (1) highly active and selective for generation of the desired end product with near 100% Faradaic efficiency at low overpotentials, (2) able to transport electrons (or holes), ions, and molecules to/from the catalytic site, and (3) affordable—meaning that they should only contain elements with reasonably high abundance and use synthetic methods that can scale to meet global demand. Unfortunately, simultaneously achieving all three desired qualities is difficult and often multi-component electrodes are necessary—for example Pt is highly active and selective for the full 4 e^- reduction of O_2 to H_2O in fuel cell electrodes but requires the incorporation of carbon black additives to minimize Pt content and reduce costs. Additionally, Pt is not ionically conductive and requires Nafion polymeric

binders to efficiently transport ions to the reaction sites.[1] Inspired by nature's design of enzymatic catalytic sites, we set out to synthesize organic electrocatalytic structures that, in principle, may achieve all three desired qualities.[2]

In this talk, we will describe the development of electrocatalysts based on n-type (electron conducting) organic semiconducting (OSC) polymers and their applications towards the production of H_2O_2 from O_2. These polymeric OSC's are mixed ionic-electronic conductors with redox active polaronic states formed through electrochemical ion insertion reactions. Rational design of the chemical structure of the OSC polymer backbone can be used to tune the energy (reduction potential) of these polaronic states and the adsorption strength of reactive intermediates to optimize selectivity and catalytic activity. Simultaneously, the attachment of a mixture of polar and non-polar side-chains to the backbone modifies the hydrophilicity of the polymer to tune the ionic and molecular transport properties through the bulk of the electrode. This approach enables full utilization of electrochemically active redox sites while simultaneously ensuring robust mechanical and chemical stability.[3] *Operando* UV-Vis spectroelectrochemistry and transport measurements performed during active electrochemical oxygen reduction in electrolytes at various pH's yield insights into the nature of the reaction site and mechanism of the reaction, providing chemical design principles for future development of this emerging class of electrocatalysts.

A Highly Active and Selective Redox Active 2D Metal Organic Framework Catalyst for Electrosynthesis of Hydrogen Peroxide in Neutral Media R. Dominic Ross, Hongyuan Sheng and Song Jin; University of Wisconsin-Madison, United States

Hydrogen peroxide (H_2O_2) is a widely produced green oxidant with applications in paper bleaching, chemical synthesis, and disinfection. H_2O_2 could be electrochemically produced safely and on-demand by using a catalyst selective for the two-electron oxygen reduction reaction ($2e^-$ ORR) as opposed to the four-electron ($4e^-$) pathway, though development of such catalysts has been hindered by lack of systematic design principles. Recently, well-defined crystalline two-dimensional conductive metal organic frameworks (2D-MOFs) with a square planar metal-nitrogen ($M-N_4$) motif have shown selective $2e^-$ ORR but the origins of the catalytic activity and selectivity remain unclear. Here, we demonstrate that one such 2D-MOF, Ni-HAB (HAB = hexaaminobenzene), has high selectivity compared to other similar 2D-MOFs with $M-N_4$ motifs. Bulk electrolysis experiments prove the practical efficacy of Ni-HAB as a $2e^-$ ORR catalyst in buffered near-neutral electrolyte and reveal a strong dependence on operating potential. Operando X-ray absorption spectroscopy reveals highly stable metal coordination sites and charging of the organic linkers that occurs during ORR that directly competes with the production of H_2O_2. These results confirm the dominant active site during ORR in these MOF catalysts and reveal a unique interplay between the material's catalytic and redox properties that can guide the future design of similar MOFs for enhanced catalytic activity.

SESSION EN11.08: Water Splitting

Oxygen Evolution Reaction Over Catalytic Single-Site Co in Well-Defined Brookite TiO_2 Nanorod Surface Chang Liu[1], Sen Zhang[1], William Goddard[2] and Jin Qian[3]; [1]University of Virginia, United States; [2]California Institute of Technology, United States; [3]Lawrence Berkeley National Laboratory, United States

Oxygen evolution reaction (OER) is an essential reaction and often a limiting step in many electrochemical devices that hold great potential for clean energy conversion and fuel transformation. The two paramount questions remain unclear in OER heterogeneous catalyst design: (1) how to identify and construct well-defined catalytic centers for efficient OER catalysis, and (2) how to delineate unambiguously the atomistic mechanism and kinetics for OER and competitive reactions at this center. In this work, we developed a new synthesis for the single-site cobalt (Co) doped TiO_2 nanorods with well-defined catalytic surface (210). This material was systematically studied with a suite of operando probes under electrochemical conditions and exhibited a record-high intrinsic activity for the OER reported to date. Moreover, based on grand canonical quantum mechanics (GCQM) calculations on well-defined single-site Co atomic structure, we establish a full description of reaction kinetics for the Co-TiO2 as a function of applied potential, revealing an adsorbate evolution mechanism for the OER. The computationally predicted Tafel slope and TOFs also exhibit unprecedently good agreement with experiment. Moreover, we demonstrated a methodological advance for the study of OER by combining the atomic-precision synthesis of nanocrystals and GCQM calculations. With the accuracy of GCQM calculations validated here, it can potentially allow us to perform high-accuracy in-silico design of rational catalyst and subsequently maximize its benefit through controlled synthesis of nanocatalysts.

Leveraging the Inductive Effect to Promote Oxygen Evolution on Oxides and Metal-Hydroxide-Organic Frameworks Jiayu Peng, Shuai Yuan, Bin Cai, Livia Giordano, Yuriy Román-Leshkov and Yang Shao-Horn; Massachusetts Institute of Technology, United States

Late transition metal oxides are reported to be the most active non-precious catalysts for oxygen evolution reaction (OER),[1] but the most active oxides based on Ni or Co[2] still have turnover frequencies per metal site at least one order of magnitude lower than that of oxygen-evolving complex (OEC) in biological systems.[3] The OEC contains an intricate manganese-calcium-oxo cluster, and its unparalleled OER activity can be attributed to the unique characteristics of Mn centers regulated by Ca^{2+} cations.[4,5] Such electronic structure tuning can be generalized as the inductive effect.[6] Specifically, substituting metal oxides and complexes using foreign metals with higher electronegativity can effectively increase their redox potentials and promote their activity. We have recently employed this concept to design bismuth-substituted strontium cobaltite, where the strongly electronegative Bi^{3+} ions give rise to Co centers with record intrinsic OER activity in alkaline solutions.[7]

Unfortunately, metal substitution in oxides exhibits a much smaller tunability of electronic structures than that found in metal-oxo clusters. For instance, Ca^{2+} substitution of Mn^{4+} in synthetic $[CaMn_3O_4]$ clusters can tune the $Mn^{3+/4+}$ redox potential by ~1 V,[4,5] whereas negligible changes of ~0.02 V are typically observed for oxides.[6] To tackle this limitation, we have designed metal-hydroxide-organic frameworks (MHOFs) that combine the great tunability of enzymatic systems with known oxide-based chemistries. A series of MHOFs were constructed by transforming layered hydroxides into 2D sheets composed of metal-octahedra chains cross-linked with neighboring chains using organic linkers. MHOFs can act as a tunable platform for OER,

where the nature of π-π-interactions between adjacent stacked linkers and the transition metals in the layered metal hydroxides dictate stability and activity, respectively. Substituting MHOF nanosheets with more electron-withdrawing cations increased their OER activity, where Fe-substituted Ni-based MHOFs exhibited three orders of magnitude enhancement in activity per metal site, rivaling those of state-of-the-art OER catalysts. This enhancement was correlated with the MHOF-based modulation of Ni redox potentials and the optimized binding of reaction intermediates. These results represent a step forward towards designing active metal centers with ligand fields akin to those in homogenous/enzymatic systems, where MHOFs can act as a versatile platform to design catalysts with unparalleled tunability.

Tuning Confined Water Structure and Hydrogen Evolution/Reduction Through Water-in-Solvent Yirui Zhang, Botao Huang, Graham Leverick and Yang Shao-Horn; Massachusetts Institute of Technology, United States

The production of molecular hydrogen by catalyzing water splitting is central to achieving the decarbonization of sustainable fuels and chemical transformations. While the hydrogen evolution reaction (HER) and hydrogen oxidation reaction (HOR) have been studied on a variety of electrode materials and pH, the mechanisms at play in the electrochemical double-layer and the roles of water structure are poorly understood. Especially changes in water structure have gained interest because of its direct implications on many of its properties, such as diffusion, dielectric function and H-bond dynamics. In this work, we achieved to confine water in organic solvents, and tune the water structure and hydrogen-bonding networks by changing the water concentration and organic solvents. Fourier-transform infrared spectroscopy (FTIR) and nuclear magnetic resonance (NMR) reveals the change of water structure confined in organics, and the HER/HOR kinetics are altered accordingly. We further perform surface-enhanced infrared absorption spectroscopy (SEIRAS) measurements to probe the water structure change during the reactions, and understand the role of water structure, and more specifically confined water, in reaction kinetics. This work highlights immense opportunities to control the water activity and HER/HOR kinetics by tuning interfacial structures of water and solvents. The understanding in controlling water activity would also be impactful across other reactions crucial to improving decarbonizing efforts in energy storage such as CO_2 reduction and aqueous batteries.

11:15 AM *EN11.08.05
Decoupling Mass Transport Effects from Intrinsic Kinetics on the Study of Electrocatalytic Materials Carlos G. Morales-Guio; University of California, Los Angelse, United States

Understanding the underlying mechanisms for the electrocatalytic transformation of CO_2 to fuels and chemicals, the electrochemical oxidation of methane to methanol or the electrocatalytic transformation of nitrogen to ammonia is a significant challenge for the scientific community. In our group, we have recently discovered that the H-type and gas diffusion electrode cells broadly used for the study of electrocatalytic transformations suffer from ill-defined mass and heat transfer characteristics obscuring the results obtained in kinetic studies and thus complicating further development of the field.
The complexity of electrocatalytic reactions is due to the coupling between reaction and diffusion and requires a profound understanding of processes occurring at multiple scales. In this work, a novel electrochemical cell is presented with well-defined mass transport properties where the hydrodynamics of the cell can be controlled from Reynolds numbers from 200 to 20,000 while the dimensionless mass transfer coefficient, the Sherwood number, is varied over an order of magnitude. Using this advanced electrochemical cell, we show that the product distribution obtained on a flat polycrystalline electrode for the electrocatalytic reduction of CO_2 varies widely under different mass transport regimes. Under the same applied potential, low Sherwood numbers favor the generation of >2 electrons reduction products such as ethylene and alcohols while high Sherwood numbers favor the production of hydrogen, carbon monoxide and formate. We also show that changes in the hydrodynamics of the cell can be used to change the selectivity of transition metal oxides for the electrocatalytic oxidation of methane to methanol. We show for the first time that various transition metal oxides are indeed selective for the transformation of methane to methanol under optimized conditions of applied potential and mass transfer. Through the study of these systems at different temperatures it is possible to decouple thermal from electron transfer steps in the electrochemical activation and oxidation of methane and extract intrinsic kinetics for this process. Understanding the coupling between reaction and diffusion should facilitate the study of electrocatalytic materials and the scale-up of electrocatalytic reactors in the near future.

Microfluidic System for Solar Energy Conversion Based on Metal-Doped Carbon Nitride Ewelina M. Kuna, Izabela Stefanowicz-Pieta and Martin Jonsson-Niedziolka; Institute of Physical Chemistry Polish Academy of Science, Poland

In recent years, a growing emphasis has been put on developing clean energy technologies and processes based on renewable energy sources. Solar power is the key to a clean energy future.[1] Artificial systems that mimic natural photosynthesis can be used to convert the Sun's energy to chemical or electrical energy. However, the effective conversion of light into a usable form of energy is mainly limited due to non-efficient charge separation and poor light-harvesting architecture.[2,3] This issue might be overcome by the proper selection of photoactive materials and the suitable engineering of photoreactors. Consequently, the challenge of developing successful solar-driven technology starts from understanding the nature of the performed chemical processes and the design of devices which can be implemented with photo-catalytic technologies. Following this trend, we have decided to examine how one of the most promising materials for alcohol photo/electrooxidation, metal-doped carbon nitrides (g-C_3N_4), can be applied to microfluidic fuel cells.[4] Our research indicates that among various materials, Ni-doped g-C_3N_4 exhibits outstanding catalytic activity towards methanol photo/electrooxidation upon batch reaction conditions.[5] Therefore, this stable and efficient catalytic reaction system has been transferred towards continuous flow technology *via* adopting a

microfluidic system.

Semiconductor/Bacteriorhodopsin Junctions for Enhanced Photoelectrochemical Water Splitting Nageh K. Allam; American University in Cairo, Egypt

In recent years, considerable efforts have been made to improve the performance of photoactive nanostructured materials for water splitting applications. Herein, we report on the assembly and use of a bacteriorhodopsin (bR)/TiO_2 nanotube array hybrid electrode system. Photoanode materials composed of ~ 7μm long self-ordered and vertically oriented nanotube array of titanium dioxide films were fabricated via the anodization of Ti foil in formamide electrolytes containing NH_4F at room temperature followed by sensitization of the electrodes with bR. The stability of bR on the TiO_2 surface was found to depend on the pretreatment process of the TiO_2 films. Our results demonstrate the opportunity to fabricate fairly stable bR/TiO_2 hybrid electrodes that can be used as photoanodes for photoelectrochemical water splitting. Under AM 1.5 illumination (100 mW/cm^2), the hybrid electrodes achieved a photocurrent density of 0.65 mA/cm^2 which is a ~ 50% increase over that measured for pure TiO_2 nanotubes (0.43 mA/cm^2) fabricated and tested under the same conditions. In the presence of a redox electrolyte, the photocurrent increased to 0.87 mA/cm^2. To the best of our knowledge, this is the first report on the use of bR/TiO_2 hybrid electrodes in photoelectrochemical water oxidation cells. We believe the proton pumping property of bR can be used in a variety of applications, especially those related to third generation photovoltaic cells.

***In Situ* Magnetic Alignment of a Slurry of Tandem Semiconductor Microwires Using a Ni Catalyst** Saumya Gulati[1,2] and Joshua Spurgeon[1,2]; [1]University of Louisville, United States; [2]Conn center for renewable energy research, United States

There has been a vast improvement in photovoltaic (PV) technology in the last couple of decades; however, solar PV technology has a lot of drawbacks, including that it is intermittent, broadly dispersed, and non-transportable. Hence, cost-effective solar energy storage is critical for widespread implementation of solar energy as the primary energy source.
Slurries of semiconductor particles individually capable of unassisted light-driven water-splitting are modeled to have a promising path to low-cost solar hydrogen generation, but they have had poor efficiencies. Tandem microparticle systems are a clear direction to pursue to increase the efficiency. However, light absorption must be carefully managed in a tandem to prevent current mismatch in the subcells, which presents a possible challenge for tandem microwire particles suspended in a liquid. In this work, a Ni-catalyzed Si/TiO_2 tandem microwire slurry was used as a stand-in for an ideal bandgap combination to demonstrate proof-of-concept alignment of unassisted water-splitting microwires with an external magnetic field. The Ni hydrogen evolution catalyst was selectively photodeposited at the exposed Si microwire core to serve as the cathode site as well as a handle for magnetic orientation. The frequency distribution of the suspended microwire orientation angles was determined as a function of magnetic field strength under dispersion with and without uplifting microbubbles. After magnetizing the Ni bulb, tandem microwires could be highly aligned in water under a magnetic field despite active dispersion from bubbling or convection.

2:15 PM *EN11.09.05
Understanding Water Oxidation Mechanisms on Heterogeneous Catalysts with Atomically Defined Active Centers Dunwei Wang; Boston College, United States

Water oxidaiton is an important first step toward artificial photosynthesis. A key challenge in this field is the lack of clarity on how water is oxidized. As a result, a durable but highly active heterogeneous catalyst that is also low-cost has not been found. Important questions on why certain catalysts are more active than others also remain unanswered. This problem has been difficult to solve because, at least in part, there is a lack of clarity on the structure of the active sites. The fact that the catalyst structure also evolves during the catalytic reaction further excerbates the situation. Here we present a new catalyst platform that has the potential to address this issue. Starting from molecular catalysts whose structure is well resolved, we synthesize heterogeneous catalysts that preserve the active site structure. The resulting material is a dinuclear catalyst that is highly active but also durable. More importantly, it provides an opportunity to test the various hypotheses concerning water oxidation mechanisms.

Engineering PdCu Bimetals for Enhanced Electrochemical Nitrate Reduction to Nitrogen and Ammonia Jeonghoon Lim, Seung Woo Lee and Marta Hatzell; Georgia Institute of Technology, United States

Nitrate (NO_3^-) pollution of groundwater is an arising issue due to the high input of nitrogen-rich agriculture fertilizers. Furthermore, nitrite (NO_2^-), which is the product of NO_3^- reduction, is also a major threat to human health such as methemoglobinemia (“blue baby syndrome”) and cancer. Electrochemical conversion of harmful nitrate has attracted attention to produce benign dinitrogen (N_2) and ammonia (NH_3) as a means of transforming waste into fertilizers. Designing structure of PdCu bimetallic nanoparticles is important for developing highly efficient and selective electrocatalysts. Here, we engineered the atomic structure of PdCu and controlled Cu surface coverage on Pd nanocube nanoparticles for enhancing the NO_3^- conversion rate and steer the selectivity of N_2/NH_3. Highly ordered structure of PdCu nanoparticles showed high nitrate reduction activity, excellent dinitrogen selectivity and robust stability in a neutral electrolyte compared to disordered PdCu nanoparticles. We also develop Pd nanocube nanoparticles and introduce Cu metals on

the surface by underpotential deposition (UPD) method. The decorated Cu metals catalyze the reduction of NO_3^- to NO_2^- and the Pd (100) enhances the activity and selectivity of NO_2^- to N_2. Rotating disk electrode (RDE) and H-cell tests were conducted for NO_3^-/NO_2^- reduction activity and the selectivity of PdCu bimetal electrocatalysts were examined by UV-vis and *in-situ* mass spectrometry. This study demonstrates that designing nanostructure of PdCu is an efficient approach to facilitate the nitrate reduction process and control the selectivity of N_2/NH_3 as reducing environmental issues associated with removing NO_3^- and NO_2^- from water.

4:15 PM EN11.10.04
Oxide-Derived Silver Nanocatalysts with Tunable Selectivity in Electrocatalytic Nitrate Reduction Jaeryul Park, Hengzhou Liu, Yifu Chen, Wenzhen Li and Luke T. Roling; Iowa State University, United States

Nitrate contamination in groundwater due to agricultural runoff is one of the most significant modern environmental challenges, with substantial implications on wildlife and human health. The electrochemical reduction of nitrate has demonstrated promise for its elimination; however, developing methods for improving selectivity to desired products is paramount toward its effectiveness. Nitrogen gas (N_2) is benign and a desirable target for wastewater remediation, though maintaining its production at sufficient activity and current efficiency has been elusive.

This presentation describes our recent computational and experimental work[1] in developing transition metal nitrate reduction catalysts. Our experimental results, combining rigorous electrochemistry with online gas chromatography, have found that Ag electrocatalysts demonstrate a unique activity and selectivity for nitrate to nitrite not found on other transition metal catalysts. In particular, an oxide-derived (OD-)Ag catalyst demonstrated up to 98% nitrate-to-nitrite selectivity with 95% faradaic efficiency. The product selectivity can be tuned simply by changing the electrode potential to more reducing conditions, yielding ammonia with faradaic efficiency of 89%. Alternatively, the nitrite generated by the electrocatalytic process can be efficiently and selectively reduced to N_2 in a separate (nonelectrochemical) catalytic process on Pd/C to yield a clean two-step process for nitrate reduction.

Density functional theory (DFT) calculations on model surfaces show that the undercoordinated nature of the OD-Ag catalysts is particularly advantageous for nitrate reduction relative to traditional Ag nanoparticles. The Ag-based catalysts have difficulty in directly activating N-O bonds, instead relying on proton-mediated pathways to perform N-O bond dissociation. The unique selectivity arises from the relative ease of nitrate vs. nitrite reduction along these proton-mediated pathways, with the undercoordinated nature of OD-Ag aiding the electrocatalytic performance due to the preferential adsorption of nitrate. In contrast, Cu-based catalysts demonstrate poorer selectivity to nitrate due to their ability to directly activate N-O through non-electrochemical routes. Together, these results open the possibility of electrochemical nitrate remediation to close the nitrogen cycle (by forming N_2) and/or the potential use of nitrite as a platform for the generation of other N-containing compounds (e.g., ammonia, hydroxylamine) when treating concentrated nitrate sources.

8:00 AM EN11.11.01
Water and Solute Activities Regulate CO_2 Reduction at High Current Densities Nathan T. Nesbitt[1] and Wilson Smith[1,2,2]; [1]National Renewable Energy Laboratory, United States; [2]University of Colorado Boulder, United States

High current density electrochemical CO_2 reduction (CO_2R) (~1 A cm^{-2}) can create concentrated hydroxide at the cathode, causing the activity coefficient of water and hydroxide to deviate from the "dilute solution approximation." Also, for CO_2 reduction to CO, as the ratio of CO_2 to CO changes along the gas flow channel at a gas-diffusion electrode the reaction equilibrium potential will shift. Here I discuss the implications of these effects for CO_2R energy efficiency and product selectivity based on Nernstian analysis. Promising reactor designs are suggested, accordingly.

8:15 AM EN11.11.02
Single Site M-N_4-C Electrocatalysts for the CO_2 Reduction Reaction Peter Bogdanoff[1], Stephen Paul[2], Yi-Lin Kao[1], Iris Herrmann-Geppert[3], Roel van de Krol[1] and Ulrike I. Kramm[2]; [1]Helmholtz-Zentrum-Berlin, Germany; [2]TU-Darmstadt, Germany; [3]HS-Mittweida, Germany

The influences of various transition metal ions (Ni, Fe, Co, Cu, Mn, Zn, and Sn) in metal- and nitrogen-doped carbon (M-N-C) are systematically investigated for the electrochemical reduction of water and CO_2 (CO_2RR). By careful pyrolysis of carbon-supported porphyrins at low loading predominately M-N_4-centers embedded in a carbon matrix are achieved, while avoiding significant amounts of undesired metal- and nitrogen byproducts. The catalysts were electrochemically investigated in a Gas Diffusion Electrode (GDE) arrangement coupled in-line to a mass spectrometer, allowing the almost simultaneous detection of product selectivity, Faraday efficiencies and current densities in linear sweep voltage (LSV) experiments. Among these catalysts, Fe– and Ni-based samples have shown remarkable high Faraday efficiencies of > 90% for the formation of CO even at current densities exceeding 175 mA cm^{-2} in pH 7.5 carbonate buffer. The comparison of measurements with different gas supply (Ar vs CO_2) underlines that this is achieved by an almost completely suppressed hydrogen evolution in the presence of CO_2, as theoretically expected for single site centers like MeN_4. The Fe-N-C and the Cu-N-C catalyst show a change in reaction mechanism for potentials more negative than -1.5V/NHE accompanied by a steep increase of the formation of CH_4, H_2 (and C_2H_4 on Cu-N-C) whereas CO formation is partially suppressed. *Post mortem* XPS analysis of Cu-N-C reveals that Cu^{2+} of the Cu-N_4 centers is partially reduced to Cu° in that potential range, which led us assume that also in M-N-C catalysts Cu° structures are involved in the formation of hydrocarbons. While Zn-N-C and Mn-N-C in our study generally show only little CO2RR activity, Sn-N-C produces as main product formate with an FE of about 40% and production rates of about 20 µmol h^{-1} cm^{-2} at potentials smaller than -1.5V/NHE. Our work allows new insights into the potential dependent behavior of M-N-C catalysts and reveals the high selectivity of MN_4 centers for the CO2RR.

8:30 AM EN11.11.04
Late News: Conductive Metal Organic Frameworks with Molecularly Defined M-O4 Active Sites as Highly Active Biomass Valorization Electrocatalysts Yuxuan Zhang and Nikolay Kornienko; Université de Montréal, Canada

The electrochemical oxidation of biomass platform 5-hydroxymethyl furfural (HMF) to 2,5-furandicarboxylic acid (FDCA), is an important reaction in the

emerging area of renewably powered biomass valorization. To this end, the efficiency of catalytic systems still needs to be improved to render these systems economically competitive. In the electrochemical HMF oxidation reaction (HMFOR), the utilization of well-defined active sites is critical for fundamental insights into their function and subsequently rationally turning them to maximize catalytic activity. However, heterogeneous catalysis of HMF conversation often feature poorly defined catalytic surfaces, hampering the community's complete understanding of the reaction mechanism. To the end, we report the use of reticular chemistry to design a conductive metal organic framework-based electrocatalytic model system with well-defined M-O_4 active sties for HMFOR. The activity of MOFs bearing Ni-O_4 (Ni-CAT) and Co-O_4 (Co-CAT) active sites were analyzed with electrochemical and operando spectroscopic techniques to elucidate the reaction mechanism occurring on the surface. Electrochemical experiments reveal that Co-CAT has an earlier onset potential for enabling HMFOR, relative to other known catalysts thus far, while the Ni-CAT shows faster kinetics for the conversion of HMF to FDCA.
Also, Ni-CAT exhibits efficient charge transfer properties and intrinsically high kinetic towards HMFOR. It achieved FDCA yields of 98.7% yield with 86.8% faradic efficiency at 1.42 V vs RHE.
Infrared spectroscopy captures the surface-bound aldehyde group as the key intermediate in the catalytic cycle, which forms once M(II\III) oxidation occurs. This work illustrates the advantage of utilizing molecularly defined active sites coupled with operando spectroscopy to provide fundamental insights into a variety of electrosynthetic reactions and pave the way for future catalyst design.

8:45 AM EN11.11.05
Tandem Architectures for High-Rate CO_2 Electrolysis Toward Multicarbons Chubai Chen; University of California, Berkeley, United States

CO_2 electrolysis is a promising technique for CO_2 recycling and utilization offering carbon-neutral chemical feedstocks for downstream applications. Electrocatalyst development for CO_2 reduction reaction (CO_2RR) toward single carbon products has achieved enormous progress. However, copper has been found the only metal that can efficiently catalyze CO_2 to higher-value and energy concentrated multicarbon products (e.g., ethylene, ethanol, acetate). Therefore, how to tune the selectivity and boost productivity towards multicarbons based on Cu catalysts becomes a central question in CO_2RR. Here, we highlight that tandem electrocatalysis can be a promising approach towards this target. With tandem strategy, a chemically complicated pathway can be decoupled into individual steps within via multicomponent catalyst design. As a demonstration, we show that a Cu-Ag tandem catalyst on a GDE can enhance the multicarbon production rate from CO_2 through CO_2 reduction to CO on Ag and subsequent carbon coupling on Cu. With added Ag, the multicarbon partial current over a Cu surface increases by 4-fold at -0.70 V vs RHE in 1M KOH. Corresponding CO reduction experiments have been conducted to show that no mutual interference between these two metals can be observed at the catalytic level. More interestingly, the intrinsic C_2H_4 and C_2H_5OH turnover frequency in the tandem platform are significantly higher than Cu alone under either pure CO_2 or CO atmosphere. Such results highlight the unexpected superiority of the tandem strategy for CO_2RR in a flow cell, which offers the opportunity to enhance the efficiency of C-C bonding on a Cu surface beyond conventional CORR during high-rate electrolysis. Considering that the tandem strategy is an independent approach and can be further conjugated with catalyst surface engineering, we aim to optimize the Cu-Ag nanostructure and further boost the catalyst performance.
Meanwhile, *operando* spectroscopy can be a powerful method to explore the microenvironment tunability and structure-catalysis relationship.

9:00 AM *EN11.11.06
Shape-Controlled Nanocrystals to Unlock Selectivity Pathways in the Electrochemical CO2 Reduction Reaction Raffaella Buonsanti; Ecole Polytechnique Federale de Lausanne, Switzerland

In the electrochemical CO2 reduction reaction (CO2RR) selectivity still remains an important issue.
In this talk, I will showcase a few examples which highlight how shape-controlled nanocrystals can contribute to address this challenge. First of all, I will discuss how size control of Cu nanocubes (Cu_{cub}) and Cu octahedra (Cu_{oh}) has revealed the importance of facet-ratio to maximize the selectivity towards ethylene and methane, respectively. Second, I will present our recent computational-experimental efforts towards using well-defined NCs to elucidate selectivity rules at the hydrocarbons/alcohols branching nodes in the CO_2RR pathway. The formation of ethanol via *CH_x-*CO coupling or *CO-*CO coupling is an open debate in the literature. As a platform to address this question, we have used CH_4 favoring (i.e. *CH_x populated) Cu_{oh} and C_2H_4 favoring (i.e. *CO-*CO populated) Cu_{cub} under enhanced *CO coverage induced by the presence of Ag NCs. The selective promotion of ethanol in the Cu_{oh} provided evidence for *CH_x-*CO coupling being the preferred pathway. Having learned this, we have also explored the size-dependent edge/face ratio of the Cu_{cub} to interrogate the reactivity of the high index (711) copper surface. The results of this last study indicate the propensity of (711) step sites towards ethanol production.

SESSION EN11.12: CO2 Reduction IV

Scalable Cu/Metal-Oxide-Based Catalysts for the Sustainable and Tunable CO_2 Electroreduction to Value-Added Products Simelys Hernandez, Hilmar Guzman, Federica Zammillo, Daniela Roldan and Micaela Castellino; Politecnico di Torino, Italy

The electrocatalytic (EC) CO_2 reduction (CO_2R) driven by renewable energy can be exploited for the future energy transition, for the carbon storage into valuable products like syngas (H_2/CO mixtures), organic acids (formic acid) and chemicals/fuels (C_{1+} alcohols).[1,2] A big challenge for the industrialization of this technology is to find low-cost electrocatalyst, efficient reactors and process conditions. In our lab, we are exploiting the current knowledge of the thermocatalytic CO_2 hydrogenation to develop noble-metal-free CO_2R electrocatalysts.[3] Our results open a promising path for the prospective implementation of metal-oxides nanostructures for the CO_2 conversion to the chemicals and fuels of the future.
We have developed novel structures of Cu/Zn/Al-based catalysts, which produce methanol and CO from the CO_2 thermocatalytic (TC) hydrogenation (at H_2 pressure (P) of 30 bar and temperature (T) > 200 ºC) and are able to generate H_2, CO and other C_1 to C_3 liquid products like alcohols, during the electrochemical CO_2R in a gas-diffusion-electrode (GDE) system at ambient T,P. We have also developed B,N-doped Cu oxide catalysts, inducing the formation and stabilization of Cu^{+1}/Cu^0 interfaces and promoting the dimerization of the *CO intermediate. Incorporating both B and N heteroatoms led to greater selectivity for reducing CO_2 to products of interest: that is, a total FE of 64% to CO_2 reduction products with 49% of liquid products (*i.e.* 77% selectivity towards formate and alcohols) at a relevant current density of 23 mA cm^{-2}. The catalysts and electrodes have been prepared by scalable techniques (i.e. co-precipitation and spray-coating) and characterized ex-situ by different physico-chemical methods like X-ray diffraction, BET, porosimetry, filed-emission scanning electron microscopy (FESEM), X-ray photoelectron spectroscopy (XPS) among others. A correlation has been found between their activity and selectivity with respect to their porosity and superficial Cu states. The physical and chemical properties of these Cu-based

materials can be manipulated to tune the performance of the electrochemical reaction. In addition, the electrochemical reactor configuration (GDE vs. CO_2 dissolved in liquid electrolyte) also play an important role in the final selectivity and productivity.[4] These interesting results could help find a suitable electrocatalytic systems for the future implementation of this technology at industrial level.

Late News: Improved Electrochemical Conversion of CO2 to Multicarbon Products by Using Molecular Doping Huali Wu, Kun Qi, Philippe Miele and Damien Voiry; Institute of European Membrane, France

CO_2 conversion has been proposed as a potential way to close the carbon cycle and generate chemical fuels. The electrocatalytic reduction of carbon dioxide, powered by renewable electricity, to produce valuable fuels and feedstocks provides a sustainable and carbon-neutral approach to the storage of energy produced by intermittent renewable sources.
The development of such a technology is currently hampered by the lack of catalysts, which can drive the reaction at industrially relevant current densities with high efficiency and selectivity. Examples of strategies for optimizing the CO_2RR performance include alloying, surface doping, ligand modification, and interface engineering. Our investigations focus on exploring the role of functionalization on the catalytic activity of Cu towards the conversion of CO_2 to hydrocarbon products.
We developed a method to modify the surface of bimetallic silver-copper (Ag-Cu) catalyst with aromatic heterocycles such as thiadiazole and triazole derivatives. By combining operando Raman and X-ray absorption spectroscopy with electrocatalytic measurements and analysis of the reaction products, we identified that the electron withdrawing nature of functional groups orients the reaction pathway towards the production of C_{2+} species such as ethanol and ethylene and enhances the reaction rates on the surface of the catalyst. As a result, we achieve a maximum Faradaic efficiency for the formation of C_{2+} of ≈ 80% and full-cell energy efficiency of 20.3% with a specific current density of 261.4 mA cm^{-2} for C_{2+} using functionalized Ag-Cu electrodes, compared to only 33.8% and 70.6 mA cm^{-2} for the pristine Ag-Cu electrodes. We anticipate that our strategy can further be extended in order to improve the selectivity of the reaction towards the production of specific multicarbon molecules.

11:00 AM *EN11.12.05
Designing Efficient Zero-Gap Carbon Monoxide Electrolyzer Jiao Feng and Sean Overa; University of Delaware, United States

Carbon monoxide electroreduction is a rapidly developing field for the production of valuable commodity chemicals. When coupled with CO_2 capture and electrochemical conversion, it can be used as a clean CO_2 negative process for the production of a variety of products. Carbon monoxide reduction has the distinct advantage over direct electrochemical CO_2 reduction to multi-carbon products (C_{2+}) in that it does not suffer from carbonate formation, allowing for higher single pass conversion and electrolyte stability. This work focuses on the design and production of a zero gap membrane electrode assembly carbon monoxide electrolyzer, which operates at low cell potentials (< 2.5 V), and industrially relevant current densities (> 200 mA/cm^2) for the production of acetate and ethylene. Acetate and ethylene are valuable target products due to their high value and market potential. Zero gap electrolyzers place the cathode and anode in direct contact with a conductive polymer membrane, whereas conventionally carbon monoxide electrolyzers have relied on a three-compartment design where the cathode is in contact with a liquid electrolyte layer.
By utilizing the zero-gap design, liquid products can be collected in either cathode or anode chamber. To enhance product selectivity, we choose suitable electrocatalysts for both cathode and anode to maximize the selectivity towards carboxylates. By utilizing a suitable combination of electrocatalysts, we have successfully improved the product selectivity towards acetate substantially. The system was also found to have improved current densities and cell voltages when compared to conventional three-compartment carbon monoxide electroreduction systems. Increased residence time of the anolyte by recirculation also allowed for the production of highly concentrated acetate streams with >90% purity relative to other liquid CO reduction products.

Partial Oxidation of Ethylene to Valuable Chemicals with Hydrogen Co-Production Yanwei Lum[1,2] and Edward H. Sargent[1]; [1]University of Toronto, Canada; [2]National University of Singapore, Singapore

There is significant interest in developing efficient electrochemical processes for commodity chemical manufacturing, all directly powered by renewable electricity. Here we report a one-step electrochemical route at ambient temperature and pressure in aqueous media for the selective anodic partial oxidation of ethylene to ethylene glycol with co-production of hydrogen at the cathode[1]. Tuning of the catalyst OH binding energy was hypothesized to be crucial for facilitating the transfer of OH to $*C_2H_4OH$ to form ethylene glycol. Computational studies suggested that a gold-doped palladium catalyst could perform this step efficiently, and experimentally we found it to exhibit an approximate 80% Faradaic efficiency to ethylene glycol, retaining its performance for 100 hours of continous operation. I will also describe our efforts in developing an electrochemical system for the electrosynthesis of ethylene oxide from ethylene using a chloride mediator[2]. A 2 step integrated system involving CO2-to-ethylene conversion and subsequent conversion to ethylene oxide was also demonstrated. In summary, these findings represent a significant advance in the development of selective anodic partial oxidation

reactions in aqueous media under mild conditions.

Bifunctional Nickel and Copper Electrocatalysts for CO_2 Reduction and the Oxygen Evolution Reaction Hanqing Pan and Chris Barile; University of Nevada, Reno, United States

In this study, a bifunctional electrocatalyst for CO_2 reduction and the O_2 evolution reaction (OER) was constructed from the electrodeposition of cuprous oxide (Cu_2O) and Ni on a carbon substrate. Different Ni thicknesses on Cu_2O were achieved by varying the time of chronopotentiometric deposition of Ni. Electrochemical CO_2 reduction was carried out at -0.89 V and -1.89 V vs. RHE, and it was found that formate and CO were the two major products. Cu_2O modified with a Ni overlayer with a thickness of ~700 nm resulted in the highest formate Faradaic efficiency of 18%, and Cu_2O resulted in highest CO Faradaic efficiency of 7.9%. The enhanced Faradaic efficiency for formate is attributed to the synergistic effect between Ni and Cu_2O due to maximized amounts of exposed bimetallic sites that facilitate CO_2 reduction. The electrocatalyst also produces ~9 times more current density than previous studies using Ni-Cu_2O electrocatalysts for the OER. The ability of the Ni-Cu_2O thin films to catalyze both the OER and CO_2 reduction allows them to be incorporated in the first demonstration of a two-electrode CO_2 conversion device with a bifunctional catalyst.

1:30 PM EN11.13.04

Nanostructured Fe-Based Materials for Electrocatalytic Energy Conversion Christopher Simon and Roland Marschall; University of Bayreuth, Germany

Electrocatalytic water splitting can be regarded as promising method to store electrical energy in form of hydrogen as a sustainable green energy carrier. However, water splitting typically suffers from the sluggish reaction kinetics of the oxygen evolution half reaction (OER). By employing electrocatalysts, the required overpotential of the OER can be decreased significantly.
In recent years, earth-abundant spinel ferrites have emerged as auspicious materials for applications in photoelectrochemistry and electrocatalysis. Spinel-type first-row transition metal oxides (TMOs) or their composite compounds containing nickel, manganese, iron, or cobalt are attractive materials for the electrocatalytic oxygen evolution reaction in alkaline media. However, Mn-based electrocatalysts often lack due to stability issues, and the use of cobalt is further discussed critically due to its toxicity hazards and limited availability. Therefore, low cost and high abundant bimetallic NiFe spinel oxide with the elemental composition $NiFe_2O_4$ has gained attention in the field of alkaline water electrolysis, combining remarkable stability in alkaline media with excellent redox properties.[1,2]
We developed a fast microwave-assisted synthesis yielding phase-pure spinel ferrite nanoparticles of e.g. $MgFe_2O_4$, $CoFe_2O_4$, $NiFe_2O_4$ and $ZnFe_2O_4$ at temperatures as low as 170-200 °C.[3-6] The crystallite size can be tailored by post-synthetic heat treatment, however the materials are already (partly) crystalline as-prepared, with specific surface areas of around 200 m^2/g and good colloidal stability. Photocatalytic and electrocatalytic experiments will be presented, as well as the conversion of some spinel oxides into sulfides, e.g. pendladites.[7] A new direct microwave synthesis for nickel-iron sulfides for electrocatalytic CO_2 reduction will also be presented.[8]

Late News: Zirconium Phosphate Supported Electrocatalysts for the Oxygen-Evolution Reaction Jorge L. Colón[1], Mario V. Ramos-Garcés[2], Joel Sanchez[3], Kálery La Luz-Rivera[1], Andrea R. Cortés-Ortiz[1], VIctoria M. Figueroa[1], Yannelly A. Serrano-Rosario[1], Isabel Barraza-Alvarez[4], Yanyu Wu[5], Dino Villagran[6] and Thomas Jaramillo[3]; [1]University of Puerto Rico, United States; [2]The Pennsylvania State University, United States; [3]Stanford University, United States; [4]University of California at Santa Barbara, United States; [5]University of Houston, United States; [6]The University of Texas at El Paso, United States

We are studying new applications of layered zirconium phosphate (ZrP) inorganic
nanomaterials. The θ phase of ZrP can be directly ion-exchanged with large metal complexes, producing intercalated phases useful for artificial photosynthesis schemes for water splitting, amperometric biosensors, and drug delivery applications. Recently, we have demonstrated improved electrocatalytic activity of ZrP nanomaterials loaded with metal ions suitable for the oxygen evolution reaction (OER) of water splitting.
Adsorbing Co and Ni catalysts on the ZrP nanoparticles surface proved to improved OER activity compared to intercalated catalysts. A comparison between adsorbed Co or Ni catalysts and those catalysts on exfoliated ZrP nanoplatelets proved that those on exfoliated nanoplatelets were more active, with diminished overpotentials and reduced Tafel plot slopes as well as higher mass activities. More recently, comparison
between Co and Ni catalyst on ZrP particles with different morphologies (hexagonal platelets, rods, cubes, and spheres) revealed that the more active Co catalysts are those on hexagonal ZrP platelets, whereas the best Ni catalysts are those on ZrP spheres. We are exploring the OER activities of mixed-metal catalysts and porphyrins, as well as operando synchrotron X-ray absorption spectroscopy studies to elucidate the nature of the active catalysts.

2:00 PM *EN11.13.06

Integrating Materials Design and *Operando* Spectroscopy for the Development of Next Electrocatalytic Systems Nikolay Kornienko; University of Montreal, Canada

Electrochemical conversion of abundant feedstocks to fuels and value-added chemicals is rapidly gaining significance as a promising method to harness renewable electricity. Specific reactions within this context that my research group is focused on are the reduction of CO_2 and oxidation of biomass platforms to fuels and value-added chemicals. Because the design of new catalytic systems is inherently linked to a precise understanding of how these

reactions proceed on heterogeneous surfaces, we put considerable efforts in developing methodology for *operando* probing with vibrational spectroscopy. In all, I show how using these experiments provide the key mechanistic information on surface reaction mechanisms that enhance our understanding of functional hybrid interfaces and how the research provide avenues for future materials design within the context of electrosynthesis of fuels and chemicals.

2:30 PM EN11.13.07
Tuning Catalyst-Ionomer Coverage and Interactions Towards Selective and High Current Density CO_2 Reduction Oyinkansola Romiluyi[1,2], Nemanja Danilovic[2], Alexis T. Bell[1] and Adam Z. Weber[2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

CO_2 electrolyzers operating at high current densities and product selectivities are essential for the commercialization of electrochemical CO_2 reduction (CO_2R) systems to chemicals and fuels. An electrolyzer based on a membrane-electrode assembly (MEA) enables the achievement of these desired criteria. A critical component of an MEA is its catalyst layers, which are composed of catalyst nanoparticles and an ionomer. The latter component provides a pathway for ion transport from the catalyst to the ion-conducting membrane.

The materials design parameters that characterize these ionomer-based catalyst-layers are the ionomer-to-catalyst ratio (I:Cat), catalyst loading, and catalyst-layer thickness. In this study, we systematically analyze the effects of these parameters on the activity and product selectivity of a Ag cathode CO_2R MEA. An optimum I:Cat ratio of 3 is rationalized based on electrochemically-active surface area (ECSA) and ionomer coverage/distribution arguments, where the extent of this coverage and the resulting ionomer-catalyst interaction significantly impacts the total current density and CO selectivity. Coverage regimes range from a patchy/sparse ionomer distribution at low I:Cat ratios (i.e., I:Cat < 3) suffering from poor ECSA and ionic pathway to excessive coverages at high I:Cat ratios (i.e., I:Cat > 3) suffering from poor electronic contact and CO_2 utilization. The effect of decreasing the catalyst loading and/or catalyst-layer thickness changes mainly the CO_2R product selectivity (in agreement with previous modeling work) and the CO FE is shown to be highly sensitive to this metric. By changing these catalyst-layer design parameters, our results demonstrate that the MEA architecture can behave similarly to traditional cells in their ability to highly tune CO_2R selectivity with their electrode/electrolyte interfaces.

The crucial insights gained from the reported trends are compounded to yield an efficient Ag CO_2R MEA cell that operates at current densities of 200 mA cm^{-2} to 1000 mA cm^{-2}, CO faradaic efficiencies of 78 to 91%, and an area-specific resistance under 1 Ω cm^2. These findings can be applied to a broad range of CO_2R MEA-based devices, including CO_2-to-CO tandem devices and flexible manufacturing systems where changing the aforementioned catalyst-layer properties can effectively tune the outlet CO:H_2 ratio for various syngas applications. The scientific and experimental design learnings from our Ag-cathode MEA studies are subsequently applied to a Cu-cathode MEA, which has farther reaching and impactful applications due to its ability to produce value-added chemical precursors such as ethylene and ethanol.

2:45 PM EN11.04.10
Quasi-Graphitic Carbon Shell-Induced Cu Confinement Promotes Electrocatalytic CO_2 Reduction Toward C_{2+} Products Ji Yong Kim[1], Deokgi Hong[1], Gun-Do Lee[1], Dae-Hyun Nam[2] and Young-Chang Joo[1]; [1]Seoul National University, Korea (the Republic of); [2]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

The electrochemical CO_2 reduction reaction (CO_2RR), which converts CO_2 to value-added chemical products with high energy density, is a promising solution for fossil fuel-induced energy and environmental issues because it can help realize a sustainable energy cycle. A commercially feasible CO_2RR requires the development of an electrocatalyst that can steer the reaction pathway toward specific products on a multidimensional scale by controlling the binding energy of the reaction intermediates to design a reaction configuration. This enables economic earnings to be achieved by renewable energy conversion-induced electrochemical reactions in terms of energy efficiency, current density and stability.
For steady electroconversion to value-added chemical products with high efficiency, electrocatalyst reconstruction during electrochemical reactions is a critical issue in catalyst design strategies. Here, we report a reconstruction-immunized catalyst system in which Cu nanoparticles are protected by a quasi-graphitic C shell. This C shell epitaxially grew on Cu with quasi-graphitic bonding via a gas-solid reaction governed by the CO (g) - CO_2 (g) - C (s) equilibrium. The quasi-graphitic C shell-coated Cu was stable during the CO_2 reduction reaction and provided a platform for rational material design. C_{2+} product selectivity could be additionally improved by doping *p*-block elements. These elements modulated the electronic structure of the Cu surface and its binding properties, which can affect the intermediate binding and CO dimerization barrier. B-modified Cu attained a 68.1% Faradaic efficiency for C_2H_4 at -0.55 V (vs RHE) and a C_2H_4 cathodic power conversion efficiency of 44.0%. In the case of N-modified Cu, an improved C_{2+} selectivity of 82.3% at a partial current density of 329.2 mA/cm^2 was acquired. Quasi-graphitic C shells, which enable surface stabilization and inner element doping, can realize stable CO_2-to-C_2H_4 conversion over 180 hours and allow practical application of electrocatalysts for renewable energy conversion.

Evaluation of Catalytic Activity and Durability of Pt/Carbon-Sphere Catalyst in Acidic Environment Takahiro Saida, Yuto Nohara and Takahiro

Maruyama; Meijo University, Japan

Polymer electrolyte fuel cell (PEFC) is expected to the next generation power sources, but its high cost and low service life are inhibited the wide-spread commercialization. In particular, the platinum utilization and the durability of the carbon supported platinum (Pt/C) used as cathode catalyst are big problems for PEFC. To improve the catalyst activity and durability, many researchers have developed the new catalyst nanoparticle. However, the development of catalyst support is not enough in comparison with the catalyst nanoparticles. In general, the activated carbon, which has a high surface area, is employed as the catalyst support to realize the high dispersion supporting of catalyst nanoparticles. However, the activated carbon leads to the low platinum utilization by its high substance diffusion resistance attributed to the complex pore structure. And the functional groups on the surface conduces to the carbon corrosion. Graphitized carbon is well known as one of the high corrosion tolerance carbon materials. But it is hard to disperse catalyst nanoparticles highly due to the low surface area of the graphitized carbon. When developing the new catalyst support, it is necessary to consider the balance between the catalytic activity and the carbon-corrosion tolerance.
We developed the carbon-sphere composing with the reduced graphene oxide (rGO) wall and SiO_2 core as a new familiar of carbon materials [1]. The carbon-sphere is expected to have low substance diffusion resistance due to its simple pore structure compared to conventional carbon. Previous reports indicate that the rGO trends to disperse the platinum nanoparticles highly [2-8]. Thence, the carbon-sphere developed by our group can be expected to balance the catalytic activity and the carbon corrosion tolerance. In this study, the carbon-sphere supported platinum (Pt/CS) was synthesized and evaluated the oxygen reduction reaction (ORR) activity and durability.
Carbon sphere was prepared as previously reported. [1] Pt/CS was synthesized by an impregnation method. Morphology, crystalline structure and electronic state of Pt/Carbon-sphere were observed SEM, XRD, and XPS. The electrochemical measurement was conducted by the rotating disk electrode (RDE) method.
The morphology of Pt/CS was maintained to the uniform sphere shape. The presence of Pt was confirmed by XRD, SEM and XPS. The platinum particle size on CS was around 5 nm. The ORR activity of Pt/CS was higher than that of a commercial catalyst (TEC10E50E, TANAKA KIKINZOKU KOUGYOU). After the durability test, the activity of Pt/CS remained about 50% of the initial state, although a commercial catalyst showed almost no activity. We concluded that Pt/CS could balance the catalytic activity and the carbon corrosion tolerance.

***In Silico* Design of Niobium Based MXenes for Acidic Electrocatalysis** Ebrahim Ghasemy, Kulbir K. Ghuman and Ana Tavares; Institut National de la Recherche Scientifique, Canada

MXenes, as the newest family of 2-dimensional materials, can pave the way toward passing the obstacles against developing novel energy materials. However, among different MXene compositions, negligible attention has been paid to Nb-based MXenes in electrocatalysis, where, Niobium possesses a high number of empty orbitals, providing more opportunities for properties engineering. In addition, various synthesis methods in exfoliating the Nb-based MAX phase can lead to the formation of different terminating groups, each of which can result in different catalytic properties. Up to now, no works have been devoted to perusing the role of terminating groups in varying the MXenes' electrocatalytic properties. Moreover, exploiting computational methods can facilitate the properties engineering of MXenes significantly, by which, the synthesis process can be optimized as a function of each catalytic reaction. In the presented work, by employing DFT calculations, the acidic and basic stability of Nb-based MXenes, terminated by F, S, Cl, FS, FCl, ClS groups, will be deciphered. Furthermore, the effect of each terminating groups on electronic properties and activity of the Nb2C Mxene will be revealed. Therefore, considering the descriptors of the electrocatalytic reactions, the suitablity of each Nb2C MXene in electrocatalysis will be studied.

Evaluating the Stability and Catalytic Reactivity of Binary and Ternary Molybdenum Chalcogenides Joseph Perryman; University of California, Davis, United States

The development of precisely tailored catalyst materials is predicated on a fundamental understanding of their composition-structure-function relationships. In this work, rapid micowave-assisted synthetic methods were employed to generate dimensionally controlled binary and ternary chalcogenide materials wherein compositional and structural variations modulated charge transport dynamics, interfacial reaction kinetics, as well as bulk and surface energetics. Through an interplay of synthetic materials chemistry, synchrotron X-ray spectroscopy analysis of electronic and atomistic structure, CO_2 reduction and hydrogen evolution electrocatalysis, as well as computational modeling, material design principles are established and the evolution of electrochemical reactivity is evaluated in order to gain fundamental insights into energy conversion and storage. Of note, catalytic performance metrics for the Chevrel-Phase $M_yMo_6X_8$ (M = alkali, alkaline, transition or post transition metal; y = 0-4; X = S, Se, Te) and Psuedo-Chevrel-Phase $M_2Mo_6X_6$ (M = alkali metal; X = S, Se, Te) composition spaces indicate that proton reduction overpotentials decrease significantly over M-X bridging sites with increased ionic character. Selective conversion of aqueous CO_2 to methanol and formate is also observed at mild applied potentials over metal-promoted Mo_6S_8 cluster frameworks, which is explored via electrochemistry as well as X-ray absorption spectroscopy in order to correlate frontier electronic structure with interfacial reactivity. Lastly, to further advance the discovery of new materials, we integrate a new feature regression machine learning methodology for extracting stability and synthesizability metrics for the expansive $M_yMo_6X_8$ composition space in order to expand the library of functional materials with applicaitons in energy conversion, energy storage, and electronic devices.

Extensive Benchmarking of Nonempirical DFT+*U* Calculations for Band Gap Predictions and Photocatalytic Materials Discovery Nicole Hall[1], Wayne Zhao[1], Yihuang Xiong[1], Iurii Timrov[2] and Ismaila Dabo[1]; [1]The Pennsylvania State University, United States; [2]École Polytechnique Fédérale de Lausanne, Switzerland

Molecular hydrogen is a sustainable energy carrier of primary interest to draw down carbon dioxide emissions and accelerate the transition to renewable modes of energy production for transportation, commercial, and residential applications. Photocatalytic materials use solar energy to split water and generate hydrogen, emitting oxygen as the only byproduct, but many of the known water-splitting photoactive semiconductors have limited solar-to-hydrogen conversion efficiency. We present a high-throughput screening protocol that was collaboratively developed to discover water-splitting

photocatalysts [1] and yielded 7 newly predicted photoactive materials from an initial set of 70,150 candidate materials from the *Materials Project* database [2]. We also provide a comparison of the computational and experimental data to test the validity of computational predictions using a Hubbard-corrected density-functional theory (DFT+*U*) approach, in which the *U* parameters are obtained self-consistently from density-functional perturbation theory to impose the piecewise linearity of the total energy with respect to the occupations of a subset of electronic states in the system (typically, of *d* or *f* character) [3]. By systematically comparing DFT+*U* results obtained using nonorthogonalized and orthogonalized atomic orbitals as Hubbard projectors for a representative set of 20 compounds containing transition-metal or p-block (group III-IV) elements, including oxides, nitrides, sulfides, oxynitrides, and oxysulfides, we find that the predicted band gaps are extremely sensitive to the type of projector functions and that the orthogonalized projectors give the most accurate band gaps. These results demonstrate that DFT+*U* may serve as a useful method for high-throughput workflows that require reliable band gap predictions at moderate computational cost.

Development of Three-Dimensional Boron-Doped Diamond Electrodes for (Photo)Electrochemical Reduction of CO_2 and Water Treatment in Water-Based Electrolytes Petr Ashcheulov, Simona Baluchova, Andrew Taylor, Marina Davydova, Joris More-Chevalier and Vincent Mortet; FZU – Institute of Physics of the Czech Academy of Sciences, Czechia

Electrochemical methods are currently seen as a promising approach to convert CO_2 into a variety of value-added chemical products such as formic acid, formaldehyde and carbon monoxide [1]. In addition, the electrochemical approach is commonly utilized for the removal of various contaminants/pollutants from wastewater [2]. However, for these processes to be efficient and economically viable, inexpensive and chemically robust electrodes with long operation life-time in harsh electrochemical conditions are required.

Recently, electrochemical reduction of CO_2 from the seawater and water-based electrolytes into various chemical products using boron-doped diamond (BDD) polycrystalline electrode has been reported [3]. In general, BDD electrodes are known for their superior chemical and mechanical characteristics, and such electrodes can be fabricated using chemical vapor deposition (CVD) techniques in a variety of forms (e.g. planar, porous) on different substrates and at different temperatures [4,5].

In this work, we fabricate nanocrystalline boron-doped diamond BDD electrodes of planar and porous (3D) geometries using the CVD method. Additionally, photoelectrodes based on Si solar cell absorber and BDD electrodes were constructed. We examine fabricated BDD electrodes for the (photo)electrochemical of CO_2 from the water-based electrolytes. Furthermore, fabricated BDD electrodes were utilized for the (photo)electrochemical treatment/degradation of organic pollutants (i.e. phenol) in water-based electrolytes.

This work has been supported by the Grant Agency of the Czech Republic (GACR) contract 19-09784Y.

Late News: C-N Triple Bond Cleavage via Trans-Membrane Hydrogenation Yuxuan Zhang and Nikolay Kornienko; University of Montreal, Canada

The renewable energy-driven valorization of excess feedstocks into commodity chemicals and societally useful products constitutes a longstanding push in energy and sustainability research. To this end, this work pushes to expand the scope of green electrosynthesis by innovating a new approach to convert acetonitrile, industrially generated in excess and burned off, to in-demand ammonia and acetaldehyde products. Success here was enabled through the use of a Pd-membrane based reactor which abstracted hydrogen atoms from water, which subsequently diffused through to a separate organic compartment in which they carried out the hydrogenation reaction. In this geometry, the reaction proceeded at 5.2 mA/cm^2 partial current density and 60% Faradaic efficiency towards ammonia generation. Further, the transmembrane hydrogenation approach gave rise to an onset potential of $0.2V_{Ag/AgCl}$, surpassing previous state-of-the-art systems by 0.7V. A customized infrared spectroelectrochemcal setup was built up to probe the mechanism of the reaction, which was shown to proceed through an imine hydrolysis-like pathway, with the hydrogenation of the NH_x species that remained to be the rate-limiting steps in the process. This work establishes a new route in electrochemical nitrile hydrogenation and general opens up promising avenues in green electrosynthesis.

5:50 PM EN11.14.08
Late News: Mechanism of Electrosynthesis of Amides by Coupling CO2 Reduction Reaction with Ammonia Junnan Li; Université de Montréal, Canada

CO_2 electroreduction reaction (CO_2RR) is a promising method to produce fuels or useful chemicals in a clean and sustainable way. Electricity can be derived from the conversion of other clean energy sources, such as solar or wind, and the extra electricity can be converted into chemical fuels and stored in the form of chemical bonds. The consumption of CO2 can also release greenhouse effect, thus this reaction has the potential to solve energy crisis and environmental problems. Varies of products (carbon monoxide, methanol, methane, ethanol, ethylene, n-propanol) can be produced by CO_2RR, but products with heteroatoms like acetamide or urea are more valuable than these products. Recently, nitrogen source (such as N2 or ammonia) was added into CO2RR system and products with C-N bonds was obtained, but the mechanism of the formation of C-N bonds is still unclear.
Herein, we combine electrochemical method with in-situ spectroscopy to reveal the intermediate of the reaction, and propose the possible reaction pathways. Cu or CuO nanoparticles (NPs) commercial powder was used as electrocatalyst, CO_2 and NH_4OH was used as the precursor, acetamide and formamide was observed as the final products with heteroatom. Electrolysis experiment shows that formamide is preferential to be formed on Cu catalyst, while CuO is more likely to produce acetamide. The faradaic efficiency (FE) is maximum for the formation of acetamide at -1.8V, which is 0.63%. While for Cu, the formation of formamide reach maximum (3.78% FE) at -2.0V. As the formation of acetamide and acetate share the same intermediate, the production of formamide and formate may also undergo the same reaction pathway at the initial stage of the reaction. In-situ infrared (IR) spectroscopy was conducted to prove this speculation.

5:55 PM EN11.04.07
III-V Core/Oxide Shell Nanowires for Light-Driven Water Splitting Thomas Dursap[1], Philippe Regreny[1], Cristina Tapia Garcia[2], Mariam Fadel[2], Céline Chevalier[3], Nicolas Chauvin[3], Michel Gendry[1], Alexandre Danescu[1], Matthieu Koepf[2], Vincent Artero[2], Matthieu Bugnet[4] and José Penuelas[1]; [1]Univ Lyon, CNRS, INSA Lyon, ECL, UCBL, CPE Lyon, INL, UMR 5270, France; [2]Univ Grenoble Alpes, CNRS, CEA, IRIG, Laboratoire de Chimie et Biologie des Métaux, France; [3]Univ Lyon, INSA Lyon, ECL, CNRS, UCBL, CPE Lyon, INL, UMR 5270, France; [4]Univ Lyon, CNRS, INSA Lyon, UCBL, MATEIS, UMR 5510, France

Photoelectrochemical cells (PEC) are one of the most promising approaches for the production of alternative energy carrier in the global effort to diminish the usage of fossil fuels[1]. In this context, III-V nanowires (NW) based photoelectrodes[2] are particularly attractive thanks to their high surface/volume ratio and their efficient charge separation and collection. However III-V NWs suffer from corrosion in aqueous electrolyte that prevents their utilization for long period. In order to avoid the surface degradation of the III-V NW under working conditions, a particular attention has to be given to their surfaces. We proposed to grow an oxide shell transparent to visible light and compatible with the carrier transfer from the III-V semiconductor to the electrolyte to increase the viability of these photoelectrodes.
GaP and GaAs NWs were grown by molecular beam epitaxy (MBE) using the vapor-liquid-solid (VLS) mechanism on silicon substrate and a TiO_2 shell was deposited by atomic layer deposition (ALD). The morphology, interface, and structure of the NWs were studied by scanning transmission electron microscopy and electron energy loss spectroscopy before and after the measurements of their photoelectrochemical activity after combination with suitable hydrogen or oxygen evolution catalysts.[7]

Insight Into the Synergy Between Metal Transition Phosphide and the Carbonaceous Based Support for High Current Density Hydrogen Production Maria Isabel D. Garcia[1], Sebastian Murcia[1], Mohammad Qamar[2] and Joan Ramon Morante[1]; [1]Institut de la Recerca de la Energia de Catalunya, Spain; [2]King Fahd University of Petroleum & Minerals, Saudi Arabia

There are needs for finding anodic and cathodic electrocatalysts having high efficiencies and durability based on abundant, environmentally friendly materials and low-cost materials. Among the electrode materials fulfilling these requirements, iron phosphide has engaged interest in the last years as electrocatalyst in the cathode. It is composed of two elements highly abundant in the Earth's crust and the synthesis routes are making this catalyst simpler and cheaper. Nevertheless, aside of these performances, support's microstructure is also critical in determining the catalytic activity, selectivity and overall energy efficiency of the supported catalytic nanoassemblies. In this work, ultrathin interconnected carbon nanosheets (CN) are prepared and used as robust support for dispersion of iron phosphide (FeP) nanoparticles, and the resulting catalytic system is evaluated as a low-cost electrocatalyst for hydrogen evolution reaction (HER). A different approach consists of the direct deposition of FeP on the carbonaceous substrate composed by carbon microfibers. Firstly, intermediate iron species are deposited and then, they are converted to FeP by in situ PH_3 generation at 300-400 ºC. In both cases, high coverage of the substrate is achieved as observed by SEM. The electrochemical current density-overvoltage curves for HER will be evaluated in both acidic and alkaline electrolytes. The differences between both approaches in terms of reference overpotentials at different low, medium and high current density values and stability tests under cathodic conditions will be addressed. Electrodes under the most outperformed conditions have been tested in a flow cell using a cation exchange membranes (CEM) or anion exchange membranes (AEM) to evaluate the feasibility of the cathodes for HER in continuous operation and the obtained data will be discussed according to the employed support material characteristics.

8:15 AM EN11.15.05
Bimetallic Transition Metal Material as Robust Anode for Oxygen Evolution Reaction Maria Isabel D. Garcia[1], Guillem Montaña[1], Marc Botifoll[2], Andreu Cabot[1], Jordi Arbiol[2] and Joan Ramon Morante[1]; [1]Institut de la Recerca de la Energia de Catalunya, Spain; [2]Institut Català de Nanociència i Nanotecnologia (ICN2), Spain

Catalytic materials employed in both half-reactions of the water splitting must have high electrocatalytic activity and low Tafel slope for lowering the applied voltage to the electrochemical cell and long-term stability for the durability of the device vanishing the degradation mechanisms. Additionally, these catalyst materials must be composed by Earth-abundant elements and the synthetic route should be cheap and scalable for industrial production. In general, OER required higher overpotentials than HER, then mostly contributing to the required applied voltage in practical devices. Although Ir/Ru oxides have demonstrated good performance for OER, there is a need for research in cost-effective materials that could compete with the precious metal-based catalysts for OER in order to reduce electrode fabrication costs. Cobalt and iron elements have been reported as electrocatalysts active centers enhancing OER. In this work, we investigate the use of CoFeP nanoparticles to obtain ultra-disperse CoFeP particles supported on metallic foam. It allows achieving high current densities with lower overpotentials as the prepared electrode are showing a low Tafel slope. Under operando conditions for OER in alkaline media, chemical species are found to be different from the ones present in the freshly prepared electrode due to the reactivity of the electrodic material under anodic conditions. Nonetheless, after few initial minutes, the electrodes were stable for long-time tests under anodic currents. A deep analysis is performed for identifying the electrochemically active species for OER in alkaline media by XPS, TPR and IR spectroscopy and their functional role discussed taking into account the initial composition of the freshly prepared catalyst.

Designing Electrocatalytic Devices Across Multiple Length Scales from Atom to 3D Integration Yi Cui[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

Some of the most important electrocatalytic reactions related to clean energy often involves gas reactants or products, including CO_2, H_2, O_2, N_2 mixed with liquid electrolyte and solid catalysts. The efficient electrocatalytic systems need to consider multiple length design from the atomic scale to 3D electrode integration. Here I will present key results from my lab, including: 1) Atomic design and understanding of catalysts for improving catalytic reaction selectivity and throughput; 2) Tuning the activity of catalysts by lithium ion interaction; 3) A novel concept of self-selective catalyst (SELF-CAT) to rapidly identify the proper catalyst for a certain chemical reaction by having the target reaction itself select its own catalyst. 4) 3D electrochemical concept to optimize the electron and mass transport involving three-phase reactions.

Core–Shell Dendritic Superstructural Catalysts by Design for Highly Efficient and Stable Electrochemical Oxygen Evolution Reaction Yifei Liu and Donglei Fan; The University of Texas at Austin, United States

Efficient, stable, and low-cost oxygen evolution reaction (OER) catalysts are in great demand for the practical application of electrochemical water splitting for energy conversion and storage. This work reports a rationally designed and innovatively fabricated three-dimensional (3D) core-shell dendritically porous OER catalyst that exhibits outstanding and highly reproducible performance. The porous superstructure provides not only substantially enhanced loading capacity of electrochemical catalysts but also easy access of electrolyte to active catalysts. With a facile and designed sulfurization process followed by anodization, core-shell (FeCoNi)OOH@dendritic foam can be obtained and exhibits a remarkably low overpotential of 204.4 mV at a current density of 10 mA cm^{-2}, which are among the best of the reported FeCoNi OER catalysts. Such value is also highly reproducible and stable with over 18-hour operation time. This excellent performance could be attributed to the synergism of trimetal chemistry, the unique structure with metal/metal sulfide as the conductive core and (oxy)hydroxide catalysts as the active shell, and the enhanced superstructural surface area. This work points towards a synergistic way based on rational design and innovative fabrication for creating scalable, stable, low-cost, and high-performance OER catalysts.

10:45 AM EN11.16.03
Late News: Microfluidic Photoelectrochemical CO2 Based Reduction Using Perovskite Oxides and Their Nanocomposites José C. Zárate[1], Srinivas Godavarthi[2], Luis A. Ortíz[1], Jesús A. Díaz[1], Goldie Oza[1] and Clifford Kubiak[3]; [1]CIDETEQ, Mexico; [2]UJAT, Mexico; [3]University of California, San Diego, United States

CO_2 emissions have contributed largely to climate change (over 60%), negatively impacting the environment through its increase due to anthropogenic activities; its close relation to the energetic crisis, as a decrease in the supply of energy resources (oil shortage) and its economic impact, forces the search of sustainable and integral solutions. Transforming CO_2 (a very inert molecule with no direct use in the market) to value-added products (renewable fuels and other material precursors) is no easy task, as its reduction is thermodynamically and kinetically unfavored. Taking into consideration costs, mild reaction conditions, energetic requirements, and sustainability of the reaction system to be designed, photoelectrocatalytic (PEC) systems seem to be the pathway to follow towards environmentally-friendly reduction of CO_2; and microfluidic designs offer quite the advantages (lower energetic consumption, higher active surface equaling higher yields, and easier flow dynamics). Therefore a microfluidic PEC device for CO2-based reduction using $SrTiO_3$ based nanocomposites is proposed. As photocathodes, nanomaterials are a good choice as larger active surfaces mean greater catalytic activities, and perovskite oxides ($SrTiO_3$ NPs) are desired in novel PEC systems for their great stability, energy conversion, and low costs. Coupling with g-c3N4 NSs in order to generate a heterostructure enhances CO2 adsorption, and light absorption resulting in greater energetic conversion towards value-added products. The resulting hydrothermally synthesized composite (20% g-C_3N_4/$SrTiO_3$) has already shown enhanced photoelectrochemical activity, as well as adequate band gap (2.85 eV) and enhanced band alignment (E_{CB} -1.63 V vs. NHE) minimizing possible hydrogen evolution, and maximizing possible CO_2 reduction yield.

11:00 AM EN11.16.04
Late News: Linker Modulated Peroxide Electrosynthesis Using Metal-Organic Nanosheets Kirankumar Kuruvinashetti and Nikolay Kornienko; University of Montreal, Canada

Electrochemical oxygen reduction to peroxide has garnered significant interest as a green alternative to the conventional anthraquinone production process. Electrochemical synthesis offers potentially economical and environmentally friendly route to peroxide (H_2O_2) synthesis. The significant challenge in electrochemical oxygen reduction reaction is to have selectivity for peroxide production vs oxygen reduction to water by modulating the binding strength of intermediates. Herein linker modulated Ni-based metal-organic nanosheets (Ni-MONs) catalysts were investigated as catalysts for peroxide synthesis. The electronic structure of the Ni active sites was tuned by constructing analogous Ni-MONs with electron-withdrawing groups - fluorine (Ni-F-MON) and electron-donating groups such as (hydroxyl, amine) (Ni-OH-MON, Ni-Amine-MON) grafted onto their linkers. The electronic structure of the Ni active sites of the MONs was investigated through a series of electrochemical experiments and X-ray photoelectron spectroscopy measurements. Amongst the Ni-MONs studied, the Ni-MONs with an electron-donating group –hydroxyl and amine have demonstrated higher activity and selectivity. In a gas diffusion electrode set up with Ni-Amine-MON partial current density of 21.7 $mAcm^{-2}$ were obtained. Subsequently the system is scaled up to obtain the higher partial current density. Our interpretation is that modifying the Ni electronic structure modulates the binding energy to the *OOH intermediate and is thus the determining factor for H_2O_2 vs. H_2O selectivity in this system and electron-donating groups (hydroxyl and amine) linkers regulated the Ni catalytic activity. This study puts forward design principles towards attaining higher selectivity of electrosynthesis of H_2O_2 through rational modulation of catalytic sites.

11:15 AM *EN11.16.05
CO_2 Photoreduction Using Porous Amorphous Catalysts Giulia Schukraft[1], Ravi Shankar[1], Robert Woodward[2] and Camille Petit[1]; [1]Imperial College London, United Kingdom; [2]University of Vienna, Austria

Reshaping our energy portfolio considering the sustainability of global energy resources is central to the European Energy Roadmap 2050. Hence, researchers need to identify efficient routes towards solar fuels production. Unlike H_2 evolution, CO_2 photoreduction has been poorly studied. Given the

scope for CO_2 utilisation in a carbon-constrained future, there is an exciting opportunity to devote targeted research towards CO_2 photoreduction. Photocatalysis is one route towards CO_2 reduction. Yet, the design of a cost-effective, sustainable, efficient and robust photocatalyst remains a highly challenging task.

To date, the majority of studies on CO_2 reduction photocatalyst focuses on crystalline and non-porous materials, with TiO_2 remaining the 40-year old benchmark in the field. Yet, porous amorphous materials can present interesting photocatalytic features. The high surface area allows one to favour access to catalytic sites, tune the strength of adsorption/desorption of reactants/products and possibly control electronic transfer mechanisms. Scaling up amorphous materials synthesis can be easier than for crystalline materials.

Herein, we will discuss our recent work towards the development of CO_2 photoreduction catalysts that present both a porous and an amorphous character. We will highlight in particular our studies on boron nitride and hypercrosslinked polymers, two types of materials that do not involve any rare-earth metals. For both types, we show that the selective conversion of CO_2 into CO is possible under both UV and visible light. Using analytical and spectroscopic tools, we are starting to understand the mechanisms of reaction of these materials.

11:45 AM *EN11.16.06
Photoelectrocatalytic Biofilms for Solar Energy Conversion—A Sustainable Alternative to Bioenergy? Jenny Zhang; University of Cambridge, United Kingdom

Biohybrid systems for solar energy conversion have the potential to combine the strengths of artificial and natural regimes to overcome their respective limitations and deliver efficient electricity and chemical generation. Already, efficient biohybrid approaches exist that couple synthetic 'light' reactions to microbial 'dark' reactions for chemical synthesis. Could photosynthetic microbial 'light' reactions also be coupled to other dark reactions for alternative biohybrid regimes? In this talk, I will show our recent efforts to electrochemically wire into the photosynthetic electron transfer chain in vivo, thereby applying photosynthetic microorganisms as living photoelectrocatalysts. First, we investigate how electron flux from the photosynthetic pathway can be streamlined via exogenous mediators, then we use 3D-printing to design bespoke electrode interfaces that can address the complex needs of the biofilm-electrode interface to optimise photocurrent output. Overall, we will show how this is a more efficient and sustainable means of utilising photosynthetic materials compared to classical bioenergy conversion.

1:00 PM EN11.17.01
Design of Cu-Ni Based Alloys for Electrochemical Ammonia Production Parastoo Agharezaei and Kulbir K. Ghuman; Institut National de la Recherche Scientifique, Canada

Ammonia is highly used in the fertilizer industry, causing 1% of total GHG emissions. The design of proficient and low-cost catalysts is highly challenging for CO_x-free ammonia production. Alloying non-noble with noble metals is a good approach to obtain elevated catalytic activity. Ni-based materials are known to have a great potential to improve the catalytic activity by tuning the d-band center of Cu and enhance the adsorption energies of intermediate compounds. However, today's development in understanding this reaction remains inexplicable by the lack of a clear image of how catalyst structure can be altered to enhance its properties. This research provides further information on catalytic properties of Cu/Ni alloys for Nitrate reduction reaction (NO_3^- RR). Using Density Functional Theory (DFT), different compositions of Cu/Ni alloys are modeled. In order to further understand the NO_3^-RR mechanism, the energy path of the reaction along with the active sites, adsorption energies of reactants and intermediate compounds are investigated and compared in pure Cu and Cu/Ni alloys. This research paves the way for further development and design of economical bimetallic catalysts for NO_3^-RR.

Cobalt doped BiOCl Nano-Coins for Efficient N_2 Photo-Fixation Under UV-Visible Light without Sacrificial Reagent Mohammadjavad Mohebinia and Jiming Bao; University of Houston, United States

Photocatalytic ammonia production is an ideal solution to mitigate carbon dioxide emission in two different ways; firstly, by obsoleting the old Haber-Bosch-based factories and secondly, by storing clean hydrogen fuel in the form of ammonia. However, there is a long way to achieve these goals due to the inertness of nitrogen molecules and rapid recombination of the charge carriers in the photocatalyst nanoparticles. In this work, we have proposed a novel method to modify BiOCl nano-coins by cobalt doping for the photocatalytic nitrogen reduction reaction. The modified BiOCl nano-coins showed a notable photocatalytic NH_3 generation rate in pure water. The strong OER catalytic performance of nano-coins and boosted electron/hole separation efficiency, due to separation of NRR and OER active sites, allowed 4.6 times improvement of ammonia evolution rate. Thus, this study provides a blueprint for the development of new and practical photocatalysts for solar fuel production.

Highly Selective Ion Pumping for Product Specific Electrocatalysis Alon Herman, Eran Weil, Itamar Eyal and Gideon Segev; Tel Aviv University, Israel

Highly selective electrocatalysis is one of the key challenges impeding sustainable chemical and fuel production. However, the product distribution of CO_2 and N_2 reduction systems is extremely sensitive to the physical and chemical environment at which the reaction takes place. Thus, control of the electrolyte ionic content at the vicinity of the electrodes can enhance their selectivity towards the desired products. In this contribution we show that ion pumps based on a ratcheting mechanism can drive ions selectively. The integration of ratchet based ion pumps (RBIPs) with electrochemical devices may provide a necessary step for product specific electrocatalysis.
Flashing ratchets are devices that utilize temporal modulation of a spatially asymmetric electric field to drive a non-zero time averaged current. Electronic flashing ratchets have been demonstrated experimentally by pumping electrons through organic semiconductors. We have recently demonstrated experimentally first-of-their-kind ratchet-based ion pumps. RBIPs were fabricated by coating the two surfaces of nano-porous alumina wafers with gold forming nano-porous capacitors. The electric field within the nano-pores is modulated by oscillating the capacitors voltage. Thus, when immersed in solution, ions within the pores experience a modulating electric field resulting in ratchet based ion pumping.

An important hallmark of ratchets is the ability to invert the direction of particle flow with a change in the input signal frequency. The current inversion frequency, which is the input signal frequency at which the particle flux changes its direction, is determined by the potential distribution and particles transport properties. As a result, for a given ratchet, there can be a frequency at which particles with the same charge but different diffusion coefficients are transported in opposite directions resulting in particle sorting. This effect was used to sort gold nanoparticles and micron scale colloidal particles according to size and shape. In this talk we will show how this effect can be used to selectively pump ions in different directions according to their diffusion coefficients. Selective ion pumping may allow tuning the electrolyte content at the vicinity of the electrodes performing the electrochemical reaction independent of their potential thus providing another degree of freedom for the electrochemical process.

1:45 PM *EN11.17.06
Propsects and Challenges for Photoinduced Dinitrogen Fixation Marta Hatzell; Georgia Institute of Technology, United States

Reports of photocatalytic nitrogen fixation on various environmental and synthetic photocatalyst have surfaced for decades. Demonstrations have occurred in both the gas and aqueous phase, and with various reactants (oxygen, nitrogen, water, hydrogen). Nearly all experimental observations suggest that photocatalytic nitrogen fixation is possible at ambient temperature and pressure, and that nitrogen is converted to ammonia through a direct reduction process. This is impactful as it promotes the possibility for ammonia based fertilizer production from environmentally abundant materials using only the sun as a source of energy. This is in contrast with state of the art methods for ammonia production, which are energy and carbon intensive. Despite this promise, there is lack of molecular-scale understanding on how this reaction proceeds, with the reaction pathway and active sites still largely misunderstood.

Given the growing interest in this field, it is critical to begin to demystify how this reaction proceeds through conducting fundamental studies aimed at observing molecular level processes. Thus the main goal of this presentation will be to outline what molecular-scale processes which may allow for nitrogen fixation to proceed on titania. We will provide an overview of a new reaction pathway which was observed through the use of advanced spectroscopy (XPS, IR Spectroscopy, EPR), and electroanalytical testing. Furthermore, we will highlight the role catalyst design may play in enabling aerobic nitrogen fixation. Finally, we will end on discussing the economic and systems related challenges which must be overcome to transition toward a real technology.

High-Throughput Electrochemical Characterization of Multi-Element Catalysts Olga A. Krysiak, Lars Banko, Alfred Ludwig and Wolfgang Schuhmann; Ruhr University Bochum, Germany

Electrochemical processes play an essential role in energy conversion reactions inevitable for the mitigation of climate change. To make these processes at the same time efficient, cost-effective and as climate-neutral as possible new catalysts are needed. One of the approaches in catalyst discovery is combining multiple chemical elements. Adjusting the configuration (i.e., which elements) and composition (i.e., the ratio of elements) allows tailoring the final material's properties. There are about 50 chemical elements that are available for the development of novel and sustainable catalysts (i.e. elements, which are abundant, non-radioactive, and non-toxic). If, for example, five of these potentially plausible elements are combined, there are more than 2 million possible combinations, and this is without considering different ratios of the elements. The various combinations lead to diverse electrochemical properties, making the material disparately suitable for a given reaction. Therefore, the challenge is to find a material from the large number of possible combinations that meets the given electrochemical requirements particularly well. This is like looking for a needle in a haystack, and testing many catalysts usually requires serious investment in time and money. Considering the number of possible compositions of new catalysts, which activity cannot be predicted, finding and synthesizing new materials needs to be coupled with high-throughput characterization to accelerate the discovery process. Speeding up the characterization process should not be accomplished by lowering the quality of measurements but by automatization and unsupervised operation.
Electrochemical characterization needs a three-electrode cell under potentiostatic control. In high-throughput processes, this is successfully realized with the use of a scanning droplet cell (SDC). The set-up consists of a positioning system, an electrochemical probe head and an electrolyte-delivery system controlled by the software. The electrolyte is replaced using a pump to the probe head after each measurement providing a fresh solution for reliable measurements. Reference electrode and counter electrode are built into the probe head. The working electrode is created on the sample by the tip, and its surface area is defined by the tip opening size and can be as small as 0.8 mm^2.
High-throughput screening of materials libraries by means of SDC was successfully used to discover novel complex solid solution electrocatalysts, e.g. (TiNi)-Cu-Hf-Pd-Zr, in an unconventional search space.[1] Introducing unusual elements allows the discovery of catalytic activity for hitherto unknown compositions. Moreover, it was shown that material libraries with very similar composition spreads could show different activity vs composition trends for different reactions. A combination of high-throughput experimentation with theoretical prediction led to identifying the optimal composition of Ag-Ir-Pd-Pt-Ru complex solid solution electrocatalyst.[2] Unsupervised machine learning together with high-throughput experimentation applied to the Rh-Ir-Pd-Pt-Ru system, revealed that electrochemical activity is governed by the complex interplay of chemical and structural factors.[3] Results obtained from high-throughput experimentation are crucial input data for future data-driven materials discoveries and will be shown in this contribution.

Late News: Unlocking the CO2 Electrolysis to Multicarbon Products via Supersaturation Strategy Kun Qi, Yang Zhang, Huali Wu and Damien Voiry; Institut Européen des Membranes, France

The fast-increasing atmospheric carbon dioxide (CO_2) concentration is a critical challenge for human society. In the quest for developing techniques for carbon neutrality and CO_2 utilization, electrochemical reduction offers a potential route for the conversion of CO_2 into value-added chemicals and fuels is of interest to close the carbon cycle. While active and selective catalysts for CO_2 reduction to the C_1 product have been developed and shown economic output potentials over the past few years, the formation of multi-carbon (C_{2+}) products at industry-relevant rates remain challenging.
Among the transition metals, copper-based catalysts are the only candidates able to generate C_{2+} products at significant rates. However, the use of copper is still hampered by poor selectivity towards high-value and high-energy-density multicarbon chemicals with 3 or more carbons (C_{3+}). Besides, the most restrictive parameter for CO_2 mass transport resides in its aqueous solubility, which plagues the electrocatalytic performance of the catalysts. From a mechanical point of view, during the CO_2RR, the *CO intermediate has been identified as a key intermediate involved in the C-C coupling to produce multicarbon hydrocarbons and oxygenates. The moderate coverage of *CO on the surface of the catalyst was also found to be beneficial for the CO_2RR into C_{3+} products.
Herein, we report a co-deposition method using CO_2 as a surfactant for the growth of Cu-Ag alloy catalyst on the electrode. The use of CO_2 during the deposition protects the alloy and avoids the aggregation of Ag on the catalyst surface. Our *operando* Raman measurements revealed that the peculiar alloy structure of the catalyst gets rapidly covered with *CO on the bridge and atop sites, which translates in a record-high selectivity for the 2-propanol (C_3H_8O)

of 57.61 % at a partial current density of 59.33 mA cm^{-2}. We finally report retentions of both the Faradaic efficiency and the current density for C_{3+} of 98.3 % and 97.5 %, respectively for 200 hours.

SESSION Tutorial EN12: Emerging Tools for Battery Technologies—Cost, Materials and Performance Analysis and Prediction
Session Chairs: Weiyang Li, Giuliana Materzanini and Stefano Passerini
Monday Morning, November 29, 2021
Virtual

8:30 AM
A Cost and Resource Analysis of Lithium/Sodium-Ion Batteries Stefano Passerini; Karlsruhe Institute of Technology, Germany

In this tutorial, I will review the use a Battery Performance and Cost model to undertake a cost analysis of the materials for sodium-ion and lithium-ion cells, as well as complete batteries, and determine the effect of exchanging lithium with sodium, as well as the effect of replacing the material used for the anode current collector foil, on the cost. Moreover, I will compare the calculated production costs of exemplary sodium-ion and lithium-ion batteries and highlight the most relevant parameters for optimization. Finally, the major raw materials for lithium-ion cathodes will be examined in terms of potential supply risks because supply issues may lead to increased costs. Through the use of a scenario-based supply and demand analysis, the risks to the supply of lithium and cobalt will be assessed, and implications for battery research will be discussed.

10:00 AM BREAK

10:15 AM
Ab Initio Techniques in Li-Ion Battery Materials—Addressing Ionic Diffusion Giuliana Materzanini; Université Catholique de Louvain, Belgium

In the last two decades, Li-ion batteries have proven to offer some of the best performance among the existing electrochemical energy storage technologies, striving to firm variable renewable generation and mass-market full electrification. A Li-ion battery cell exploits the redox activities of the anode and cathode to generate electricity outside the cell while reversibly intercalating Li ions between the two electrodes through an ionic conducting electrolyte. The difference in electrochemical potential between the electrodes is the thermodynamical driving force of the cell, while its rate capability is governed by the kinetics of the ion transport in the electrodes and in the electrolyte. Ab initio techniques, relying on the knowledge of the physical laws without the need of experimental inputs, provide insight onto the materials' electronic and structural properties, and shed light onto the dynamical processes that underlie the battery performance. Calculation of intercalation potentials, pre- diction of electrochemical, chemical and phase stabilities, study of dissolution and diffusion phenomena in the electrolytes and electrodes, and characterization of mechanical properties are a few examples of the various applications of the state-of-the-art ab initio approaches for the modelling of battery materials. In this tutorial, we provide an overview of the ab initio methods to study ionic diffusion in battery materials. First, we discuss the simulation approaches to probe the dynamic evolution of a system of atoms via the quantum mechanical potential, namely the Born-Oppenheimer and the Car-Parrinello first-principles molecular dynamics (FPMD) techniques. Thus, the extraction of the diffusion coefficients from the sampled trajectories according to the Green-Kubo relation is described, together with the role of ionic correlations in these systems (tracer/charge diffusion coefficient), and the use of the Nernst-Einstein equation to compute the ionic conductivity from the diffusion. To conclude, we present few benchmark cases from the recent literature and we discuss intrinsic 1 limitations together with recently proposed solutions, as the use of ab initio molecular dynamics in conjunction with machine learning, to give reliable ambient temperature diffusion coefficients that can be directly compared with the experiments.

SESSION EN12.01: Metal Batteries I
Session Chairs: Dominic Bresser and Weiyang Li

10:30 AM *EN12.01.01
Microstructural Design Principles for Achieving Stable Electrochemical Interfaces for Metal Anodes David Mitlin; The University of Texas at Austin, United States

Lithium metal battery systems (LMBs) are being sought as an ultimate replacement to LIBs, potentially increasing the cell energy by over fifty percent due to the high capacity and low voltage of the metal anode. Analogous improvement in energy is possible with sodium metal batteries (NMBs) and with potassium metal batteries (KMBs), where existing ion insertion anodes can be replaced by plating/stripping metal. However, in all three cases safety and performance are compromised by an unstable solid electrolyte interphase (SEI) that consumes metal ions and electrolyte, and ultimately leads to dendrites. This presentation provides a series of case studies derived from the group's LMB, NMB and KMB research on the microstructural design principles that provide for long-term cycling and fast-charge stability of metal anodes. The approaches may be categorized as the following: a) design of plating/stripping supports and templates with tuned geometry and functionality; b) design of secondary interlayers placed between the metal anode and the separator; and c) design of multifunctional hybrid separators to replace the conventional polymer separators employed with LIBs. It is demonstrated that despite appearing distinct, the efficacy of each in enabling electrochemical stability originates from three fundamental features that are directly interrelated. The wetting behavior of the electrolyte on the anode must be optimized, the wetting/stripping behavior of the metal anode on the current collector must be controlled, and a geometrically and chemically modified SEI must be established. Simultaneously achieving all three leads to stable plating/stripping, while missing even one leads to rapid dendrite growth. Cryogenic FIB cross sections and cryo-TEM are combined to yield new insight regarding film wetting behavior and early dendrite formation in optimized versus baseline specimens, analyzing growth in several representative electrolytes.

11:00 AM EN12.01.02
Iterative Solvent Molecule Tuning for High-Performance Lithium Metal Battery Electrolytes Zhiao Yu, Jian Qin, Yi Cui and Zhenan Bao; Stanford University, United States

Electrolyte engineering has enabled improved cycling of Li metal batteries and anode-free cells at low current densities; however, fast ionic conduction and high-rate capability are desirable yet less-studied. Meanwhile, the understanding of tuning ionic transport in advanced electrolytes is still lacking. Herein, we iteratively design and synthesize a family of fluorinated-1,2-diethyoxyethanes (fluorinated-DEEs) as electrolyte solvents. The position and amount of fluorine atoms functionalized on the DEE were found to significantly impact Li cyclability, oxidative stability, and ionic conduction. The partially-fluorinated, locally-polar $–CHF_2$ is identified as the optimal group rather than fully-fluorinated $–CF_3$ in common designs. Paired with 1.2M LiFSI, these developed single-salt-single-solvent electrolytes simultaneously enable high conductivity, low and stable overpotential, >99.5% Li || Cu efficiency (up to 99.9%), and fast activation (Li || Cu efficiency >99.3% within two cycles). Combined with high-voltage stability, these electrolytes achieve ~200 cycles in thin-Li || high-loading-NMC811 full batteries and >140 cycles in fast-cycling Cu || microparticle-LFP pouch cells under realistic testing conditions, which stand among the state-of-the-art. The correlation of Li ion–solvent coordination, solvation environments, and battery performance is investigated. Our electrolyte design and systematic study point out the path towards practical Li metal batteries.

11:15 AM EN12.01.03
Ultra-Low Temperature Li Metal Batteries Enabled by Highly Resilient Solid-Electrolyte Interphase Yiwen Zhang and Weiyang Li; Dartmouth College, United States

One of the key challenges in the development of energy storage devices is the ability to operate efficiently under extremely cold environments (i.e. below -20 °C), especially for batteries in temperature-sensitive applications such as portable electronic devices, transportation, and stationary energy storage. As reported, at low temperature, the increased internal resistance and sluggish ion diffusion in batteries lead to declined charge-delivering capability, which deteriorates cell performance and eventually terminates the power output. Although lithium (Li) metal battery (LMB) with ether electrolyte is considered promising in overcoming these issues due to the low viscosity of ether solvent and its distinctive electrode structure, the low-temperature performance of LMBs remains unsatisfactory. A series of problems are observed upon the anode-electrolyte interphase, including aggravated side reactions, abnormal Li deposition, and dramatically increased solid-electrolyte interphase (SEI) resistance. Thus, building a stable SEI layer on the Li metal anode is critical for the development of low-temperature LMBs.
Here, we demonstrate a dioxolane (DOL)-based electrolyte with dimethyl sulfoxide (DMSO) as the low-temperature additive, which helps to construct a robust SEI layer that possesses uniform structure and good composition consistency even under extremely cold condition. In this electrolyte, DOL works as the primary electrolyte component that defines the basic electrochemical properties, while DMSO further tunes the SEI composition to boost the low-temperature performance. To elucidate the modified microstructure and chemical composition of the SEI film, cryogenic transmission electron microscopy, X-ray photoelectron spectroscopy, and energy-dispersive X-ray spectroscopy are conducted to make a comprehensive investigation. Moreover, a series of electrochemical tests are conducted under extremely cold environments, and results demonstrate that the adjusted SEI is resilient to the stripping and plating cycles of Li metal at temperatures as low as -80 °C. Full cells with lithium iron phosphate as the cathode material are assembled and good electrochemical performance is achieved at -40 °C at 0.2 C. The solvation structure of DMSO added electrolyte is also investigated to fundamentally understand how it affects the SEI formation. Our work establishes fundamental insights into the low-temperature electrolyte additives and paves the road to the further applications of LMBs in harsh environments.

11:30 AM EN12.01.04
Accelerating the Electrochemical Kinetics of Sulfur Intermediates in Lithium-Sulfur Batteries Fang Liu[1], Geng Sun[2], Bruce S. Dunn[2], Philippe Sautet[2] and Yunfeng Lu[2]; [1]Stanford University, United States; [2]University of California, Los Angeles, United States

The sluggish electrochemical kinetics of sulfur species has impeded the wide adoption of lithium-sulfur battery, which is one of the most promising candidates for next-generation energy storage system. Here, we present the electronic and geometric structures of all possible sulfur species and construct an electronic energy diagram to unveil their reaction pathways in batteries, as well as the molecular origin of their sluggish kinetics. By decoupling the contradictory requirements of accelerating charging and discharging processes, we select two pseudocapacitive oxides to enable the efficient transport of electron/Li^+ to and from sulfur intermediates respectively. After incorporating pseudocapacitive oxides, the electrochemical kinetics of sulfur cathode is significantly accelerated by a factor of 5 times and 1.8 times, respectively. This strategy, which couples a fast-electrochemical reaction with a spontaneous chemical reaction to bypass a slow-electrochemical reaction pathway, offers a solution to accelerate an electrochemical reaction, providing new perspectives for the development of high-energy battery systems.

SESSION EN12.02: Metal Batteries II & Na-Ion Batteries

1:30 PM *EN12.02.01
Rational Design of Multivalent Metal Batteries—Enolization Cathode and Nonporous Separator Yan Yao; University of Houston, United States

Batteries based on multivalent metals have the potential to meet the future needs of large-scale energy storage. However, the complexity of multivalent metal-ion chemistries has led to technical challenges. Mg^{2+} interacts strongly with electrolyte solutions and cathode materials, leading to sluggish ion dissociation and diffusion, and consequently low power. With better understanding of electrolyte-electrode interactions and recognizing the strong influence of electrolyte solutions on cathode storage mechanism, fast Mg^{2+} storage could be realized by combining a highly performing single salt electrolyte and heterogeneous enolization redox chemistry in a Mg battery that delivers a specific power nearly two orders of magnitude higher than that of state-of-the-art Mg batteries. In a separate work, we studied zinc plating/stripping behavior in the presence of porous and nonporous separators. We find that adoption of porous separators results in directional metal penetration upon plating and “dead zinc” formation upon stripping. Using a nonporous separator, zinc plating/stripping was limited beneath the separator. The uniform ion flux generated by intermolecular solvent channels leads to a dense and uniform metal deposition morphology and reversible stripping. These results emphasize the microstructure of separators can serve to stabilize metal and provide guidelines for developing novel separators for long-cycle-life aqueous zinc batteries.

2:00 PM EN12.02.02
Bifunctional Surfactants as Electrolyte Additives for High Performance Sodium Metal Anodes Jianmin Luo, Weiyang Li and Yiwen Zhang; Dartmouth College, United States

Sodium (Na) based batteries are the promising alternative to Li-ion batteries due to the similar physical and chemical properties between Na and Li, as well as the natural abundance and therefore low cost of Na resources. Among all possible anodes for Na batteries, Na metal anode exhibits exceptional advantages because of its high theoretical capacity (1166 mAh/g) and low redox potential (-2.71 V vs. SHE). However, highly reactive Na metal anodes suffer from rapid electrode degradation and short-circuit related safety issues caused by the formation of unstable and fragile solid electrolyte interphase (SEI) and dendritic Na growth. Herein, we present a bifunctional and inexpensive electrolyte additive, hexadecyl trimethylammonium bromide (CTAB) that provides a synergistic effect to stabilize Na metal anode from CTA^+ cation and Br^- anion. Previous study on Li metal anode indicated that cationic surfactant used as an electrolyte additive could suppress Li dendrites growth by the role of lithiophobic surfactant cations, whereas the anions are ineffective on the anode protection**.** However, in this work, **we discovered that the cation CTA^+ and anion Br^- can work synergistically to enhance the stability and electrochemical performance of Na metal anode**. Specifically, sodiophobic CTA^+ can be absorbed onto the Na protuberant areas of the Na metal surface by electrostatic forces, which promotes preferential deposition of Na to surrounding regions by sodiophobic repulsion mechanism, thereby enabling uniform Na plating. More promisingly, Br^- anions can facilitate the formation of a stable NaBr-rich SEI layer, which has been confirmed by the cryogenic transmission electron microscopy (**Cryo-TEM**). The NaBr-rich SEI layer exhibit low energy barrier for Na^+ transport, which restrain the propensity of dendrite nucleation. We show that with the addition of 5 mM CTAB in the electrolyte, a superior electrochemical performance of Na metal anode with high areal capacity (**up to 30 mAh/cm^2**) and high current density (**up to 8 mA/cm^2**) can be achieved over long-term cycling for **800 h**. As a proof of concept, the constructed Na-S full cell delivers high performance with a **high cathode loading of 4 mg/cm^2**.

2:15 PM EN12.02.04
Low-Temperature Liquid Metals for Next-Generation High-Energy-Density Energy Storage Applications Driven by Interfacial Chemistry Study Xuelin Guo and Guihua Yu; The University of Texas at Austin, United States

Rapidly developing technologies call for sustaining, safe, and cost-efficient rechargeable energy storage devices for portable electronics and electrical vehicles beyond traditional lithium-ion batteries. Alkali metal batteries allowing high battery voltages and high electrode capacities are intensively studied aiming to fulfill this increasing need of efficient energy storage, whereas the dendrite issue as well as interfacial issues are threating the battery safety, limiting the battery performance, and therefore being hindered in commercialization. Low-temperature liquid metals including mainly fusible alloys are considered as promising alternatives of alkali metals as anode materials thanks to their dendrite-free or self-healing features, as well as superior mechanical and electrochemical properties. Beside the dendrite-free feature, liquid metals could also promise coherent electron and ion conduction at the interfaces in a battery. As another one of the competitive high-energy-density battery components, the solid-state electrolytes have been suffering from the poor interfacial contact, which could potentially be solved by the conformal liquid metal electrodes. Since multiple species of elements can be obtained in a liquid alloy, the interfacial charge selection behavior with various interfaces is an interesting and crucial designing principle that needs further study for deeper understandings. With deeper understanding of the interfacial behaviors and rational designs of battery, liquid metals can promise a bright future for next-generation high-energy-density and safe energy storage applications.

2:30 PM EN12.02.05
Gel Polymer Electrolytes Based on Cross–Linked Poly(ethylene glycol) Diacrylate for Calcium–Ion Conduction Shreyas Pathreeker, Saeid Biria, Francielli S. Genier, Fu-Hao Chen, Hansheng Li, Cameron Burdin, Paul A. Chando, Nannan Ding and Ian Hosein; Syracuse University, United States

Calcium batteries are promising alternatives to lithium batteries owing to their high energy density, comparable redox potential, and Earth abundance. However, to meet practical demands in high-performance applications, suitable electrolytes are required, which, for Calcium batteries remains a challenge. Here, we report the synthesis and characterization of poly(ethylene glycol) diacrylate (PEGDA)–based gel electrolytes using calcium salts in a mixture of ethylene carbonate (EC) and propylene carbonate (PC) solvents. We report room-temperature conductivity between 10^{-5} and 10^{-4} S/cm, an electrochemical stability window of ~3.8 V, full dissociation of the salt, and minimal coordination with the PEGDA backbone. Cycling of symmetric Ca metal cells using this gel electrolyte proceeds but with increasing overpotentials, which can be attributed to interfacial impedance between the electrolyte and calcium surface, which inhibits charge transfer. Calcium may still be plated and stripped yielding high-purity deposits and no indication of significant electrolyte breakdown, indicating that high overpotentials are associated with an electrically insulating, yet ion-permeable solid electrolyte interface (SEI). This work provides a contribution to the study and understanding of polymer gel materials toward their improvement and application as electrolytes for calcium batteries[1].

2:45 PM EN12.02.06
Interfacial Chemistry of Nanoscale Sodium-Ion Solid State Batteries Fabricated by Atomic Layer Deposition Ramsay B. Nuwayhid, Alexander C.

Kozen, David Stewart, Gary Rubloff and Keith Gregorczyk; University of Maryland, United States

Lithium-ion batteries (LIBs) dominate today's renewable energy storage market, however increasing energy storage demands will require use of more abundant materials in order to keep cost under control. Sodium-ion batteries (SIBs) are considered a promising route given its vast abundance but they suffer worse reactivity issues than LIBs. Developing all solid state Na ion batteries (SSBs) is not only needed to ensure device safety but may be enabling for market entry. We propose, building on our architecture-based approach successful in solid-state LIBs[1], to solve the problems mentioned above. This approach uses nanoscale area enhanced topographies (i.e. nanopores, trenches, pillars, etc) to dramatically improve both energy and power density (areal and volumetric). Here we present initial steps toward expanding this concept into solid state Na systems.

We recently developed an atomic layer deposition (ALD) process for sodium phosphorus oxynitride (NaPON), analogous to the well-known lithium phosphorus oxynitride (LiPON) solid-state electrolyte (SSE). ALD NaPON exhibited an ionic conductivity of 2.5×10^{-6} S/cm at 80 °C, comparable to those of ALD fabricated Li^+ conductors and high enough to use in 3D Na-SSBs.[2] In this presentation, we will report on the underlying materials chemistry and challenges of fabricating the first thin-film nanoscale Na-SSB using an evaporated Na metal anode and an ALD V_2O_5 (30 nm) cathode, and offer direct comparisons to the analogous lithium-based devices.

V_2O_5 was chosen as the cathode material due to its success in thin-film LIBs and its capability to reversibly intercalate Na^+ up to a capacity of 235 mAh/g. Initial electrochemical analysis was conducted with NaPON-coated V_2O_5 vs. Na metal in liquid electrolyte cells. The observed redox chemistry suggests that V_2O_5 is sodiated to $Na_2V_2O_5$ during the NaPON ALD deposition. However, when NaPON-coated V_2O_5 is used with a liquid electrolyte, NaPON acts as a stable solid electrolyte interphase layer, extending cycling lifetime and reducing interfacial resistance. All solid-state device (Na/NaPON/V_2O_5) electrochemical characterization suggests further sodiation of the V_2O_5 cathode during the Na metal evaporation to a fully sodiated $Na_3V_2O_5$ state. We use TEM, ToF-SIMs, and XPS analysis to infer the underlying processing phenomena and the subsequent electrochemical effects on the Na-SSB. Unlike their sodium analogues, V_2O_5 remains unlithiated during ALD LiPON deposition and subsequent Li evaporation.[1] This finding highlights the nontrivial contrast between a Na/NaPON/V_2O_5 SSB to a Li/LiPON/V_2O_5 SSB, assembled identically except for the Li and LiPON (i.e. same deposition techniques).

3:00 PM EN12.02.07
Computational Investigation on the Role of Al Doping on $Na_2Mn_3O_7$ Cathodes for Enhanced Na-Ion Storage Yong-Seok Choi[1,2], Begoña Silván[3,2], Nuria Tapia-Ruiz[3,2] and David O. Scanlon[1,2,4]; [1]University College London, United Kingdom; [2]Faraday Institution, United Kingdom; [3]Lancaster University, United Kingdom; [4]Diamond Light Source Ltd., United Kingdom

Owing to its low-cost advantage, Na-ion batteries (NIBs) have been widely studied as a promising candidate competitive with conventional Li-ion batteries (LIBs) for large-scale applications. Nevertheless, the current energy-normalized cost of NIBs ($0.14/Wh^{-1}$) is more expensive than that of LIBs ($0.11/Wh^{-1}$)[1] and the development of high-capacity electrodes for NIBs are essential for future energy storage system. Of electrodes discovered to date, layered Na-Mn-O cathodes have attracted much attention due to its high specific capacity and operating voltage.[2] These materials commonly accommodate Na ions by the redox reactions between Mn^{3+} and Mn^{4+}, allowing large theoretical capacity (e.g. 244 $mAhg^{-1}$ for Na_xMnO_2). However, the Mn^{3+}/Mn^{4+} redox reaction necessarily accompanies with the Jahn-Teller distortion[3] that lowers the capacity retention, which hinders the use of Na-Mn-O-based cathodes.
One effective way to avoid the Jahn-Teller effect is to change the chemical composition; recent studies reported that $Na_2Mn_3O_7$ layered oxides can accommodate Na^+ ions without the Mn^{3+}/Mn^{4+} redox reaction and display improved cyclability.[4] In addition, introducing Al dopants is also known to be effective in soothing the Jahn-Teller effect.[5] In this context, the addition of Al dopants on $Na_2Mn_3O_7$ may enable the further enhancement in cathode performance. Still, the effect of Al dopants on $Na_2Mn_3O_7$ is yet to be elucidated. In this study, using density functional theory calculations, we performed a comparative study between pristine $Na_2Mn_3O_7$ and Al-doped $Na_{2.4}Al_{0.4}Mn_{2.6}O_7$ to analyse the effect of Al dopants on the cathode performance. Calculations suggest that the substitution of Al for Mn makes Na^+ ions to be inserted in various sites other than those in $Na_2Mn_3O_7$, resulting in smooth voltage profiles with improved capacity. Furthermore, owing to relatively high electronegativity of Al, the addition of Al dopants alters anionic redox reactions and associated structural changes of $Na_2Mn_3O_7$ upon charge. Based on above findings, we also discuss potential strategies for finding dopants that enable high performance sodium manganese oxide cathodes.

The Perspective of Multivalent Batteries Robert Dominko[1,2,3], Tjasa Pavcnik[1], Alen Vizintin[1], Sara Drvarič Talian[1] and Jan Bitenc[1]; [1]NIC, Slovenia; [2]University Ljubljana, Slovenia; [3]Alistore ERI, France

Magnesium, calcium and aluminum are promising elements for future low-cost batteries due to the attractive energy density of metals and possible application of metal anodes in battery cells. All three elements are highly abundant in the earth's crust whit homogenous distribution on the globe. They are considered sustainable elements for batteries used in renewal energy storage, contributing to the decrease of cell cost.
Besides the above-mentioned benefits, there are several challenges connected with stripping and deposition of the metals, with the appropriate electrolyte formulation compatible with the metal anode and potential cathode materials, with current collectors, the housing of the cell and with the choice of appropriate cathode materials. A combination of multivalent anodes with classical insertion cathodes typically results in low electrochemical activity, while much better activity can be obtained with cathodes that allow coordination redox reaction or conversion redox reaction. Among those, the highest applicability can be obtained with redox-active polymers and sulfur-based cathodes.
In this presentation, an overview of recent achievements in our group in the field of multivalent batteries will be discussed with a focus on the proper selection of battery components in order to achieve electrochemical properties attractive for commercialization.

A Liquid Metal as a Self-Healing Electrocatalyst to Surpass Shuttle Effect in Lithium Sulfur Batteries Saisaban Fahad and Akihiro Kushima; University of Central Florida, United States

Lithium sulfur batteries (LSBs) are a promising next generation energy storage technology due to their high theoretical capacity, low cost, and environmental friendliness surpassing that of current lithium ion batteries (LIBs). However, the LSB still has challenges that restricts its practical applications. A major obstacle that limits its performance is the dissolution of long-chain lithium polysulfides into the electrolyte which results in loss of active material and capacity fade during the charge/discharge cycles. Here, we developed a novel sulfur composite with a liquid metal (LM) and graphene oxide dispensed on carbon cloth electrode to achieve a long cycling of lithium sulfur batteries. The liquid nature of the metal results in many advantages. It provides a strong encapsulation of the sulfur particles, which inhibits the polysulfide shuttle effect. In addition, it prevents the detachment of the sulfur particles from the current collector albeit large volume changes and cracking of the sulfur during lithiation and delithiation, maintaining the electron conduction paths. This innovative composite resulted in a high discharge capacity, an outstanding capacity retention over 300 cycles at 0.2 C, and a high coulombic efficiency. Our results demonstrate an effective method to surpass the polysulfide shuttle effect and pave a new way towards practical applications of lithium sulfur batteries by using multifunctional liquid metal composites.

Local and Bulk Probe of $K_xV_yMn_{8-y}O_{16}$ Electrochemistry in Li Batteries Diana M. Lutz[1], Mikaela Dunkin[1], Killian Tallman[1], Lei Wang[2], Shize Yang[2], Bingjie Zhang[1], Ping Liu[2], David Bock[2], Yimei Zhu[2,1], Amy Marschilok[1,2], Esther S. Takeuchi[1,2] and Kenneth Takeuchi[1,2]; [1]Stony Brook University, United States; [2]Brookhaven National Laboratory, United States

Manganese oxides have been highly studied as cathode materials for Li-ion batteries (LIBs) due to their low cost, environmentally benign nature, high theoretical capacity, and unique morphologies that allow for facile ion intercalation. Demonstrated here, V-substituted alpha-MnO2 was successfully synthesized with no crystalline or amorphous impurities, as evidenced by X-ray diffraction (XRD) and Raman spectroscopy. TEM revealed a morphological evolution from nanorods to nanoplatelets as V-substitution increased, while electron-energy loss spectroscopy (EELS) confirmed uniform distribution of vanadium within the materials. Rietveld refinement of synchrotron XRD described an increase in bond lengths and larger range of bond angles with increasing V-substitution, indicating structural distortion. X-ray absorption spectroscopy (XAS) of the pristine materials revealed the V valence to be above 4+ and the Mn valence to decrease as V content increases. Upon electrochemical lithiation, increasing amounts of V were found to preserve the Mn-Mn relationship at higher depths of discharge, which relates to enhanced structural stability. Electrochemical testing showed the 10%V-substituted sample delivered the highest capacity and capacity retention after 50 cycles and had the lowest polarization resistance according to pulse test results. This enhanced electrochemistry is related to the high level of V-substitution and the nanoplatelet morphology of the 10% V-substituted material. DFT calculations predicted that the high stability of highly oxidized V ions upon lithiation is essential to ensure the structural stability and polarization-resistance by enhancing the stability of the K^+centered 2 by 2 tunnel and promoting symmetric structural changes, which likely lead to the observed enhancement in structural stability.

EN12.03.03
Lithium Trivandate ($Li_{1.1}V_3O_8$) Utilization in Thick Porous Electrodes with High Rate Capacity Upon Extended Cycling Elucidated via *Operando* Energy Dispersive X-ray Diffraction Alison McCarthy[1], Karthik Malyilvahanan[2], Mikaela Dunkin[1], Steven King[1], Calvin D. Quilty[1], Lisa Housel[3], Jason Kuang[1], Kenneth Takeuchi[1,3], Esther S. Takeuchi[1,3], Alan West[2], Lei Wang[3] and Amy Marschilok[1,3]; [1]Stony Brook University, United States; [2]Columbia University, United States; [3]Brookhaven National Laboratory, United States

New energy storage systems require developments in electrode design and architectures to enable high energy density along with high power and fast charge rates. A balance between active material loading and full utilization of the electrode needs to be made when considering conventional battery electrode fabrication techniques such as slurry-caste electrodes and dense pelletized electrodes. In this work, thick porous electrode fabrication techniques have been developed to obtain a higher active mass loading in an architecture which also enables ion and electron transport. Synchrotron-based *operando* energy dispersive X-ray diffraction (EDXRD) was used to examine the homogeneity of the phase distribution in a thick porous electrode (TPE) of lithiated LVO over extended high rate cycling. Three locations were probed, while cycling at a fast rate of 1C, revealing a homogeneous phase transition across the thickness of the electrode at the 1st and 95th cycles. Continuum modelling results agreed with the EDXRD results, indicating

homogenous lithiation across the electrode upon discharge at 1C and ascribed decreasing accessible active material to be the cause of capacity fade between the 1st and 95th cycles. The model was supported by the observation of significant particle fracture by *ex situ* SEM, consistent with loss of electrical contact. The absence of the beta phase peaks in the EDXRD over extended cycling are consistent with electrochemical accessibility of only part of the active material. Overall, through combining *operando* EDXRD, continuum modeling, and *ex situ* measurements we gained a deeper understanding of lithium vanadate transport properties and the capacity loss mechanism under high rate extended cycling within a thick highly porous electrode architecture.

EN12.03.04
Impact of Charge Voltage on Factors Influencing Capacity Fade—An *Operando* X-Ray Study of Li/NMC622 Batteries During Extended Cycling Calvin D. Quilty[1], Garrett Wheeler[2], Lei Wang[2], Alison McCarthy[1], Shan Yan[2], Killian Tallman[1], Steven Ehrlich[2], Lu Ma[2], David Bock[2], Esther S. Takeuchi[1,2], Kenneth Takeuchi[1,2] and Amy Marschilok[1,2]; [1]Stony Brook University, United States; [2]Brookhaven National Laboratory, United States

Ni-rich NMC, such as NMC622, is an attractive Li-ion battery cathode material due to its balance of energy density, thermal stability, and reversibility. However, a compromise must be struck between higher energy density associated with a more positive upper voltage limit, and better reversibility at lower voltage limits. Improved understanding of structural transformations occurring as a function of voltage window, and their associated impacts on capacity fading, are critically needed to rationalize electrochemical behavior. Through *operando* X-ray characterization of cells cycled at 3-4.3 V and 3-4.7 V both before and after extensive cycling, this study presents an in-depth investigation into the effects of voltage window on the structural transformations of NMC622 over extended cycling. The utilization of this *operando* methodology over many cycles enables the collection of data on the structural transformations that can cause capacity fade as the fade occurs in real time. Cycling at 3-4.7 V, initially led to a higher delivered capacity along with greater lithium extraction and greater structural distortion. However, charging at this higher potential led to significantly more capacity fade along with reduced lithium (de)insertion, increased structural distortion, and significant particle cracking. This study provides important insights into the mechanisms of capacity fade in NMC622/Li-ion batteries, which will enable the design of NMC622 electrodes that deliver both higher capacities and exhibit better capacity retention.

EN12.03.05
Development of Low and No-Cobalt Cathode Materials for Lithium-Ion Batteries Au Nguyen and Donghai Wang; The Pennsylvania State University, United States

High-nickel layered cathode $LiNi_xCo_yMn_{1-(x+y)}O_2$ material is the center of attention for high energy density cathode materials and sustainable resources. In this work, cathode material with low or no cobalt ($0 <= y <= 0.06$) was synthesized successfully by the co-precipitation method followed by the lithiation process. The resulted materials have spherical and uniform size distribution morphology. Coatings and dopings (such as transition metal doping and Li containing glass material coating) on these materials were studied to show a significant improvement in cycling stability. The post-cycling TEM and SEM characterization indicate that the doping and coating can reduce the reconstruction layer of the layer structured, high-Ni and low-Co cathode materials and maintain the spherical morphology in contrast to bare control materials. The procedure for synthesizing single-crystals cathode using these precursors was also explored and promising potential for a long-cycling low-Cobalt material.

EN12.03.06
Functional Lithium-Ion Affinity Polymer Binder for Fast-Charging Lithium-Ion Batteries Pei Shi, Yuming Zhao and Donghai Wang; The Pennsylvania State University, United States

The fast charging of lithium-ion batteries (LIBs) is vital for the broad adoption of electric vehicles. However, the poor ionic conductivity of the electrolyte, low electronic conductivity of thick graphite anode electrodes, and increased impedances at electrode/electrolyte interphases upon cycling is the critical barrier to achieving the fast-charging performance of LIBs. The polymer binder of battery electrodes is used to ensure their mechanical integrity. It significantly influences the Li^+ transport and charge transfer in the electrode materials, particularly for ultrathick electrodes. Herein, a new Li^+ affinity polymer material is proposed as a binder for graphite anode with a practical level of areal capacity (4 mAh cm^{-2}). The functional polymer binder can not only deliver higher ionic conductivity than conventional graphite binder, but it also can facilitate Li^+ transport in anode by creating additional ion transport pathways through surface conduction when the Li-ion transport rate is limited to a liquid electrolyte at extreme fast charging conditions. As a result, the $LiNi_{0.8}Co_{0.1}Mn_{0.1}O_2$ || graphite full cell with a high mass loading (3.5 mAh cm^{-2}) and high charging rate (6 C) can stably operate over 100 cycles.

EN12.03.07
Electrode Design Considerations for High Capacity Magnetite Anodes Genesis Renderos[1], Krysten Minnici[2], Yo Han Kwon[2], Lisa Housel[3], Kenneth Takeuchi[1,3], Esther S. Takeuchi[1,3], Elsa Reichmanis[4] and Amy Marschilok[1,3]; [1]Stony Brook University, United States; [2]Georgia Institute of Technology, United States; [3]Brookhaven National Laboratory, United States; [4]Lehigh University, United States

Current electrodes for lithium ion technology rely on graphite-based anodes that have a relatively low theoretical capacity (372 mAh g^{-1}). Alternative materials such as transition metal oxides provide higher specific capacities due to multiple electron transfers. Particularly appealing is magnetite, Fe_3O_4, as it is a low cost, earth abundant and environmentally friendly material with the potential to deliver 924 mAh/g. Despite significant research on the design and synthesis of electrode active materials, the design and composition of the electrodes has also been shown to affect the function of the battery including the rate capability and capacity retention. Herein, is the exploration of electrode factors and binders that aid in electron and ion transport of magnetite (Fe_3O_4) based anodes. Water-soluble polymers in conjunction with polyethylene glycol (PEG) are studied to determine the role of carboxylate functionalities on overall function. Overall, this study compares a series of electrode designs to identify materials that can be manipulated to assist overall electrochemical performance of composite Li-ion battery anodes.

EN12.03.08
Investigating the Effects of Doping Layered Lithium Nickel Oxide Lavan Ganeshkumar[1,2,3], Christopher Savory[1,2], Maud Einhorn[1,2] and David O. Scanlon[1,4,3]; [1]University College London, United Kingdom; [2]Thomas Young Centre, United Kingdom; [3]The Faraday Institution, United Kingdom; [4]Diamond Light Source, United Kingdom

Lithium ion batteries have long been established as the leading technology for energy storage devices due to their high energy density and longevity[1]. Common cathode materials for these batteries are layered oxides. $LiCoO_2$ (LCO) is a popular layered oxide which is commonly used within the electronic industry. Yet, due to increasing environmental impacts tied with the price of the cobalt, there has been a substantial push for cobalt-free cathode materials, especially for the automotive application[2].

The isostructural compound $LiNiO_2$ (LNO) has been identified as the ideal replacement for LCO. This is principally due to LNO's comparably high theoretical capacity, however, the material is affected by mechanical and thermodynamical instabilities. Recent work has demonstrated that substitution strategies can cater for the instabilities whilst also minimising the reduction in capacity[3,4]. In this study, density functional theory calculations have been

carried out in order to fully understand the doped structure with the aim to find a stable nickel-rich cathode with a high theoretical capacity. Experimentally it has been reported that the ground state structure of LNO has the *R3m* space group. However, computational calculations have demonstrated that it is in fact the $P2_1/c$ structure[5]. Using the true ground state structure, point defects will be investigated in these cathode materials in order to fully understand the doped structure.

EN12.03.09
A Comparative Study of Electrolytes for Next Generation High Power Li-Ion Batteries Based on LNMO‖LTO Chemistry Sidsel Hanetho[1], Peter Molesworth[1], Kaushik Jayasayee[1] and Nils Wagner[1,2]; [1]SINTEF Industry, Norway; [2]Norwegian University of Science and Technology, Norway

The application of secondary batteries for electric propulsion, personal consumer electronics as well as power tools has grown immensely over the last decade and battery chemistries can be tailor made to meet the requirements of the application. Super high charge rates and cycle-life can be achieved employing zero strain anodes based on LTO ($Li_4Ti_5O_{12}$). With a (de)intercalation potential of 1.55V vs. Li/Li^+, LTO based batteries are inherently safer as lithium plating at high charge rates is omitted.
However, the high operation potential and the rather low specific capacity of LTO (~170 mAh/g) comes with the cost of a reduced cell potential and hence gravimetric and volumetric energy density. Pairing LTO based anodes with high capacity cathodes such as NCA ($LiNi_{0.8}Co_{0.15}Al_{0.05}O_2$) or NMC 811 ($LiNi_{0.8}Mn_{0.1}Co_{0.1}O_2$) increases the energy content of such a battery concept. Yet, these materials rely on cobalt, which is not viable from an ethical nor sustainable perspective. A more pronounced effect with respect to the energy density as well as sustainability is apparent when pairing LTO anodes with high voltage materials such as LNMO ($LiNi_{0.5}Mn_{1.5}O_4$). This spinel cathode has a rather moderate capacity of 147 mAh/g, but an almost 1 V higher intercalation potential compared to layered oxides. This combination could in principle increase the gravimetric energy density of LTO based cells by up to 30% compared to a NMC442‖LTO cell. Unfortunately, the $LiPF_6$ containing carbonate-based electrolytes are deemed inapplicable at these potentials, and a cobalt free LTO based battery with increased energy is contingent on a high voltage electrolyte that allows for high cycling stability.
This study screens the cyclability of LNMO‖LTO full cells with alternative electrolytes aiming for a high voltage tolerable solution with adequate properties such as conductivity, safety, and operational temperature. Alternative solvents such as sulfones, nitriles and fluorocarbonates and combinations thereof, as well as different high voltage additives, are screened and characterised in this study. The results are benchmarked against a state-of-the-art electrolyte based on LiPF6 in EC/EMC.

EN12.03.10
Revisiting Polyethyleneimine as the Basis for Solid Polymer Electrolytes (SPEs) for Next Generation Li-Ion Batteries Peter Molesworth, Wilhelm R. Glomm, Marius Sandru, Roberto Scipioni, Le T. Truong and Nils Wagner; SINTEF Industry, Norway

Replacement of liquid electrolytes in Li-ion batteries with all solid systems based upon polymers (SPEs), ceramics or composites will enable Li-ion batteries to achieve enhanced safety characteristics by reducing the flammability, removing solvents and providing resistance to lithium metal dendrite formation. To achieve this safety goal, it is critical that these replacements function without plasticiser, or the need for even small amounts of solvent additives. However, the potential benefits of SPEs are tempered by reduced Li^+ conductivity when contrasted to conventional liquid systems, and the need to run at elevated temperature to ensure the highest possible conductivity.
Much effort has been directed at the replacement of polyethylene oxide (PEO) which, despite significant effort cannot be easily used above 4 V. PEO is vulnerable to oxidation and degradation caused by Li salts and electrode by-products under operating conditions. Replacement for PEO has involved the study of many systems including polyesters, polycarbonates and polynitriles, with more exotic systems looking at co-polymers and composite SPEs. Polyethyleneimine (PEI), is the nitrogen bearing analogue of PEO, and contains NH which allows for Li salts anion sequestration via H-bonding. Theoretically, it should be weakly Li co-ordinating and strongly anion-coordinating, thus promoting Li^+ transport. However, early studies have shown low conductivity for PEI systems, thought in part to be due to high crystallinity.
This study will look at the preparation of novel, plasticiser free polyethyleneimine (PEI) co-polymers designed with the aim of reducing crystallinity in the SPE. The route from monomer to SPE, and subsequent testing and benchmarking against PEO systems will be shown. Performance data from studies using a flexible cell solution, that allows simultaneous, *in operando* measurement of SPE thickness under electrochemical characterisation, at a range of temperatures will be shown. This method allows for accurate determination of SPE conductivity and Li^+ transference number at different temperatures.

EN12.03.11
Plasmon-Enhanced Lithium–O_2 Batteries Kyunghee Chae, Filipe Marques Mota and Dong Ha Kim; Ewha Womans University, Korea (the Republic of)

Rechargeable lithium–oxygen batteries have high theoretical energy density (~3600 Wh kg^{-1}). During operation, oxygen undergoes a reduction reaction (ORR) to generate the discharge product of Li_2O_2, which is decomposed during the recharge process with oxygen evolution (OER).[1] However, this recharging process is primarily disturbed by the large overpotential attributed to the sluggish OER kinetics. Very recently, photo-assisted Li–O_2 batteries with semiconductor-containing cathodes have gained attention as a promising approach for enhanced energy storage.[2] Plasmonic materials (such as Au, Ag, Cu, Pd, and Al) have unique properties interacting with light, known as surface plasmon resonance (SPR).[3] Under light illumination, plasmonic effects such as near-field enhancement, FRET, local heat, and hot carriers have found increasing application in catalysis. In this study, we demonstrate plasmonic effect in the Li–O_2 battery system by incorporating gold nanoparticles on the Ketjen Black (KB) cathode with different amounts and sizes. Upon light irradiation, during discharge, the presence of plasmonic Au NPs induce a morphology change to thin and small Li_2O_2 particles, which can be easily decomposed during the charging process. Most importantly, during both discharging and charging processes, the hot carrier from plasmonic Au NPs help to form and decompose the Li_2O_2 with decreasing charge voltage. As a result, the cell with Au NP/KB shows a significant increase in the round-trip efficiency from 75.2 to 80.2%. Our approach, further supported by a meticulous analysis of the near-field enhancement and local heat effects, is the first report individually showcasing the promise of plasmonic metal nanostructures in high-energy storage.

3D Network of Sepia Melanin and N,S-Doped Graphitic Carbon Quantum Dots for Sustainable Electrochemical Capacitors Abdelaziz M. Gouda; Ecole Polytechnique Montreal, Canada

Organic electrode materials operating in aqueous electrolytes offer the opportunity to avoid toxic, critical and expensive materials but often feature limited cyclability. In this work, we report on a 3D network composite material, based on natural melanin (sepia melanin, extracted from the ink sac of cuttlefish) and nitrogen and sulfur doped graphitic carbon quantum dots (N,S GCQDs). N,S GCQDs not only improve the conductivity of the formed composite but also provide functional groups and active sites, and add faradaic activity for better electrode wettability and electrochemical performance. We also investigated the effect of various undoped and doped CQDs, synthesized from acetic acid and sucrose, on the electrochemical performance of sepia melanin, a quinone macromolecule. The sepia/N,S GCQD (8:2 W/W) composite shows optimum areal capacitance (ca. 180 mF/cm^2) that is about 2 times higher than sepia alone (ca. 77 mF/cm^2) with enhanced charge transfer resistance (1 ohm for sepia/N,S GCQDs compared to 10 ohms for sepia) evaluated through electrochemical impedance spectroscopy. Sepia/N,S GCQD symmetric supercapacitor in 0.5 M Na_2SO_4 aqueous electrolyte features promising capacitance retention ca. 92% after 10 000 cycles at 5 A g^{-1}, 100% coulombic efficiency, 11 µW h cm^{-2} and 102 mW cm^{-2} maximum energy and power densities. This work aims at easy preparation of stable and potentially biodegradable supercapacitor electrode materials from green resources for applications in environmentally benign electrochemical energy storage devices.

EN12.03.14
Highly Stable Energy Storage Devices Based on Electrospun Mesoporous Mn–V–O@ C Nanofibers Nageh K. Allam; American University in Cairo, Egypt

Supercapacitors (SCs) are being considered the next-generation power storage devices due to their many favorable properties. In this regard, mesoporous nanostructures are excellent supercapacitor electrodes as they enjoy a large number of active sites and high surface area promising the utilization of the full capacitance of the active materials. In this study, we report on the assembly of electrospun, binder-free mesoporous $Mn_{0.56}V_{0.42}O$@C fibrous electrodes. The morphological and structural analyses of the fabricated $Mn_{0.56}V_{0.42}O$@C electrodes were investigated using field emission scanning electron microscopy (FESEM), high-resolution transmission electron microscopy (HRTEM), and glancing angle X-ray diffraction (GAXRD). The X-ray photoelectron spectroscopy (XPS) and GAXRD confirm the formation of $Mn_{0.56}V_{0.42}O$ nanofibers and their successful bonding to carbon during crystal growth. Those fibrous composite electrodes showed excellent specific capacitance of 668.5 F g^{-1} at 1 A g^{-1}. The highly obtained capacitance is attributed to the multiple oxidation states of the Mn–V oxides, the binder-free electrodes, surface roughness, and the mesoporous nature of the fabricated nanofibers. The asymmetric supercapacitor composed of the mesoporous $Mn_{0.56}V_{0.42}O$@C nanofibers as the positive electrode and graphene hydrogel as the negative electrode possesses ultrahigh energy density of 37.77 W h kg^{-1} and a power density of 900 W kg^{-1} with superior Coulombic efficiency over 13000 charge/discharge cycles.

EN12.03.15
Late News: Electrodeposition for Low-Cost, Water-Based Li-Ion Battery Electrode Manufacturing Kevin Sylvester; PPG Industries, United States

The state-of-the-art manufacture of lithium ion battery (LIB) cathodes is slot-die coating of a high viscosity slurry consisting of active materials, conductive additives, and a polymeric binder in N-methyl-2-pyrrolidone (NMP). The operation of slot-die is costly due to the 2-coat/2-cure electrode processing and the use of NMP solvent, which is an expensive consumable with serious health concerns. An alternative approach is the use of waterborne binder systems applied to metal foils using electrocoat. Electrocoat is a process widely recognized to be a high-throughput, low cost, coating application method that allows simultaneous coating of both sides of metal. This presentation will demonstrate the development of novel binders to enable electrodeposited lithium-ion battery electrode coating system. The novel binders were designed for flexibility, ionic mobility, and compatibility with high-energy density active materials and formulated to result in stable water-based cathode coating systems. Furthermore, electrodeposition process parameters were explored and validated in proof-of-concept, semi-continuous lab scale testing. Compared to the conventional NMP based coatings with slot-die process, the electrocoat process is environmentally friendly and capable of reducing the cell costs by at least 20% while improving battery performance.

EN12.03.16
Late News: Ni Coated Iron Fluoride Cathode for Lithium-Ion Batteries Hyeong Cheol Roh, Young Ah Park, Ji Hyeok Choi, Jisu Na, Jeong Hye Jo and Young Soo Yoon; Gachon University, Korea (the Republic of)

Iron fluoride ($FeF_3{\cdot}0.33H_2O$) is a candidate for Lithium Ion Battery (LIB) due to great theoretical capacity and low cost. However, the poor electric conductivity hinders its application to LIB. The electric conductivity of cathode part is factor that influence to battery performance such as capacity and cycle stability. Thus, conductive materials are essential for improve electric conductivity. Generally, composite with carbon material for example Carbon Black (CB) and Multi-Wall Carbon Nano-Tubes (MWCNTs) are applied [1]. Nevertheless, poor cycle stability is an obstacle to become the dominant cathode material in the LIB market. Herein, we suggest that electro-less Nickel plating on $FeF_3{\cdot}0.33H_2O$ powder for improving electric conductivity. We carried out X-Ray Diffraction pattern analysis (XRD), Scanning Electron Microscopy (SEM), Transmission Electron Microscopy (TEM) and Energy Dispersion Spectroscopy (EDS) for material characteristics. Also, we carried out Four-point prove, charge-discharge test and Electrochemical Impedance Spectroscopy (EIS) for electrochemical properties. Ni layer which is coating on iron fluoride powder layer with thicknesses of 10 nm~ 20 nm is observed by SEM and TEM. Respectively, Ni-coated $FeF_3{\cdot}0.33H_2O$ powder show 150% increased electric conductivity then $FeF_3{\cdot}0.33H_2O$ powder. Also, It shows good capacity up to 150 mAhg^{-1} at 0.2C (cut-off voltage 1.0V) and capacity retention ~80% after 50 cycles.

Enhanced Mobility of Ions in Polymer Electrolytes with the Addition of Inorganic Nanofibers Mounesha Garaga[1], Sahana Bhattacharyya[1,2], Domenec Paterno[3], Sophia Suarez[3,2] and Steven G. Greenbaum[1,2]; [1]Hunter College-CUNY, United States; [2]CUNY Graduate Center, United States; [3]Brooklyn College, CUNY, United States

Polymer electrolytes have received increasing attention in battery materials research and development. Their performance can be improved with addition of ionic liquids (ILs), which increases the ionic conductivity and provides enhanced safety. In a recent study, self-healing capability that reduces lithium dendrite formation at the electrolyte/electrolyte interface has been reported, for example, in PVDF-HFP-ILs electrolyte containing Al_2O_3 nanofibers. [1] In

this work, a series of PVDF-HFP-ILs with different ratios of Al_2O_3 nanofiber content were prepared through solution cast technique. The dynamics of ions confined within polymer-Al_2O_3 matrix were explored by impedance and pulsed field gradient NMR spectroscopy. The distribution of Al_2O_3 nanofibers in the polymer network was probed through SEM-EDX analysis. Lastly, the local environment of ions and their interaction with polymer and Al_2O_3 nanofibers were established through a detailed solid-state NMR analyses detecting ^{1}H, ^{27}Al, ^{13}C, ^{19}F, ^{7}Li nuclei including 2D $^{13}C\{^{1}H\}$ HETCOR experiments. In addition to mechanical reinforcement, enhancement of ionic conductivity was observed with the addition of Al_2O_3 nanofibers.

EN12.03.18
Late News: Engineering One Dimensional Organic Material for Ultra-High Rate Pseudocapacitive Energy Storage Mingyu Jung and Hoseok Park; Sungkyunkwan University, Korea (the Republic of)

Among the electrochemical energy storage devices, batteries have attracted tremendous attention of scientific society due to its amazing feature of high power, good cycle life, tunable energy density. The development of active and safe organic materials for electrochemical storage devices is another area of interest for electrochemical energy storage system, which can be contained low cost, natural abundance, possibly green compounds (i.e., C, H, O, N or S), and simple synthesis. [1] Until now, many organic materials have been investigated but only conducting polymers are used for energy storage system and others restricted due to their electrical conductivity issue and material loading. Herein, we attempted new material and engineering strategies to resolve the key issues facing the electrochemical energy storage system. Our material with new synthesis approach is able to offer optimistic electrochemical performance and reach unmatched ultra-high rate pseudocapacitive performance.

Sustainability in 3D—Distributing Local Electrochemistry by Wiring Transport Functions in Architected Electrodes Debra R. Rolison, Brandon J. Hopkins, Jeffrey Long, Jesse S. Ko, Christopher N. Chervin, Megan B. Sassin, Ryan H. Deblock and Joseph F. Parker; U.S. Naval Research Laboratory, United States

A sustainable, carbon-neutral future will be an aspiration, not a reality, without cost-effective energy storage. Batteries will be a critical technology in the suite of choices for energy storage, especially for electrification of vehicles. But shouldn't batteries themselves be sustainable? We evaluated the supply risk of elements versus their abundance in the earth's upper crust [1]. A supply risk of 1 or less and an abundance above 0.003 wt% includes such battery-relevant elements as Ni, Zn, S, Mn, Ti, Fe, and Al. Our team has focused on rechargeable zinc-based batteries whose aqueous electrolytes impart a safer battery chemistry over lithium-based batteries as well as competitive gravimetric and volumetric energy at the system-level. Designing electrodes as architectures in which the entire volume of the electrode is electron- and ion-wired in 3D distributes the available electrified interface thereby lowering local current density. Formulating zinc as a sponge creates an alkaline anode that cannot form zinc dendrites. Similarly, formulating layered MnO*x* as a nanometric coating throughout a carbon nanofoam improves the rate performance of zinc-ion cathodes.

Securing Li Resource for Sustainable Battery Technology Development Chong Liu; University of Chicago, United States

The demand for lithium has grown tremendously over the past decades due to Li-ion battery development for electric vehicles, portable electronics, and stationary energy storage. Electrochemical intercalation is a new platform method for separation. It allows selective Li extraction from complex aqueous systems such as brines and seawater. However, the high concentration of Na poses a great challenge to compete (co-intercalate) with Li during extraction. In this talk, I will present the host electrode materials' structural response upon co-intercalation of Li and Na which have big ionic radius differences. I will also discuss strategies to promote Li intercalation during co-intercalation from both aspects of materials design and electrochemical methods development.

11:15 AM EN12.04.03
Redox-Active Polymers Designed for the Circular Economy of Energy Storage Devices Siew Ting Melissa Tan, Alberto Salleo and Alexander Giovannitti; Stanford University, United States

Electrochemical energy storage is a keystone to support the rapid transition to a low carbon emission future for grid storage and transportation. While research on electrochemical energy storage devices has mostly dealt with performance improvements (energy density and power density), little attention has been paid to designing devices that can be recycled with low-cost and low environmental impact. Thus, next-generation energy storage devices should also address the integration of recyclability into the device design. In this talk, we present the development of recyclable energy storage devices based on solution processible redox-active conjugated polymers [1]. The high electronic and ionic charge transport in these polymers enables the operation of single-phase electrodes in aqueous electrolytes with C rates >100 with excellent electrochemical stability when charged to 1.2 V. Finally, we demonstrate the recyclability of these devices, achieving >85% capacity retention in each recycling step and recycled devices twice. Our work provides a new direction for developing recyclable devices for sustainable energy storage technologies.

11:30 AM EN12.04.04

Hard Carbon Derived from Avocado Peels as a High-Performance Anode Material for Sodium-Ion Batteries Francielli S. Genier[1], Shreyas Pathreeker[1], Robson Schuarca[1], Mohammad Islam[2] and Ian Hosein[1]; [1]Syracuse University, United States; [2]State University of New York at Oswego, United States

Sodium-ion conduction is a promising alternative to lithium-ion batteries (LIB). The advantages of sodium include higher natural abundance, similar physicochemical properties to lithium, and lower cost of battery active materials. However, a simple technology transference from LIB to sodium-ion batteries (SIB) is impeded by differences in intercalation mechanisms. Particularly, graphite, an established anode material in LIBs, is unsuitable to SIBs because the interlayer distance between its graphene sheets is too small for effective Na+ insertion. For this reason, some of the preferred anode materials for SBIs are disordered carbons with larger interlayer spacing, such as hard carbons. Hard carbons (HCs) also have the advantage of being predominately produced by the carbonization of biomass and residues, which contributes positively to the environmental and economic impact of SIBs. However, the method of HC production often includes chemical activation steps and high carbonization temperatures. In this work, we produced HC from avocado peels by simply water washing and relatively mild temperatures of carbonization (900 and 1100 °C). We chose avocados due to the considerable waste generated and its constant increase in consumption. Avocados generate waste from their peels, seeds, and parts of the pulp, which can amount to a total of up to 30% of its weight in solid waste. Efficient ways to process and repurpose this waste are especially relevant due to the continuous market growth of avocados. In 2019, they were the 8th most consumed fruit or vegetable in the USA, partially due to lifestyle trends and potential health benefits. To the best of our knowledge, the possibility of producing HC from avocado peels for energy storage has never been explored. HC produced by avocado peels was characterized regarding its crystalline properties (XRD), surface area and porosity (BET and BJH analysis), morphology and atomic composition (SEM-EDX), and degree of graphitization (Raman spectroscopy). The material characterization revealed the conversion of the avocado peels in carbon powders with a carbon content of > 92 at. %, graphene interlayer distances of 3.95 Å (superior to the required for Na+ intercalation), pore size of approximately 4.8 nm, and degree of graphitization of 0.96. After confirming the suitability of the produced HC as anode materials, electrochemical characterization was carried out with coin cells containing HC anodes and sodium metal discs as cathodes. Our samples demonstrated reversible intercalation and deintercalation of sodium ions and excellent cycling performance, namely, a reversible capacity of 352.55 mAh/g at 0.05 A/g, rate capability up to 86 mAh/g at 3.5 A/g, capacity retention of >90%, and 99.9% Coulombic efficiencies after 500 cycles. This study shows for the first time avocado peels as a sustainable source to produce hard carbon that can provide excellent anode performance in sodium-ion batteries.

11:45 AM EN12.04.05
Critical Sustainability Evaluation of Multi-doped SnO_2 as Anode Material for Li-Ion Batteries and In-Depth Insights into the Synergistic Impact of the Dopants Adele Birrozzi[1,2], Jakob Asenbauer[1,2], Sebastián P. Bautista[1,2], Marcel Weil[1,2], Thomas E. Ashton[3], Alexandra R. Groves[3], Jawwad Darr[3] and Dominic Bresser[1,2]; [1]Helmholtz Institute Ulm, Germany; [2]Karlsruhe Institute of Technology, Germany; [3]University College London, United Kingdom

Tin oxide-based materials have been intensively investigated as alternative anodes for lithium-ion batteries due to their high specific capacity, non-toxicity, and ease of handling.[1] However, the initial formation of Li_2O upon lithiation is essentially irreversible, which has a severe effect on the first cycle Coulombic efficiency and the reversibly achievable capacity upon cycling.[2] It has been shown that the incorporation of transition metal dopants can address this issue, as it enables the reversible formation of Li_2O. The choice of the dopant, however, plays a critical role for the long-term cycling stability, rate capability, and eventual energy density of the resulting lithium-ion cells.[3]
Herein, we show that the incorporation of specific combinations of different dopants allows for further tailoring the electrochemical properties. We also demonstrate the production of such materials using a scalable continuous hydrothermal flow method. The performance of the best performing composition was further improved by applying a carbonaceous coating. The electrochemical investigation of the coated anode material was conducted in half-cells and in high-energy full-cells using high-voltage $LiNi_{0.5}Mn_{1.5}O_4$ as active material for the cathode[4] – in addition to the realization of some large-scale battery cells to power a remotely controlled model car. Following these first scale-up activities, we conducted a preliminary life cycle assessment to compare the sustainability and suitability of such materials with the state of the art. Simultaneously to these rather application-oriented research, we performed also an in-depth investigation of the synergistic impact of the different dopants via ex situ synchrotron X-ray absorption spectroscopy to elucidate the de-/lithiation mechanism at the atomic scale. This comprehensive and extensive analysis provides additional insights into the potential application of (multi-doped) SnO_2 for lithium-ion batteries.

1:30 PM EN12.05.02
Bio-Inspired Vascularized Electrodes for Fast-Charging Batteries Designed by Deep Learning Po-Chun Hsu; Duke University, United States

Vascular structures are ubiquitous in nature. Examples such as roots, blood vessels, and lung alveoli are the outcomes of millions of years of evolution to balance between surface area and mass transport. For lithium-ion batteries, it is anticipated that creating vascular channels in the electrodes also enhances the kinetics by ensuring the fresh electrolyte supply to achieve fast charging. Ideally, such optimal vasculature can help to fully utilize the electrode uniformly and to minimize overpotential. However, it is challenging to find the right parameters out of the immense parameter hyperspace. Herein, we use artificial neural network (ANN) to accelerate the computation of possible structures with high accuracy. An inverse searching library is compiled to find the top-ranked vascular structures under different industrial fabrication criteria. The prototype delivers a customized package containing optimal geometric parameters, and their uncertainty and sensitivity analysis. Finally, the full-vascularized cell shows a 75% improvement of charging capacity than the traditional homogeneous cell under 3.2C current density. This research provides an innovative methodology to solve the fast-charging problem in batteries and broaden the applicability of data-driven deep learning to different scientific or engineering areas.

1:45 PM EN12.05.03

Surface-Stabilized Cobalt-Free and Manganese-Rich Cathodes and Bio-Derived Binders for Sustainable Lithium-Ion Batteries Markus Binder[1,2], Annika R. Schür[1,2], Matthias Kuenzel[1,2], Vidur Kumar[1,2], Arefeh Kazzazi[1,2], Stefano Passerini[1,2] and Dominic Bresser[1,2]; [1]Helmholtz Institute Ulm, Germany; [2]Karlsruhe Institute of Technology, Germany

Lithium-ion batteries have enabled the continuous transition from gasoline-powered to electric vehicles and several "traditional" car-makers have (very) recently announced their "exit" from combustion engines in the near future. The impressive success of this technology, however, raises also an increasing awareness of sustainability issues – not least with regard to critical elements such as cobalt, commonly comprised in the positive electrode active material, and the use of toxic and harmful solvents for the (positive) electrode preparation.[1–3] Cobalt-free and manganese-rich $LiNi_{0.5}Mn_{1.5}O_4$ (LNMO) would provide a viable solution to overcome these issues, especially in combination with the utilization of water-soluble, bio-derived polymers as binders, but the pronounced water-sensitivity and high de-/lithiation potential of LNMO are still hampering the commercial breakthrough.[3–5] Apparently, the key towards overcoming these issues relies on the stabilization of the LNMO|water and LNMO|electrolyte interface.
Herein, we will report a comprehensive overview of our activities in this field, covering (i) an in-depth understanding of the processes occurring at the interface with the LNMO particles, (ii) the development of suitable active material and electrode treatments prior to the cell assembly, (iii) the optimization of the electrolyte composition to achieve stable interphases for both the anode and the cathode, as well as (iv) the tailored design of suitable binder compositions that allow for suitable mechanical properties and stable long-term cycling of commercially relevant sized electrodes – in half-cells and high-performance full-cells. We will show that only the combination of these complementary approaches appears capable of overcoming the present challenges and, thus, enabling the commercial application of LNMO-based cathodes in (more) sustainable lithium-ion batteries.

Quantifying the Role of Reaction Inhomogeneity on Optimizing Capacity and Reducing Lithium Plating in Conventional and Architectured Electrodes During Fast Charging Aleksandar Mijailovic[1], Guanyi Wang[2], Yejing Li[3], Jian Yang[2], Wenquan Lu[3], Qingliu Wu[2] and Brian W. Sheldon[1]; [1]Brown University, United States; [2]Western Michigan University, United States; [3]Argonne National Laboratory, United States

Non-uniform lithium intercalation in porous electrodes during charging reduces the capacity of lithium ion batteries at fast charge rates. Recent work highlights the importance of the thermodynamics of cathode materials in dictating charging capacity at high rates. The analogous thermodynamic behavior of negative electrodes and its relationship to Li plating have not been investigated at high charge rates. In this study, we use finite element analysis and simplified numerical and analytical models to study conventional and architectured electrode structures (i.e., layered with varied porosity, patterned with secondary channels, etc.) at high charge rates. While some of these strategies can increase capacity at a given rate, the benefits in reducing lithium plating are generally more striking. For example, layered designs can reduce the overpotential that drives plating even though these structures do not substantially increase capacity. Our modeling results are compared to and validated by experiments. Further, we demonstrate that reaction inhomogeneity is substantially affected by staging behavior in the equilibrium potential in ways that can contribute to Li plating events at high charge rates. The overall results of this study provide guidance for designing both electrode architectures and optimized charging protocols for fast charging applications.

2:15 PM EN12.05.05
Porous Electrode Architecture Design towards High-Performance Lithium-Ion Batteries Xiao Zhang[1], Zhengyu Ju[1], Zeyu Hui[2], Lei Wang[3], Steven King[4], Amy Marschilok[4], Kenneth Takeuchi[4], Esther S. Takeuchi[4], Alan West[2] and Guihua Yu[1]; [1]The University of Texas at Austin, United States; [2]Columbia University, United States; [3]Brookhaven National Laboratory, United States; [4]Stony Brook University, The State University of New York, United States

Developing lithium-ion battery electrodes with high energy and power is essential to meet the ever-growing portable electronics and electric vehicle markets, which calls for achieving high utilization of the active material in thick electrode designs and elevating the overall energy density. In this talk, I will present our recent research progress on high-performance electrode architecture design and the impacts of structural parameters on the underlying kinetics. A low-tortuosity design could provide faster ion transport across electrode thickness, enabling thick electrode composed of graphene oxide (GO) supported magnetite (Fe_3O_4) nanoparticles with excellent rate capability, achieving areal capacity of 3.6 mAh cm^{-2} under 10 mA cm^{-2}. In addition, further fine tuning of the lamellar thickness and the pore size in low-tortuosity architecture shows significant impact on the electrochemical kinetics in thick $LiNi_{1/3}Mn_{1/3}Co_{1/3}O_2$ (NCM111) electrodes, where a better capacity retention with increasing C-rates (70% retention under 2.5 C) is found in electrodes with thinner lamellar thickness (~ 5 μm) and relatively large pore size (~ 20 μm) compared to those with thicker lamellar walls. Providing similar low-tortuosity morphology, this could be ascribed to faster diffusion into thin lamellar walls as opposed to their thick counterparts. Our research reveals more insights into structure-affected electrochemistry and highlights more delicate designs in low-tortuosity electrode architectures.

2:30 PM EN12.05.06
Decreasing LIB Separator Cost of Manufacturing with Facile One-Step Method Alexander Manly and Wyatt E. Tenhaeff; University of Rochester, United States

Microporous separators are critical components in lithium ion batteries (LIBs). Most battery separators serve two key functions: to physically separate the electrodes to avoid electrical shorting, and to allow the transport of ions. Conventional separators are fabricated from low cost, commodity thermoplastics, such as polyethylene and polypropylene, but make up 20% of the total material cost of a cell due to complex, energy-intensive manufacturing process. Moreover, conventional separators are considered passive components, providing adequate electrolyte uptake and ohmic resistance but contributing little other functionality to the cell. Thus, developing low cost, multifunctional separators is a potential strategy to reduce battery costs, while addressing cell cycle/calendar life.
In this presentation, we will introduce a novel separator fabrication process, where microporous separators are coated directly onto electrode foils in a facile, one-step additive process. This process promises to reduce energy consumption and manufacturing steps, and microporous poly(1,4-butanediol diacrylate) (pBDDA) separators fabricated using this approach possess superior performance metrics compared to commercial separators. These separators have a porous morphology with an average pore diameter of 40μm, and a porosity of 38%. In a lab setting, the fabricated separators have a thickness between 40-50μm. We have demonstrated that pBDDA separators hold 30% more electrolyte by mass when compared to Celgard 2500, and have an effective ionic conductivity of 3.32mS/cm – a 66% improvement over the same commercial benchmark. When incorporated into an electrochemical cell, the capacity retention of pBBDA separators is on par with Celgard over long-term cycling, showing the material is stable and effective during use.

In addition to simplifying separator manufacturing and cell fabrication, our approach provides for facile incorporation of novel polymer chemistries without additional processing steps. For example, novel copolymer compositions have been designed to scavenge HF contamination that is intrinsic to LiPF6-based liquid electrolytes. These functional separators mitigate the buildup of HF in the electrolytes, thereby suppressing Mn^{2+} dissolution in $LiMnO_2$ cathodes and improving capacity retention and lifetime of the lithium ion cells.

2:45 PM EN12.05.08
Flame Spray Synthesis of Single Crystal Nickel-Rich Cathode Materials of Lithium-Ion Batteries Jianan Zhang, Valerie L. Muldoon and Sili Deng; Massachusetts Institute of Technology, United States

Cathode material plays a dominant role in determining the capacity and cost of lithium-ion batteries (LIBs). Reducing the cost and improving the performance of cathode materials is critical for further advancing the application of LIBs in areas such as electric vehicles and grid energy storage. One type of the most promising cathode materials is nickel-rich metal oxides including $Li(Ni_{0.6}Co_{0.2}Mn_{0.2})O_2$ (NCM622) and $Li(Ni_{0.8}Co_{0.1}Mn_{0.1})O_2$ (NCM811) due to their high capacity and low cobalt content, especially considering the high price and toxicity of cobalt. Nevertheless, current nickel-rich cathode materials are experiencing challenges such as a fast capacity fading and low thermal stability, which are the result of structural degradation, microcracks, and side reactions related to the polycrystalline structure. An efficient way to solve those issues is using single crystal cathodes (SCC) that have better thermal stability and lower capacity fading because of improved structural stability and mechanical strength. However, current synthesis methods of SCC are facing various challenges, inhibiting their application for large-scale low-cost production of high-performance SCC. For instance, the coprecipitation method needs long-time preparation of precursor, whereas the solid-state molten salt method usually introduces impurity phase due to non-uniform mixing and post-treatment. Therefore, a flame spray synthesis (FSS) method is proposed for SCC materials with following features: (1) all needed metal elements are dissolved in the form of salt in precursor solution to guarantee homogeneous mixing and avoid extra steps of solid-state mixing; (2) the droplet-to-particle route allows easy control of the size of particles by adjusting spray properties; (3) the high temperature operating condition allows fast decomposition of raw material. In the current work, nickel-rich NCM811 cathode materials were synthesized with an FSS setup that has two heating sections, with a low-temperature section for evaporation control and a flame section for fast decomposition of precursor. The as-prepared sample was then post-annealed to produce the single crystal material. To obtained materials with optimized performance, we are investigating a wide range of parameters including the precursor concentration, amount of additives, operating temperature and residence time in each heating section, and post-anneal temperature and time. Our current coin cell tests showed that single crystal NCM811 synthesized with FSS had an improved cycling performance when compared with polycrystalline NCM811. We believe that FSS is promising in advancing the production and application of single crystal cathode materials because of its features such as fast production, homogenous mixing, and high scalable potential.

EN12.06.01
Impact of Sodium Vanadium Oxide (NaV3O8, NVO) Material Synthesis Conditions on Charge Storage Mechanism in Zn-Ion Aqueous Batteries Christopher Tang[1], Gurpreet Singh[1], Lisa Housel[2], Sung Joo Kim[2], Calvin D. Quilty[1], Yimei Zhu[2,1], Lei Wang[2], Kenneth Takeuchi[1,2], Esther S. Takeuchi[1,2] and Amy Marschilok[1,2]; [1]Stony Brook University, United States; [2]Brookhaven National Laboratory, United States

The use of zinc negative electrodes and aqueous electrolytes is an appealing modality for low cost scalable batteries. Further, transition metal oxides are viable options for cathode materials in these systems. Specifically, the electrochemical charge storage of sodium vanadate (NaV_3O_8 or NVO) cathodes in aqueous Zn-ion batteries has been demonstrated and is hypothesized to be influenced by the inclusion of structural water for facilitating ion transfer in the material. Materials properties considered important (morphology, crystallite and particle size, surface area) are systematically studied herein through investigation of two NVO materials, NaV_3O_8. $0.34H_2O$ [NVO(300)] and NaV_3O_8.0.05H2O [NVO(500)], with different water content, acicular morphologies with different size and surface area achieved via post-synthesis heat treatment. The electrochemistry of the two materials was evaluated in aqueous Zn-ion cells with 2 M $ZnSO_4$ electrolyte using cyclic voltammetry, galvanostatic cycling, and rate capability testing. The thinner NVO(300) nanobelts demonstrate greater specific capacities and higher effective diffusion coefficients relative to the thicker NVO(500) nanorods. Notably however, while cells containing NVO(500) deliver lower specific capacity, they demonstrate enhanced capacity retention with cycling. The structural changes accompanying oxidation and reduction are elucidated via ex situ X-ray diffraction, transmission electron microscopy, and operando V K-edge X-ray absorption spectroscopy (XAS), where NVO material properties are shown to influence the ion insertion. Operando XAS verified that electron transfer corresponds directly to change in vanadium oxidation state, affirming vanadium redox as the governing electrochemical process.

EN12.06.02
A Bioinspired Vanadium Compound as a Robust Scaffold for Next-Generation Flow Batteries Patrick J. Cappillino[1], Shyam K. Pahari[1], Jennifer Bolibok[1], Benjoe R. Visayas[1], Tugba Ceren Gokoglan[2], Maricris L. Mayes[1] and Ertan Agar[2]; [1]University of Massachusetts Dartmouth, United States; [2]University of Massachusetts Lowell, United States

Modern electrical grids, especially those comprising energy from intermittent, renewable sources, such as wind and solar, require storage.[1] Nonaqueous redox flow batteries (NRFB) are a promising technology to meet this growing need.[2] Compared to their aqueous counterparts, they have the potential to approach the energy density of lithium-ion batteries, while maintaining the advantages of flow systems, including decoupled scaling of power and energy ratings and thermal stability.

Despite their promise, fundamental technical obstacles have limited the application of NRFB so far. These include low solubility and poor stability of active-materials as well as poor electrochemical performance. To address these issues, we have developed an active-material known as vanadium bis-hydroxyiminodiacetate (VBH), which is based on a family of molecules that is naturally occurring and produced biologically.[3] Biosynthesis of this molecule evolved in mushrooms of the *Amanita* genus, to bind vanadium selectively and with the highest stability ever reported, using a unique, tetradentate, bis-carboxylato-η^2-hydroxyimino- motif.[4] Ligand-substitution is suppressed, shutting down a major mechanism of decomposition. In this way, natural selection serves as a toolkit for molecular design, elucidating a scaffold for optimized NRFB active materials.

In this presentation we provide an overview of some key challenges in NRFB development, along with our recent efforts at addressing them, and some strategies we are pursuing to make further in-roads. We will show that our bioinspired active-material exhibits excellent chemical stability during long durations of electrochemical cycling to high states-of-charge.[5] Further, we will demonstrate that the thermodyamics of the electrolyte can be tuned to greatly enhance the solubility of the active-material.[6] Finally, we will report our recent progress on a modular synthetic scheme, whereby the VBH scaffold can be covalently modified to tune its electronics and steric properties.

A Molecular Dynamics Study of the Effect of Coordination Behavior in Polymer Electrolytes for Sodium-Ion Conduction Francielli S. Genier and Ian Hosein; Syracuse University, United States

The establishment of sustainable energy sources highly depends on efficient storage devices to guarantee a consistent power supply. The growing demand for lithium-ion batteries (LIBs) for this purpose combined with concerns about lithium availability has motivated the search for viable storage alternatives. Sodium-ion conduction is a suitable candidate due to sodium's abundance in the earth's crust and similar monovalent storage mechanism as Li+. In recent years, the development of components specifically for sodium-ion batteries (SIBs) have inspired much research interest, but fundamental inquiries on ion transport remain unanswered. Notably, solid polymer electrolyte (SPE) studies remain almost solely concentrated on Li-ions, even though revolutionary storage devices could result from the combination of sodium's natural availability with the possibility of higher energy density in solid-state devices. The challenges associated with SPEs, such as low ionic conductivities, could be further addressed by characterizing the ion-transport properties of the polymer host and the strength of the salt-polymer interactions. In this work, we used atomistic molecular dynamic simulations of sodium SPEs to observe the influence of oxygen density in polymer chains on the resulting electrolyte's diffusivity, coordination, and cation-anion interactions. For this purpose, we characterize sodium-ion transport in two polymer hosts, namely, polyethylene oxide (PEO) and poly(tetrahydrofuran) (PTHF) that contain two and four carbons in their repeating units, respectively. Sodium perchlorate was added to the systems in a concentration of EO/Na (EO = ethylene oxide) or BO/Na (BO = butylene oxide) equal to 15. The simulation boxes were created using the software MedeA 3.1 from Materials Design, and the molecular dynamics package LAMMPS was used in the equilibration and production runs, with the universal forcefield PCFF+. To mitigate the limitations of our non-polarizable model, we multiplied the charges of Na, Cl, and O by 0.75 to reproduce transport properties without overestimation. Production runs were carried out in NPT at 353 K (80 °C), 1 atm, with timestep of 1 fs, for 100 ns. The radial distribution function (RDF) between Na-O from the polymers PEO and PTHF was calculated to investigate the local solvation environment, which confirmed the stronger coordination of sodium cations with PEO's polymer backbone, while, in PTHF, the lower oxygen density in its chains resulted in weaker coordination. The differences in oxygen density in the polymer chain also influence the hopping mechanism in each electrolyte. In PTHF, interchain hopping was more prevalent, while in PEO, intrachain hopping happened more often due to the stronger coordination with the polymer chains. Additionally, sodium cations showed a higher probability of coordinating with 2-3 oxygens from PEO while in PTHF, Na+ coordinated with only one polymer oxygen. Consequently, the Na+ decomplexation could easily be achieved in the PTHF electrolytes. This caused the faster motion of Na+ in PTHF, as demonstrated by the sodium ion self-diffusivity 2.3x higher in PTHF than in PEO. However, significant ion cluster formation was seen in the PTHF system. In PTHF, only 8.11% of ions were fully isolated from each other, mostly because Na+ was free to form larger clusters with ClO4-. In PEO, 32.2% of all ions were dissociated due to a greater dispute of coordination between PEO oxygens and perchlorate ones. The significant presence of clusters in the PTHF electrolyte could potentially result in the transport of Na+ ions in the opposite direction from where cations should move during battery cycling, which could be verified by lower transference numbers experimentally. This work's findings elucidate the fundamental influences and correlations of polymer ether content on ion transport, which can inform on novel syntheses to improve future sodium polymer electrolytes.

EN12.06.04
Investigating Ion Transport in Aqueous Electrolytes for Aluminum–Ion Batteries Allen Zheng[1,2], Glenn R. Pastel[3], Mounesha Garaga[1], Michael Ding[3], Kang Xu[3] and Steven G. Greenbaum[1,2]; [1]Hunter College-CUNY, United States; [2]CUNY Graduate Center, United States; [3]U.S. Army Research Laboratory, United States

Among the candidates competing with lithium ion battery technology for large-scale energy storage applications are aluminum-based systems, which have significant cost and safely advantages. In this work, we investigate aqueous electrolytes containing aluminum trifluoromethanesulfonate ($AlTf_3$) ranging in concentration from 0.1m to 3.6m. Cation, anion, and water molecular self-diffusion coefficients were determined by pulsed field gradient nuclear magnetic resonance (NMR) measurements of the ^{27}Al, ^{19}F, and ^{1}H nuclei, respectively. A special high-gradient probe was used for the ^{27}Al measurements due to short relaxation times associated with nuclear quadrupole interactions characteristic of this spin-5/2 nucleus. Together with ionic conductivity measurements, the NMR results yield information on the degree of salt dissociation and Al ion transference at all concentrations.

EN12.06.05
A Strategy to Decrease the Viscosity of Ionic Liquids for Electrochemical Applications—A Broadband NMR Relaxometry Study Sophia Suarez[1,2], Frederik Philippi[3], Tawhid Pranto[1,2], Daniel Rauber[4], Christopher Kay[4], Tom Welton[3] and Steven G. Greenbaum[5,2]; [1]Brooklyn College of CUNY, United States; [2]CUNY Graduate Center, United States; [3]Imperial College London, United Kingdom; [4]Universität des Saarlandes, Germany; [5]Hunter College-CUNY, United States

Ionic liquids (ILs) have become ubiquitous due to their many attractive characteristics including their task specific tunability. In their application as electrolytes, low viscosity is a necessity to allow fast ion dynamics. One of the ways in which low viscosity can be achieved is by using large asymmetric ions with high conformational flexibility. Towards this, large cations such as 1-butyl-3-methylimidazolium ($BMIM^+$) with relatively short and flexible alkyl chains have been successful. Additionally, the use of large weakly interacting anions such as bis(trifluoromethanesulfonyl)imide ($TFSI^-$) have found similar success. In this study, we performed ^{1}H and ^{19}F NMR Fast Field Cycling (FFC) broadband relaxometry measurements on four ILs comprised of the $BMIM^+$ cation combined with the tetracyanoborate (BCN_4^-), acetyl(trifluoromethylsulfonyl)imide ($TfNAc^-$), (methylsulfonyl) 2,2,2 – trifluoroacetyl amide ($MsNTFA^-$), and bis(trifluoromethanesulfonyl) methane ($TFSM^-$) anions. The objective of the study is to determine how the anion's conformational flexibility affects the dynamics of both ions.

Variable temperature ^{1}H relaxation dispersion (R_1) results followed the anion order: $MsNTFA^- > NTfAc^- > TFSM^- > B(CN)_4^-$. These results demonstrate that the $MsNTFA^-$ and $B(CN)_4^-$ anions provide the least and most favorable environments, respectively, for the cation's transport. This result is also

supported by solution viscosity (η), ionic conductivity (σ) and cation self-diffusion coefficient (*D*) measurements.

EN12.06.10
Silicon/Germanium Nanostructures via Photonic Curing—A Facile Approach to Synthesize Nanomaterials in Large Scale Najma Khatoon, Binod Subedi and Douglas B. Chrisey; Tulane University, United States

Silicon/Germanium (Si/Ge) nanostructures are promising materials for energy storage applications due to their high energy density (both volumetric and gravimetric), large lithiation capacity, low toxicity, and high thermal stability. The challenge to utilize these tremendous properties of Si/Ge nanostructures for desired applications is controlled growth over large scale. Here, we report a unique approach to achieve controlled synthesis of Si/Ge nanostructures. We have used a novel photonic curing technique, which uses an intense pulsed light with a broad spectrum (220-1500 nm), to instantaneously prepare these nanoparticles. Unlike conventional methods like rapid thermal annealing where there is enough time to relax to the preferred equilibrium state, quenching during photonic curing occurs much more rapidly (milliseconds), allowing the trapping of metastable states to form unique nanostructures. Si/Ge precursors were spray coated on glass and processed with PulseForge. At capacitor bank voltage of 600V, 10 pulses of light with 8 J/cm^2 fluence each (total fluence of 80 J/cm^2) were used to produce Si/Ge nanoparticles (20 nm – 60 nm). Scanning Electron Microscopy (SEM) and Energy Dispersive Spectroscopy (EDS) showed presence of Si/Ge nanostructure resulting from instantaneous photonic curing process. 3-Aminopropyltrimethoxysilane was used to improve attachment of the Si/Ge precursors on the substrate, and it was observed through EDS analysis that it increased the carbon content in the synthesized nanomaterial. The present work shows that photonic curing route for Si/Ge nanostructures can be promising way for low-cost large scale-controlled synthesis of energy efficient Si/Ge nanostructures.

Late News: Metal-Free Organic Batteries with a Sustainable Design and Enhanced Performance Jakob Asenbauer[1,2], Kai Shi[1,2], Cleber Marchiori[3], Moyses Araujo[3,4], Rodrigo Carvalho[4], Daniel Brandell[4], Stéphanie Pouget[5], Lionel Picard[5], Simon Jestin[6], Marie Völlmer[6], Sylvie Bayle[7] and Dominic Bresser[1,2]; [1]Helmholtz Institute Ulm, Germany; [2]Karlsruhe Institute of Technology, Germany; [3]Karlstad University, Sweden; [4]Uppsala University, Sweden; [5]University Grenoble Alpes, France; [6]CANOE – Platform for Composites and Advanced Materials, France; [7]Bernard Dumas, France

Organic batteries are composed of abundant elements (i.e. C, H, O, N and S) and can be produced through eco-friendly procedures. Thereby they provide the possibility for electrochemical energy storage with a –compared to conventional inorganic batteries – smaller environmental footprint and lower cost.[1–3] Despite an increased interest in the scientific community within the last years, there are still unresolved issues with organic battery materials that need to be addressed before commercialization. First, the electric conductivity of organic materials is frequently very low. Thus, large amounts of conductive carbon need to be added and the achievable areal mass loading is too low for practical applications. Second, the processing of the electrode should be without the usage of hazardous solvents and binders to be in line with the general goal of sustainability. And third, the understanding of the reaction mechanism of organic active materials upon cycling is so far still limited, but essential to rationally improve the materials. Herein, we present an in-depth analysis of the (de-)lithiation mechanism of tetra-lithium perylene-3,4,9,10-tetracarboxylate ($PTCLi_4$) as an exemplary organic active material. Furthermore, we replaced the metallic current collector foil with a carbon current collector (CCC), made of ex cellulose carbon fibers, i.e. from cheap and renewable sources. This in combination with an environmentally friendly aqueous processing allowed us to produce metal-free organic electrodes with good electrochemical performance, a high active material content (80 wt%), an excellent cycling stability (>10,000 cycles), and a very high areal mass loading (>50 mg cm^{-2}).

Predicting Topotactic Ion-Insertion Reactions in Manganese Oxides for Low-Cost Aqueous Battery Cathodes Evan Z. Carlson[1], William C. Chueh[1], J. Tyler Mefford[1] and Michal Bajdich[2]; [1]Stanford University, United States; [2]SLAC National Laboratory, United States

To eliminate power sector emissions, low-cost energy storage of weekly to seasonal duration must accompany renewable generation. Recent analysis suggests that long-duration energy storage systems must cost less than $20/kWh to facilitate the transition.[1] These storage systems must simultaneously be safe, energy-dense, and have long cycle/calendar life to ensure market adoption. One intriguing approach to satisfy all of these criteria is the development of aqueous batteries with electrodes made from cheap, energy-dense materials. Manganese oxides, which are earth-abundant, water-stable, and have rich ion-insertion chemistry, are attractive candidates for aqueous battery cathodes. However, rational design of these batteries demands a better understanding of their ion intercalation mechanisms and the relationships between voltage, electrolyte composition and electrode structure.

In this talk, we will discuss our efforts to predict insertion voltages of protons and alkali ions (H^+, Li^+, Na^+, K^+) into manganese oxides using first-principles DFT calculations. Despite the success of the SCAN functional in predicting the polymorphic structure of manganese oxides grown during chemical synthesis,[2] we will show that a DFT+U approach is required for accurate computation of manganese oxide energetics. We will discuss our computed energy referencing scheme that captures the appropriate physics of the manganese oxide system (e.g. magnetic structure, 3d electron energies, zero point energies and entropies) and ensures reasonable predictive accuracy while avoiding overfitting. In doing so, we will highlight some of the tradeoffs associated with this computational approach. We will also analyze how the computed Pourbaix diagrams predict electrode thermodynamic behavior for a specific alkali ion and manganese oxide polymorph. Emphasis will be placed on the implications for the design of aqueous batteries with different alkali intercalant ions. Finally, we will compare our computational results to our own experiments and suggest promising strategies for improved aqueous battery cathodes.

Reversible Charging of Redox-Active Conjugated Polymers Beyond the Polaronic State in Aqueous Electrolytes Alexander Giovannitti[1], Anna Szumska[2], Iuliana P. Maria[3], Davide Moia[4] and Jenny Nelson[2]; [1]Stanford University, United States; [2]Imperial College London, United Kingdom; [3]University of Oxford, United Kingdom; [4]Max Planck Institute for Solid State Research, Germany

Redox-active conjugated polymers are an interesting class of materials for electrochemical devices since their properties can be tuned by chemical design to enable redox activity in various electrolytes. In our presentation, we will introduce design rules for the development of conjugated polymers with high electronic and ionic charge transport properties to enables fast charging of single-phase electrodes in aqueous electrolytes [1,2]. While the choice of the polymer backbone is important for achieving electrochemical stability of the charged polymer states, it is found that the tuning of the local environment of the polymers is equally important. The tuning of the local environment of the materials is achieved by attaching hydrophilic (polar) side chains to the polymer backbone to enable fast ion transport, swelling, and reversible phase changes. Electrodes fabricated with these polymers can utilize more than 70 % of the available redox-active state in the bulk of the polymer while maintaining high electrochemical stability during continuous cycling. Our work shows the importance of chemical design strategies for achieving high electrochemical stability for conjugated polymers in aqueous electrolytes.

11:15 AM EN12.07.05
High Energy Density Redox-Mediated Flow Batteries Using Bio-Inspired Electrolytes Tugba Ceren Gokoglan[1], Shyam K. Pahari[2], Joseph M. Egitto[1], Sundar Rajan Aravamuthan[1], Patrick J. Cappillino[2] and Ertan Agar[1,1]; [1]University of Massachusetts Lowell, United States; [2]University of Massachusetts Dartmouth, United States

Redox flow batteries (RFBs) are considered as a prime candidate for addressing the intermittency problem in renewable energy sources, due to their unique architecture that allows for unparalleled scalability and flexibility required for grid integration. [1]. Among several types of RFBs under development, non-aqueous redox flow batteries (NRFBs) have the potential to approach the energy density of lithium-ion batteries, while maintaining the advantages of flow systems, including ability to decouple power and energy ratings, and thermal stability [2]. Regardless of the active materials used, NRFBs suffer from low energy densities because the energy density is primarily dependent on the electrolyte concentration used [3]. The solubility values of redox active materials in non-aqueous organic solvents are relatively lower compared to aqueous systems, which negatively affects the energy density of the flow cell [4]. One promising approach for drastically improving the energy density of NRFBs is the utilization of solid charge storage materials, which are reversibly oxidized/reduced in the electrolyte tanks upon interaction with the redox active species dissolved in electrolyte [5].

Herein, we aim to demonstrate a redox-mediated flow battery using a highly stable bio-inspired electrolyte and a suitable solid storage material to provide evidence that the addition of a compatible solid material greatly improves the energy density. To accomplish this objective, a highly stable bio-inspired electrolyte, vanadium(IV/V)bis-hydroxyiminodiacetate (VBH) [6], is selected as the redox active material. Implementing VBH as a high-stability testbed (i.e., no interference from side reactions) would allow the detailed analysis required for the elucidation of the indirect redox mediation reactions between the solid storage and redox active materials. For the solid storage material, cobalt hexacyanoferrate (CoHCF), a Prussian blue analog, is selected based on its formal potential, which overlaps well with the formal potential of VBH. After sufficient evidence of improvement in the capacity is established, the solid charge storage material is optimized to further improve the energy density. Optimization of the critical parameters such as the amount of solid storage material, the operating current density, and the electrolyte flow rate is presented. The performance characteristics of the RFBs with and without solid charge storage materials present are reported and compared using a suite of electrochemical methods, including charge/discharge cycling.

1:30 PM EN12.08.01
Alloys for Magnesium Batteries—From Bulk Electrode to Surface Protection Clément Pechberty[1,2], Lorenzo Stievano[1,2] and Romain Berthelot[1,2]; [1]ICGM, CNRS, Univ Montpellier, France; [2]Reseau sur le Stockage Electrochimique de l'Energie (RS2E), France

In the context of looking beyond the lithium-ion technology, magnesium batteries appear as promising candidates. Indeed, magnesium is abundant and less reactive than alkali metals, and its low redox potential opens the way to high energy density batteries. However, two major roadblocks slow down the development of magnesium batteries: the strong passivation of the magnesium surface with classical electrolytes and the lack of suitable positive electrode materials.
Alloy-type materials that can react electrochemically with magnesium have been widely evaluated as negative electrode materials, with very high corresponding capacities as well as a good behavior with classical electrolytes. However, their application as bulk electrode materials replacing magnesium metal lowers significantly the total energy density, in some cases below a critical threshold where the system becomes not competitive.
In the ongoing revival of lithium-metal batteries, the protection of lithium metal by alloy-type materials has been proposed. Such coating strongly influences the evolution of the electrode-electrolyte interface and induces long lifespan, with especially less polarization and less dendrite formation.
The purpose of our work is to adapt such coating strategy to protect the magnesium surface, thus enabling the use of classical electrolytes based on the

$Mg(TFSI)_2$ salt. Here, we aim to show our attempts to deposit a thin layer of a p-block element on the surface of a magnesium electrode, through chemical reduction of metallic salt in solution, or via solid-solid and liquid-solid reactions. Coating are characterized by combining X-ray diffraction and electronic microscopy with surface-scale techniques such as X-ray photoemission spectroscopy. The positive impact of the coating is checked by evaluating the behavior of unprotected and protected electrodes in full cells, first with standard Chevrel phase Mo_6S_8, and then with more promising sulfur-based composites as high energy density systems are targeted. In comparison with bare magnesium electrodes, lower capacity decay and long battery lifespan is observed. These preliminary works are very promising and pave the way to the development of magnesium-metal batteries with very simple electrolytes.

1:45 PM EN12.08.02
Late News: Picoliter-Sized Zn-Air Batteries for Releasable Microscopic Sensors and Colloidal Robots Ge Zhang, Michael Strano, Volodymyr Koman, Jingfan Yang, Yuwen Zeng, Matthias Kuehne, Albert T. Liu, Sungyun Yang and Allan M. Brooks; Massachusetts Institute of Technology, United States

The recent interest in microscopic autonomous systems, such as microrobots, colloidal state machines and *smart dust* has created a need for microscale energy storage and harvesting. However, the incompatibility of material properties used at the macroscale with micro-fabrication techniques creates significant challenges to realizing microscale energy systems. Herein, we use photolithography to create picoliter (10^{-12} L) devices that scavenge ambient air for Zn oxidation, achieving the highest recorded energy densities of 760 to 1070 Wh L^{-1} at a scale less than 100 μm in lateral size. We have elucidated the critical role of phosphate buffered electrolyte in achieving such high energy densities. Zinc phosphate precipitates contributed to a higher discharge voltage in phosphate buffered saline compared to other neutral electrolytes. More than 10,000 devices per wafer can be released into solution as functional colloids with in-built power supplies. Within a volume of only 2 pL, these batteries can deliver open circuit voltages of 1.16 V with total energies ranging from 5.5 ± 0.3 to 7.7 ± 1.0 μJ and maximal power around 2.7 nW. Such systems can power a memristor providing access to two-state memory, as well as bimorph actuators for colloidal robotic applications. The high energy density, tiny size and simple configuration promise the mass fabrication and adoption of such picoliter Zn-air batteries for micron-scale, colloidal robotics with autonomous functions.

2:00 PM EN12.08.03
Bioinspired, Tree-Root-Like Interfacial Designs for Structural Batteries with Enhanced Mechanical Properties Tianwei Jin and Yuan Yang; Columbia University, United States

In the past decades, lots of efforts are made by researchers to promote the development of structural lithium ion batteries, which endow energy storage ability to structural parts for vehicle lightweighting. However, the two strategies people normally use nowadays still have major challenges. One method is introducing thick or heavy packaging and mechanically supporting parts to or inside cells, which intrinsically decreases the energy densities of these energy storage devices. The other one is replacing conventional cell parts like electrodes and electrolytes with materials which have strong mechanical properties but poor electrochemical cycling stability, which sacrifice cycling performance of batteries.
By finite element analysis, we find that the reason of unsatisfying flexural behavior of conventional lithium ion batteries is the sliding of separator and electrode layers relative to each other, and it will greatly increase if we can suppress this sliding. The reason is that if layers are bonded together, all components will participate in the resistance of bending rather than slide relatively, which inspires us with a new idea to improve the mechanical behavior of batteries.
Here we propose a bioinspired and scalable interfacial design to make cell parts of lithium ion batteries robust by applying suitable and strong “binders” to each interface inside. With a thin coating layer of porous PVDF-HFP, which is previously shown without detriment to cycling performance, electrodes can be bonded with PVDF-coated separators tightly by hot pressing. With these techniques, all components in cells can contribute to the overall mechanical strength with more efficient load transfer, which dramatically enhances the flexural modulus of pouch cells from 0.28 to 3.1 GPa. On the other side, on account of the chemical simplicity of this strategy, the structural battery in this work can deliver a comparable specific capacity of 148.6 mAh g^{-1} with conventional cells and show 95.5% capacity retention after 500 cycles. Moreover, the specific energy only decreases by 3%, which is the smallest reduction reported so far in structural batteries. A prototype of “electric wings” is also demonstrated, which allows an aircraft model to fly steadily. This work comes up with a new and straightforward way to design structural batteries, with both mechanical performance and energy density satisfied, and the method can be easily transferred to large-scale production in industry.
In addition, we apply finite element analysis to conduct simulations to compare the contribution of materials' intrinsic mechanical properties and interfacial adhesion strength in flexural behaviors of batteries, which provides a valuable insight into feasible structural batteries with balanced mechanical and electrochemical properties.

2:15 PM EN12.08.04
Bio-Inspired Quinone Macromolecules Grafted on O, N, S, P Codoped Carbon Paper for High Energy Density Electrochemical Capacitors Abdelaziz M. Gouda; Ecole Polytechnique Montreal, Canada

Developing sustainable biosourced electrode materials for energy storage applications is an urgent need, to keep pace with the ongoing increase in energy demand combined with the rapid use of electric vehicles and portable electric devices. Growing environmental concerns have spurred investments in renewable but intermittent energies. The need to switch to environmentally friendly, widely available, organic materials is confronted by the low conductivity and stability of most candidates and the difficulties of creating an efficient, metal-free current collector. In this work, we present a sustainable high energy density supercapacitors based on bio-sourced materials grafted on surface treated carbon paper electrode. An acidic and thermal treatment is used to induce O, N, S, and P surface doping and increase the surface area of the carbon paper. This doping improves wettability, conductivity (through the formation of graphene quantum dots), and adds faradaic activity improving the capacitance of the bare electrode. Additional deposition of sepia melanin and catechin (a tannin) with high specific capacitance and energy density shows very promising results for supercapacitors. Up to 2850 mF/cm^2 (228 F/g) capacitance, with 100% retention after 5 000 cycles at 20 A/g, 100% coulombic efficiency, 0.87 and 1.01 mW h/cm^2 (69.71, 81.25 W h/kg) and 277.15 and 158.10 mW/cm^2 (22.20 and 12.66 kW/kg) energy and power densities for sepia melanin and catechin, respectively, were achieved for symmetric supercapacitor devices in 0.5 M Na_2SO_4 (pH 5) electrolyte. This work provides a general guidance to design high-performance supercapacitor electrodes based on bio-sourced and potentially biodegradable materials

2:30 PM EN12.08.05
Relaxometry and Diffusometry Investigation of Deep Eutectic Solvents Based on Choline Chloride Carla C. Fraenza and Steven G. Greenbaum; Hunter College of CUNY, United States

The development of the new generation of electrolytes for energy storage, which simultaneously enable substantial improvements in energy and power density, safety and reductions of environmental impacts and cost, is a big challenge at the present time. Deep eutectic solvents (DESs), which sometimes are considered a sub-class of ionic liquids due to their similar properties, have shown to be promising as electrolytes.[1,2] These solvents are defined as a mixture of two or more species, typically a hydrogen bond donor (HBD) species and a hydrogen bond acceptor (HBA) species which may be solid or liquid, and that at a particular composition present a melting point depression usually being liquids at room temperature. Among their most relevant

properties, they have low volatility, low flammability and wide electrochemical and thermal stability windows. Unlike typical ionic liquids, DESs can be inexpensive, readily synthesized, and can often be prepared from biodegradable, and nontoxic constituents. In this work, the molecular rotational and translational dynamics of three different DESs based on choline chloride (ChCl) were studied using the fast field-cycling nuclear magnetic resonance relaxometry (FFC-NMR) and pulsed-field gradient (PFG) NMR techniques. Specifically, ChCl was chosen as the HBA at concentrations between 5 and 33mol% and glycerol, ethylene glycol (EG) or phenol were used as the HBDs. It was observed that the translational and rotational motions of all species became slower with increasing ChCl concentration for EG and phenol as the HBDs, but the opposite trend was observed for glycerol. Moreover, the PFG-NMR diffusion measurements identified a slow exchange process between the hydroxyl (OH) groups of choline and the HBDs.

2:45 PM EN12.08.06
Using Classical Molecular Dynamics to Investigate the Lithium Transport Mechanisms in Various Solvent–Lithium-Salt Systems in Lithium-Oxygen Batteries Emily J. Crabb[1], Graham Leverick[1], Ryan Stephens[2], Yang Shao-Horn[1] and Jeffrey C. Grossman[1]; [1]Massachusetts Institute of Technology, United States; [2]Shell International Exploration & Production Inc., United States

Lithium-oxygen batteries have higher energy densities than traditional lithium-ion batteries. However, they are not yet commercially viable due to poor efficiency, high charging voltages, and low cycle lifetimes. These issues could be addressed with a deeper fundamental understanding of the atomistic behavior of these batteries, especially how different factors impact lithium transport behavior. We have used classical MD simulations to examine lithium transport behavior in ten different solvents. We have validated our classical force fields by experimentally measuring the densities, viscosities, and ionic conductivities of our solvent–LiTFSI systems for comparison. However, our classical MD simulations have allowed us to go beyond these measurements and investigate properties that can be more difficult to access experimentally, such as the residence time of solvent molecules in the lithium solvation shell.

3:00 PM EN12.08.07
Toward VBH Based High Energy Density Flow Batteries—A Computational and Experimental Approach Shyam K. Pahari[1], Benjoe R. Visayas[1], Jennifer Woehl[1], Tugba Ceren Gokoglan[2], Maricris L. Mayes[1], Ertan Agar[2] and Patrick J. Cappillino[1]; [1]University of Massachusetts Dartmouth, United States; [2]University of Massachusetts Lowell, United States

In last few decades, mounting concerns about the sustainability of fossil fuel-based energy and ever-increasing energy demand around the globe has led to the exploration of clean and renewable energy sources.[1,2] As a result, incorporation of renewable energy sources such as wind and solar into the electrical grid is taking place rapidly. [3] However, the inherent intermittency of these sources results in demand-supply imbalance which impedes efficiency. [4] One of the ways to tackle this problem is assuring reliability by integrating energy storage systems into the grid. [5] Redox flow batteries (RFBs) are a promising technology for grid level energy storage with a potential to match the performance of state-of-the-art Li-ion batteries with numerous additional advantages including decoupled power and energy rating [6], a wide range of working temperatures and a good safety profile.
Despite the numerous benefits of RFBs, the technology is still at its infancy and widescale implementation of them is hindered due to following three fundamental issues namely poor stability (cycling and calendar life), low energy density resulting from poor solubility of active material, and poor performance. In our previous study, we bio-mimicked an octa-coordinated dianionic vanadium complex, vanadium-bis-hydroxyiminodiacetate (VBH), from a naturally occurring biomolecule, amavadin, as a redox active molecule for flow battery application and established its extraordinary stability during exhaustive cycling. [7,8,9] Herein, we utilize the VBH scaffold to tune thermodynamic parameters including solvation free energy and lattice enthalpy by designing molecules with varying counter cations and provide the clear pathway to further solubilize the VBH based active materials. In particular, we present evidences that increasing alkyl chain length of quaternary ammonium counter-cations, despite less favorable solvation energy, increases the solubility by facilitating the weakening of the crystal lattice. We further report electrochemical cycling of this material at moderate concentration in both symmetric and full-cells, in conjunction with an anthraquinone negolyte.

Neural Equivariant Interatomic Potentials for Large-Scale Electrolyte Simulations Nicola Molinari, Albert Musaelian, Juan Felipe Gomez, Robert D. Newman, Simon L. Batzner and Boris Kozinsky; Harvard University, United States

Electrolytes control battery recharge time and efficiency, anode/cathode stability, and ultimately safety, thus their optimization is crucial for the design of modern energy storage devices. In this work, we focus on ionic liquid-based electrolytes. This promising class of electrolytes possesses superior chemical stability compared to standard organic solvents, however, poor and anomalous transport properties are hindering their applicability [1]. Unfortunately, classical energy models struggle to provide the level of accuracy needed to reliably predict and investigate ionic conductivity.

Here we study the applicability to such systems of state-of-the-art equivariant graph neural networks (NequIP [2]). Ionic liquid-based electrolytes provide a unique challenge due to their strong ionic interactions and liquid nature. Additionally, substantially diverse inter-atomic environments are expected as a function of lithium-salt doping [3], raising the question of model transferability. Our promising results show that we can circumnavigate the ad-hoc and system-dependent tweaks to the classical energy models (for instance charge rescaling or polarizability), while retaining computational speed and near-DFT accuracy for large-scale ionic transport molecular dynamics investigations.

Late News: Mutually Exclusive MXene and Graphene Oxide Multilayer Composites in Lithium-Sulfur Battery Sanghee Nam, Il-Kwon Oh and Manmatha Mahato; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The shuttle effect of soluble lithium polysulfide (LiPS), which results in the gravest capacity degradation, is one of the critical issues to hinder the commercialization of lithium–sulfur batteries (LSBs). Here, we report mutually exclusive $Ti_3C_2T_x$ MXene and graphene oxide multilayer composite to suppress the shuttle effect by both physical inhibition of micro/mesoporous and chemical absorption of surface functional groups. The abundant surface functional groups of GO and MXene attract the positively charged lithium ion (Li^+) and eject the negatively charged polysulfides (S_n^{2-}) through electrostatic affinity and repulsion. A simple approach using vacuum filtration was utilized to encapsulate elemental sulfur (S_8) between GO and MXene film (GSM), playing role in a permselective separator and functionalized current collector, respectively. The functionally antagonistic GSM is directly utilized as cathode for LSBs and exhibits a specific capacity of 1,425 mAh g^{-1} at 0.1C in the initial cycle. The abundant functional groups, which can chemisorb the LiPSs, result in a high cyclic retention of approximately 85.1% after 500 cycles. Furthermore, we demonstrate a flexible LSB with a PEO-LiTFSI electrolyte based on the flexibility of the exceptionally thin GSM due to the 2D nanomaterials, MXene and graphene oxide.

Aqueous Electrolytes for Aluminum-Carbon Rechargeable Batteries Jasmin Smajic, Bashir E. Hasanov, Amira Alazmi, Abdelhamid Emwas, Nimer Wehbe, Alessandro Genovese, Abdulrahman Ellabban and Pedro Costa; KAUST, Saudi Arabia

By virtue of their chemical and mechanical resiliency, carbon cathodes have shown excellent electrochemical behavior in aluminum batteries. Oppositely, this was possible only with expensive ionic liquid electrolytes, whose biodegradability, corrosivity and moisture sensitivity is an issue. By contrast, their use in Al systems operating in the aqueous electrolytes has scarcely been explored and the reported results were consistently poor. In this work, we assemble an Al-C battery with an aqueous electrolyte (aluminum trifluoromethanesulfonate) and study the electrode-electrolyte interactions. On the anode side, we find that both the electrode pretreatment and the electrolyte concentration play essential roles in solid-electrolyte interface (SEI) formation. While on the cathode side, we find pore size and hydrophilicity as important parameters in enabling superior performances. Consequently, employing a hydrophilic reduced graphene oxide (rGO) as the active cathode material enables an aqueous Al-C battery with a high energy density (136 Wh kg^{-1} per cathode mass) and one of the best capacity retentions reported (>60% across a range of current densities and constant Coulombic efficiency close to unit). Furthermore, our rGO cathode more than doubles the benchmark for life cycles (to +200 cycles) and can be charged rapidly (<5 minutes). To explain this response, we propose a charge storage mechanism wherein the $[Al(H_2O)_6]^{3+}$ ions do not get desolvated when inserted into the cathode. The guest Al ions (surface adsorbed or intercalated) act as proton donors and may get anchored on the oxygen moieties of the rGO, further promoting the formation of an electrochemical double layer. A mixed charge-storage regime follows that stabilizes the carbon cathode and enables unprecedented response.

Towards Low-Cost and Sustainable Na-Ion Batteries Using Vanadium Phosphate Positive Electrode Materials Laurence Croguennec[1], Long H.B. Nguyen[1,2], Chloé Pablos[1,2], Emmanuel Petit[1], François Rabuel[2], Grégory Gachot[2], Paula Sanz Camacho[1], Antonella Iadecola[3], Jacob Olchowka[1], Mathieu Morcrette[2], Dany Carlier[1] and Christian Masquelier[2]; [1]ICMCB, CNRS, Bordeaux Univ., Bordeaux INP, France; [2]LRCS, Picardie Jules Verne Univ., France; [3]RS2E, Réseau Français sur le Stockage Electrochimique de l'Energie, FR CNRS 3459, France

Polyanionic materials are intensively studied as promising positive electrode materials for Na-ion batteries thanks to high stability and fast ionic mobility within their structural framework.[1-3] Among those polyanionic materials, $Na_3V_2(PO_4)_2F_3$ and $Na_3(VO)_2(PO_4)_2F$ are the two most attractive ones due to their high voltage for two Na^+ ions extraction and their high theoretical energy densities of ~ 500 mAh.g^{-1}. These two compositions are indeed the two end members of a family of compounds described with the general formula $Na_3V_2(PO_4)_2F_{3-y}O_y$ where $0 \leq y \leq 2$. We will first discuss the stability of these active compounds in aqueous media, and at different states of charge and discharge.[4] Then, we will compare the performance of optimized carbon-coated stoichiometric $Na_3V_2(PO_4)_2F_3$ in a large panel of cycling conditions, at different rates and temperatures.[5-6] Finally, we will show how cationic and anionic substitution have been widely explored with the target to reversibly de-intercalate and re-intercalate the third Na^+ ion from/in the structure.

Towards Cobalt Free and Manganese Rich Cathode Materials for Lithium–Ion Batteries Peter Axmann, Marilena Mancini, Nicola Jobst and Margret Wohlfahrt-Mehrens; ZSW, Zentrum für Sonnenenergie, und Wasserstoffforschung, Germany

Lithium ion batteries are the state of the art electrochemical storage systems in many mobile applications. The further development of high-performance, cost-efficient and sustainable energy storage systems continues to be a key technology both for the full transition from combustion engines to full electric vehicles and for the intermediate storage of renewable energies. The rapidly increasing market for lithium-ion batteries in the transport and energy sectors is leading to a rapidly growing need for materials for these cells, whose supply security and environmental compatibility must be ensured – especially for critical raw materials such as cobalt, which is a component in state of the art cathode materials. The high costs of cobalt have led to the development of nickel rich layered materials with reduced cobalt content and the next generation of cathode material will contain less than 5 percent cobalt by weight (NCM811).

The development of cobalt free, manganese rich cathode materials with reduced nickel content such as $LiNi_{0.5}Mn_{1.5}O_4$ (LNMO) or $Li_{1+x}Ni_{0.5}Mn_{1.5}O_4$ ($0<x<1$) can contribute significantly to further reduction of cost, high electrochemical performance and higher safety compared to lithium ion batteries with nickel-rich layered oxides. The lithium-nickel-manganese oxide compounds can be tailored with respect to composition and crystal structure in order to reach high capacities up to 250 mAh g^{-1} [1-3] The presentation will give an overview on synthesis routes and electrochemical performance of LNMO and a series of $Li_{1+x}Ni_{0.5}Mn_{1.5}O_4$ ($0<x<1$) cathode materials. Strategies to increase the electrochemical performance and the long life stability include i) development of tailored crystallite and particle design, ii) a profound understanding of the reaction mechanisms during lithium insertion and extraction, iii) the analysis of underlying ageing mechanisms in half and full cells, iv) development of protective surface coatings and v) the optimization of electrode/electrolyte interfaces. We will present full cell data with LNMO and $Li_{1+x}Ni_{0.5}Mn_{1.5}O_4$ ($0<x<1$) cathode materials using various electrolytes and will discuss strategies for further optimization.

A Water-Soluble Lignosulfonate Binder for Hard Carbon Anodes in Sodium-Ion Batteries Ritambhara Gond[1], Habtom D. Asfaw[1], Omid Hosseinaei[2], Kristina Edstrom[1], Reza Younesi[1] and Andrew Naylor[1]; [1]Uppsala University, Sweden; [2]RISE Research Institutes of Sweden, Sweden

Sodium-ion batteries (SIBs) have rapidly gained interest for their potential usage in large-scale grid energy storage, due to the higher abundance of sodium over lithium [1-2]. Inspired by electrodes common in lithium-ion batteries (LIBs), analogous materials are often considered in the development of SIBs [3]. However, while graphite anodes (~360 mA h g^{-1}) are most frequently used for LIBs, it is hard carbon (~300 mA h g^{-1}) which are one of the most promising for SIBs. The electrode binder, which connects particles of the electrode to one another as well as to the current collector, is regularly found to be polyvinylidene fluoride (PVDF). To improve sustainability of batteries, PVDF should be replaced with non-fluorinated, environmentally friendly binders. Lignin is an abundant natural polymer, and Kraft lignin, a by-product from pulp mills, has previously been reported as an inexpensive and environmentally-friendly NMP (*N*-methyl pyrrolidone)-soluble binder for LIBs [4].
Here, sodium lignosulfonate, a sulfonated lignin derivative, is introduced as a non-toxic, *water-soluble* binder for hard carbon electrodes. Its electrochemical performance in half- and full-cells against Prussian White is compared with other water-soluble binders, sodium carboxymethyl cellulose (CMC) and sodium alginate, as well as the NMP-soluble lignin. Furthermore, the impact of the lignosulfonate and CMC binders on the composition of the solid electrolyte interphase (SEI) layer is determined by X-ray photoelectron spectroscopy (XPS).

Mg^{2+} Intercalation into Nanostructured $H_2V_3O_8$—A Post-Mortem Study Yuri Surace, Martina Romio, Damian M. Cupid and Marcus Jahn; AIT - Austrian Institute of Technology GmbH, Austria

Magnesium-ion batteries (MIBs) have received great attention in recent years as an alternative battery chemistry to Li-ion technologies thanks to the intrinsic advantages of Mg over Li. Mg has a significantly larger volumetric capacity (3832 mAh cm^{-3} vs 2061 mAh cm^{-3} for Li), higher natural abundance and lower cost than Li [1]; Mg also has a relatively low standard redox potential (-2.37 V vs. SHE [1]). Furthermore, due to the divalent nature of the Mg^{2+} cation, for the same amount of ions stored in a host material (usually the cathode), the specific capacity is doubled in comparison with a monovalent cation. Thanks to these key advantages MIBs can theoretically achieve higher energy densities at a lower cost than LIBs [2] making MIBs a very attractive battery technology. However, one of the main fundamental challenges in MIBs is the slow Mg^{2+} ion solid state diffusion into the cathode active material's lattice. This is generally attributed to the high charge/radius ratio of the Mg^{2+} ion, which results in strong interactions between the anions and cations of the host structures [3]. As consequence, cathode materials for MIBs usually show very poor electrochemical performance (low specific capacities, high overpotentials and poor rate capability).
Vanadium-based oxides cathodes have been the object of intense study over the past few years due to their relatively high potential of 2.5 V vs Mg^{2+}/Mg, and the possibility to explore multiple oxidation states of vanadium, i.e. V^{5+}/V^{4+} and V^{4+}/V^{3+}, resulting in higher theoretically achievable specific capacities [4]. Within this family, the $H_2V_3O_8$ (HVO) phase shows promising structural and morphological characteristics which could favour Mg^{2+} intercalation. Specifically, $H_2V_3O_8$ has a relatively large interlayer distance of 8.4 Å and can crystallize in a nanowire morphology. However, $H_2V_3O_8$ has only recently been tested in a MIB for the first time, showing a specific capacity of around 80 mAh g^{-1} at room temperature, even though its theoretical specific capacity is 190 mAh g^{-1}, for the intercalation of 1 eq. of Mg^{2+} [5].
In our study, a post-mortem analysis of HVO electrodes upon charge and discharge at specific cycle numbers was carried out to investigate the intercalation mechanism of Mg^{2+} into HVO. For the first time, we demonstrate the electrochemical performance of HVO in TFSI-based electrolytes with a specific capacity approaching 200 mAh g^{-1} at room temperature. Furthermore, by combining bulk and surface characterization techniques, changes in the HVO crystal structure, morphology and surface chemistry were analysed in-depth. Depending on the cycle number, Mg^{2+} intercalation upon discharge resulted in a 0.5% to 4% change in the unit cell parameters compared to the pristine electrode. The intercalation caused a change in the V^{5+}/V^{4+} ratio, with a

lower ratio (i.e. higher amount of V^{4+}) associated with cycle numbers showing the highest capacity values. However, Mg^{2+} ions could not be completely extracted upon charge, resulting in lattice parameters which do not return to their original values. Although the nanostructured morphology of HVO did not change over cycling, surface roughening of the nanowires was observed at high cycles numbers, indicating formation of a TFSI-containing surface layer. Evidence of V dissolution could also be confirmed, resulting in capacity fading after about 35 cycles.

The Critical Role of Electrolyte Selection in Sodium Oxygen Batteries Nagore Ortiz-Vitoriano[1,2]; [1]CIC Energigune, Spain; [2]Ikerbasque, Spain

Research into new energy storage technologies, for both portable and stationary applications, has become imperative in order to meet present and future energy requirements. Recently, rechargeable sodium oxygen batteries are receiving a great deal of interest as possible alternatives to lithium ion batteries, because of their potentially higher gravimetric energy densities (1605 or 1108 Wh/kg based on Na_2O_2 or NaO_2 discharge products, respectively)[1].

In order to facilitate the advancement of this technology, the development of targeted approaches to dealing with the technology's unique chemistry are required. The vast majority of the work reported on sodium oxygen batteries has been devoted to the development of suitable air cathodes[2] (primarily focused on carbon), catalysts, and - to a lesser extent - redox mediators, neglecting electrolytes despite their importance. Electrolytes, consisting of a salt and a non-aqueous solvent, are a key component of any optimized system. The parameters affecting electrolyte physiochemistry (solvent-salt structure and dynamics) are, therefore, critical to battery performance, lifetime and safety. The composition of the electrolyte (solvent and salt) has been identified as key parameter which controls the crystal growth during the discharge process, and subsequently the dissolution of discharge products during charge. Glyme-based solvents have been widely – but arbitrarily – used, and to date no clear correlation between solvent/electrolyte properties and battery performance have been outlined.
In this work, we will discuss and clarify the relationship between glyme chain length and cell chemistry and performance. We will, moreover, demonstrate how solvent selection helps define cell chemistry and performance, by linking salt-solvent interactions to solvation energies - and subsequently to sodium battery electrolyte properties - through the combination of both experimental and computational methodologies. In addition, we will unravel how careful combination of different solvents such as ionic liquids can modify the speciation and solvation of the discharge products, so as to obtain the desired deposition mechanism and crystal growth.

Lower Temperature, Lower Cost Molten Sodium Batteries Martha M. Gross, Stephen J. Percival, Rose Lee, Amanda Peretti, Erik D. Spoerke and Leo J. Small; Sandia National Laboratories, United States

Molten sodium batteries are a grid-scale energy storage technology with over 500 MW/4 GWh deployed worldwide that utilize inexpensive sodium and sulfur or aluminum-containing materials. Despite their legacy of reliably and safely providing large capacity energy storage for decades, they do not enjoy widespread popularity as an alternative to grid-scale lithium-ion batteries. This can largely be attributed to the high temperatures necessary to operate these systems (270 – 350 °C), which greatly increases the capital cost to install them ($600-700/kWh) despite their use of low-cost active materials. Lowering the temperature to near the melting temperature of sodium (97.8°C) can create dramatic savings by reducing the cost of inactive materials such as the insulation, wiring, and seals, while increasing battery longevity by slowing aging of all system components. Traditional battery chemistries such as sulfur/polysulfides and nickel/nickel chloride, while effective for high temperatures, simply do not work at low temperatures (< 150 °C) as materials solidify. To lower the temperature by nearly 200 °C, complete re-engineering of the cathode is necessary. Here we describe the development of a low temperature catholyte utilizing low-cost and earth-abundant materials to create a high performance, low temperature molten sodium battery. This was achieved by first identifying redox-active molten salts composed of sodium iodide and a metal halide salt that are liquid at 100 °C. The effect of sodium iodide content and choice of metal halide salt on battery voltage and power performance was studied to identify compositions capable of near-commercially relevant levels of power and energy density. The long-term cyclability of catholyte compositions was evaluated in batteries at 110 °C, with some catholyte compositions capable of cycling in some cases for up to 8 months. Electrochemical performance was weighed against constraints in molten salt cost to create a low-cost, high performance catholyte.

Sandia National Laboratories is a multi-mission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

EN12-Virtual

10:30 AM *EN12.10.01
An In-Depth Assessment of Zinc-Ion Diffusion in Solid-State Hosts Arumugam Manthiram; The University of Texas at Austin, United States

As the energy-storage market is accelerating and expanding globally with lithium-ion batteries, cost and sustainability of the technology for electric vehicles and grid-storage are becoming a serious concern. This has prompted immense interest on battery chemistries based on earth-abundant, low-cost materials. In this regard, batteries based on multivalent ions, such as magnesium, calcium, zinc, aluminum, *etc.* have generated much interest, as they occur at much higher terrestrial concentrations, diminishing the issues associated with sustainability and supply chain. Also, multivalent ions can theoretically store more charge than monovalent lithium or sodium, although with a lower operating voltage. However, multivalent-ion batteries are faced with a few scientific and technological challenges.

First, nonaqueous multivalent-ion batteries suffer from a lack of appropriate electrolytes, which makes a true assessment of their performance difficult. Second, except for zinc, the lack of appropriate anode/electrolyte combinations also makes the reversible plating and stripping of the multivalent metallic anodes challenging. Without proper assessment of the electrochemical cells, it will be hard to understand the true behavior of the cathode. Therefore, this presentation will focus first on the use of chemical insertion/extraction reactions of multivalent ions with appropriate reagents to assess the potential of various hosts.

Among the various multivalent-ion batteries, much of the fundamental research has focused on aqueous zinc-ion batteries, and attractive performances have been reported with high capacity and rates with oxide-based cathodes. Despite the apparent success with zinc-ion batteries in aqueous electrolytes, the concept of multivalent-ion batteries remains elusive, as witnessed by a lack of sensible progress in other multivalent-ion chemistries, such as magnesium-ion and aluminum-ion batteries. This mismatch points to a fundamental gap in the knowledge surrounding aqueous zinc-ion batteries, especially the hidden role of protons originating from aqueous electrolyte or from any water present in the cathode.

To delineate the actual solid-state diffusion behavior of zinc ions, the presentation will provide a series of studies to assess the relative extent of zinc-ion versus proton insertion in common solid-state hosts. The use of a microwave-assisted insertion technique for chemical insertion of zinc ions into hosts and elevated-temperature electrochemical zinc-ion insertion will be discussed. Our results indicate that in general and as expected, the diffusion of zinc ions in oxidic hosts is an energy-demanding process that prohibits its efficient utilization in rechargeable batteries. On the contrary, the inclusion of aqueous electrolytes allows the introduction of charge-compensating protons that can readily diffuse into the solid-state hosts, with the release of an equivalent amount of zinc ions into the electrolyte. Therefore, the utilization of aqueous electrolytes with zinc anode is conceptually similar to other systems in which protons are the actual working ions.

Overall, our study reveals that attempts to insert zinc ions strictly in non-aqueous electrolytes are accompanied by severe thermodynamic and kinetic limitations, often encountering significant host-guest electrostatic repulsions due to the higher charge on Zn^{2+} and subsequent capacity loss. This issue can be suppressed by employing more covalent chalcogenide-based hosts, but at the cost of lower cell capacity and voltage. Even in the chalcogenides, zinc-ion diffusion tends to be slow compared to that in other rechargeable batteries. Given the slow native diffusivity of multivalent ions in solid-state hosts, it appears that the possibility of multivalent-ion batteries hinges on the development of alternative cathode architectures that do not rely on the long-range solid-state diffusion of guest ions.

11:00 AM EN12.10.04
Stabilizing Nanostructured α-Ni(OH)$_2$ for High Energy Density Rechargeable Nickel–Zinc Batteries Samuel W. Kimmel[1,2], Ryan H. Deblock[2], Christopher N. Chervin[2], Jeffrey Long[2], Joseph F. Parker[2], Brandon J. Hopkins[2], Debra R. Rolison[2] and Christopher Rhodes[1]; [1]Texas State University, United States; [2]U.S. Naval Research Laboratory, United States

Rechargeable aqueous Ni–Zn batteries can provide an energy-dense, safer alternative to Li-ion batteries for a wide range of applications including electric vehicles, portable electronic devices, and grid-level energy storage. We investigate approaches to obtain high-capacity cathodes that can support the performance of dendrite-suppressing Zn sponge anodes pioneered at the U.S. Naval Research Laboratory. We substitute metal ions (aluminum, cobalt, manganese, or zinc) into α-Ni(OH)$_2$, a phase that stores greater than one-electron per Ni, but requires stabilization to avoid transformation to the lower capacity β-phase. We use a microwave-assisted process that expresses α-Ni(OH)$_2$ in a high surface-area nanosheet morphology, and show that this morphology is retained for all metal-ion substituents.[1] The substituents do, however, influence aggregate growth, interlayer spacing, and Raman vibrational frequencies. The metal-ion-substituted materials are fabricated into powder-composite cathodes and tested versus zinc sponge anodes in alkaline electrolyte. We find that of the substituents evaluated, only Al^{3+}-substitution favorably increases the discharge capacity, discharge voltage, and oxygen evolution reaction onset voltage and improves the cycling stability of the α-phase. The enhanced electrochemical performance and phase stability of Al^{3+}-substituted α-Ni(OH)$_2$ nanosheets correlate to the presence of interlayer ordered nitrates and changes to the environment of intralayer Ni. The rational selection of substituents and rethinking the electronic wiring within the cathode structure provide a pathway to realize energy dense, safe, rechargeable Ni–Zn batteries.

Achieving Stable Molybdenum Oxide Cathodes for Aqueous Zinc-Ion Batteries in Water-in-Salt Electrolyte Lei Wang[1,2], Amy Marschilok[2,2,1], Shan Yan[1,2], Calvin D. Quilty[2,2], Jason Kuang[2,2], Mikaela Dunkin[2,2], Steven Ehrlich[1], Lu Ma[1], Kenneth Takeuchi[2,2,1] and Esther S. Takeuchi[2,2,1]; [1]Brookhaven National Laboratory, United States; [2]Stony Brook University, The State University of New York, United States

A layered MoO_3 material with large interlayer spacing represents a promising cathode for aqueous rechargeable Zn-ion batteries (ARZIBs), but the implementation of this material is limited due to the intrinsically low conductivity and poor structural stability. A 30 m $ZnCl_2$ water-in-salt electrolyte (WISE) was introduced to a MoO_3 nanobelt cathode for the first time, significantly increasing the stability of MoO_3 cathodes compared to those in 3 M $ZnSO_4$ and 3 M $ZnCl_2$ electrolyte. The Zn/MoO_3 cell in WISE unambiguously demonstrated significantly improved rate performance delivering 349, 253, and 222 mAh/g at 100, 500, and 1000 mA/g, denoting a 2x, and 12x capacity increase of those achieved in 3 M electrolytes at 500 and 1000 mA/g, respectively. A capacity retention rate of 73% was achieved after (dis)charging at 100 mA/g for 100 cycles, and no obvious capacity fading was observed at higher current densities of 500 mA/g and 2A/g. A compilation of structural and morphological characterization was systematically performed to provide insight into the mechanisms of the improved performance in $ZnCl_2$ WISE for the MoO_3 cathode materials. Specifically, our data collectively suggested that the drastic fading in 3M electrolytes can be attributed to the parasitic surface deposits on Zn originated from Mo dissolution and H_2 formation due to Zn corrosion and hydrogen evolution reaction (HER), which were significantly suppressed in the $ZnCl_2$ WISE. The direct visualization of these side reactions was achieved for the first time in the Zn-MoO_3 system, using an in situ optoelectrochemical measurement.

$Li_{10}GeP_2O_{12}$ Electrolyte for All-Solid-State Batteries Giuliana Materzanini[1,2,3], Leonid Kahle[3,4], Aris Marcolongo[3,4] and Nicola Marzari[2,3]; [1]Université Catholique de Louvain, Belgium; [2]École Polytechnique Fédérale de Lausanne, Switzerland; [3]National Centre for Computation Design and Discovery of Novel Materials, Switzerland; [4]IBM RSM Zurich Research Laboratory, Switzerland

All-solid-state battery technologies point toward a sustainable energy future, aiming to replace the ammable liquid organic electrolytes currently used with safer solid-state inorganic electrolytes. Oxides generally show better electrochemical properties but weaker ionic conductivity when compared to their sulfide counterparts. Here we use first-principles molecular dynamics simulations to extensively simulate LGPO, the oxide analogue of LGPS, one among the best conducting solid-state electrolytes. From canonical simulations we predict that a hypothetical tetragonal phase mirroring that of LGPS would be highly conductive. We thus explore the dynamical stability of this phase and of an existing orthorhombic phase of LGPO via isobaric-isothermal simulations, while extracting from the trajectories the relevant elastic moduli.

Metal-H_2 Batteries for Large Scale Stationary Energy Storage Yi Cui[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

Grid scale stationary energy storage is critical for integration of renewable electricity such as solar and wind into electric grid, and also enable the new opportunity for resilient and smart grid. The cost, life and temperature range of batteries need to be significantly improved for this purpose. My lab we developed a breakthrough metal-H_2 battery chemistry to meet the needs of grid scale storage, in which hydrogen gas electrodes is anodes and transition metal oxides are cathodes. This battery chemistry is low-cost, with long life over 30,000 cycles and 30 years. It can be operated in a wide range of temperature of -40 to +60 °C and is maintenance-free. The fast charging/discharge up to 10min is possible in this chemistry. The spinout company EnerVenue has realized very exciting commercial prototypes based on this technology. The metal-H_2 battery affords an ideal storage solution to integrate solar and wind electricity into the grid.

1:30 PM *EN12.11.02
New Anode Materials for Sustainable Sodium-Ion Batteries Marca M. Doeff; Lawrence Berkeley National Laboratory, United States

Sodium-ion batteries (NIBs) are the closest of the “Beyond Lithium-Ion” batteries to commercialization. Their benefits include reduced cost and potentially better safety compared to lithium-ion analogs as well as sustainability, due to the greater earth abundance of sodium compared to lithium. Layered titanate anodes are proposed as alternatives to the more commonly used hard carbons, and have advantages such as greater density and higher first cycle coulombic efficiencies. For this talk, we will discuss several examples of this materials.

2:00 PM EN12.11.03
Investigation of Olivine Structured Phosphate as Potential Cathode Material for Magnesium–Ion Batteries Martina Romio[1], Damian M. Cupid[1], Yuri Surace[1], Marcus Jahn[1] and Isaac Abrahams[2]; [1]Austrian Institute of Technology (AIT), Austria; [2]Queen Mary University of London, United Kingdom

Batteries based on the magnesium-ion chemistry are considered as promising alternatives to lithium ion technologies due to the high theoretical volumetric capacity (3833 $mAhcm^{-3}$ for the Mg-anode), low toxicity and natural abundance of magnesium, as well as the di-valent character of the Mg^{2+} cations. Furthermore, since magnesium deposition takes place without dendrite formation on the Mg-metal anode surface, the Mg-cell is expected to be considerably safer than comparable cells based on Li metal.[1]

Despite these positive attributes, the development of Mg secondary batteries is hindered by the slow solid-state diffusion of Mg^{2+} ions into the cathode lattice, which lead to relatively low practical capacities, irreversible capacity losses and poor cyclic stability. In this work, this issue is explored by synthesising and characterising a phosphate-based system with olivine-related structure to investigate its suitability as cathode materials for Mg-ion batteries, with phosphates building-blocks chosen due to their open three-dimensional framework, structural stability and safety under oxidizing conditions.[2] Therefore, in this work the novel olivine-related $(Mg_{0.5}Ni_{0.5})_3(PO_4)_2$ compound was synthesised by the solid-state method and investigated as a potential electrode active material.

$(Mg_{0.5}Ni_{0.5})_3(PO_4)_2$ was subjected to a comprehensive physico-chemical characterization in order to optimize the synthesis conditions, determine the phase purities and assess the particle morphologies. Furthermore, the reaction mechanisms and electrochemical behaviour of the orthophosphate-based material with monovalent Li^+ and divalent Mg^{2+} ions were investigated using post-mortem analysis (XRD, FTIR and XPS) in order to establish the nature of the charge storage reaction mechanisms.

In addition to the challenges associated with the development of novel electrode materials, it is well known that Mg-based electrolytes, which consist of ionic salts (*i.e.* $Mg(ClO_4)_2$) dissolved in aprotic organic solvents (*i.e.* acetonitrile), form passivating layers on the surface of the Mg metal anode, leading to poor performance of the overall cell. In order to address this problem, activated carbon was used as the counter electrode to replace the metallic magnesium Our results show that $(Mg_{0.5}Ni_{0.5})_3(PO_4)_2$ has a first cycle discharge capacity of 90 $mAhg^{-1}$ when a 0.5 M $Mg(ClO_4)_2$ in acetonitrile solution is used as the electrolyte. Post mortem XRD, FTIR and XPS analysis of the electrode after cycling suggest that a conversion reaction takes place during discharge due to the extrusion of Ni^{2+} cations from the host material lattice. In a similar fashion, Cu-Ni alloys and amorphous Li_3PO_4 form during the electrochemical reaction between $(Mg_{0.5}Ni_{0.5})_3(PO_4)_2$ and lithium metal using a $LiPF_6$-based electrolyte, achieving a practical capacity of 600 $mAhg^{-1}$. Based on the electrochemical data, it is possible to conclude that the conversion reaction of $(Mg_{0.5}Ni_{0.5})_3(PO_4)_2$ with Mg metal as the counter electrode should occur as observed for lithium, if an electrolyte is found which does not passivate the Mg surface. However, since the Mg-electrode is passivated, our findings show that the use of a carbon-based counter electrode significantly improves the practical capacity of $(Mg_{0.5}Ni_{0.5})_3(PO_4)_2$ when a Mg-electrolyte is used.

Late News: The Economically Sustainable Hydrothermal Synthesis of Dextrosil-Viologen as a Robust Anolyte in Aqueous Redox Flow Batteries Dawei Feng, Patrick Sullivan and Xiuliang Lyu; University of Wisconsin--Madison, United States

Aqueous organic redox flow batteries (RFBs) are promising for grid-scale energy storage, but identifying stable and inexpensive organic redox couples suitable for practical applications has been challenging. Here we report a new, inexpensive, and robust anolyte, Dextrosil-Viologen (Dex-Vi), that demonstrates a record overall RFB performance for viologen redox species in neutral aqueous media, including reduced anion-exchange membrane permeability, increased volumetric capacity capability, and improved chemical stability. At 0.1 M, the first redox state of Dex-Vi demonstrates no distinguishable capacity decay over two weeks of cycling (1,200+ cycles) when paired with BTMAP-Fc catholyte in an anolyte-limiting cell configuration. Even at a high concentration of 1.5 M in a practical capacity-balanced RFB, Dex-Vi demonstrates extremely stable cycling performance for one-electron utilization as well as flowable and soluble behavior when it is doubly reduced. Furthermore, by rationalizing a high-yield hydrothermal synthetic approach that has never been applied to viologen RFB molecules along with a low-cost precursor, the predicted mass production cost of Dex-Vi is below $10/kAh. These results not only establish a new benchmark organic anolyte promising for practical RFB applications but also shows that the properties of organic redox species for RFB can be enhanced with minute performance tradeoffs through rationalized structural and synthetic design.

Effect of Fluorination and Li-Excess on the Li Migration Barrier in Mn-Based Cathode Materials Zinab Jadidi[1], Tina Chen[1], Penghao Xiao[2], Alexander Urban[3] and Gerbrand Ceder[1]; [1]University of California, Berkeley, United States; [2]Lawrence Livermore National Laboratory, United States; [3]Columbia University, United States

Disordered rock-salt Li-rich transition metal (TM) oxides, especially those based on Mn, are exciting prospective high-energy-density cathode materials for the next generation of LIBs due to their potential to replace Co-based cathodes [1]. Recently it has been shown that F substitution can reduce oxygen redox by lowering the average anion valence and increasing the amount of redox-active TM [2] as well as improve energy density, average voltage, and rate performance [3]. The substituting F tends to be incorporated in Li-rich environments due to its preference to bond with Li rather than TM [2]. We have investigated how both F substitution and Li excess affect the migration energy for Li diffusion in various local atomic configurations using first-principles calculations in combination with the nudged elastic band (NEB) method [4]. We use orthorhombic-$LiMnO_2$as a model case to investigate the effects of F substitution and Li excess. Based on our results, we demonstrate that F has only a small effect on Li migration barriers while Li excess has a strong positive effect and actually decreases Li migration barriers. Hence, we do not expect any detrimental impact on Li transport when fluorination is used as a design strategy to increase the TM redox [4].

Low Temperature Molten Sodium Batteries for Long-Duration Energy Storage Erik D. Spoerke, Martha M. Gross, Melissa L. Meyerson, Leo J. Small and Stephen J. Percival; Sandia National Laboratories, United States

The importance of long-duration energy storage (LDES) in the emerging sustainable, carbon-free global energy infrastructure continues to become increasingly clear. While several different types of storage are likely needed to meet growing LDES demands, new or adapted battery technologies are expected to play key roles in the future LDES technology space. Here, we describe how emerging low temperature, high voltage molten sodium batteries offer promise as one of these batteries. LDES can refer to storage from several different perspectives and application sets: 1) long discharge duration (e.g., >6-10 hours), 2) long storage duration between charge and discharge, or 3) long battery lifetime (>10-15 years). We will describe here the structure and chemistry of a developing low temperature (near 100°C) molten sodium-halide battery and discuss why it may be especially well-suited for LDES applications. These batteries comprise a molten sodium anode, a fully inorganic, molten sodium iodide-based metal halide salt catholyte, and an efficient solid state sodium ion-conducting separator. The specific composition of the molten salt catholyte and the engineering of the solid-state separator allow for the operation of these batteries at the low temperature of 110°C with a stable cycling voltage of 3.65V. We will discuss recent extended battery cycling behavior and the stability of battery performance during extended “frozen” storage experiments. Connecting our findings to LDES applications including extended discharge duration, extended storage duration, and long-lifetime storage, we outline the potential impact of low temperature molten sodium batteries to the rapidly evolving LDES technical landscape.

Reversible Ketone Hydrogenation and Dehydrogenation for Aqueous Organic Redox Flow Batteries Wei Wang; Pacific Northwest National Laboratory, United States

Aqueous soluble organic (ASO) redox-active materials have recently shown great promise as alternatives to transition metal ions to be employed as energy-

bearing active materials in redox flow batteries for large-scale energy storage because of their structural tunability, cost-effectiveness, availability, and safety features. Development so far however has been limited to a small palette of organics that are aqueous soluble and tend to display the necessary redox reversibility within the water stability window. There is however noticeably much larger number of organic molecules that exhibit some degree of irreversible redox activities. In this presentation, we show how the molecular engineering of fluorenone enables the alcohol electro-oxidation needed for reversible ketone hydrogenation and dehydrogenation at room temperature without the use of a catalyst. Flow batteries based on these fluorenone derivative anolytes operate efficiently and exhibit stable long-term cycling at ambient and mildly increased temperatures in a non-demanding environment. These results suggest the potential for identifying other atypical organic redox molecules for energy storage.

4:30 PM EN12.12.02
A Low-Cost Flexible Full Ammonium-Ion Battery Enabled by a Novel Concentrated Hydrogel Electrolyte Ying Wang and Shelton Kuchena; Louisiana State University, United States

Nonmetal ammonium (NH4+) ions have recently been explored as effective charge carriers in battery systems due to their abundancy, light weight, small hydration shells in water. The research concerning the use of redox chemistry in ammonium ion batteries, particularly in flexible ammonium ion batteries, is still in its infancy. For the first time, we report a flexible full ammonium ion battery (AIB) composed of a concentrated hydrogel electrolyte sandwiched between nanosized hydrated ammonium vandate cathode and polyaniline (PANI) anode, for enhanced performance. The hydrogel electrolyte is simply synthesized by using ammonium sulfate, xanthan gum and water. As a reference, the AIB based on the liquid aqueous electrolyte is prepared first, which exhibits a capacity of 121 mAh g^{-1} and a capacity retention of 95% after 400 cycles at a specific current of 0.1 A g^{-1}. The simple synthesis of the hydrogel electrolyte allows us to facilely tune and optimize the salt contents in the electrolyte, to maximize the ionic conductivity, transport kinetics, mechanical characteristics, and consequently the battery performance. It is found that the flexible battery based on the hydrogel electrolyte prepared from 3 M ammonium sulfate solution shows the best electrochemical performance, i.e., a capacity of 60 mAh g^{-1} while maintaining a capacity retention of 88% after 250 cycles at a specific current of 0.1 A g^{-1}, which are better than the few results reported for flexible AIBs in literature. Moreover, the flexible AIB retains excellent electrochemical performance when bent by 90 and 180 degrees, demonstrating remarkable mechanical strength and flexibility. Therefore, this study sheds new light on the utilization of concentrated hydrogel electrolyte in the AIB chemistry, for future developments of new electrochemical energy storage technology with high safety and low cost.

Copper Oxide Cathodes for Rechargeable Alkaline Zinc Batteries Noah B. Schorr[1], David J. Arnot[1], Andrea M. Bruck[2], Joshua Gallaway[2] and Timothy N. Lambert[1]; [1]Sandia National Laboratories, United States; [2]Northeastern University, United States

Relegated to the annals of history, Zn/CuO batteries have long thought to be solely a primary battery system. Surpassed by Zn/MnO_2 in both the commercialization as a primary cell and focus on fundamental investigations into generating secondary versions of the battery, very little research has been performed on CuO alkaline cells. However we have recently demonstrated that by including a bismuth additive into the CuO cathode formulation, Zn/CuO cells are capable of cycling over 100 times at > 124 Wh/L, with capacities from 674 mAh/g (cycle 1) to 362 mAh/g (cycle 150).[1] To mitigate the capacity losses of long-term cycling CuO cells, we demonstrate two limited depth of discharge (DOD) strategies capable of cycling at 202 mAh/g for over 250 cycles or for ~ 40 mAh/cm^2 and unprecedented energy densities of ~ 260 Wh/L for up to 80 cycles. Using a suite of electrochemical and spectroscopic techniques, including rotating ring disk electrochemistry, impedance, and energy dispersive x-ray diffraction the role of the bismuth additive in enabling the CuO cycling is elucidated. This work serves as a steppingstone for the development of low-cost, safe, and energy dense secondary batteries based on often overlooked conversion chemistries.

Prototypical Study of Double-Layered Cathodes for Aqueous Rechargeable Static Zn-I_2 Batteries Dun Lin and Yat Li; University of California, Santa Cruz, United States

Aqueous rechargeable zinc-iodine batteries (ZIBs) are promising candidates for grid energy storage because they are safe and low-cost and have high energy density. However, the shuttling of highly soluble triiodide ions severely limits the device's Coulombic efficiency. Herein, we demonstrate for the first time a double-layered cathode configuration with a conductive layer (CL) coupled with an adsorptive layer (AL) for ZIBs. This unique cathode structure enables the formation and reduction of adsorbed I_3^- ions at the CL/AL interface, successfully suppressing triiodide ion shuttling. A prototypical ZIB using a carbon cloth as the CL and a polypyrrole layer as the AL simultaneously achieves outstanding Coulombic efficiency (up to 95.6%) and voltage efficiency (up to 91.3%) in the aqueous ZnI_2 electrolyte even at high-rate intermittent charging/discharging, without the need of ion selective membranes. These findings provide new insights to the design and fabrication of ZIBs and other batteries based on conversion reactions.

5:15 PM *EN12.12.05
Developing Ionogel Electrolytes for Solid-State Batteries Ryan H. DeBlock[1] and Bruce S. Dunn[2]; [1]U.S. Naval Research Laboratory, United States; [2]University of California, Los Angeles, United States

Ionogels are pseudo-solid state electrolytes in which an ionic liquid electrolyte is confined in an organic or inorganic matrix. One well established ionogel synthesis route is based on sol-gel chemistry where silica precursors dissolved in an ionic liquid electrolyte (ILE) undergo hydrolysis and condensation polymerization. By using an ionic liquid as the solvent, no evaporation occurs and the resulting material is a macroscopically rigid, nonporous material in which the ionic liquid is trapped by capillary forces in the nanometer sized pores in the silica network. Using this approach, it is possible to develop pseudo-solid state materials that possess the electrochemical, thermal and chemical properties of the ionic liquid. Moreover, sol-gel synthesis enables the precursor sol to penetrate porous electrodes before solidifying, a feature which is especially attractive for solid-state batteries.

In this presentation, we review our recent work on synthesizing Li-ion and Na-ion conducting ionogels and their incorporation in solid-state battery structures. We developed Li-ion conducting ionogels based on using an ILE comprised of 0.5M LiTFSI in [BMIM] [TFSI] that exhibited conductivity and

electrochemical properties comparable to those of the parent ILE. These pseudo-solid state materials were also incorporated in '2.5D' batteries comprised of a $LiFePO_4$ cathode array with a lithium anode. More recently we have focused on Na-ion conducting ionogels. One approach was based on using an ionic liquid electrolyte consisting of 0.5M NaFSI in [PYR14][TFSI]. The resulting material exhibited good ionic conductivity (0.7 mS cm^{-1}) and a nearly 5V electrochemical stability window. Sodium-ion solid-state batteries with excellent reversibility were demonstrated using this Na-ion conducting ionogel in conjunction with two Na-ion intercalation materials which served as positive and negative electrodes. We have also begun to investigate the synthesis and properties of ionogels that incorporate glyme-based electrolytes as such electrolytes have shown excellent stability in contact with sodium metal. We have successfully developed tetraglyme-based ionogels and incorporated them in sodium metal batteries using $Na_3(VO)_2(PO_4)_2F$ as the cathode. Capacities in excess of 400 Wh kg^{-1} were achieved at 0.5C. In summary, the ability to design the ion transport properties of ionogels coupled with their thermal and electrochemical stability makes these materials a very promising direction for use in solid-state energy storage devices.

Potassium-Insertable Graphite and PBA Electrodes Tomooki Hosaka[1,2], Daisuke Igarashi[1], Kei Kubota[1,2], Ryoichi Tatara[1,2] and Shinichi Komaba[1,2]; [1]Tokyo University of Science, Japan; [2]Kyoto University, Japan

K-ion battery (KIB) has recently attracted much attention as a potential high-voltage and high-power battery due to low standard electrode potential of K^+/K and fast ionic diffusion of K^+ ion in electrolyte solutions, respectively [1]. In 2015, our group reported graphite negative electrode, which delivered a reversible capacity of more than 250 mAh g^{-1} with excellent reversibility and rate performance [2]. We also confirmed that a K-graphite intercalation compound of KC_8 was electrochemically formed with several stage transformations [3]. Furthermore, a Prussian blue analog (PBA) of $K_2Mn[Fe(CN)_6]$ (KMnHCF) showed highly reversible potassium insertion/extraction and ca. 4 V vs. K^+/K operation to realize a 4 V-class graphite // $K_2Mn[Fe(CN)_6]$ full cell [4]. The cycle performance of the full cells drastically improved using the proper electrolytes, such as KPF_6-$KN(SO_2F)_2$ binary salt electrolytes [5]. In contrast, the bulk properties that affect the electrochemical properties of graphite and PBA have not been fully understood. Thus, we investigated the predominant bulk properties affecting the potassium insertion reaction into graphite and PBA electrodes.
Potassium insertion properties of several types of graphite were investigated, and we found that the crystallinity significantly affects the reversibility of K^+ ion intercalation. Although the high reversible capacity and Coulombic efficiency of graphite electrodes in K cells were achieved during initial cycles regardless of the crystallinity, high crystallinity graphite demonstrated less potential-hysteresis and superior capacity retention to low crystallinity graphite. Operando XRD measurement confirmed a similar staging process of K-GICs for both graphite samples. However, high crystallinity graphite was transformed into higher crystallinity K-GIC as well as higher reversibility of potassium de-/intercalation than low crystallinity graphite. A turbostratic disorder in low crystallinity graphite led to the redox-potential split and lower crystalline K-GIC and potassium-extracted graphite. Thus, we concluded that high crystallinity is important for applying graphite to long-life potassium-ion batteries.
In addition to the graphite electrodes, we investigated the K^+ insertion reaction into KMnHCF. Although the particle size and the number of $[Fe(CN)_6]^{n-}$ anion vacancies may affect the electrochemical performance of PBAs, the difficulty of independently controlling the particle size and number of anion vacancies has hindered understanding the impact of each factor [6]. We successfully synthesized KMnHCFs through a precipitation route, and the particle size and number of the anion vacancies were varied by employing a proper chelate agent and Na/K ionic exchange route. When nearly stoichiometric KMnHCF was synthesized and tested, smaller particle sizes were important for achieving superior electrochemical performance in capacity and rate capability. However, even in larger particles, introducing a suitable number of anion vacancies enabled KMnHCF to exhibit comparable electrode performance, which would be due to the enhancement of K^+ ion diffusion. From these results, we will present future insight into electrochemical potassium insertion chemistry.

Aqueous Battery for Large-Scale Energy Storage—Towards Both High Energy Density and Superior Safety Chunyi Zhi; City Univ of Hong Kong, Hong Kong

Development of energy storage system in the past year focus on improvement of energy density. While the progress is remarkable, safety problems of lithium ion batteries (LIB) have been intensively exposed. On one hand, LIB is not intrinsically safe with very active anode, flammable electrolyte and oxygen-releasing cathode; on the other hand, many application scenarios actually don't require very high energy density.
We work on aqueous electrolyte batteries to achieve both high energy density and superior safety performance. we show how to activate the desired reversible I^0/I^+ redox at a potential of 0.99 V *vs. SHE* by electrolyte tailoring *via* F^-, Cl^- ions-containing salts. The electronegative F^- and Cl^- ions can stabilize the I^+ during charging. In an aqueous Zn ion battery based on an optimized $ZnCl_2$ + KCl electrolyte with abundant Cl^-, I-terminated halogenated $Ti_3C_2I_2$ MXene cathode delivers two well-defined discharge plateaus at 1.65 V and 1.30 V, superior to all reported aqueous I_2-metal (Zn, Fe, Cu) counterparts. Together with the 108% capacity enhancement, the high voltage output results in a significant 231% energy density enhancement.
In addition, we also develop various approaches to stabilize the Zn anode. We accurately quantifying the hydrogen evolution in Zn metal battery by *in-situ* battery-gas chromatography-mass analysis. Then, we propose an vapor-solid method for an highly electronically insulating (0.11 mS×cm^{-1}) but high Zn^{2+} ion conductive (80.2 mS×cm^{-1}) ZnF_2 solid ion conductor with high Zn^{2+} transfer number (0.65) to isolate Zn metal from liquid electrolyte, which can not only prohibit over 99.2 % parasitic hydrogen evolution reaction during cycling but also guide uniform Zn electrodeposition. Meanwhile, $Zn@ZnF_2//Zn@ZnF_2$ symmetric cell exhibits excellent stability over 2500 h (over 6250 cycles) with 1 mAh×cm^{-2} of Zn reversibly cycled at 5 mA×cm^{-2}, and stable cycling under ultrahigh current density and areal capacity (10 mA×cm^{-2}, 10 mAh×cm^{-2}) over 590 h (285 cycles), which far outperforms all reported Zn metal anode in aqueous system. In light of the superior $Zn@ZnF_2$ anode, the practical-level aqueous $Zn@ZnF_2//MnO_2$ batteries (~3.2 mAh×cm^{-2}) shows remarkable cycling stability over 1000 cycles with 93.63 % capacity retained at ~100 % coulombic efficiency.

Stabilizing Zn Anodes Through Trace Functional Polymer Additives in Low-Cost Dilute Aqueous Electrolytes Huilin Pan; Zhejiang University, China

Recently, a variety of approaches have been proposed to address the key challenges of Zn anodes for Zn batteries, i.e., Zn dendrites, low reversibility, hydrogen generations and limited cycle life. Fundamentally, the electrolyte and electrode-electrolyte interface play a vital role in the electrochemical performance of Zn anodes. Nevertheless, the principles of stabilizing the Zn anode interface are not well developed so far.

In this talk, we will systematically discuss the fundamental principles of developing high-performance Zn anodes in low-cost dilute aqueous electrolytes with a trace amount of functional polymer additives. The correlation between the reaction kinetics and the stability of Zn anodes and polarity of the polymer additive in dilute 1 M $ZnSO_4$ aqueous electrolytes was revealed. The polymer additive tailors the electrochemical performance by rearranging the"Zn^{2+}-H_2O-SO_4^{2-}-polymer" bonding network and the space charge region of Zn anodes. PAM polymer with moderate polarity exhibits synergic enhancement as the "smoother" and "thruster" for the diffusion of Zn^{2+} towards the Zn anodes, showing uniform Zn deposition with minimal impact on reaction kinetics in both half and full cells. This work significantly provides useful insight on designing low-cost and high-performance aqueous electrolytes through functional electrolyte additives.

Development of Layered Oxides Cathodes and Phosphorus Anode for High-Energy and Low-Cost Sodium-Ion Batteries Guiliang Xu and Khalil Amine; Argonne National Laboratory, United States

Considering the natural abundance and low cost of sodium resources, sodium ion batteries (SIBs) have received much attention for large scale electrochemical energy storage. However, rational electrode materials design and good mechanistic understanding are required to enable advanced SIBs with high energy density. On the cathode side, P2 type and O3 type layered oxides are promising cathode materials due to their high specific capacity. However, they both suffer from rapid capacity degradation during high-voltage operation, and yet the mechanism remained poorly understood. On the anode side, phosphorus delivers the highest theoretical capacity (ca. 2600 mAh/g) among various anode materials, but undergo huge volume changes during sodiation/de-sodiation and severe capacity degradation. In this work, we will present our mechanistic understanding on the degradation of layered oxide cathodes during high-voltage charge and how intergrowth structure can mitigate these problem. We will also introduce our strategies to stabilize and improve the rate performance of high-capacity phosphorus anode through structure design and Sb doping. We expect our findings could promote the development of high-energy and low-cost SIBs based on layered oxides cathode and phosphorus anode chemistry.

Digitalization of Lithium–Ion Battery Manufacturing—From Physics-Based Modeling to Artificial Intelligence and Augmented Reality Alejandro A. Franco[1,2]; [1]Universite de Picardie Jules Verne, France; [2]Institut Universitaire de France, France

The needed massive deployment of lithium ion batteries (LIBs), in particular to satisfy the demand from the Electric Vehicle (EV) sector, encourage battery manufacturers to multiply the number of giga-factories to reduce the cost of production. Such a production consists of a complex process involving multiple steps, such as the slurry preparation, its coating, drying, calendering, electrolyte infiltration and formation. The choice of the manufacturing parameters along the process strongly impacts the overall LIB cell performance. However, the optimization of the manufacturing parameters to obtain the desired characteristics of LIB cells is currently based on a forward "trial and error" approach. This approach is inefficient in terms of time and cost due to the infinite number of possibilities for adjusting the manufacturing parameters. The integration of digitalization into giga-factories such as Artificial Intelligence (AI) and multiscale modeling is essential to accelerate the manufacturing process optimization and significantly raise the work efficiency of scientists, engineers and production line operators. Here I present our efforts in developing a digital twin of battery manufacturing within the context of the ERC-funded ARTISTIC project [1,2], supported on a combination of physical and AI/machine learning models trained with data arising from in house high throughput characterizations. This digital twin allows simulating the different steps along the manufacturing process, predicting in three dimensions the resulting electrode properties and evaluating the associated electrochemical performance upon battery cell cycling. The predictive capabilities of this digital twin are illustrated with results for different electrode materials (graphite, Silicon/graphite, NMC, LFP) and formulations, paving the way towards manufacturing digital optimization. I also present the online free services that the project is offering, such as a tool for battery manufacturing simulation from an internet browser and a tool for stochastic generation and meshing of lithium ion battery electrodes and separators [3]. Finally, I conclude with our recent work by us (extending our work published in Ref. [4]) on the implementation of our computational models in novel Augmented Reality interfaces to assist the battery manufacturing work.

Molecular Modeling of Electrolytes for Lithium and Divalent Batteries Oleg Borodin; U.S. Army Research Laboratory, United States

A molecular scale insight into ion transport and compatibility with electrodes is important for understanding deficiencies of the currently used aqueous and non-aqueous electrolytes. In this presentation I will summarize recent progress made towards improving molecular scale understanding of the structure and electrochemistry for a wide range of aqueous and non-aqueous electrolytes for lithium and divalent batteries. Accurate molecular dynamics (MD) simulations of these electrolytes using polarizable force field will be used to establish a correlation between the ion transport mechanisms, electrolyte structure and transference number. Reactive modeling will focus on the competitive solvent and salt reduction and oxidation at the passivated electrochemical interfaces using Born Oppenheimer Molecular Dynamics (BOMD) simulations using DFT functionals. These BOMD simulations included critical factors needed to realistically represent electrolyte reactivity at electrodes such as explicit description of the substrate – electrolyte interactions; accurate representation of electrolyte structure, ion pairing and aggregation near an electrode.

Organic Electroactive Materials For The Lithium Metal Polymer Technology Joel Gaubicher and Philippe Poizot; CNRS Nantes Université, France

Lithium metal polymer (LMP^{Ò}) solid-state batteries based on the use of dry PEO-based electrolytes have been developed since the early 2000's by the Bolloré's group and its subsidiary Blue*Solutions* company. The reliability of this technology which derives from polymer electrolyte (SPE) membrane Li batteries proposed by M. Armand in the late 70's[1],[2] has been demonstrated in different applications with the first practical deployment in the world in full electric vehicles in 2011. This technology is now widely utilized not only in multiple e-mobility scenarios but also in stationary storage applications all over the world (Europe, North America, Asia and Africa). Like many other electrochemical storage technologies, the search for efficient, cheaper but also earth-abundant insertion electroactive materials remains an ongoing challenge to mitigate environmental issues. In this respect, the potential interest of electroactive organic materials to build eco-friendlier batteries has been the subject of intense research[3]. However, little is known about their behavior when implemented in the LMP^{Ò} technology. We therefore embarked in the investigation of the electrochemical and physicochemical behaviors of neutral molecule and salt compounds as positive electrode material of LMP^{Ò} cells.

Structured Electrodes for Improved Performance of Lithium-Ion Batteries Chuan Cheng[1], Ross Drummond[2], Stephen Duncan[2] and Patrick Grant[2]; [1]University of Warwick, United Kingdom; [2]University of Oxford, United Kingdom

Electrode structures of commercial lithium-ion cells are isotropic at the macro-scale, comprising a homogenous mixture of constituents including active materials, carbon conductive additives, polymetric binders, and randomly distributed inter-connected porosity. Due to restricted ion mobility in the tortuous pore channels and anisotropic electric-field distribution when in operation, the Li-ion concentration and activation overpotential are inevitably inhomogenous through the electrode thickness, especially at fast charge-discharge rates when the concentration and overpotential gradients become steeper. As a result, the electrochemically active material is inhomogeneously utilized and the reaction rate is spatially varying, which have detrimental effects on battery performance and lifetime, local capacity degradation, overheating and stress concentration. This is an electrode-scale problem, regardless of the specific electrode materials.
We design, manufacture and assess the performance of carefully controlled heterogeneous, graded electrode structures with the aim of promoting greater uniformity in overpotential distribution, and reaction rates across the electrode thickness. We investigate the arising polarization, and impedance behavior, as well as side reactions such as SEI formation. We demonstrate that micro-scale composition-graded electrodes provide enhanced capacity retention at fast charge-discharge rates to mitigate the long-lasting challenge of energy-power trade-off of lithium-ion batteries, and reduce battery degradation rate in both half-cell and full-cell lithium-ion batteries.

***In Silico* Discovery of Organic Lithium-Ion Positive Electrodes Driven by Artificial Intelligence** Rodrigo Carvalho[1,1], Cleber Marchiori[2], Daniel Brandell[1] and Moyses Araujo[2,1]; [1]Uppsala University, Sweden; [2]Karlstad University, Sweden

Electrical energy storage (EES) devices have staged important technological revolutions in the past years, with special attention given to Li-ion batteries (LIBs). However, novel socioeconomical paradigms[1] have urged for environmentally friendly and sustainable alternatives regarding these technologies. In this context, organic materials have attracted attention as potential candidates to pave the way toward the achievement of truly green batteries. They offer several advantages like cost efficiency, sustainability, synthesis from renewable or feedstock and tunable properties.[2] Nonetheless, hindrances related to cyclability and energy density need to be solved before the achievement of such alternative technologies. In this study, we report the development of a novel Artificial Intelligence (AI) methodology to accelerate the discovery of organic electroactive materials, with special focus given to LIBs positive electrodes. This framework has rendered an AI-*kernel* that enabled us to tap into the almost limitless organic library in a fast and accurate fashion. Requiring only the molecular SMILES representation as input, the *kernel* is divided in three levels, each composed by an independent learning scheme. The **first level** is based on Graph Neural Networks (GNN) and is responsible to identify if a given molecule is redox stable. The **second level** predicts the oxidation and reduction potentials (P_{Ox} and P_{Red}) of the redox-stable molecules by using a combination of Natural Language Processing (NLP) to analyze the SMILES and Recurrent Neural Networks (RNN). Finally, the **third level** is composed by a least squares multi-regression model that connects the molecular redox potentials (P_{Ox} and P_{Red}) predicted in the previous level to the battery open circuit voltage (OCV) (V vs. Li/Li$^+$). To fuel the AI, two different databases have been developed: a small set of predicted molecular crystals following an interplay between DFT and an evolutionary algorithm[3,4]; and a larger set of more than 30000 unique molecules with redox properties extracted from DFT. We demonstrate the AI-*kernel* efficiency by performing a high-throughput screening in 20 million molecules following a *capacity (mAh/g) → OCV (V vs Li/Li$^+$)* selection to find suitable electrode candidates. As the final part of this screening, new DFT calculations were performed for the selected molecules with a two-fold goal: to validate the AI-*kernel* performance and to further filter the candidates list. This process led to the discovery of about 500 promising molecules for cathode compounds, with some exhibiting theoretical energy densities superior to 2000 Wh/kg. Moreover, the AI-*kernel* accurately identified common molecular characteristics

that lead to such higher-voltage electrodes and pointed out an interesting donor-accepter-like effect that may drive the future design of cathode-active materials.

Mechanistic Investigations of Manganese and Vanadium Oxide Electrochemistry in Aqueous Zinc Batteries Esther S. Takeuchi[1,2], Amy Marschilok[1,2] and Kenneth Takeuchi[1,2]; [1]Stony Brook University, United States; [2]Brookhaven National Laboratory, United States

Implementation of intermittent renewable energy sources derived from wind and solar power motivates development of safe, sustainable, low cost energy storage devices, specifically batteries based on aqueous electrolytes. As a negative electrode material, Zn has a high theoretical capacity (820 mAh/g), low redox potential (-0.76 V vs. SHE), and low toxicity such that aqueous electrolyte zinc based batteries may prove to be a desirable alternative for Li-ion batteries for some applications. Recent studies on aqueous Zn ion batteries using mildly acidic electrolytes have demonstrated the possibility of zinc anodes with high cycle life. Several classes of cathode materials have been explored as possible candidates including metal-inserted vanadates and manganese oxides.
Vanadium based materials are appealing for aqueous electrochemical energy storage due to the multiple accessible redox states for the vanadium center. Layered vanadates, supported by cation pillars, are of interest for Zn-ion batteries as the vanadium redox center allows for high capacity and the layered structure promotes facile ion transfer. In particular, sodium vanadium oxides (NVO) show promise as cathode materials for Zn-ion aqueous batteries. Manganese oxides are also of interest due to their low cost and low environmental impact. Manganese oxide structural chemistry is synthetically rich and a number of polymorphs have been considered. Tunnel-type materials such as α-MnO_2 are particularly noteworthy owing to their facile synthesis and high energy density. Despite its appealing electrochemistry, however, the exact reaction mechanism of α-MnO_2 in zinc batteries has remained unclear where zinc insertion, proton insertion, and/or structural changes have been proposed.
Understanding the key parameters that govern the charge storage mechanisms of the Zn aqueous systems remains a critical challenge in order to advance these systems to next generation products. Thus, investigations that probe mechanisms can provide a pathway for ultimately controlling electrochemical outcomes. This presentation will discuss the influence of material properties on the electrochemistry of NVO in Zn-ion aqueous cells and operando studies clarifying the dominant redox mechanism of α-MnO_2 in zinc batteries.

11:30 AM EN12.15.03
Cu/Ni/Co Ordered Mesoporous Oxides as High-Performance Cathode Catalysts for Li-O_2 Batteries Tatiana Priamushko[1], Nicolas Eshraghi[2], Jürgen Kahr[2], Marcus Jahn[2] and Freddy Kleitz[1]; [1]University of Vienna, Austria; [2]AIT Austrian Institute of Technology GmbH, Austria

In recent years, rechargeable lithium-oxygen (Li-O_2) batteries have been studied as a future battery system mainly due to their ultrahigh theoretical capacity, low cost, and environmental friendliness. However, the further development of Li-O_2 batteries into commercial applications is hindered by issues such as low energy efficiency, short cycle life, parasitic reactions, and poor rate capability. These issues are mainly the result of the voltage hysteresis and high overpotential in the cathode side. The voltage hysteresis during cycling is large, giving rise to low energy efficiencies and high overpotentials, which in turn, cause significant electrode and electrolyte decomposition. Thus, it is necessary to develop high-performance catalysts for the cathode to address the challenges raised by the overpotential and to boost the performance of Li-O_2 batteries. Three groups of positive-electrode catalysts for Li-O_2 batteries were studied by researchers: carbon materials, noble metal-based materials, and transition metal-based materials.
Considering that the cathodic process is a complicated redox reaction taking place in the triple-phase of gas, liquid, and solid, the structural design of cathode electrodes is critical to achieving high-performance Li-O_2 batteries. Indeed, the catalysts used in cathodes generally have a high surface area to provide transport pathways for oxygen, lithium ions, and electrons and thus increase the reaction sites for the Oxygen reduction reaction (ORR).
Among the transition metal-based materials, Co_3O_4 can reduce the charge overpotential and improve the cycling performance of Li-O_2 batteries. Co_3O_4 crystallizes in the spinel structure ($Co^{II}Co^{III}{}_2O_4$), with edge-sharing CoO_6 octahedra (Co^{3+} centered) interconnected by corner-sharing

CoO_4 tetrahedra (Co^{2+} centered), this structure can accommodate vacancies and lattice defects, that potentially act as active sites to promote electrochemical reactions. Cu/Ni substitution of Co in the structure would ensure a more sustainable material development as well as the improved electrical conductivity of the material to increase the electron supply to reaction sites. Furthermore, using ordered mesoporous Co-based oxides is beneficial due to their high surface area.
In this context, a series of ordered mesoporous Cu/Ni/Co oxides are prepared via nanocasting with varied Cu/Ni ratios to establish their impact on the electrochemical performance of the catalysts. The performance of non-aqueous Li-O_2 batteries is directly determined by the reversible formation mechanism of the discharge products, being either Li_2O_2 or LiOH [1]. Therefore, the nature and evolution of the discharge products, in different voltage steps for the first discharge cycle was investigated by *ex situ* XRD tests. These tests show the formation of LiOH as a discharge product in presence of mesoporous Cu/Ni/Co oxides in the cathode. A lower overpotential was observed both in ORR and oxygen evolution reaction (OER) with a discharge capacity in the range of 4000-6000 mAh/g_{carbon} based on different Cu/Ni ratios. During discharge, O_2 reduction was detected along with the LiOH formation with a voltage plateau at 2.8V (≈ 0.1V discharge overpotential). During charge, O_2 evolution was detected along with LiOH decomposition up to 3.55 V, and at higher voltages, products from parasitic reactions can be detected. These results show promising properties of the mesoporous Cu/Ni/Co oxides as catalysts that can effectively promote the OER at a low overpotential. This lower overpotential is a key step in the development of reversible Li-O_2, particularly in LiOH-based Li-O_2 due to the increased stability of LiOH over other discharge products.

11:45 AM EN12.15.06
Bottom-Up Mechanochemical Synthesis of Tin (Sn) Nanoparticles for Sodium-Ion Batteries Katherine A. Mazzio[1,2], Baris Akduman[2] and Philipp Adelhelm[2,1]; [1]Helmholtz-Zentrum Berlin, Germany; [2]Humboldt-Universität zu Berlin, Germany

Sodium-ion batteries (NIBs) are attractive alternatives to lithium-ion batteries (LIBs) due to the high earth abundance and low cost of Na, the cathodes do not require cobalt, and their device architectures can be similar to those of LIBs, thereby streamlining production. One challenge associated with the development of NIBs is that the cost reduction must make up for the lower energy densities relative to LIBs, and as a result there is a strong drive towards development of alloying anodes for NIBs due to their high storage capacity and favorable redox potentials. Sn nanoparticles appear as an attractive option to increase the capacity of NIB anodes. This is because of a desirable redox potential of around 0.2 V vs. Na^+/Na combined with a very high theoretical capacity of 847 mAh/g and high rate capability.[1,2] Nanosizing can further help prevent cracking and pulverization of the electrodes arising from volume expansion during alloying. The combination of chemical and mechanical resilience during electrochemical cycling ultimately enhances both the maximum capacity and lifetime of devices employing these materials.
Bottom-up synthesis methods rely on chemical pathways utilizing different precursor materials and chemical reducing agents for the production of nanomaterials. These methods have been successfully employed at the lab scale for the production of nanomaterials with good control over their dimensions, dispersity, morphology, and composition, but are severely lacking in the ability to scale up to industrial levels. Mechanochemistry is a technique that has been widely used on the industrial scale for the production of materials for battery anodes, but almost exclusively via top-down approaches relying on comminution of bulk materials that does not allow for control over the resulting morphology or composition. In this work we demonstrate a new method for the bottom-up mechanochemical synthesis of Sn nanoparticles with controlled dimensions for use in NIBs. The synthesis itself is entirely solid-state, employing only a metal halide precursor and a reducing agent during ball milling, and does not necessitate any capping agents for size control or solvents until the workup of the synthesized materials. The sizes of the particles are controlled by adjusting the milling time, and the influence of particle size on the electrochemical performance was investigated in proof of concept NIBs. The milling time does not have a direct relationship with the particle size because once the particles grow for long enough, they will begin to experience comminution and not continuously grow. The product from the shortest milling time demonstrated capacities of 475 mAh/g at 0.1C alongside the highest current rates in the series, which can be attributed to the fast diffusion of Na^+ in the nano-sized particles. The samples milled the longest showed the highest capacity of 594 mAh/g at 0.1C. Rate capability studies demonstrated stable CE values close to 100%, indicating high reversibility and structural resilience. Overall these results demonstrate proof of concept for Sn nanoparticles in NIBs synthesized via a new scalable synthesis method based on solid-state bottom-up mechanochemistry.

1:00 PM *EN12.16.01
Sodium Batteries—From Small to Large-Scale Stationary Energy Storage Stefano Passerini; Karlsruhe Institute of Technology, Germany

The European Strategic Energy Technology Plan established the transformation to climate neutrality by 2050 since energy production is responsible for 75% of the greenhouse gas emission in the EU.[1] For this transformation, the use of renewable energy sources and clean energy carriers should be drastically increased. In parallel, the mobility should implement sustainable and smart technologies in transportation. In this scenario, energy storage devices, especially batteries, are a key technology towards a low-carbon energy system, as large-scale stationary energy storage and electric vehicle applications. Lithium-ion batteries (LIBs) are excellent candidates due to their high energy and high-power density. In fact, LIBs dominate the market for portable electronics and electric vehicles. However, the demand of LIBs is increasing, and the future supply of the raw materials (cobalt and lithium) makes uncertain their feasibility for massive renewables' energy storage.[2] Therefore, there is an urgent need to develop alternative energy storage devices that meet the cost, raw material availability and good performance requirements.

In this context, Sodium-ion batteries (SIBs) have been postulated as potential low-cost energy storage devices for large-scale stationary applications and light electromobility due to the almost infinite and widely distributed sodium resources and a 30% cost reduction respect with LIBs.[3,4] In fact, SIBs employing non-aqueous liquid electrolyte are rather close to commercialization.[5,6] Among cathode chemistries, different positive materials have been selected, being the main used one layered oxides while as negative electrode Hard Carbon (HC) is considered the anode of choice.[7]

With regards to large-scale stationary energy storage, sodium-based battery systems appear to be promising even for seasonal/annual storage systems. In particular, Na-seawater batteries, making use of multiple electrolytes, i.e., seawater as the catholyte (as well as the cathode material), a solid electrolyte physically separating the two electrode compartments, and a non-aqueous anolyte, appear very promising.[8] Because natural seawater is also the active material in the open-structured cathode, the Na seawater battery can be supplied infinitely with Na^+ cations, which are transferred to the anode side during charging. The generated sodium can be stored inside (for daily/weekly storage) and/or outside (for seasonal/annual storage) the cell. The process can be reversed during discharge, delivering electricity on demand.
As additional benefits, Na-seawater batteries upon charge produce desalinized water (for industrial and residential uses), and chlorine (for bleach, disinfectant, and polymer chemistries) while during discharge generates NaOH, which can be used for CO_2 capture.

Interface Design of All-Solid-State Batteries Xueliang A. Sun; University of Western Ontario, Canada

The state-of the-art rechargeable Lithium-ion batteries (LIBs) use liquid electrolytes and are the major choice for current EVs and portable electronic applications. However, these LIBs still suffer from many issues related to safety, lifespan and energy density. Accordingly, solid-state lithium batteries (SSLBs) have recently emerged as a promising alternative energy storage device due to their ability to overcome the intrinsic disadvantages of liquid-electrolyte LIBs and possess a greater volumetric energy density due to the use of solid-state electrolytes (SSEs). However, the interfacial issues between SSEs and electrodes (both cathode and anode) have a significant impact on the stability and lifetime of SSLBs **[1-3]**. The origin of these interfacial phenomena is the unstable contact and chemical reactions between electrodes and electrolytes to form an interlayer with extremely low electronic and/or ionic conductivities, which restricts the performance of the SSLBs. An artificial, uniform and ultrathin interfacial layer is critical to address these challenges **[2, 3]**. Atomic layer deposition (ALD) and molecular layer deposition (MLD) are unique coating techniques that can realize excellent coverage and conformal deposition with precisely controllable at the nanoscale level due to its self-limiting nature, which are ideal for addressing the challenges of interface in SSLBs **[2, 3]**. In addition, design of SEI in SSLBs is very important for obtaining high performance of SSLBs.
In this talk, we will report to addresses the interfacial challenges in SSLBs via two strategies: (i) develop ALD/MLD to rationally design novel coatings for sulfide-based interface design [4-7]; and (ii) SEI design of solid-state Li-S batteries [8-10]. The goal is to prevent capacity degradation of SSLBs caused by high interfacial resistance and chemical/electrochemical reactions between electrodes and electrolytes.

Protective Li^+ Conducting Polymer Coatings for Lithium-Metal Anode Yumi Kim, Amaresh Pandian, Anthony Fong, Maxwell Giammona and Younghye Na; IBM Almaden Research Center, United States

Lithium (Li) anode has been actively investigated in the battery R&D in order to achieve advanced batteries with higher energy density. Among various studies, Li protection strategies have been a crucial topic of interest since the evolution of a thick solid electrolyte interface (SEI) layer on the reactive lithium metal anode and dendrite growth caused by irregular lithium deposition result in poor cyclic performance and low coulombic efficiency of lithium-metal batteries. In this study, to reduce the undesirable side reactions on the surface of metallic Li anode, Li^+ conducting polymer coatings have been investigated for the application of a lithium-halide battery. The Li anode protected by a crosslinked PEG-POSS polymer coating demonstrated enhanced specific capacity, rate performance, and cyclability compared to the battery with bare Li anode. In addition, we confirmed that Li deposits with a round shaped-granular morphology are uniformly formed underneath the polymer layer, which indicates that this polymer layer is successfully functioning as a Li^+ conducting protective layer on the lithium anode. Detailed experimental data and the working mechanism for the performance enhancement will be addressed in the presentation.

2:15 PM EN12.16.04
A System-Level Approach to Li Metal/Iron Fluoride Batteries Enabled by Optimal Electrolyte Choice Bryan R. Wygant, Laura Merrill, Timothy N. Lambert and Katharine L. Harrison; Sandia National Laboratories, United States

Moving beyond Li-ion/intercalation cathode batteries to Li and other alkali metal batteries paired with high capacity metal fluoride conversion cathodes like FeF_x (x = 2 or 3) represents a promising route to high capacity secondary batteries. Fe is considerably more earth abundant and environmentally friendly than elements like Co, and Fe-based conversion cathodes have significantly higher capacities than intercalation cathodes like $FePO_4$. However, the pairing of a Li metal anode with an FeF_x cathode presents new challenges for battery design. While studies on Li have long emphasized the importance of a protective solid-electrolyte interphase (SEI) on anode performance, recent work has shown that the cathode-electrolyte interphase (CEI) is likewise important to FeF_x cathode performance. Therefore, it is important to find an electrolyte that is compatible with, and creates a protective layer on, both the Li metal anode and the FeF_x cathode.

Here, we present a series of electrolytes optimized for either Li metal or FeF_3 and identify an electrolyte that enables a system-level solution for a Li metal/FeF_3 full cell battery. We show that while an electrolyte with high Li(T)FSI concentration results in high coulombic efficiency (CE) at the Li anode, it produces a poorly performing organic-rich CEI on the FeF_3 surface. Conversely, the FeF_3 cathode shows excellent performance in a pyrrolidinium-based ionic liquid electrolyte, but the Li anode appears to exhibit parasitic side reactions and very poor CE. Bridging the gap between these two results, we will report on our work that demonstrates using an electrolyte that forms an inorganic-rich CEI and a Li2O-rich SEI, stabilizing the cathode and the anode, respectively leads to high overall coulombic efficiencies. Using this electrolyte, we demonstrate a coin cell-scale full cell battery that retains 80% of its post-formation cycle capacity over 50 cycles. Additional characterization including STEM, XPS, and other techniques is also presented. These initial results using well-studied Li metal provide a launching point for the further development of such system-level approaches, as well as the investigation of Na metal as an anode. While more reactive and possessing a lower theoretical capacity than Li, Na is more earth-abundant and its system-level compatibility with conversion cathodes is of great interest.

Cryogenic TEM Characterization of and Control Over the Native Oxide Interphase on Calcium Electrodeposits Scott A. McClary, Daniel Long, Alan Landers, Paul Kotula, Katherine Jungjohann and Kevin Zavadil; Sandia National Laboratories, United States

Calcium anodes are attractive for use in beyond lithium-ion batteries due to their high theoretical energy densities (1337 mAh g^{-1}, 2073 mAh mL^{-1}), high natural abundance, and reported low propensity for dendrite formation [1, 2]. To achieve high (> 99.9%) coulombic efficiencies (CE), calcium anodes require a robust solid-electrolyte interphase (SEI) that suppresses parasitic reduction of electrolyte components while permitting cationic transport at appreciable rates. While high CEs for long cycling life have not yet been achieved in calcium-based electrolyte systems, the $Ca(BH_4)_2$-THF system (≤ 99% CE) can serve as a model for identifying surface components responsible for protective and transport functions. Several research groups have explored the native SEIs that form on $Ca(BH_4)_2$-THF electrodeposits. Wang et al. used X-ray diffraction and chemical digestion (i.e. bulk techniques) to suggest that CaH_2 is the primary surface interphase component [3], while Jie et al. used X-ray photoelectron spectroscopy (i.e. a surface-sensitive technique) to identify $CaCO_3$ and CaO as interphase constituents [4]. These contrasting experimental results, coupled with reports of significant nonuniformity during plating and stripping of calcium [5, 6], underscore a critical need to clarify the chemical identity of the species in calcium interphases and to spatially map their chemistry and microstructure.

In this contribution, we present detailed characterization of interphases of calcium electrodeposits generated from high concentration $Ca(BH_4)_2$-THF electrolytes. Central to our work is the use of cryogenic transmission electron microscopy (cryo-TEM), which enables analysis of calcium deposits with the liquid electrolyte vitrified in place, thereby preserving the native interphase generated upon electrodeposition. By applying techniques such as electron energy loss spectroscopy (EELS) mapping, selected-area diffraction (SAD), and high-resolution transmission electron microscopy (HRTEM) imaging to cryogenic samples, we demonstrate that the native interphase is a nanometric calcium oxide with a heterogeneous distribution of secondary phases, including borates. Furthermore, we find that CaH_2 exists as segregates in the bulk calcium deposit rather than at the surface. Further cryo-TEM studies, supplemented with electrochemical measurements, elucidate the protective function of the evolving oxide interphase during open-circuit holds. Finally, we leverage our findings to manipulate the heterogeneity and chemistry of the oxide interphase; by employing mixed solvents and mixed anions, the cationic transport properties are significantly enhanced.

Our results are a critical step towards the design and realization of an ideal solid-electrolyte interphase for high-efficiency rechargeable calcium metal batteries.

Facile Protection Layer Suppressing Surface Contamination of Cobalt-Free Cathodes for Lithium-Ion Batteries Ju-Myung Kim, Yaobin Xu, Mark Engelhard, Jiangtao Hu, Hyung-Seok Lim, Hao Jia, Bethany Matthews, Chongmin N. Wang and Wu Xu; Pacific Northwest National Laboratory, United States

In recent years, tremendous researches have been conducted to achieve high-energy-density lithium (Li)-ion batteries. Among various candidates, cobalt (Co)-free/nickel (Ni)-rich layered cathode materials are considered as one of the promising candidates that can provide practical battery use and cost reduction. However, the Co-free/Ni-rich layered cathode materials have a highly reactive surface that can easily lead to inevitable contaminations in air by forming residual Li compounds such as LiOH and Li_2CO_3 which cause capacity decay and poor cell performance. Here, we demonstrate the effectiveness of a thin polyimide/polyvinyl pyrrolidone (PI/PVP, as referred to as PP) layer to protect $LiNi_{0.96}Mg_{0.02}Ti_{0.02}O_2$ (NMT) cathode particles under storage in an atmosphere with ~30% humidity for two weeks. Compared to the fresh bare NMT, the stored bare NMT shows visible contaminated surface, Li consumption and decreased lattice O due to exposure to limited moisture and CO_2 in the air. On the other hand, the PP coated NMT (PP@NMT) has practically the same surface and structure before and after exposure to air. In the cycling performance test using a conventional $LiPF_6$/carbonate electrolyte at the current density of C/3 (1C = 1.5 mA cm^{-2}) under 25 °C, the graphite (Gr)-based Li-ion battery of Gr||NMT system with stored bare NMT shows a continuous capacity decay, resulting in the capacity retention of merely 49.5% after 100 cycles, while the Gr||NMT cell with stored PP@NMT has the capacity retention of 84.7% after 100 cycles. In addition, after cycling, not only the stored bare NMT cathode material has more cracks inside the particle with NiF byproducts and structural degradation than stored PP@NMT but also the Gr anode pared with stored bare NMT has more generation of byproducts on the surface than Gr anode pared with PP@NMT. Furthermore, an advanced localized high-concentration electrolyte can enable the cell with stored PP@NMT cathode to achieve capacity retention of 89% over 400 cycles at 25 °C. This work offers a promising facile approach to protection of Co-free/Ni-rich layered cathodes for practical applications.

Nanocellulose Batteries Liangbing Hu; University of Maryland, United States

I will start by giving an overview of our work on assembly and functionalization strategies of nanocellulose aimed at specific properties, with an eye toward high impact applications including energy, electronics, building materials. Examples include transparent nanopaper for optoelectronics (as a replacement of plastics), super strong and tough wood (replacement of steel, Nature 2018), and radiative cooling wood (Science, 2019). I will then focus on our work on applying nanocellulose/wood as building blocks for advanced energy devices, including flexible, thick battery electrodes with nanocellulose binder, three-dimensional carbon derived from wood for advanced batteries (replacement of metal current collectors for beyond Li-ion batteries), and all solid-state Li metal batteries using nanocellulose ion conductors (*Nature*, 2021).

Enhanced Stability and Rate Performance of Sodium Batteries by Tuning SEI Formation Through Ionic Liquid Chemistry and Controlled Formation Cycles Maria Forsyth[1,2], Patrick C. Howlett[1,2], Jun (Jenny) Sun[1], Shammi Ferdousi[1], Dmitrii Rakov[1,2] and Fangfang Chen[1,2]; [1]Deakin University, Australia; [2]ARC Centre of Excellence for Electromaterials Science, Australia

Lithium ion batteries are ubiquitous in our society with uses extending from personal electronics to EVs and stationary storage. However, due to the environmental and ethical issues of raw materials (i.e., lithium, high purity graphite and cobalt) and increasing demands for lower cost and high safety, emerging battery technologies such as those based on sodium chemistries are becoming more attractive. Sodium metal provides the opportunity for higher energy density devices while the possibility of carbonising waste biomass to produce hard carbons for Na ion batteries offers a more sustainable energy solution. Ionic liquid electrolytes have been investigated for over two decades as a safe alternative to traditional organic solvents, in particular for higher energy density, metal anodes. IL electrolytes based on fluorosulfonimide (FSI) anions have particularly favourable properties with respect to enhanced ion transport, high sodium salt solubility and the stable SEI formation. Even within this family of IL electrolytes, the salt concentration, IL cation chemistry and molecular additives have a dramatic effect on the electrochemical performance of both Na metal and carbon anodes. Using solid state NMR, SEM and XPS, we show that this is related to the SEI composition on the anode surface. The effect of anode pre-conditioning on cycling stability is also discussed. MD simulations provide some insights into the influence of chemistry and preconditioning on stability. Finally, we also demonstrate significant stability enhancement at high rate and high capacity cycling of Na metal when a phosphonium IL cation is present in contrast to the pyrrolidinium IL cation.

Hexacyanometallates for Rechargeable Batteries Hyun-Wook Lee; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Hexacyanometallates have gained great attention due to their interesting properties originating from their flexibility in synthetic methods, allowing a large degree of chemical tunability. Hexacyanometallates can be prepared by bottom-up assembly of molecular precursors via the formation of continuous chemical bonding between transition metal ions and ligand molecules. These cyanide ligands can enable the long-range charge transport with abundant CN triple bonds that can provide free electrons for electrical conduction. Due to such flexibility in their design and resultant properties, they can have a wide variety of applications including energy storage, harvesting, catalysis, and magnetic applications. In this talk, I will introduce diverse applications of hexacyanometallates for electrode, coating, and redox mediator materials. First, a new Cr-based negolyte coordinated with strong-field ligands will be introduced. The complex of $[Cr(CN)_6]^{4-}$ prefers low-spin states, facilitating a stable and fast redox reaction, capable of mitigating strong Jahn–Teller effects, thereby facilitating low redox potential, high stability, and rapid kinetics. The prototype full-cell configuration features a high-energy density of 11.4 Wh L^{-1} and a stable lifetime of 250 cycles. Second, manganese hexacyanometallates (MnHCMn) shows a monoclinic crystal structure composed of nonlinear Mn–N≡C–Mn bonds and containing eight large interstitial sites occupied by Na^+ ions. The experiments demonstrate a high specific capacity of 210 mAh g^{-1} and excellent capacity retention at high rates. Here, we discover a novel mechanism wherein small lattice distortions allow for the unprecedented storage of 50% more sodium cations than in the undistorted case. These results represent a step forward in the development of high-performance redox flow and sodium-ion batteries.

Chloroaluminate Ionic Liquid Electrolytes for Safe and High-Performance Sodium and Potassium Metal Batteries Hao Sun; Shanghai Jiao Tong University, China

Rechargeable sodium and potassium metal batteries are considered to be important to various energy applications in modern society. The pursuit of higher energy density should ideally come with high safety, a goal difficult for electrolytes based on organic solvents. Room temperature ionic liquids have been widely explored as promising candidates due to their non-flammable nature[1]. Among them, ionic liquids comprised of $AlCl_3$ and 1-ethyl-3-methylimidazolium chloride are a classical chloroaluminate based electrolyte system with many desired properties including non-flammability, non-volatility, low viscosity, high conductivity, and high thermal stability and chemical inertness[2]. However, it remains challenging to realize ideal battery performances on the basis of chloroaluminate ionic liquids, due to the severe corrosion of chloroaluminate based compounds to alkali metal.

Here we report chloroaluminate ionic liquid electrolytes comprised of aluminium chloride/1-methyl-3-ethylimidazolium chloride/sodium chloride ionic liquid spiked with important additives, e.g., ethylaluminum dichloride and 1-ethyl-3-methylimidazolium bis(fluorosulfonyl)imide. This leads to the first chloroaluminate ionic liquid electrolyte for rechargeable sodium metal battery[3]. The obtained batteries reached voltages up to ~ 4 V, high Coulombic efficiency (up to 99.9%), and high energy and power density of ~ 420 Wh kg^{-1} and ~ 1766 W kg^{-1}, respectively. More than 90% of the original capacity can be retained after 700 cycles. In addition, stable and high-energy-density potassium metal batteries were obtained on the basis of chloroaluminate ionic liquid electrolyte[4], which could stably work at high temperature up to 60 °C. These results provide a new approach to advanced alkali metal batteries with high energy/high power densities, long cycle life and high safety[5].

Correlations Between Structural Disorder, Covalent Bonding and Oxygen Redox Chemistry in Lithium-Rich Layered Oxide Electrodes Byunghoon Kim; Seoul National University, Korea (the Republic of)

The oxygen redox is expected to offer a new route to attain an unprecedentedly high energy density for lithium-rich layered oxides, thus regarded as an alternative cathode chemistry beyond the high-nickel layered materials. However, the complexity from the dynamic changes in the structure, *e.g.* cation migrations/disorders and local oxygen bond alternations, and the corresponding redox activity change prohibits the full understanding of this class of materials, making it difficult to achieve the highly reversible oxygen redox. Herein, we present a consistent theoretical framework for the triptych of structural disorder, subsequent oxygen bonding rearrangement and redox chemistry, encompassing a wide range of layered oxides both in Charge-Transfer and Mott-Hubbard systems. It is unraveled that cation disorders stabilize oxygen redox by promoting strong oxygen-oxygen and/or metal-oxygen π hybridization, which hinges on the occupancy of oxygen non-bonding states and metal-oxygen covalency. On the other hand, anion disorders compensate for the electron deficiency of oxygen network without significantly regulating bonding arrangements. More importantly, we address how the formation of short covalent bonds affects electrochemical and structural reversibility, and report oxygen dimers that freely move in the structure as a key catalyst of the poor structural resilience. Our findings rationalize long-reported phenomenological correlations between structural disorders and oxygen redox, and offer a fundamental basis for optimizing the reversibility of oxygen redox taking into account of inevitable formation of structural disorders.

An Aqueous Battery with a Tear Electrolyte for Flexible Smart Contact Lenses Jeonghun Yun, Moobum Kim and Seok Woo Lee; Nanyang Technological University, Singapore

As the demand for healthcare increases, various types of wearable devices have been developed for monitoring physiological information and biomarkers. Among these, smart contact lenses are attracting attention due to their huge applications ranging from health monitoring to digital entertainment. Inserting batteries inside contact lenses is still a challenge due to the need for miniaturization and the high safety requirements of placing batteries in the ocular system. Conventional batteries are not suitable to contact lenses because it can cause serious damage to the eyes if they break due to the release of toxic substances. We introduced a safe aqueous battery that utilizes tears as an electrolyte and supplies electric power to a microprocessor. Prussian blue analogues (PBAs), known as biocompatible host materials for Na- or K- ions, have been used as cathode and anode materials for electrochemical cell operation in the tears solution containing low concentrations of ions. The ultraviolet (UV) polymerized hydrogel was utilized as an ion-permeable separator as well as soft contact lens with embedding the electrodes which consist of carbon nanotubes and PBA. The battery embedded in the contact lens showed a discharge capacity of 155 µAh at potentials between 0.2 V and 0.9 V in an artificial tears solution. Bending tests and cytotoxicity tests while charging and discharging the battery were conducted to verify the mechanical stability and biocompatibility of the battery, respectively. For practical application, stable charge and discharge cycles of the battery in commercial contact lens cleaning solutions have demonstrated. The battery can supply high enough power to operate the low-power static random access memory. It could supply electric power to smart contact lenses without worrying about damage to eyes due to leakage of harmful substances from mechanical failure of the battery.

2D-Layered Coordination Polymer of Nickel Dithioxamide as a Precursor of Bifunctional Catalyst for Metal-Air Batteries Ihsan B. Rachman[1], Ridwan P. Putra[1], Hideyuki Horino[2] and Izabela Rzeznicka[1]; [1]Shibaura Institute of Technology, Japan; [2]Tohoku University, Japan

Two-dimensional (2D) layered materials have been an important part of rechargeable battery research and development. Graphite and inorganic layered compounds such as transition metal dichalcogenides found application in low-capacity Li-ion batteries as electrode components. On the other hand, the commercialization of high-capacity rechargeable batteries such as metal-air batteries for electric vehicles is hampered by poor kinetics of oxygen redox chemistry. In order to efficiently harvest the energy density of metal-air batteries (theoretical specific energy of Li-O_2 is 13 kWh/kg [1]), a bifunctional catalyst is needed to catalyze oxygen reduction reaction (ORR) and oxygen evolution reaction (OER). Here, we propose to use an organic 2D-layered coordination polymer of transition metals (Ni, Fe, Cu) as a precursor of a highly efficient bifunctional catalyst [2, 3].
In this presentation, we will introduce our work on Ni(II) dithiooxamide (dto) coordination polymer and discuss OER and ORR electrochemistry in alkaline solutions on a nanocomposite derived from Ni(dto). Ni(dto) forms a coordination polymer with a layered structure composed of sheets of four Ni(II) atoms in planar configuration with five dto ligands. The interlayer distance is 3.6 Å [4]. Electrochemical cycling of Ni(dto), dispersed in a carbon matrix, in the potential range of 0.4 to 1.6 V vs. RHE, resulted in the formation of g-NiOOH which was found active towards OER and ORR in 1 M KOH solutions. The nanocomposite showed an enhanced ORR activity with the onset potential of 0.78 V and the half-wave potential of 0.72 V vs. RHE in O_2-saturated 1 M KOH solutions. The overpotential, *h*, for OER on NiOOH/C was 390 mV at I =12 mA/cm^2 [5]. At the same current density, the h_{OER} for Fe-doped NiOOH was 308 mV. Fe doping was found to improve OER kinetics. In this presentation, we will discuss the effect of Fe doping on OER and ORR performance with the help of *in-situ* Raman spectroscopy.

9:10 PM EN12.18.04

Interpretation of Low Temperature Behavior of Highly Concentrated Aqueous Electrolyte Based Supercapacitor Jaeil Park[1], Jongyoon Kim[1], Myung-Han Yoon[1], Dong Wook Lee[2] and Seung Joon Yoo[1]; [1]Gwangju Institute of Science and Technology, Korea (the Republic of); [2]Hongik University, Korea (the Republic of)

Water-in-Salt Electrolyte (WiSE) which is highly concentrated aqueous solution is a promising electrolyte for energy storage devices such as battery and supercapacitor. WiSE shows three surprising features; a) very stable SEI formation during the first few charging/discharging cycles; b) more than 3 V electrochemical stability window; c) fast ion transfer in a highly viscous solution. Despite such superior electrochemical properties, however, there exist no research suggesting a theoretical boundary between dilute solution and WiSE. In this research, we propose a new approach to understand WiSE based on an eutectic mixture. Although potassium acetate (KOAc) WiSE is an aqueous solution, liquid state was observed at sub-zero temperature. As salt is added in water, the number of strongly bound water molecules to a point charge is increased in the solution. This non-freezing water renders aqueous solution difficult to crystalize. Eventually the freezing temperature (T_f) of the aqueous solution dropped to below -60 ºC near the critical point. After the lowest or critical point is reached, T_f increases again. Therefore, we suggest that before the critical point, the solution is sufficiently dilute where colligative properties are observed, and after the critical point, the solution is called WiSE. Finally, we demonstrated the sub-zero operation of WiSE based supercapacitor. The capacitance of a symmetric cell using activated carbon electrodes is measured approximately 50 F/g at -20 ºC.

9:15 PM EN12.18.05
Atomic-Scale Observation of Multiphase Evolution During Zinc-Ion Insertion in Vanadium Oxide Pilgyu Byeon, Youngjae Hong and Sung-Yoon Chung; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

An initial crystalline phase transforms into another phases as cations are electrochemically inserted into its lattice. Precise identification of phase evolution at an atomic level during transformation is thus the very first step to comprehensively understand the cation insertion behavior. By using atomic-column-resolved scanning transmission electron microscopy, we directly visualize the simultaneous intercalation of both H_2O and Zn during discharge of Zn into V_2O_5 with an aqueous electrolyte. In particular, when further Zn insertion proceeds, multiple intermediate phases, which are not identified by a macroscopic powder diffraction method, are clearly imaged, showing structurally topotactic correlation between the phases. These findings suggest that smooth multiphase evolution with a low transition barrier is significantly related to the high reversible capacity of oxide cathodes for aqueous rechargeable cells.

9:20 PM EN12.18.06
Electrolyte Design for High Voltage and Safe Sodium Ion Batteries Yan Jin, Phung M. Le, Thanh D. Vo and Ji-Guang Zhang; Pacific Northwest National Laboratory, United States

Sodium (Na) ion battery (NIB) is an attractive alternative solution for stational energy storage and electrical vehicles because of its low cost and abundant availability. Although rapid progress has been made on electrode materials, the stable electrolyte that is compatible with both cathode and anode is still limited, which hinders large-scale application of NIBs. Here, we report a low flammable electrolyte for highly reversible and high voltage sodium ion batteries. The high capacity retention (>80% for 300 cycles) and high columbic efficiency can be achieved for high voltage (4.2 V) full cells because of the stable interphases on both cathode and anode sides. These interphase layers can minimize undesirable reactions between the electrode and the electrolyte, and block the dissolution of transition metals from cathode. The interphase analysis, including XPS, TEM and EIS, has been used to identify the correlation between electrochemical performance and electrolyte properties. The insights obtained in this work can be used to guide the further development of stable electrolyte to enable safe and long cycle life of rechargeable batteries.

9:25 PM EN12.18.07
Enhanced Thermal Stability of $LiPF_6$-Based Carbonate Electrolyte in Li-ion Battery at Elevated Temperatures Mal-Soon Lee, Kee Sung Han, Sujong Chae, Vijayakumar Murugesan and Karl T. Mueller; Pacific Northwest National Laboratory, United States

Electrolytes play a crucial role in lithium-ion batteries (LIBs) by strongly affecting longevity and safety. Lithium hexafluorophosphate ($LiPF_6$) salt in carbonate-based solvents has been widely used as an electrolyte in commercial LIBs for over three decades. However, its insufficient thermal stability limits the cycle-life of LIBs. Studies have shown that the PF_6^- decomposition at elevated temperature is initiated by the reaction: $LiPF_6 \rightarrow LiF + PF_5$. Nevertheless, the underlying process that triggers thermal decomposition of PF_6^- at elevated temperatures is still unknown and impedes our ability to design optimal electrolytes. We report that the presence of urea (2 wt %) suppresses the decomposition reaction in 1 M $LiPF_6$ dissolved in propylene carbonate (PC) at elevated temperatures. A combined study of nuclear magnetic resonance (NMR) and ab initio molecular dynamics (AIMD) simulations elucidate the structure and dynamic properties of the $LiPF_6$/PC electrolytes in the absence and presence of urea additive, which are correlated with the stability of the electrolyte at elevated temperatures. Spin-lattice (T_1) relaxation time measurement and pulsed-field gradient (PFG) NMR reveal that (i) rotational motion of PF_6^- and PC changes from small-angle libration to reorientation with elevated temperatures, and (ii) the hopping motion of Li^+ at elevated temperature ($\geq$ 80 °C) seen in the electrolyte is suppressed when urea additive is present. The latter is inferred due to preferential solvation with urea leading to capture of Li^+ within a solvation cage. To attain atomic understanding of the observations, we performed AIMD simulations at room temperature and 100 °C with and without urea. AIMD simulation at 100 °C reveals an elongated P-F bond and a shortened Li^+-F when PF_6 binds to Li^+ which are not seen at room temperature, which may prompt the PF_6^- decomposition. In the presence of urea, a shorter Li^+- O_{urea} bond length is observed relative to Li^+-F_{PF6} and Li^+-O_{PC} bond lengths, indicating a stronger interaction of urea with Li^+ than PF_6 and PC. Based on these observations, we infer that thermally activated dynamics of PF_6^- accelerate the first decomposition reaction to form LiF and PF_5. In this presentation, we will discuss the correlation between macroscopic thermal stability and molecular level ion/solvent dynamics of the $LiPF_6$-based carbonate electrolytes.

Understanding Electrochemical Processes in Molten Salt Catholytes for Low-Temperature Molten Sodium Batteries Leo J. Small, Rose Lee, Stephen J. Percival, Martha M. Gross, Amanda Peretti, Melissa L. Meyerson and Erik D. Spoerke; Sandia National Laboratories, United States

Molten sodium batteries offer a promising technology for grid scale energy storage. Typical molten sodium battery chemistries such as Na-S and Na-$NiCl_2$ (ZEBRA) require temperatures near 300 and 200 °C, respectively, to operate. Driving operating temperatures down to near 100 °C would decrease operating costs, minimize materials aging effects, and minimize system-level materials costs through use of polymeric seals, thinner wires, and less insulation. To enable battery operation at such low temperatures, we have developed a suite of redox-active molten salt catholytes based on metal halide-sodium iodide chemistries that melt at <100 °C. While each metal halide-sodium iodide system provides a unique phase stability, conductivity, and redox potential, they all share the same underlying I^-/I_3^- redox used to store energy in the molten sodium battery. Nevertheless, each system shows distinct electrochemical performance. We couple idealized electrochemical measurements in a three-electrode cell with electrochemical modeling to better understand the electrochemical reactions and chemical equilibrium present during the deceptively simple oxidation of iodide. This modeling effort provides insights as to the factors which limit electrochemical performance, enabling targeted improvements to catholyte composition that significantly improve overall electrochemical kinetics. Leveraging this understanding, we identify cost-competitive metal halide-sodium iodide catholyte compositions for use in

a molten sodium battery.

Sandia National Laboratories is a multi-mission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC., a wholly owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

9:35 PM EN12.18.09

Highly Porous Aramid Nanofiber Separators for Suppression of Li Dendrite Formations in Li Metal Batteries Arum Jung[1], Nayeon Kim[2], Jeong Gon Son[2] and Bongjun Yeom[1]; [1]Hanyang University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

Lithium metals for anode of secondary batteries are drawing great attentions due to high theoretical capacity, high potential, and low density for next-generation high-energy storage systems. However, dendritic growth of lithium (Li) metal during repetitive charge and discharge cycles can cause severe problems such as low lifespan and risks of explosions raised from short circuits. In this study, we synthesized highly porous aramid nanofiber film (PANF) separators by sequential solvent-substitution methods to suppress Li dendritic growth. Porosities and pore sizes of PANF were controlled by self-assembly processes of aramid nanofibers during solvent-substitutions. Highly porous nanostructures enabled to improve wettability to electrolytes and ionic conductivities for PANF. Symmetric cell tests showed stable cycle operations up to 3000 cycles at currunt density of 50 mA/cm^2 with cycling capacity of 1 mAh/cm^2 , that could be attributed to effective suppressions of Li dendrite formations. For the full cell tests with $LiFePO_4$ (LFP) cathodes, PANF samples showed higher capacity than commercialized separator samples from 1 C to 30 C rates. The PANF separators are expected to one of most promising candidates for advanced separators for the Li metal batteries.

Intrinsic Defect Study on High-voltage Spinel $LiMn_{1.5}Ni_{0.5}O_4$ Cathode Material for Li-ion Batteries Jiayi Cen[1,2,3], Bonan Zhu[1,2,3] and David O. Scanlon[1,2,3]; [1]University College London, United Kingdom; [2]The Faraday Institution, United Kingdom; [3]Thomas Young Centre, United Kingdom

High-voltage spinel $LiMn_{1.5}Ni_{0.5}O_4$ (LMNO) is an attractive cobalt-free cathode material which can deliver high energy density (650 W h kg^{-1}) due to its high operating voltage ~4.7 V (*vs* Li^+/Li) arising from the Ni^{2+}/Ni^{4+}couple.[1] The spinel framework offers a 3D diffusion channel for Li^+, leading to high ionic conductivity. Another unique characteristic of the material arises from the potential to tune performance through harnessing cation disorder.[2] Introducing cation disorder during synthesis inevitably brings additional complexity (e.g. oxygen vacancies), making it challenging to rationalise the most significant factors towards designing LMNO with optimum electrochemical performance.[3–5]

In this study we used quantum chemistry techniques[6,7] to predict the defect landscapes of LMNO under various synthesis conditions. Analysis of the formation energy of all intrinsic defects in the ordered phase *$P4_332$* LMNO using the supercell approach, can provide logical explanations for experimental observations and reveal insights on the charge compensation mechanisms and changes to local cation-ordering associated with those defects, which cannot be obtained easily through experiments and characterisations.

Improvement of Charge/Discharge Characteristics with Surface Structure Controlled Bismuth Anode Materials by Electrodeposition for Magnesium-Ion Batteries Takeyasu Saito, Natsuki Narumoto and Naoki Okamoto; Osaka Prefecture University, Japan

The magnesium ion secondary battery (MIB) has attracted much attention because magnesium (Mg) metal has high theoretical capacity (3,755 mAh/cm^3), high electrochemical stability, and high abundance in the earth. However, developing anode and cathode materials with superior capacity for conventional electrolytes has required considerable study. Bismuth (Bi) has high capacity as an anode and also resists oxidation in Mg-containing electrolyte, so is a promising candidate material. However, experimental studies suggest that the available capacity has not yet reached the theoretical limit, and that the cycle life is short. This is due to sluggish diffusion of Mg^{2+} into the anode material and the slow interfacial charge transfer. We aimed to improve the electrochemical properties by atomizing the internal and surface structure of the Bi anode and enhancing the diffusion of Mg^{2+}. In this study, we prepared Bi films by an electrodeposition method, in which the structure of the Bi electrodes could be controlled by changing electrodeposition conditions. We also evaluated the electrochemical properties of Bi anode materials deposited with different deposition times and current densities, to elucidate the relationships between the structure of the Bi anode and its capacity and cycle life.

We prepared an electrolytic bath by dissolving H_2SO_4, Na_2SO_4 and polyethylene glycol in pure water, and subsequently added H_2SO_4 to the electrolytic bath to control the pH at 1.2. Before electrodeposition, we removed organic species and native oxide from the Cu foil surface with NaOH and HCl. We employed a Cu plate with an exposed foil area of 2 × 2 cm^2 and a carbon plate as the cathode and anode, respectively. The Bi electrodeposition was carried out, while changing the deposition time and current density (from 10 to 50 mA/cm^2). The film thickness was controlled by the deposition time (from 1.5 to 3.0 μm), and was calculated based on the weight increase under the assumption that the film was uniform. The surface morphology and crystal structure of the Bi films were evaluated by scanning electron microscopy (SEM) and X-ray diffraction (XRD), respectively. In addition, the characteristics were compared before and after discharge/charge. The cycle characteristics of the Bi anodes were studied in PhMgCl/THF electrolyte. The bipolar half-cells were assembled with Mg plate as the anode and Bi electrode as the cathode. We established representative galvanostatic charge/discharge profiles of the Bi electrodes, at a current density of 50 mA/g within 0–0.6 V, versus Mg^{2+}/Mg. We evaluated the cyclic stability of the Bi electrodes under the same conditions until the 50th cycle. The elemental composition and chemical bonding state of the Bi films after charge/discharge were evaluated by energy dispersive X-ray spectroscopy (EDS) and X-ray photoelectron spectroscopy (XPS).

The cycling performance of Bi films with thicknesses of 1.5, 2.0, and 3.0 μm until the 50th cycle. Each film showed a capacity of about 300 mAh/g at the early stage of cycling, which is the maximum capacity. The capacities were about 1.5 times those of the Bi anodes which Niu et al. prepared by powder metallurgy. The cycle performance differed among Bi films differing in thickness, and the 1.5-μm Bi film maintained the maximum capacity until the 25th cycle. Thus, film thickness had an impact on the cycle performance. The surface morphology of Bi films with different thicknesses before and after the charge/discharge reaction shows agglomerates involving a large number of particles with increasing film thickness, which consists of particles from 1 to 3

µm. after charging/discharging, and also consists of Mg dendrites with thicknesses of 2 and 3 µm. The localized formation of Mg dendrites on the Bi surface could explain the decreased cycle performance of the Bi films prepared in this study.

Late News: Multi-Principal Metal Chalcogenides as the Air Electrode with CNT-Zn Modified Anode for Rechargeable Zinc-Air Battery Chetna Madan and Aditi Halder; IIT Mandi, India

Metal-air batteries happen to be more viable and sustainable energy storage systems due to high safety, low cost and less environmental repercussions. Li-air battery despite of having the highest theoretical energy density lags behind Zn-air battery in terms of resource availability and operation safety. Also, the electrode potential of such metals like Li, Na, Al is very negative, thus making them more susceptible to anodic corrosion in aqueous environment by evolution of hydrogen, further compromising the safety of the battery. Zinc being the most promising candidate for metal-air batteries is extensively being studied to improve the short-comings of by-product saturation and precipitation, dendritic growth during Zn plating and hydrogen evolution. In this work, conductive substrate modified with carbon nanotube is deposited with zinc to be utilized for the improvement of life-cycle and durablity of the anode for zinc-air battery. To construct a flexible rechargeable battery, CNT can provide larger surface area for Zn deposition and improves its performance by allowing better flow of electrolyte as well as prohibits the dendritic growth by anchoring strongly. On the other hand, multi-principal 2-D metal chalcogenides have been used a bifunctional oxygen electrocatalyst for the cathode of ZAB giving maximum charge-discharge cyclic stability and constant discharge voltage (close to 1.65 V). These high-entropy materials comprising of quasi-equimolar quinary or higher principal metals, provide numerous combinations of surface structure and therefore, adsorption sites and electronic environments. The tunable properties influence the catalytic behavior through charge transfer, adsorption, etc. The high-entropy metal sulfides, as in this study, stabilized by configurational entropy are ideal to explore the structure-property relationship.

A Critical Evaluation of the Separate Contribution of Carbon Fiber and Carbon Nanotubes Activated for Pseudocapacitance of Composite Electrodes Camila A. Escanio, Erica F. Antunes, Evaldo J. Corat and Vladimir J. Trava-Airoldi; National Institute of Space Research, Brazil

Carbon-containing materials are a promising alternative to develop novel technologies applicable in supercapacitors and energy storage devices. Among these materials, Carbon Fibers (CF) are base electrodes of wide use in electrochemical cells mainly because of their good flexibility and high mechanical resistance. Carbon nanotubes (CNT) films have high electrical conductivity, high resistance to acid electrolytes, and high specific surface area. This work aims to develop CNT/CF electrodes and study the electrochemical behavior of both separated materials, CF and CNT, and in the composite. A viscose fabric pyrolysis produced the CF, using a temperature ramp-up to 850 °C at a 5 °C/min heating rate. The CNT was deposited over two different substrates: the CF and silica fabric. The latter was used to evaluate only the contribution of the CNT since the silica fiber presents no electrochemical response. Thermal Assisted Chemical Vapor Deposition (TA-CVD) at atmospheric pressure was the CNT film growth technique. The precursors for floating catalyst growth were the mixture of 84% camphor and 16% ferrocene, in which 12.5 g was dissolved in 50 mL of n-hexane. It was evaporated while inserted dropwise in a chamber at a temperature of 220 °C. An argon gas flow (200 sccm) carried this vapor into the reactor at 850 °C. The process lasted for 15 minutes, promoting the CNT growth. To increase the CNT samples' hydrophilicity, we performed a surface activation process using steam and CO_2 simultaneously. The electrochemical behavior of the CF, CNT, and CNT/CF samples was measured using a three-electrode cell setup with an Ag/AgCl saturated reference electrode and a platinum grid counter electrode. The electrolyte was an aqueous sulfuric acid solution of 1.0 M. Electrochemical characterization of the samples involved electrochemical impedance spectroscopy (EIS) technique, cyclic voltammetry (CV), and galvanostatic charge and discharge (GCD) routines. In addition, the samples were morphologically and structurally characterized by scanning electron microscopy (SEM), and Raman spectroscopy, respectively. The results got by electrochemical measurements showed a distinct behavior for the samples. The FC acts as a double-layer electrochemical capacitor (EDLC) while CNT exhibited typical Faradaic behavior. The CNT/FC composite showed an intermediate behavior between EDLC and battery, characterized as a supercapacitor. Electrochemical purification to remove electrochemically available iron residues shows that the Faradaic behavior was because of these residues. The combination of FC and CNT properties provides a composite with high specific capacitance (150F/g) and high conductivity and presents a prospective application as supercapacitors and energy storage devices.

10:35 AM EN12.19.04
Copper Sulfide—A Conversion Cathode Material for Mg-Batteries Michael Wilhelm, Veronika Brune, Khan Lê and Sanjay Mathur; University of Cologne, Germany

Magnesium secondary batteries have been regarded as promising candidates for large-scale storage systems with high safety, high energy density, and low production costs. Magnesium batteries profit from the use of a metal anode due to the dendrite-free deposition of magnesium ions. In addition to the challenge of finding suitable liquid or solid-state electrolytes, the hunt for viable cathode materials is a key success factor for battery fabrication. Copper sulfide can be reversible converted into magnesium sulfide and delivers high capacity (560 mAh g^{-1}). Interestingly, the charged and discharged products (CuS/Cu_2S and Cu) are electrically conductive, which is profitable for the positive electrode. Copper (0.01 %) and sulfur (0.05 %) as well as magnesium (2.4 %) are highly earth-abundant and are therefore sustainable raw materials.
Conventional battery cell production makes use of common current collectors like Al and Cu foil, which is on the one hand side non-active material and on the other side not feasible because of undesirable side reactions with sulfur and the electrolyte. This makes the battery heavier and less efficient. Therefore, we designed electrospun cathode material of copper sulfide and carbon nanofibers with flexible network architecture and promising properties as the positive electrode for magnesium batteries. These copper sulfide loaded fibers have been analyzed using XPS, SEM, and Raman spectroscopy. The advantages of the composite material are large surface area, high porosity, large liquid permeability, and good electrical conductivity, making these prepared fibers ideal candidates for application as electrode material in Mg-based secondary batteries for large-scalable, sustainable, and low-cost energy storage devices.

10:40 AM EN12.19.07
Temperature-Dependent Structural Analysis of $NaFePO_4$ Using Neutron Powder Diffraction Elizabeth Brown and Hillary Smith; Swarthmore College, United States

Olivine $NaFePO_4$ is a promising cathode material for Na-ion batteries, but aspects of the phase diagram for Na_xFePO_4 ($0<x<1$) remain poorly understood. Reports using x-ray diffraction have found the $NaFePO_4$ phase diagram to be quite distinct from $LiFePO_4$ with both a solid solution forming at $x>2/3$ and an intermediate ordered phase at $x=2/3$. The larger differential in unit cell size for Na_xFePO_4 with $x=1$ and $x=0$ compared to $LiFePO_4$ is thought to allow for more structural relaxation in the sodium material. In this work, the phase diagram of Na_xFePO_4 is investigated for $x=0$, $x=2/3$, and $x=1$ using neutron powder diffraction. We find new insight into the lattice volume expansion as a function of temperature for the intermediate phase. Our measurements extend to higher temperatures than previously reported and the reversibility of high-temperature structural transformations are examined.

10:45 AM EN12.19.08
SiOC Functionalized Transition Metal Monochalcogenides as Electrodes for Beyond Lithium-Ion Batteries Shakir Bin Mujib and Gurpreet Singh; Kansas State University, United States

The development of feasible, scalable, and environmentally safe electrode materials that provide stable cycling performance is critical for the success of beyond lithium-ion batteries. With respect to the sodium- and potassium-ion battery anodes fabricated using transition metal monochalcogenides such as germanium and tin sulfides and tellurides show poor cycle stability and fast capacity degradation, due to low electronic conductivity and dissolution of chemical species in the electrolyte. Herein we report chemical functionalization of monochalcogenide nanosheets with polymer-derived silicon oxycarbide (SiOC) with the aim to preserve the electrodes from dissolution in the organic electrolyte, without compromising its role in charge/discharge processes. The high performances of electrodes are attributed to the high electric conductivity and structural stability of the SiOC fibers with unique structure, which not only buffers the volume change of monochalcogenides with the internal space but also acts as high-efficient transport pathways for ions and electrons Our results suggest that monochalcogenides–SiOC composite electrode are effective in bringing improved cycle stability over neat monochalcogenides.

10:50 AM EN12.19.09
Study of Gallium-Based Liquid Alloys as Electrodes for Na-Ion Batteries Ronan Le Ruyet, Florent Mohimont, Andrew Naylor and Reza Younesi; Uppsala University, Sweden

Gallium has always been an intriguing metal, especially because of its low melting temperature (30°C). This melting temperature can even be lower when alloying Gallium with elements such as Indium and Tin. The $Ga_{86}In_{14}$, $Ga_{92}Sn_8$ and $Ga_{77}In_{15}Sn_8$ alloys have melting temperatures of 16 °C, 25 °C and 11 °C, respectively. These alloys are extensively studied to design stretchable and self-healing electronic circuits.[1] In the recent years, they have been also studied in the field of Li-ion batteries as self-healing electrode materials with prolonged cycle-life.[2] Indeed, after delithiation, the liquid alloys recover their initial shape due to the transition from the solid lithiated phases back to the pure liquid delithiated phase. However, as they are being tested in Li-ion batteries, almost no study has been performed for their use in beyond Li-based technologies such as Na-ion batteries.

In this presentation, our results on using Gallium, $Ga_{86}In_{14}$, $Ga_{92}Sn_8$ and $Ga_{77}In_{15}Sn_8$ as electrodes in Na-ion batteries will be presented.[3] The electrochemical reactions of these compounds with Na were carefully studied. Electrochemical measurements were coupled with ex-situ PXRD and SEM analyses to have a complete overview of the involved reactions, their potentials, their capacities and the self-healing properties of the alloys. Finally, the possible applications of these liquid alloys in Na-ion batteries will be discussed.

Enhancing VO^{2+}/VO_2^+ Kinetics and Inhibiting Chlorine Evolution in Mixed Acid All-Vanadium Redox Flow Batteries Using C_{76} Fullerene Farah El Diwany, Basant A. Ali, Ehab N. Elsawy and Nageh K. Allam; The American University in Cairo, Egypt

The growing energy demand met by fossil fuels for decades, leading to pollution and global warming. Therefore, the shift to clean and renewable energy sources is a must to achieve carbon neutrality. However, the alternating nature of wind and solar energy necessitates the development of energy storage technologies for frequency balancing and grid stability. Batteries are thought to be the optimal solution. Among all types of batteries, all-vanadium redox flow batteries (VRFBs) have independent modularity of energy and power ratings, flexible design, and provide large-scale energy storage at a reasonable cost. However, the energy efficiency of VRFBs is still not satisfactory for widespread applications.
Commercial VRFBs use graphitized carbon-based electrodes due to their high chemical and electrochemical stability and conductivity. However, their electrochemical activity towards vanadium ions is poor. For improved electrochemical activity, the thermal treatment and its role in introducing the necessary surface functional groups and the increase of the electrode wettability were thoroughly investigated. However, to further reduce polarization losses, interest in carbon nanostructures, such as graphene[1], reduced graphene oxide[2], carbon nanotubes[3], carbon nanowalls[4], carbon nanofibers[5], and carbon nanoplatelets[6], is growing owing to their excellent conductivity, stability, and large surface area.
The fullerene family has not yet been explored in the VRFBs application. Fullerenes have a very unique cage-like structure with high surface area and conductivity, which would allow fast electron transfer. The electronic cloud surrounding the fullerene molecule could also enhance the adsorption of ions onto its surface. In this work, we, therefore, report, for the first time, the electrochemical activity of fullerene C_{76} towards VO^{2+}/VO_2^+ redox reaction in G1 and G3 VRFBs. C_{76} showed superior electrocatalytic activity in both versions of VRFBs, as evaluated by cyclic voltammetry (CV) and electrochemical impedance spectroscopy (EIS), while also inhibited the chlorine evolution in G3 VRFB when compared to thermally treated carbon cloth (TCC) electrode. It is noteworthy to point out that treatment is, thus, unnecessary and undesirable in G3 VRFBs.[7]

Catalyzing the Vanadium Redox Reactions While Inhibiting the Parasitic Ones of the Mixed-Acid All-Vanadium Redox Flow Batteries Using

Tungsten Oxide/Fullerene Nanocomposites Farah El Diwany, Nageh K. Allam and Ehab N. Elsawy; The American University in Cairo, Egypt

The penetration of clean and renewable wind and solar energies is expected to reach up to 75% of the total electrical energy by 2050. However, the electrical grid becomes unstable when the power from renewable energy sources exceeds 20% of the total generated power. Developing efficient energy storage systems is crucial for such a transition since they are required to store surplus electricity and balance supply and demand. Among all energy storage systems, vanadium redox flow batteries (VRFBs) are thought to be an optimal solution for long-term energy storage (~30 years) due to the decoupling of power and energy densities, fast response, and long cycle life, and low annualized cost.[1] However, their relatively high system capital cost, primarily due to the cell stack needs to be reduced. Increasing the kinetics of both half-cell reactions can reduce the size of the stack and, consequently, the cost. Even though carbon-based electrodes have good chemical and electrochemical stability and good conductivity, with no treatment they suffer from sluggish kinetics due to the lack of oxygen functional groups and hydrophilicity.[2,3] Therefore, different electrocatalysts were incorporated with the carbon-based electrodes, specifically carbon nanostructures[4,5] and metal oxides[6,7], to enhance the kinetics at both electrodes to increase the kinetics at the VRFB electrodes.
Herein, novel hydrated tungsten oxide (HWO) nanoparticles were synthesized *via* facile hydrothermal methods and deposited on carbon cloth electrodes for both half-cell reactions. The superior electrocatalytic activity was observed for the V^{2+}/V^{3+} reaction, in addition to suppressed HER. As for the VO^{2+}/VO_2^+ reaction, the incorporation of C_{76} was necessary to enhance the conductivity and kinetics, while the HWO inhibited chlorine evolution. Experiments were also done in the mixed acid electrolyte (H_2SO_4/HCl) to imitate the 3rd Generation (G3) VRFB for more practicality and to study the effect of HWO on the chlorine evolution parasitic reaction.

Flexible and Freestanding Carbon Nanotube and Niobium Pentoxide Composite for Sodium Electrochemical Energy Storage with Intercalation Pseudocapacitance Carla G. Real[1], Gurpreet Singh[2] and Hudson Zanin[1]; [1]UNICAMP, Brazil; [2]Kansas State University, United States

Sodium ion-based devices have been intensively investigated as a promising alternative to lithium-ion devices for large scale energy storage due to their similar electrochemical properties and sodium low-cost thanks to its abundance resources. However, many challenges remain sodium ion devices to become commercially competitive as lithium-ion devices. One of them concerns the ionic size of sodium, larger than that of lithium, resulting in slower electrochemical kinetics and significant restrictions in the intercalation process reducing performance and device lifetime. Despite these drawbacks, extensive efforts are focused on the rational design of nanostructured and novel electrodes to improve the Na^+ transport kinetics. Niobium pentoxide is promising as it presents electrochemical stability and rapid ion transport throughout the a–b plane, suitable for a wide array of electrochemical energy applications. This work reports the preparation of a flexible and freestanding film of multiwalled carbon nanotube decorated with Nb_2O_5 nanoparticles through vacuum filtration and investigate the effect of Nb_2O_5 as sodium-ion symmetric supercapacitor (SIC) and anode battery (SIB). In both cases, the results show a peseudocapacitance contribution. In a SIB half-cell configuration, the electrode delivers a reversible sodium-ion storage capacity of ~ 163 mA h g^{-1} at 25 mA g^{-1} and present a retention of capacity of ~ 68 mA h g^{-1} after 100 cycles at 25 mA g^{-1}. The SIC full cell shows a long cycling stability after 10,000 cycles and delivers a high energy density of 64.11 W h kg^{-1} with a power density of 74.98 W kg^{-1}. Even with a power density of 14,766 W kg^{-1}, it delivers a high energy density of 55 W h kg^{-1}.

11:10 AM EN12.19.13
Sn Nanoparticles and Nitrogen-Doped Activated Carbon Nanofiber Composite as Anode for Sodium-Ion Batteries Carla G. Real[1], Gurpreet Singh[2] and Hudson Zanin[1]; [1]UNICAMP, Brazil; [2]Kansas State University, United States

Sodium ion batteries have attracted attention because sodium is an abundant metal in the Earth's crust, which facilitates its obtaining and processing and, consequently, offers sustainability and low cost. Although sodium-ion batteries have a similar function to lithium-ion batteries, due to the greater atomic radius of sodium, they have poor diffusion and restrictions of the intercalation process in the interstices of the electrode. To address these deficiencies, Sn a promising anode candidate to construct viable, stable, and low-cost sodium-ion batteries for energy storage systems because it alloys high theoretical capacities, high conductivity and safe reaction potential. In this work, we related a Sn-based anode material by synthesizing a composite of Sn nanoparticles on nitrogen-doped carbon nanofibers via electrospinning technique for sodium ion batteries. The composite shows a high reversible capacity of ~1100 mA g^{-1} at 25 mA g^{-1}. Even with a current density of 1 A g^{-1}, the material delivers a capacity of ~120 mA g^{-1}. Results show a long cycling stability within 0 to 2.5 V potential window.

An *Ab Initio* Based Thermodynamic Modeling of the Si-Li System Including Charged Defects And Stress Charbel Jose El Khoury, Maylise Nastar and Fabien Bruneval; Université Paris-Saclay, CEA, France

Si-Li batteries are promising in many ways, e.g. they have high theoretical specific capacity (4200 mAh/g). However, the volume expansion upon lithiation may lead to high internal strain/stresses and fracture phenomena. We associate this phenomenon to the fact that an electrochemical insertion of Li leads to multi-phase particles with significant changes in specific volumes of phases. We introduce a thermodynamic formulation of the phase transformation including the role of charged lattice point defects, the internal stress/strain field, and the deviation from perfect stoichiometry of the compounds.

From our *ab initio* calculations, we obtain: the formation energies (Ef) of Si-Li compounds; the Ef of defects (both charged and neutral vacancies/interstitials) in pure and lithiated Si; the dielectric constants (needed for charged defect); and the elastic constants of Si and several compounds. The DFT calculations are performed with PBE and HSE06 functionals. The hybrid functional HSE06 allows us to reproduce the semi-conductor nature of the solid solution Si(Li) and the Li-poor compounds, by providing a closer-to-reality band gap and therefore, permitting us to investigate realistic properties of the charged point defects. From the formation energies of the Si-Li compounds, the neutral and charged defects in Si and its lithiated compounds, the phonon frequencies and the elastic constants, we compute the free Gibbs energies of the particle with respect to the composition, temperature, and the particle size. The increment of the Gibbs free energy with the number of Li yields the open circuit voltage (OCV).

Our results are in good agreement with measured OCV at high temperature (415°C), with respect to the off-stoichiometric composition of the stable compounds [1]. From the investigation of the metastable Si-Li phases that are only formed under electrochemical insertion of Li, we simulate the charging-discharging OCV cycles.

Bi-Functional Use of Natural Graphite in High Voltage Battery Electrodes Habtom D. Asfaw[1], Tove Ericson[1], Antonia Kotronia[1], Filip Kozlowski[2] and Maria Hahlin[1]; [1]Uppsala University, Sweden; [2]Leading Edge Materials, Sweden

New electrolytes with enhanced anodic stability have enabled electrochemical synthesis of anion-intercalated graphite (or p-doped graphite) compounds at voltages > 4.5 V vs Li^+/Li. The p-doped GICs form the basis of an emerging battery concept called dual-ion battery (DIB) in which both cations and anions from the electrolyte participate in the energy storage process. With the current state-of-the-art electrolytes and electrode materials, DIBs have been demonstrated to offer specific energy densities close to 200 Wh kg^{-1}, and are potentially attractive for stationary applicaitons. In this contribution, we will explore the design of hybrid DIB cells based on composite electrodes consisting of high voltage positive active materials such as LNMO and natural graphite, which doubles as a conductive additive and an anion intercalation host. Since it contributes (~100-120 mAh g^{-1}) to the overall capacity, natural graphite can be used in much higher proportions without affecting the specific capacity of the composite electrode, while enhancing the rate capability by virtue of its metallic conductivity. The ratios of both active materials are varied to achieve optimal combinations.
Similar to ordinary DIBs, this battery concept is, however, affected by challenges associated with instability of electrolytes within the high operating voltage required for anion intercalation (typically ranging from 4.5 to 5.2 V Li^+/Li), corrosion of Al current collector and graphite exfoliation. Highly concentrated-salt electrolytes and ionic liquids are often used as they have wider kinetic stability windows than conventional battery electrolytes. These limitations give rise poor coulombic efficiency (typically < 90 %), aggravated self-discharge and poor capacity retention over extended cycles. Efforts are geared towards understanding and mitigating the parsitic reactions by creating stable cathode-electrolyte interface (CEI) layer and generating passivated Al current collectors with the help of various electrolyte additives (salt additives and co-solvents). Using a range of surface and bulk characterizations tools, and operando gas pressure measurements we strive to understand the nature and resilience of the CEI layer forming at different states-of-charge in such electrodes. In addition, works on the design of new current collectors with improved anodic stability will be introduced.

11:25 AM EN12.19.16
Design of a Deep Eutectic Solvent Electrolyte for Sodium-Ion Batteries with Increased Durability Dries De Sloovere[1,2], Danny E. P. Vanpoucke[1], Andreas Paulus[1,2], Bjorn Joos[1,2], Lavinia Calvi[1], Thomas Vranken[1,2], Gunter Reekmans[1], Peter Adriaensens[1], Nicolas Eshraghi[3,4], Abdelfattah Mahmoud[3], Frédéric Boschini[3], Mohammadhosein Safari[1,2], Marlies Van Bael[1,2] and An Hardy[1,2]; [1]UHasselt, Institute for Materials Research (IMO-Imomec) and imec, Division Imomec, Belgium; [2]EnergyVille, Belgium; [3]University of Liège, Belgium; [4]AIT Austrian Institute of Technology GmbH, Austria

In the large-scale storage of renewable energy, sustainability and cost-effectiveness are of utmost importance. Lithium-ion batteries (LIBs) are a common energy storage technology for portable electronics and electric vehicles. However, reserves of lithium are limited and therefore, the increasing use of LIBs on larger scales could result in a significantly higher price in future. Next to lithium, sodium is the smallest and lightest alkali metal and therefore, sodium-ion batteries (SIBs) are a potential alternative technology to LIBs. Sodium is the 6th most abundant element in the Earth's crust and is widely available, which positively influences the sustainability of SIBs.
Conventional liquid electrolytes for SIBs consist of a sodium salt dissolved in (an) organic solvent(s). However, the latter cause a safety hazard because of their high flammability. At temperatures of 55 °C or higher, the solubility of the solid electrolyte interphase (SEI) components derived from such electrolytes is higher than at ambient temperature. This can have a negative influence on the electrochemical performance. Ionic liquids can be used as alternatives for organic solvents. They consist entirely out of ions, are liquid in a wide temperature range, are non-flammable, and offer a high electrochemical stability. They have a high conductivity and can also dissolve high amounts of salt. However, their main drawback is their high cost.
Deep eutectic solvents (DESs) are mixtures of Lewis/Brönsted acids and bases. The melting point of a DES is below that of the individual components. Their use as electrolyte in batteries may offer substantial benefits over conventional electrolytes and ionic liquids. They can significantly improve safety because they have a low vapor pressure and can be non-flammable, and they can be cost-effective. Thus far, DESs have not yet been reported as electrolytes for SIBs. In LIBs, however, a DES (LiTFSI dissolved in *N*-methyl acetamide (NMA)) allowed stable electrochemical cycling of full cells, even at 60 °C.[1] The low solubility of sodium salts (compared to lithium salts) and sodium's milder Lewis acidity imply that it is more difficult to create a DES based on a sodium salt than a similar DES based on a lithium salt. In the example described above, changing LiTFSI to NaTFSI might not lead to the formation of a DES at all, or will at least have a large impact on the physico- and electrochemical properties.
In this presentation, we will report non-flammable DESs, based on the dissolution of NaTFSI in NMA, that can be used as electrolyte in SIBs. Increasing the NaTFSI concentration increased the DESs' reductive and oxidative stability. First-principles modelling revealed that the increased anodic stability was related to the strong ionic interactions between NMA molecules and $TFSI^-$ with Na^+. The hydrogen bonds between individual NMA molecules are progressively disrupted with increasing NaTFSI concentration. When cycled at 55 °C, $(Na_3V_2(PO_4)_2F_3)/(Na_{2+x}Ti_4O_9/C)$ full cells showed an improved electrochemical stability when a DES was used in comparison to when a conventional electrolyte was used, with 74.8% capacity retention after 1000 cycles at 1 C and 97.0% capacity retention after 250 cycles at 0.2 C. This shows that DESs can be viable electrolytes for SIBs, as they can offer a high durability and safety.

A Combined First Principles and Grand Canonical Monte Carlo Approach to Understand Sodium (De)-Intercalation in O3 and P2 Type Na_xRhO_2 Systems Madhulika Mazumder, Abhiroop Lahiri and Swapan Pati; JNCASR (Jawaharlal Nehru Centre for Advanced Scientific Research), India

The demand for generating clean and sustainable sources of energy has lead to a huge leap in the research of efficient, high-performance electrochemical systems for energy storage and harvesting. In terms of resource availability, manufacturing expense and safety, Na ion batteries (SIBs) are now evolving as contenders for the highly successful Lithium ion battery (LIB) technology.
Layered oxide materials are promising candidates for cathode systems, because of their high capacities arising from fast ionic conduction. However, there still exist pitfalls of irreversible structural transition during electrochemical cycles, the most prominent one being the gliding of $(MO_2)_n$ layers, O3 to P3 phase or P2 to O2 phase, which eventually leads to degradation and capacity loss.

The Na_xMO_2 (M=3d transition metal) class of compounds, with 3d transition elements have been extensively researched on as cathodes. The 4d transition series is relatively newer, and sodium (de)-intercalation has been proved to occur in Nb, Mo and Rh systems [1,2]. As reported by Delmas *et al*[3], $NaRhO_2$ can be synthesised in O3 and P2 type structures with Na ions occupying octahedral and trigonal prismatic sites respectively. It is interesting to note that these systems preserve the O3 type stacking upto a high temperature (300°C).
Thus, a nearly reversible (de)-intercalation of Na in the $0.33 < x < 1$ composition range, makes it a superior cathodic system.
In this work, we have theoretically studied the electrochemistry in O3 and P2 type $NaRhO_2$, using Density Functional Theory for detailed insights into the electronic structures of the intermediates Na_xRhO_2. We have also delineated the Minimum Energy Pathways for Na diffusion with low activation barriers of ~210meV and compared it with previously reported Na_xMO_2 systems.
In addition to this, we have employed a Cluster Expansion (CE) technique followed by Grand Canonical Monte Carlo (GCMC) simulations, to reproduce the trends in the voltage profiles of O3 and P2 systems, as a function of composition *x*. The computed voltage profile from MC simulations corroborate well with the experimental observation [3], with voltage steps at ~x=0.3 and x=0.5. This cumulative approach involving First Principles theory and stochastic simulations provides a clear understanding of the (de)-intercalation mechanism, from the associated Na/vacancy orderings within the voltage window of 2.4V to 4.2V.

Electrolyte-Mediated Interfacial Dynamics in Na-S Battery Susmita Sarkar[1], Rachel Carter[2], Corey Love[2] and Partha Mukherjee[1]; [1]Purdue University, United States; [2]U. S. Naval Research Laboratory, United States

Polysulfide shuttling is an inevitable trait of metal-sulfur (S)-based batteries. Such shuttling behavior is directly related to the amount of soluble intermediate polysulfide species and is primarily affected by electrolyte constituents. While the sulfur electrode suffers from lower accessible capacity due to the loss of active S species, sodium (Na) metal is also plagued by severe plating/stripping and dendrite growth, leading to cyclable Na loss. However, it is still poorly understood whether Na or S electrode has the most deleterious consequences for overall Na-S chemistry in specific electrolyte combinations. Given the influence of electrolyte in dictating the intermediate reaction steps, electrode-electrolyte interphase formation, and effectiveness of ionic transport, this work carefully investigates the effects of single and multi-solvent electrolyte on the electrochemical signatures of S electrode. Additionally, this work probes the aging process of Na metal, altered by different types of electrolyte-specific morphological evolution, manifesting a dramatic drop-off in cell performance. This complex electrochemical interaction in both the electrodes is further compounded by the limiting ionic transport at low-operating temperatures. Current work explores the electrolyte-mediated changes in decoupled cathode-anode cell signature and impedances and performances using a three-electrode cell configuration in different temperature conditions. By correlating the electrolyte-specific structural-compositional evolution and operational specifications of both the metal and sulfur electrodes, this work aims to lay the ground for thermally versatile and high-performance Na-S batteries.

Global Thermostat Direct Air Capture Technology Miles A. Sakwa-Novak, Eric Ping, Ron Chance and Peter Eisenberger; Global Thermostat, United States

Direct air capture of CO2, or DAC, is gaining increasing attention as an important technology with significant potential as a climate change mitigation approach. DAC is a feasible technology, whose primary barrier to deployment in support of the climate is cost. Since 2010, Global Thermostat (GT) has been developing a technology platform for DAC addressing the primary cost drivers of the process. In this contribution, we discuss the primary elements of the GT DAC technology platform and their relation to reducing the cost of DAC.

The core challenges that GT has identified as critical to enabling low-cost DAC are i) efficient air processing, ii) selective and stable CO2 binding, iii) energy efficient sorbent regeneration, iv) efficient use of plant capital, and v) design for continuous improvement. Innovations in materials design and engineering spanning several decades of length scale are key to addressing these challenges. GT's technology platform is based on structured honeycomb monolith air contactors, similar to those used in automobile catalytic converters or stationary deNOx emissions abatement cartridges. Porosity is engineered into these high surface area, low pressure-drop contactors through existing industrial manufacturing techniques. Quasi-solid amine-based CO2 sorbents are utilized in targeted porosity domains of the monolith contactors. These materials are employed in a rapid temperature swing process employing direct contact phase change heat transfer with saturated steam condensing on the monolith channel surface to regenerate the bound CO2 within the pore structure. Process performance is strongly linked to fundamental material-process phenomena such as adsorption rates, desorption rates, degradative mechanisms and the condensation / evaporation of steam.

The unique properties of these materials, and their interactions with the various environments imposed by the DAC process, present both opportunities and challenges in their successful deployment. In this talk we will discuss progress in both of these areas as well as an outlook on their potential.

Turning up the Pressure on Carbon Dioxide—Towards the Commercial Application of a Green Solvent Kristoffer K. Kortsen, Joachim Christopher Lentz, Vincenzo Taresco and Steven M. Howdle; University of Nottingham, United Kingdom

Current industrial polymer particle production processes often use water as the main solvent, generally resulting in contamination of that water through the use of volatile organic compounds and chlorofluorocarbons[1]. This results in contaminated wastewater streams, with negative consequences for the environment, oceans, and availability of drinking water. Additionally, water must be removed from the final product in costly and energy intensive drying processes, further increasing the negative environmental impact[2]. As environmental impact becomes a more pressing concern, there is an increasing interest in sustainable solvents that have the potential to alleviate water contamination issues, reduce energy costs and reduce the impact on the environment[3]. Supercritical carbon dioxide ($scCO_2$) is a promising alternative solvent, combining considerable environmental advantages[4] with desirable solvation and diffusivity properties of SCFs[2]. It is a cheap, non-flammable and environmentally friendly solvent[4], with an easily attainable critical point (T_c = 31.1 °C and P_c = 73.8 bar)[2]. When returning to atmospheric conditions, CO_2 reverts to the gas phase providing a solvent free polymer product, without the need for energy and cost intensive drying processes and allowing the solvent to be reused.
A large hurdle in the development and wider adoption of $scCO_2$ as a polymerization medium is the lack of a reliable and accessible monitoring method. While the tracking of an ongoing polymerization reaction in traditional solvents can be achieved with a wide range of techniques[5], reactions in $scCO_2$ are more complicated to monitor due to the elevated pressure contained in a sealed system.
Our recent publication[6] shows a versatile and reliable on-line sampling system for polymerization reactions in supercritical fluids, unlocking the potential of this sustainable solvent. By withdrawing a small volume of a high-pressure reaction mixture and expanding it in a controlled volume before capturing it in a suitable solvent, reliable kinetic data were obtained for a range of polymerizations and reactions in $scCO_2$. The facile applicability of this monitoring method resulted in additional insights into the unique conditions found in $scCO_2$ and their effect on polymerization systems. It was discovered that the tunable density of $scCO_2$ could be exploited to control the particle size of dispersion polymerizations, further expanding on the usefulness of this green solvent.
The kinetic information gained from this research, was exploited for precise dosing control during multistage polymerizations allowing for controlled tapering between successive polymer feeds and predictable layering of core-shell polymer particles.
The combination of kinetic monitoring, solubility control, and sequential monomer addition has finally unlocked the potential to synthesize commercially desirable polymer particles in this green and sustainable solvent for a wide array of applications such as 3D printing, plastic additives, metal oxide templating and medical devices.

Capacitive Deionization for Direct Air Capture of CO_2—An Implementation of the Alkalinity Concentration Swing Andrew Bergman, Anatoly Rinberg, Daniel Schrag and Michael Aziz; Harvard University, United States

The Alkalinity Concentration Swing (ACS) is a new process for direct air capture of carbon dioxide, driven by concentrating an alkaline solution that has been exposed to the atmosphere and loaded with dissolved inorganic carbon (DIC). We theoretically and experimentally evaluate driving the ACS through capacitive deionization (CDI), a method of removing anions and cations from solution by applying a voltage across two electrodes. When voltage is applied, anions electrosorb to the positive electrode and cations to the negative electrode. When the voltage is switched off or reversed, ions are released, driving the ACS through concentration of ions in solution. Upon concentration, the DIC per unit alkalinity decreases and the partial pressure of CO_2 increases, allowing for extraction and compression. We find that higher concentration factors result in proportionally higher outgassing pressure, and higher initial alkalinity concentrations at the same concentration factor outgas a higher concentration of CO_2.

CDI has been deployed industrially in municipal wastewater treatment and brackish water desalination facilities. CDI operates best in brackish water conditions, enabling high concentration factors and access to higher efficiency ACS regimes, without the need for high pressure systems. CDI also enables selectivity of bicarbonate ions, through use of ion exchange membranes and enhanced porous carbon electrode ion selectivity, allowing for an increase in ACS efficiency.

11:30 AM EN13.01.04
Accelerated Discovery of Novel Solvents for CO_2 Capture Benjamin Wunsch[1], Stacey Gifford[1], Theodore van Kessel[1], Flaviu Cipcigan[2], James McDonagh[2], Dmitry Zubarev[3], Alexander Harrison[2] and Stamatia Zavitsanou[2]; [1]IBM T.J. Watson Research Center, United States; [2]IBM Research - UK, United Kingdom; [3]IBM Research - Almaden, United States

Today, we capture less than 1% of all emitted carbon dioxide, but in 2018, the Intergovernmental Panel on Climate Change (IPCC) reported that limiting atmospheric warming to less than 2 degrees Celsius will require both capture of carbon emissions from point sources such as power and industrial plants as well as the removal of existing atmospheric carbon dioxide. Amine solvents have gained the most traction in large-scale CCUS implementation, but limitations include high energy penalties associated with regeneration, cost, toxic degradation products, and corrosiveness. Improvements in stability, binding capacity, kinetics, and vapor-liquid equilibria have been achieved by blending different primary, secondary, and tertiary amines, but accelerating their discovery with machine learning and AI has seen limited exploration.

We have built a parallelized assay platform for rapid testing and measurement of capacity, kinetics, and thermodynamics of CO_2 binding to binary and tertiary blends of standard primary, secondary, and tertiary amines. Our platform replicates gas sparging of CO_2 through liquid solvents and leverages NDIR sensors to measure CO_2 absorption from complex mixtures of simulated flue gas. We also measure other physical parameters such as pKa, viscosity, and stability. With these data sets, we leverage machine learning to capture properties of novel blends and rank performance of these mixtures. New blends are tested and validated, and these data are delivered back to the model to improve its predictive capabilities with the end goal of generating new materials and solvent blends with improved performance for carbon capture.

11:45 AM EN13.01.05
Greenhouse Gas Capture in Metal-Organic Frameworks—Carbon Dioxide and Beyond Mary Zick, Tristan Pitt, Ronald Jerozal and Phillip Milner; Cornell University, United States

Rising atmospheric levels of the greenhouse gases carbon dioxide, nitrous oxide, and hydrofluorocarbons are contributing to global climate change. Therefore, new strategies for capturing greenhouse gas for subsequent sequestration or conversion into value-added products are needed to minimize global climate change over the next century. A promising strategy is to develop new reactivity-based separations of greenhouse gases, which will enable higher selectivities than traditional separations. Herein, we will discuss new separation strategies for greenhouse gas capture using metal-organic frameworks, which are crystalline well-defined porous materials with highly tunable pore environments. We will discuss carbon dioxide capture in frameworks bearing extra-framework and metal-bound hydroxide sites, which reversibly react with carbon dioxide to yield (bi)carbonates. In addition, we will discuss the interaction of nitrous oxide with redox-active metal centers in frameworks. Last, we will explore how hydrogen- and halogen-bonding interactions can be leveraged to capture fluorinated gases such as fluoroform and sulfur hexafluoride.

SESSION EN13.02: Climate Change Mitigation Technologies II
Session Chairs: Mert Atilhan and Thomas George
Tuesday Afternoon, November 30, 2021
Hynes, Level 3, Room 313

1:30 PM *EN13.02.01
AI for Accelerated Discovery of Materials for Carbon Capture Stacey Gifford; IBM Research, United States

In 2018, the IPCC reported that limiting atmospheric warming to less than 2 °C will require both capture and storage of anthropomorphic carbon dioxide (CO_2) emissions. Despite estimates that we will need to capture upwards of 10 $GtCO_2$ per year by 2050, today we capture less than 1% of all emitted CO_2. Dramatic reductions in the cost of carbon capture processes are needed to drive adoption at scale. IBM Research is building AI-driven tools to accelerate the discovery of materials with improved performance for carbon capture, utilization, and storage including solvents, solid sorbents, and membranes. We have also developed automated synthesis platforms for production of carbon capture materials and novel catalysts for carbon dioxide conversion. Finally, we have created a digital rock platform coupled with high-precision microfluidics to accurately simulate CO_2 fluid flow at pore scales relevant for geological storage.

2:00 PM *EN13.02.02
Clean Energy and Decarbonization Research, Development and Demonstration at Oak Ridge National Laboratory Xin Sun; Oak Ridge National

Laboratory, United States

This talk provides the overview of Oak Ridge National Laboratory's (ORNL) transformational science and technologies towards the clean and decarbonized energy future with capabilities spanning the entire spectrum from clean energy generation to distribution, at-scale storage, and end-use. Being the largest DOE Office of Science Laboratory, ORNL is well-recognized for its energy efficiency research portfolio with the most comprehensive user facilities and capabilities in fundamental science and applied energy space among all the DOE national laboratories. We are accelerating decarbonization in the US with a three-pronged approach on integrated energy systems: 1.) Achieve deeper energy savings through enhanced energy efficiency efforts across all spectrums of the energy service sectors, i.e., buildings, industry, and transportation; 2.) Accelerate net-carbon neutrality by capturing and converting CO_2 into valuable materials, fuels, and feedstocks for downstream utilizations; and 3.) Enable bi-directional electron flows between the grid and end users with at-scale energy storage and transactive controls to enable a sustainable, resilient, and secure energy infrastructure. Exemplary ORNL RD&D advancements in all the areas above will be presented and future opportunities and challenges in the integrated energy systems approach will be discussed.

2:30 PM EN13.02.03
Reverse Osmosis for Direct Air Capture of CO_2—An Implementation of the Alkalinity Concentration Swing Anatoly Rinberg, Andrew Bergman, Daniel Schrag and Michael Aziz; Harvard University, United States

The Alkalinity Concentration Swing (ACS) is a new process for direct air capture of carbon dioxide, driven by concentrating an alkaline solution that has been exposed to the atmosphere and loaded with dissolved inorganic carbon. We theoretically and experimentally evaluate driving the ACS through reverse osmosis (RO), a membrane-based separation process in which pressure is applied against a solvent-filled solution to create a concentrated and a dilute stream. RO is the most widely used desalination approach - producing approximately 100 million cubic meters of purified water per day - allowing for technological advances to be leveraged for ACS deployment. Upon concentration, the partial pressure of CO_2 increases, allowing for extraction and compression of gaseous CO_2. We find that higher concentration factors result in proportionally higher outgassing pressure, and higher initial alkalinity concentrations at the same concentration factor outgas a higher concentration of CO_2. Theoretical projections suggest the ACS poses certain challenges, such as high water and land requirements, but it also confers advantages over incumbent technologies, especially in terms of simplicity of material requirements and possibility of reaching low energy costs through tuning operation parameters.

2:45 PM EN13.02.05
An Integrated Materials Approach to Ultrapermeable and Ultraselective Polymer Membranes for Carbon Capture: Breaking Through the Upper Bound Marius Sandru[1], Eugenia M. Sandru[1], Liyuan Deng[2] and Richard Spontak[3]; [1]SINTEF Industry, Norway; [2]Norwegian University of Science and Technology, Norway; [3]North Carolina State University, United States

While a wide range of carbon-capture efforts are being developed around the world to help mitigate the adverse effects of global climate change, advances in membrane technologies that combine greatly improved CO_2 separation efficacy with low cost, facile fabrication, upscaling and implementation, and mechanical robustness are still needed. In this study, we introduce an integrated membrane strategy wherein a high-permeability thin film is chemically functionalized with a highly CO_2-philic open, brush-like surface layer. This nanofabrication scheme is based on a low-diffusivity, high-solubility mechanism that relies on enrichment of CO_2 in the surface layer naturally hydrated by the water vapor present in all targeted gas streams, followed by fast CO_2 transport through a supported thin film of a highly permeable polymer. Since this design employs commercial polymer thin films that are already available for gas separations, these new membranes can immediately be produced, upscaled and put into field operation after surface functionalization, achieved by controllably growing short, controlled amine-modified chains from the polymer surface. Spectroscopic methods confirm the existence of the amine surface layer, which also serves to enhance surface roughness and, thus, separation area. Integrated multilayer membranes prepared in this fashion are not diffusion-limited and, in some cases, are able to retain much of their inherently high CO_2 permeability while their CO_2 selectivity is increased in some cases by over ~150x, far exceeding the Robeson upper bound that traditionally reflects the trade-off between gas permeability and selectivity.

3:00 PM EN13.02.06
Development of Metal-Organic Framework (MOF) Materials as Room-Temperature Chemoresistors for Greenhouse Gas Monitoring Ignasi Fort-Grandas[1,1], Ariana Neyra-Perez[1], Alex Rodriguez-Iglesias[1], Arnald Grabulosa[1,1], Mauricio Moreno[1,1], Anton Vidal-Ferran[1,1,2], Paolo Pellegrino[1,1], Daniel Sainz[1,1] and Albert Romano-Rodriguez[1,1]; [1]Universitat de Barcelona, Spain; [2]Catalan Institution of Research and Advanced Studies (ICREA), Spain

The reduction in emission of greenhouse gases (GHGs) is an important step towards mitigating the human impact on the climate change. Technically capturing CO_2, for example, is addressed by different emerging and established technologies. To effectively monitor the actual result of such a removal of this or other greenhouse gases, especifically adapted gas measuring systems are required.
At present, to monitor the environment, each National surveillance agency uses highly sensitive, selective, complex, bulky and expensive systems, which can only be used as reference measuring units installed in few specific, mostly fixed, key locations. For a more detailed monitoring and for the development of climate change models, a more distributed control of the GHGs emission is required and can be achieved through large numbers of deployed and connected gas sensing systems, thanks to the advent of Internet of Things (IoT). The required devices need to be sensitive, selective and low energy consuming, usually with a lower level of accuracy and precision than the reference instruments. Current commercial sensors do not fulfill all the requirements together and novel improved functional nanomaterials and sensors are needed.
The goal of this work is to show the actual stage of development of advanced miniaturised gas sensing devices for their use in monitoring of GHGs emissions. These devices are based on metal-organic framework (MOF) materials, that present a high degree of porosity and a reasonable conductivity, which allows their resistance to be measured.
The synthesis of the MOFs uses triphenylene-derived ligands, namely hexahydroxytriphenylene (HHTP) or hexaiminotriphenylene (HITP), and different metal centers. The synthesis route is described in detail elsewhere [1] for Cu and Ni metals. In this work, we have extended the synthesis to Mg, Zn and Co. In this way, 2D arrangements of metal-ligand, giving rise to hexagonal structures with a center pore, are formed. Vertical arrangement of such 2D structures occur through p-p stacking, giving rise to nanostructures whose dimensions vary between 100 and 300 nm in any direction. X-ray diffraction spectra prove the crystalline nature of such nanostructures.
The MOFs have been dispersed in ultrapure water, sonicated for 10 minutes, and one drop (0.5 ml) of the solution has been dispersed on a glass chip with interdigitated Ti/Au electrodes (IDE). Next, the chips have been dry heated in a furnace at 80°C for 10 minutes. The remaining material contacted the IDE and allowed current to flow between the IDE. The sample was then mounted and bonded to a TO8 holder and this was introduced in a gas measuring system, whose volume was only 8.6 ml. Through Mass-flow controllers, different gases and their mixtures were allowed to flow into the chamber at a rate of 50 sccm while the resistance of the MOF material was simultaneously measured.
Due to the porous nature of these samples and to the charge transfer between the flowing background synthetic dry air gas and the MOF, the resistance changes over time as a result of the continuous adsorption of components of the gas. Strategies for reversing this situation and bringing back the sample to its initial resistance value consist in either controlled heating or vacuum treating the sample. By adding 500 ppm of CO_2 to the synthetic air, a sizeable increase in the resistance was observed, while after removal of the CO_2 from the atmosphere, an incomplete recovery of to its baseline was attained. This response to CO_2 has been observed for different metal core and ligands, proving that these materials are potential candidates for innovative CO_2 gas

sensors.
In this work a systematic study of the effect of the metal cores, of the ligands and of the measuring history and recovery methods will be presented with the aim of bringing forward these innovative and low power consuming gas sensor devices for greenhouse gas detection.

Redox-Mediated Bipolar Membrane Electrodialysis for Direct Air Capture of Carbon Dioxide Thomas Y. George, Cliffton Wang, Daniel Schrag and Michael Aziz; Harvard University, United States

Complementing the rapid decarbonization of energy technology, CO_2 removal will be necessary to offset some continued emissions and avoid the most harmful climate outcomes. Direct air capture (DAC), separating atmospheric CO_2 for subsequent storage with physical or chemical methods, is one CO_2 removal approach. Many DAC technologies use a solid or solvent-based sorbent to reversibly bind CO_2, and CO_2 release is driven by heating. New electrochemical methods offer opportunities because they interface readily with sources of inexpensive carbon-free electricity and may operate at very high efficiency. A central challenge for these methods is minimizing the voltage required by the electrochemical process, which is determined by ohmic resistance of the reactor components and the voltage required for electrochemical reactions.

We propose a new DAC cycle utilizing a redox-mediated bipolar membrane electrodialysis (RM-BPMED) reactor that dramatically decreases the energy required compared to other reactors of this type. RM-BPMED is used for electrochemical salt splitting (*e.g.*, NaCl) to create a strong base (*e.g.*, NaOH) and a strong acid (*e.g.*, HCl). The base is used to absorb CO_2 from ambient air; the acid is then used to extract the CO_2 by recombining with the base, essentially reversing the salt splitting process. The research presented here demonstrates the RM-BPMED reactor, which is the centerpiece of our DAC approach.

The iron (II/III) hexacyanide redox couple affords facile redox kinetics on carbon electrodes, replacing the hydrogen and oxygen evolution reactions at the anode and cathode of traditional BPMED processes to decrease the required cell voltage. In addition to the redox mediators, RM-BPMED relies on ion exchange membranes that direct the ion transport for salt splitting. The ion exchange membranes must minimize leakage of species via unwanted crossover mechanisms while enabling high ionic conductivity. Some particular advantages of this method for DAC are that the acid and base products need not be pure and the salt splitting need not reach complete desalination. This allows additional supporting salt in all electrolytes flowing through the reactor, including the product streams. We present a design process informed by a fundamental understanding of membrane phenomena: the water content of ion exchange membranes determines the available transport pathways. The effects of electrolyte composition and membrane chemistry on water content and conductivity are elucidated to design a membrane-electrolyte system for RM-BPMED. A model of this strategy of electrochemical reactor engineering predicts RM-BPMED energy use below 100 kJ/mol CO_2 removed, as well as salt splitting at up to 100 mA/cm^2 current density. We will report on experiments that are under way to test the model.

Mining Materials Literature for Rediscovery of Methane Storage and Separation in Porous Carbon Yunchao Xie, Chi Zhang, Dawei Li, Ming Xin and Jian Lin; University of Missouri-Columbia, United States

Porous carbon (PC) has been widely regarded as one of the most promising absorbents for methane storage. Studies show that its uptake capacity and selectivity highly depend on textural structures. Although much effort has been made, unveiling their detailed structure-performance relationship remains a challenge. Here, we propose an innovative study where, with the assistance of machine learning, the hidden relationship of the textural structures of PC with the methane uptake and separation can be derived from existing data in material literature. Machine learning models were trained by the data, including specific surface area, micropore volume, mesopore volume, temperature, and pressure as the input variables and methane uptake as the output variable for prediction. Among the tested models, the multilayer perceptron (MLP) shows the highest accuracy in predicting the methane uptake. In addition, the model enables to automatically construct a uptake performance map in terms of micropore volume and mesopore volume. The obtained MLP model was also extended to explore the CO_2/CH_4 selectivity by retraining it with the data collected from literature of PC for the CO_2 uptake. The constructed 2D selectivity map shows that the high selectivity can be achieved in the low CH_4 uptake region.

10:45 AM EN13.03.02
Late News: Monitoring the Carbon Paths in the Dry Reforming of Methane Over Ni/Ce-M-Cu-O (M: La, Sm) Catalyst Aseel Hussien[1,1], Constantinos M. Damaskinos[2], Dalaver Anjum[1,1], Maryam T. A. Khaleel[1,1], Michalis A. Vasiliades[2], Angelos Efstathiou[2] and Kyriaki Polychronopoulou[1,1]; [1]Khalifa University of Science and Technology, United Arab Emirates; [2]University of Cyprus, Cyprus

Dry reforming of methane (DRM) reaction ($CH_4+CO_2\leftrightarrow 2CO+2H_2$) produces synthesis gas (CO/H_2) which can be used for the production of high value-added chemicals and fuels via Fischer-Tropsch (FT) process. Despite the benefits and significance of DRM, this process has not been industrialized yet due to the absence of a stable and coke resistance catalyst. Ni-based catalysts are economically feasible, yet they suffer mainly from coke deposition and deactivation through CH_4 decomposition and CO disproportionation routes. On the other hand, supports, especially ceria-based ones, play an important role in tackling the coking challenge. In supported catalysts, both active metal and support can be engineered to inhibit carbon formation. *The approach followed in this particular work is **(a)** tuning the support's basicity and lattice oxygen mobility via ceria doping with rare-earth metals (La^{3+}, Sm^{3+}, and Pr^{3+})* and **(b)** *inducing in situ alloying of the Ni active metal* with Cu species (originated from the support).

This work's originality and significance to the field is reflected in presenting the role of trivalent M= La^{3+} and Sm^{3+} used in the ternary type of reducible support Ce-M-Cu-O composition as a carrier of Ni nanoparticles on the carbon paths in the DRM reaction. In addition, transient kinetics and isotopic experiments were designed to investigate the crucial coking factors for the DRM reaction over La vs. Sm co-dopants. The experiments studied **(a)** the

carbon formation and their relative contribution of CH_4 decomposition and CO disproportionation reaction in the coking network, **(b)** the amount of inactive carbon accumulation on the catalyst surface after DRM, and **(c)** the extent of participation of support's labile oxygen in the removal of carbon from the catalyst surface via oxidation to CO.

Due to the complexity of the catalyst composition, many analytical techniques were employed to get an insight into the catalysts' intrinsic properties and structure and relate these to catalytic performance. Powder XRD, HAADF-STEM, SAED, EELS, elemental mapping, Raman, CO_2-TPD, H_2-TPR, and H_2-TPD were employed. The La^{3+}- and Sm^{3+}-doped ceria supported Ni catalysts presented tuned intrinsic properties, such as redox behavior and oxygen vacant sites concentration, and surface basicity. Also, La^{3+}- doped support composition favored the formation of NiCu alloy nanoparticles and enhanced lattice oxygen mobility, which in turn appears to favor reduction in carbon deposition and enhanced carbon removal rates under DRM via mainly the participation of lattice oxygen.

A systematic transient kinetic study of CH_4 and CO decomposition reactions (main carbon deposition routes in DRM) by measuring initial rates of carbon deposition and the following dynamics of it, over the La^{3+}- and Sm^{3+}-doped ceria-supported Ni catalysts, along with advanced experimentation in measuring both the rates of carbon oxidation by lattice oxygen of support and by oxygen from the CO_2 activation route under DRM were conducted. Ni nanoparticles (23 nm) supported on the La^{3+}-doped ceria exhibited ~ 3 times higher rates of carbon oxidation to CO by lattice oxygen and ~13 times lower rates of carbon accumulation than Ni (18 nm) supported on Sm^{3+}-doped ceria. The oxygen vacant sites and surface basic sites were found to correlate with carbon deposition.

We strongly believe that this type of transient and isotopic work paves the way to fundamentally understand the role of dopants introduced in the ceria lattice and used as a carrier of Ni (or other metal) nanoparticles towards an efficient design of carbon-resistant doped ceria-supported Ni catalysts.

11:00 AM EN13.03.03
Atmospheric- and Low-Level Methane Abatement via Copper Zeolites Rebecca Brenneis[1], Eric P. Johnson[2], Wenbo Shi[1] and Desiree Plata[1]; [1]Massachusetts Institute of Technology, United States; [2]Yale University, United States

Climate action scenarios that limit changes in global temperature to less than 4ºC require methane controls in addition to carbon dioxide mitigation, yet few methane abatement technologies exist. Importantly, restoration of atmospheric methane from current levels 1.85 ppmv to pre-industrial concentrations of 0.76 ppmv would save 16% of global climate forcing within decades. Here, we describe the use of a biomimetic copper zeolite capable of converting atmospheric and low-level methane at relatively low temperatures (e.g., 200-300ºC) in simulated air. Depending on the duty cycle, 40%, over 60%, or complete conversion could be achieved (a two-step process at 450oC activation and 200ºC reaction, or a short and long-activation at isothermal 310oC conditions, respectively). Conversion rate increased over a range of methane concentrations (0.0002 to 2% methane), indicating promise of this technology to abate methane from any sub-flamable stream. Finally, uncompromised catalyst turnover over 300 hours (12 days) in simulated air was demonstrated under isothermal reaction conditions (310ºC). Taken together, this work illustrates the promise of using low-cost, Earth-abundant materials innovations to mitigate methane at the diffuse and dilute sources that drive growth of this important greenhouse gas, and ultimately slow the pace of climate change.

11:15 AM EN13.03.04
Development of Composite Dual Functional Catalysts and Mechanistic Insights for CO_2 Methanation Reaction Ayesha A. Alkhoori[1,2], Constantinos Damaskinos[3], Aasif Dabbawala[1], Dalaver Anjum[1,2], Angelos Efstathiou[3], Nikolaos Charisiou[4], Maria Goula[4] and Kyriaki Polychronopoulou[1,2]; [1]Khalifa University of Science and Technology, United Arab Emirates; [2]Center of Catalysis and Separation, United Arab Emirates; [3]University of Cyprus, Cyprus; [4]University of Western Macedonia, Greece

Carbon dioxide mitigation is a great challenge for the twenty-first century. The increasing atmospheric CO2 concentration peaked near 420 ppm on May 2021 at NOAA's Mauna Loa Atmospheric Baseline Observatory. Controlling CO_2 emissions can be achieved by capturing and converting it into value-added chemicals via dual function materials (DFM) for in-situ methanation. In this study, different Ni-based catalysts with composite supports i.e., $Ni/nCeO_2/mAl_2O_3$ (n = different wt.%, m = different porosities) were synthesized. A set of state-of-the-art techniques were utilized to unveil the physicochemical properties of the catalysts such as Raman, temperature programmed reduction/desorption techniques, XPS, and high-resolution imaging using HRTEM-EELS and HAADF. A key to the rational design of highly efficient catalyst is understanding the reaction mechanism of CO_2 hydrogenation via *Operando* SSITKA-DRIFTS technique. The current results show three types of CO-s correspond to linear type CO-s adsorbed on top surface defects, top hollow and 3-fold hollow nickel sites. Moreover, the catalytic results indicate that the CO_2 methanation in the 200–500°C temperature region has an optimum performance at 20 wt.% CeO_2 loading and medium alumina porosity at 300°C. However, when 450°C < T < 300°C CO production takes over, implying the predominance of RWGS side reaction. Finally, the synthetic methods towards formation of adjacent [Ni]–[Ce] sites or highly dispersed active metal entities was found to boost the catalytic activity.

Combating Global Warming—Modeling Enhanced Rock Weathering of Silicates Using Density Functional Theory Pratik P. Dholabhai and Brian Luan; Rochester Institute of Technology, United States

Negative emissions technologies target the removal of CO_2 from the atmosphere as a way of combating global warming. Enhanced rock weathering (ERW) is a vital negative emissions technology that, applied globally, could remove gigatonnes of CO_2 per year from the atmosphere. In ERW, silicate minerals exposed to the atmosphere trap CO_2 via mineral carbonation as thermodynamically stable carbonates. The present challenge is that the most reactive naturally-occurring silicates are not abundant. In order to design novel materials for ERW, a fundamental understanding of their structure and reactivity is necessitated at the nanoscale. To this end, we have employed density functional theory to predict the atomic scale structure of (100), (010), and (001) surfaces of wollastonite ($CaSiO_3$) and study the thermodynamics of their interaction with CO_2. Based on surface energy calculations, (001) and (010) surfaces of wollastonite exhibit similar stabilities, whereas (100) surface is found to be least stable. Utilizing stable surface models, molecular and dissociative adsorption of CO_2 at various surface sites has been explored. A common trend emerges, wherein the CO_2 molecule demonstrates proclivity to bond with surface layer calcium atoms. We will shed light on the electronic charge transfer between the adsorbate and the substrate and discuss the

fundamental aspects of these interactions. Results from this work will be exploited to study the reaction kinetics of CO_2 adsorption and dissociation on silicates using *ab initio* molecular dynamics. Overall, we will elucidate the fundamental mechanisms that govern the interaction between CO_2 and wollastonite. Such fundamental understanding will be imperative to guide large-scale synthesis of novel silicates for ERW.

1:45 PM EN13.04.02
Late News: Decoupling the Chemical and Mechanical Strain Effect on Steering the CO2 Activation Over CeO2-Based Oxides—An Experimental and DFT Approach Kyriaki Polychronopoulou, Shaima AlBedwawi, Sara AlKhoori, Seba Alareeqi, Nirpendra Singh and Lourdes Vega; Khalifa University of Science and Technology, United Arab Emirates

Doped ceria-based oxides are widely used as supports and stand-alone catalysts in reactions where CO_2 is involved. Thus, it is important to understand how to tailor their CO_2 adsorptive behavior. In this work, steering the CO_2 activation behavior of Ce-La-Cu-O ternary oxide surfaces through the combined effect of chemical and mechanical strain was thoroughly examined using both experimental and *ab initio* modeling approaches. Chemical strain is originated from the doping of CeO_2 with aliovalent metal cations (La^{3+} or La^{3+}/Cu^{2+}), whereas mechanical strain is originated from post synthetic ball milling able to impose mechanical forces on the oxide. Ce-La-O (111), Ce-Cu-O (111) and CeO_2 (111) surfaces were used as reference surfaces due to the complexity of the solid composition under investigation. Experimentally, microwave-reflux prepared Ce-La-Cu-O ternary oxide was imposed into mechanical forces to tune the structure, defects and CO_2 surface adsorptive properties. The purpose was to decouple the combined effect of the chemical strain (ε_C), and mechanical strain (ε_M), on the modification of the Ce-La-Cu-O surface reactivity towards CO_2 activation. During the *ab initio* calculations, the stability (energy of formation, E^f_{Ov}) of different configurations of oxygen vacant sites (O_v) was assessed under biaxial tensile ($\varepsilon>0$) and compressive ($\varepsilon<0$) strain, whereas the CO_2-philicity of the surface was assessed at different levels of imposed mechanical strain. E^f_{Ov} values were found to decrease with increasing tensile strain. Ce-La-Cu-O (111) surface exhibited the lowest E^fO_v values for the single subsurface sites, implying that O_v may occur spontaneously upon Cu addition. The structural, textural, redox and basic properties of the surface were used as descriptors to unveil the mechanical strain impact. The mobility of the surface and bulk oxygen ions in the lattice contributing to the O_v population was measured using $^{16}O/^{18}O$ transient isothermal isotopic exchange (TIIE) experiments; the maximum rate in $^{16}O^{18}O$ formation, R_{max} ($^{16}O^{18}O$) was 13.1 and 8.5 μmol $g^{-1}s^{-1}$ for the pristine (chemically strained) and dry ball-milled (chemically and mechanically strained) oxide, respectively. The CO_2 activation pathway (redox vs. associative) was experimentally probed using *in situ* DRIFTS. It was demonstrated that mechanical strain increases up to 6 times the CO_2 adsorption sites, though reduces their thermal stability. This result supports a mechanical actuation of the 'carbonate' bound species; the latter is in agreement with the DFT calculated C-O bond lengths and O-C-O angles. *Ab initio* studies shed light on the CO_2 adsorption energy (E_{ads}) suggesting a covalent bonding which is enhanced in the presence of doping and under tensile strain. Bader charge analysis probed the adsorbate/surface charge distribution and illustrated that CO_2 interacts with dual sites (acidic and basic ones) on the surface leading to the formation of bidentate carbonate species. Density of States (DOS) studies gave an insight on the electronic structure of the Ce-La-Cu-O (111) surface, and revealed the band gap (E_g) engineering which takes place in the clean and reduced surface, with a significant E_g drop in the presence of double O_v and compressive strain; a finding with design implications in covalent type of interactions. This study opens new possibilities to manipulate the CO_2 activation for a portfolio of heterogeneous reactions.

2:00 PM EN13.04.03
Novel, Smaller Contactor for Markedly Reducing the Total Cost of the Direct Air Capture of CO_2 Mansour Masoudi and Ed Tegeler; Emissol LLC, United States

Perhaps the greatest obstacle to commercialization of the Direct Air Capture (DAC) of CO_2 is the DAC cost. Aiming to reduce the cost of DAC, a novel honeycomb contactor has been developed, designed, tested and demonstrated, showing its strong potentials to markedly lower the DAC cost through reducing the amount of needed sorbent, the largest contributor to the total DAC cost [National Academy of Science, 2019*****].
Utilizing a novel approach to configure the channel internal flow in the sorbent-coated contactor, the channels develop a strong and stable secondary flow in the form of one or more pairs of Dean vortices, accelerating transport of CO_2 to the channel walls coated with a solid sorbent (Polyethylenimine/ PEI). In essence, the diffusion-dominated CO_2 transport to the sorbent, dominant in standard, mainstream honeycomb contactors, is practically replaced with the far-stronger convective transport, increasing the net CO_2 transport per unit surface area per unit time.
Both modeling investigation and experiments were utilized in this study. The high fidelity model and extensive experiments focused on examining the impact of novel flow patterns on CO_2 adsorption to the sorbent-coated walls and its desorption from the sorbent. Model contactors coated with PEI adsorbent were subjected to CO_2 adsorption and desorption tests and compared with a standard (baseline) DAC contactor, so to evaluate the impact of novel channel configuration on CO_2 transport to/from the adsorbent.
Good agreement was observed between the modeling prediction and the test data. The novel contactor well outperforms the standard contactors, displaying Sherwood number as high as 7.5, i.e., 2.5 times higher than that in standard ones, accelerating the rate of CO_2 adsorption/ desorption per channel unit surface area, enabling more efficient use of the contactor volume and its sorbent for CO_2 capture. Results indicate that the novel DAC contactor
(i) Enables reducing the sorbent use by 37%. Considering that sorbent CapEx forms more than 80% of the total DAC cost [National Academy of Science, 2019 *****], it reduces the total DAC cost by about 30%.
(ii) Enables reducing the overall volume (downsizing) of DAC contactors by up to about 40%.

Turning CO_2 Into Cementitious Binders by Mineralization Mathieu Bauchy and Gaurav Sant; University of California, Los Angeles, United States

CO_2 is usually considered as an environmental burden. Here, we reimagine CO_2 as a resource for the production of a concrete-like construction material, that is, a value-added product. We present a new carbon immobilization process based on a 3D-printable portlandite-based cementitious binder that permits CO_2 uptake by mineralization. This carbonation process is fast, inexpensive, and robust. Carbonation leads to an increase in the strength of the binder and, hence, increases its value. This process could facilitate the beneficial use of CO_2 as a key ingredient for durable construction materials, thereby resolving the apparent opposition between the needs for new infrastructure and enhanced sustainability.

2:30 PM EN13.04.05
Algae and Concrete Composites—Structural Materials as a CO2 Sink Marcos M. Hernandez, Ashley D. Atencio, Cesar R. Gonzalez Esquer, Babetta L. Marrone and Joseph Dumont; Los Alamos National Laboratory, United States

Concrete is the second most consumed material in the world only behind water, comprising a majority of construction materials.[1] As a result, global

cement production is responsible for about 8 percent of the world's carbon emissions. Biomass from algae offers serious advantages such as carbon and nitrogen capture as well as a superior growth per area than other conventional plant crops. [2] Algae production may play an important role in CO2 mitigation through the integration in existing technologies. In this work, we use algae to reduce the use of cement or replace it as a component in concrete. Samples were prepared similarly to concrete and characterized using a wide range of mechanical, chemical and spectroscopic techniques. Through this study, we evaluate the use of algae in construction materials to mitigate the CO2 emissions, reduce concrete use, lower construction costs, and utilize biomass.

Humidity Sensing Behavior of Microporous Titano/Vanadosilicate Thin Films—Effect of Film Preparation and Stability Ramona Davoudnezhad, Ibrahim Cam and Burcu Akata Kurc; Middle East Technical University, Turkey

The growing demand for environmental control for a variety of chemical molecules has led to considerable interest in the research devoted to the development of new materials for sensor devices. Since humidity is a very common component in our environment, measurements and/or control of humidity are important not only for human comfort but also for a broad spectrum of industries and technologies. The constructive design of a good humidity sensor is a rather complicated topic, because high performance humidity sensors claim many requirements, including linear response, high sensitivity, fast response time, chemical and physical stability, wide operating humidity range, and low cost.
Zeolites and zeo-type materials are known for their well-defined porous structure, moisture holding capacity, and ionic conduction properties. Therefore, a study is done to investigate humidity sensing Titano/Vanadosilicate thin films. Two different zeo-type materials with different types of quantum wires in their structures (i.e.,–Ti-O-Ti-O-Ti- and –V-O-V-O-V- in the structures of ETS-10 and AM-6, respectively) were prepared and the humidity sensors by using these types of films were fabricated for the first time.
Microporous Titano/Vanadosilicate Films were prepared by two different methods. Humidity sensing properties of these films prepared by the secondary growth method were shown to be tailored according to the desired range of humidity for sensing applications. The impedance modulus change is more than four orders of magnitude in the range from 8% to 97% at 100 Hz. High stability and low hysteresis were also observed. Complex impedance spectra, the corresponding equivalent circuit under different relative humidity was analyzed to explore the humidity sensing mechanism of these films.
The project leading to these results has received funding from the Scientific and Technological Research Council of Turkey (TÜBITAK), under grant agreement 118M631.

The Phosphate Elimination and Recovery Lightweight (PEARL) Membrane—A Sustainable Environmental Remediation Approach Stephanie Ribet, Benjamin Shindel, Roberto dos Reis, Vikas Nandwana and Vinayak Dravid; Northwestern University, United States

Anthropogenic hypereutrophication, namely the release of excess nutrients into natural bodies of water from human activity, introduces a variety of economic, ecological, and public health problems around the globe. As with other environmental problems, this challenge is projected to grow in coming years, as it is inextricably linked to climate change and rising temperatures due to increased levels of CO_2.

To bridge the gap between the laboratory-scale nature of promising nanostructure solutions and the practical benchmarks for deploying an environmental remediation tool, we have developed a nanocomposite membrane. Here, an economical, readily available, porous substrate is dip coated using scalable, water-based processes with a slurry of nanostructures with affinity for specific adsorption of pollutants. Our Phosphate Elimination and Recovery Lightweight (PEARL) membrane can selectively sequester up to 99% of phosphate ions from polluted waters at environmentally relevant concentrations. [1] Moreover, mild tuning of pH promotes at will adsorption and desorption of nutrients, leading to phosphate recovery and reuse of the PEARL membrane.

This work builds on our prior report of the OHM sponge, made with the same platform approach, which is a nanocomposite material that can be used to repeatedly remove oil from water. [2] These two distinct examples suggest that the tailored nanostructure membrane approach is potentially a versatile platform that can be tuned to remediate other contaminants with the same core principles. In this presentation, we discuss the PEARL membrane's effective and selective performance. Moreover, we use correlative microscopy and spectroscopy techniques to interrogate the complex microstructure of the PEARL membrane and its binding efficacy, further suggesting how this approach can be applied to other pollutants.

Spectroscopic Monitoring of Dissolved Carbon Dioxide for CCUS Richa Sharma[1], T.S S. Ramakrishnan[1], Quincy K. Elias[1], Susan Rempe[2] and Gauri Joshi[3]; [1]Schlumberger Doll Research, United States; [2]Sandia National Laboratories, United States; [3]Schlumberger, India

Decarbonization of the energy industry is an environment driven requirement. A sustained expansion and deployment of large-scale carbon capture, utilization and storage (CCUS), is needed to address this challenge, at least partly. Effectiveness of CCUS is contingent upon developing miscibility through partitioning into water or hydrocarbon. Our work is motivated by the need to reliably monitor dissolved CO_2 under conditions of high temperature and pressure. We propose a new Raman spectroscopy-based sensor system for translating molecular interactions into molar concentrations. We propose the utility and feasibility of field deployment of our sensing system in aquifer and hydrocarbon reservoir CO_2 injection projects.

4:30 PM EN13.04.09
Solar Thermochemical Reduction of Carbon Dioxide into Liquid Fuels Xueqian Li, Magel Su, Manar Shoshani, Harry A. Atwater and Theodor Agapie; California Institute of Technology, United States

Traditionally, industrial thermocatalytic processes for reducing carbon dioxide (CO_2) require high temperatures (>300 ºC), high pressures (>150 bar), and several recycling steps that consume up to 2% of the world's energy supply annually. Solar-driven processes under moderate pressures (<5 bar) present a sustainable alternative to synthesis of fuels, chemicals and materials while also alleviating rising atmospheric concentrations of CO_2. Normally, heat loss from thermal radiation would prevent a solar-heated thermochemical system from reaching the operating temperatures required for industrially relevant

reactions such as the Fischer-Tropsch, Sabatier, and Haber-Bosch reactions under illumination of unconcentrated solar irradiation (1 kW m^{-2}). To reach temperatures >90 °C under ambient sunlight, the spectral absorptivity and emissivity profiles of the reactor components must be redesigned such that absorption of the active catalyst region is high within the solar wavelength regime (0.3 – 2 μm) and reflectivity is high in the infrared blackbody regime (4 – 25 μm). Here, we report the design of a planar solar thermocatalytic reactor that incorporates a selective light absorber and allows for both flexibility and scalability of the desired reaction. The proposed solar thermocatalytic reactor has 4 layers from bottom-to-top: a broadband reflector, a solar thermocatalytic reaction chamber, a selective absorber layer, and a thermally insulating layer. We will discuss options for selective absorber layers using semiconductor layers for high absorption in the solar wavelength regime and optically transparent conductors for high reflectivity in the infrared blackbody wavelength regime. Thermocatalysis results will be reported for a model reaction converting ethylene into higher olefins via solar activated homogeneous catalysts.

Late News: Revealing Molecular Mechanisms in Hierarchical Nanoporous Carbon via Nuclear Magnetic Resonance Haiyan Mao[1], Jing Tang[2], Bing Wu[1], David Halat[1], Yi Cui[2] and Jeffrey Reimer[1]; [1]University of California, Berkeley, United States; [2]Stanford University, United States

Hierarchical nanoporous carbons (HNC) have been proven to be an effective adsorbent for the adsorption of volatile organic compounds (VOCs) and CO_2, although questions remain regarding the hierarchical structure regulation, the adsorption mechanisms of adsorbate uptake, and interactions within the HNC. We synthesize HNC from wood, using a microwave-induced heating method incorporating K_2CO_3 activation. HNC exhibit Murray's Law multi-scale structures, prompting a molecular scale study of adsorbate adsorption via nuclear magnetic resonance (NMR). NMR chemical shifts are consistent with ring current effects from the adsorbent. Our NMR technique provides a convenient way to quantitate the adsorption of adsorbate in HNC. VOCs vapor adsorption results show NMR chemical shift changes with time, suggesting initial adsorption into mesopores, followed by diffusion into micropores. Schroeder's Paradox is demonstrated by differences in observed shifts for adsorbed liquid vis-à-vis vapor phase in these HNC. These HNC show high CO_2 adsorption capacity, portending applications to carbon capture.

SESSION EN13.05: Climate Change Mitigation Technologies V

A New Strategy of Negative Carbon Emissions by Nanomembranes for Ubiquitous CO_2 Capture Shigenori Fujikawa[1,1], Roman Selyanchyn[1,1], Miho Ariyoshi[1,2] and Toyoki Kunitake[2,1]; [1]Kyushu University, Japan; [2]Nanomembrane Technologies Inc., Japan

Climate change caused by emissions of greenhouse gases into the atmosphere is a most important issue for our society. The anthropogenic nature of climate change necessitates the development of novel technological solutions in order to reverse the current CO_2 trajectory. Direct capture of the carbon dioxide (CO_2) from the air (direct air capture, DAC) is one among a variety of negative emission technologies that are expected to keep global warming below 1.5 °C, as recommended by the Intergovernmental Panel for Climate Change (IPCC).
Current DAC technologies are mainly based on sorbent-based systems where CO_2 is trapped in the solution or on the surface of the porous solids covered with compounds with high CO_2 affinity. These processes are currently rather expensive, although the cost is expected to go down as the technologies are developed and deployed at scale.
CO_2 capture by permselective membranes is advantageous because of its smaller and simpler set-up. Unfortunately, its efficiency is less than satisfactory for the practical operation of the DAC. Among polymeric membrane materials, rubbery poly(dimethylsiloxane) (PDMS) is known to display high CO_2 permeance and ultimate thinning of PDMS membranes is a promising and straightforward way to prepare high CO_2 flux membranes.
We developed defect-free, free-standing nanomembranes of PDMS and discussed the membrane thickness's effect on the gas permeance by using precisely defined nanometer-thick PDMS membranes systematically. Throughout the efforts on ultimate thinning of PDMS membranes, our achieved CO_2 permeance reaches almost 40,000 GPU (the highest one ever reported) and reasonable CO_2/N_2 selectivity at the thickness of 34 nm without a gas leak from pinholes. This value is much higher than those reported by other groups in the past (less than several thousand). Furthermore, the separation is achieved even at a CO_2 concentration of 1,000 ppm in N_2, which has never been investigated under such ultra-diluted concentration conditions in past reports. The advantages of extremely efficient separation of CO_2 found in our result demonstrate the feasibility of direct air capture by a membrane, which has never been considered before.

Carbfix: CO_2 Mineral Storage Edda S. Aradottir[1], Sandra Snaebjornsdottir[1], Bergur Sigfusson[1], Thomas Ratouis[1], Kari Helgason[1], Chiara Marieni[2], Martin Voigt[3], Eric Oelkers[2] and Sigurdur R. Gislason[3]; [1]Carbfix, Iceland; [2]CNRS, France; [3]University of Iceland, Iceland

Carbon capture and storage (CCS) plays a fundamental role in achieving the goals of the Paris agreement to limit global warming to 1.5-2°C, with estimated 115 $GtCO_2$ needed to be captured and safely stored by 2060 [1]. Most ongoing CCS projects inject pure CO_2 into sedimentary basins, such as saline aquifers or depleted oil or gas reservoirs where an impermeable cap rock prevents it from migrating to the surface.
Carbfix has since 2007 developed a safe and low-cost alternative in collaboration between industry and academia: By injecting dissolved CO_2 into reactive rock formations, such as mafic or ultra-mafic rocks, carbon mineralisation is promoted for CO_2 mineral storage [2]. The acidic CO_2-charged fluid releases metals from the bedrock which combine with the injected CO_2 and rapidly form stable carbonate minerals [3]. By mineralising the injected CO_2, it is permanently fixed and there is a negligible risk of it returning to the atmosphere.
Carbfix has since 2014 captured and injected over 70,000 tonnes of CO_2 at its flagship operation at Hellisheidi geothermal plant in SW-Iceland and is preparing for scale-up to maximise its potential impact. Emphasis is currently being placed on making this technology more cost effective and exploring its limits in terms of potential sites and injection methods, including injection of CO_2 captured directly from the atmosphere, and injection of seawater dissolved CO_2. Furthermore, Carbfix is working on its largest project currently under development aiming on transporting CO_2 captured from European industries to Iceland, where up to 3 Mt/CO_2 will be injected annually for permanent storage.
Mineral CO_2 storage offers a vast storage potential and unlocks large regions in the world where CCS has until now not been considered possible: The storage capacity of the Columbia River Basalts in USA alone has been estimated to be on the order of 10-100 $GtCO_2$ [4]. The largest potential lies offshore within the sub-marine basaltic crust, but suitable formations are also widespread onshore, and are found in every continent [5].

National Academies of Sciences, Engineering and Medicine—Advisors to the Nation on Climate Change Mitigation Technologies Alton D. Romig; National Academy of Engineering, United States

The National Academies have done more than 1000 consensus studies and more than 1000 workshops related to climate change, the first being done in 1936. All of these reports are downloadable at the National Academies Press website (https://www.nap.edu/). A multitude of areas has been explored from urban sustainability to adaptation to sea level rise to decarbonization of the grid and transportation to geoengineering. Approximately 10% of the studies and workshops have specific relevance to technologies for mitigating the effects of climate change. This presentation will focus on the approximately 150 consensus reports and 110 workshops with proceedings that have been done on climate change over the past 5 years. Approximately half of the studies and workshops are relevant to climate change mitigation technologies. Specific recent reports will be reviewed with a focus on mitigation technologies for decarbonizing the grid, decarbonizing transportation including light to heavy ground vehicles and air vehicles, carbon capture and storage, mitigation of sea level rise and management of flooding, and the controversial topic of geoengineering.

9:30 AM *EN13.05.04
Direct Air Capture of CO2 and Its Role in Mitigating Global Warming Carlos Jimenez Haertel; Climeworks AG, Switzerland

In recent years, Direct Air Capture (DAC) has established itself as a promising approach to atmospheric Carbon Dioxide Removal (CDR), also referred to as Negative Emissions. In fact, DAC is seen today as critical to the 1.5°C target of the Paris Climate Agreement. Numerous studies have shown negative emissions to be necessary in order to stabilize atmospheric CO2 at the required levels towards the middle of the century. Although DAC has higher specific cost per tonne of CO2 than nature-based solutions - such as afforestation or soil carbon - it can scale faster and can guarantee permanence of the CO2 removed. Due to the huge amounts of excess CO2 in the atmosphere, CDR technologies will have to reach annual capacities at the gigaton scale over the next two to three decades in order to become climate relevant.

The presentation will give an overview of DAC and, in particular, the modular low-temperature technology developed by Climeworks.
In Climeworks' systems, ambient air is ingested by a so-called collector container during a cyclic ad-/desorption process. In the adsorption step, the CO2 molecules are bound to a special sorbent material inside the collector. Subsequently, the sorbent material is regenerated by thermal energy. The concentrated CO2 collected during this desorption step can then be used in different ways. For carbon removal, it is typically sent underground, where it is permanently stored in aquifers, rock formations, or depleted oil and gas reservoirs. Captured CO2 can also be used as feedstock e.g. for the food and beverage industry or for agricultural use. Another upcoming use case is 'Power-to-X', in which hydrocarbons are produced from atmospheric CO2, water, and renewable energy. Currently, Climeworks has 14 DAC plants of different size in operation across Europe, collecting tens of thousands of hours of real-life operational experience every year. Climeworks anticipates strongly increasing demand for carbon-removal services in the future and expects further significant cost reductions as industrial mass production of components for DAC systems gears up.

Potential co-benefits of DAC in relation to the Sustainable Development Goals (SDGs) of the UN are also briefly touched upon in the talk, which concludes with suggestions for policy approaches needed to ensure climate-relevant scale is reached in time.

SESSION EN13.06: Climate Change Mitigation Technologies VI

10:30 AM *EN13.06.01
New Generation Bipolar Membranes for CO_2 Reduction Selmiye Alkan Gürsel[1,2], Begum Yarar Kaplan[2], Ahmet Can Kirlioğlu[1], Mohammad Alinezhadfar[1] and Alp Yürüm[2]; [1]Sabanci University Faculty of Engineering and Natural Sciences, Turkey; [2]Sabanci University Nanotechnology Research and Application Center (SUNUM), Turkey

Fossil fuels have been used extensively to meet the energy demand; however, their spacious use has caused to various environmental problems, particularly Greenhouse Effects because of significant carbon dioxide (CO_2) emissions. In this regard, energy efficiency and renewables are curial, yet additional technologies offering in minimal, or zero emissions of CO_2 are needed to achieve net-zero emissions. Immense efforts are being devoted to reducing CO_2 emissions in this respect. Approaches to capture CO_2 from air for permanent geological storage, power generation or fuel production and transformation are very remarkable. In addition, CO_2 reduction into valuable product, in combination with renewable energy, is another considerable approach. Transforming CO_2 by chemical reduction both eliminates the main greenhouse gas, and also converts it into useful materials. Since CO_2 is a highly stable molecule, its reduction reaction is challenging. CO_2 electrolysis is a promising technology to convert CO_2 into valuable chemicals. Membranes with high mechanical strenght, stability and durability at high density load are needed for CO_2 electrolyzers. In this study, new generation membranes for electrochemical CO_2 conversion by an electrolyzer have been developed. Bipolar membranes, exhibiting both proton and anion exchange functionalities for minimizing crossover and reducing activation energy, have been fabricated by radiation-induced grafting and electrospinning techniques. Radiation-induced grafting, a well-known method for the introduction of functional groups into a commodity polymer for design of the polymer architecture, has been proposed as an alternative method for the synthesis of novel bipolar membranes. Radiation-induced grafting offers the advantages such as simplicity and control over process without residues of initiators and catalyst as well. Electrospinning, frequently used technique to produce nanomaterials especially in the field of energy, is a promising technique for creating nanostructured materials, provides enhancement of the triple phase interface where electrochemical reactions occurred at active catalyst site. Electrospinning is a facile technique for single-step fabrication of bipolar membranes with 3D dual-fiber interface. This technique also offers advantages compared to conventional film casting or other membrane fabrication techniques due to low contact resistance, easy scale-up, easy thickness control, flexibility, and high mechanical strength. Besides, these membranes can be easily converted into dense and non-porous membrane with hot-pressing and welding steps. Herein, bipolar membranes have been fabricated with direct

physical attachment of pre-fabricated anion-exchange membrane and cation-exchange membranes and also by radiation induced grafting by means of a special and scalable grafting reactor. Optimization of radiation grafting, and electrospinning parameters have been performed to obtain high conductivity uniform membrane layers. Moreover, the membranes have been characterized ex-situ and in situ for physical and electrochemical properties and it was determined that membranes possesed promising mechanical strength and stability, and also low crossover to ensure high performance for CO_2 reduction.

11:00 AM *EN13.06.02
Role of Negative Emissions and Carbon Recycling Technologies in the Transitions of Japan's Energy Systems Toward Net-Zero Emissions Goal Etsushi Kato; Institute of Applied Energy, Japan

Transformation of energy systems toward net-zero emissions is required globally under the Paris Agreement of the United Nations Framework of Convention of Climate Change (UNFCCC). In Japan, an updated goal was announced to achieve carbon neutrality by 2050 in October 2020. And the ambitious 2030 target (46 to 50% emissions reduction from 2013 levels) is announced in April 2021. Formulating policy recommendations of RD&D strategies to achieve the goal requires quantitative analysis on cost-effective supply-demand structure in energy systems using comprehensive energy systems models. In the circumstance of the national net-zero emissions goal, considerations are required to include innovative technologies that remove CO2 from the atmosphere to compensate CO2 emissions from difficult-to-decarbonized sectors, such as heavy industry and heavy-duty transportation, and also unavoidable non-CO2 GHG emissions from the agricultural sector. However, it is relatively scarce and imperative to clearly analyze their role and RD&D needs using national energy system models containing detailed energy supply-demand technologies representations.

In this study, transitions of Japan's energy systems toward the net-zero emissions goal by 2050 are analyzed using a bottom-up energy system model, TIMES-Japan. The implication of the role of NETs and their sensitivity in Japan's energy systems are assessed with two NETs systems; bioenergy with carbon capture and storage (BECCS) in the power sector and direct air carbon capture and storage (DACCS). We also investigate the role of carbon recycling technologies using direct air capture (DAC) for the production of synthesized liquid fuel and synthesized methane. To achieve the net-zero emissions cost-effectively, both the earlier deployment of BECCS with domestic biomass and the support of the DAC in the later period are required.

Synthesized fuel productions using DAC are also effective to achieve net-zero emissions particularly in the case with limited geological CO2 storage capacity development.

11:30 AM *EN13.06.03
Fueling the Future Kuo-Wei Huang; King Abdullah University of Science and Technology, Saudi Arabia

In 2018, the estimated world population of 7.53 billion people consumed 14.31 Gtoe of energy (at an average rate of 19.0 TW). Globally, burning of carbon-based fossil fuels supplies over 81% of the energy demand, and hence the prospering industrial societies are responsible for the observed increase in carbon dioxide levels form preindustrial 280 ppm to over 410 ppm now. To reduce the environmental footprint of modern societies and address the limitations of fossil recourses, the projected increase in global energy demand must go along with the implementation of low carbon energy production and carrier systems. In this presentation, the current energy status and future options will be discussed. It will then be concluded with the introduction of some of our research efforts in utilizing formic acid as a hydrogen/energy carrier.

12:00 PM EN13.06.04
Gas Hydrate Thermal and Interfacial Properties for Natural Gas Capture and Storage via Novel Atomistic-Molecular Dynamics Simulations Samuel Mathews, Phillip Servio and Alejandro Rey; McGill University, Canada

Gas hydrates are inclusion compounds comprising a backbone of water molecules that encloses guest molecules in separate cages. Each volume of hydrate contains 160 volume equivalents of gas. Initially, large scale gas hydrate research was centered around the flow assurance problems they cause in the extraction and transportation of petroleum and its derivatives. Eventually, interest grew in the usage of hydrates in gas capture and storage, including hydrocarbons, hydrogen, and direct air greenhouse gas capture, as well as separation processes, such as the removal of environmentally harmful constituents of flue gasses. Naturally occurring gas hydrates are also studied to satisfy global energy demand: estimates put the total energetic capacity of hydrate reserves at twice that of other fossil fuel reserves combined. As global temperatures rise, these hydrate reserves risk releasing methane gas into the atmosphere, accelerating global warming. Their potential use in the removal of carbon from the atmosphere, carbon capture and storage, and for energy exploitation makes gas hydrates a prime candidate for climate change mitigation research.
Density functional theory (DFT) is a first-principles computational method that calculates that atomic energies and forces for a given atomic configuration by solving the Schrodinger equation in a numerically efficient manner. By manipulating the atomic coordinates, thermal properties can be determined across a wide range of conditions when pairing DFT with phonon theory. Molecular dynamics (MD) is a simulation method that treats larger systems at more realistic conditions than DFT by integrating Newton's equations of motions for atoms, but it requires empirical parameters and forcefields. MD can calculate time dependent behaviors while DFT cannot. DFT and MD can therefore be used together to provide accurate descriptions of many behaviors. This work used DFT as implemented in the Vienna ab Initio Simulation Package (VASP) with phonon theory as implemented in Phonopy to calculate the heat capacity, thermal expansion coefficient, and Grüneisen parameter of gas hydrate systems. This work will use MD as implemented in the Large-scale Atomic/Molecular Massively Parallel Simulator (LAMMPS) to calculate the interfacial tension of natural gas hydrate systems.
The constant volume and constant pressure heat capacity, the thermal expansion coefficient, and the Grüneisen parameter of ice and carbon dioxide, ethane, methane, and empty sI gas hydrates were calculated using DFT and phonon theory from 0 to 300 Kelvin. DFT replicated experimental constant pressure heat capacity measurements accurately at low temperatures for all systems. Guest molecules contributed to the heat capacity by an amount slightly larger than their ideal gas heat capacity. Thermal expansion was overestimated in all cases, as was the Grüneisen parameter.
The MD study of interfacial work remains ongoing. Previous work from this group studied the growth rate, interfacial tension, and work of formation in methane hydrate systems. The interfacial energy of natural gas hydrate systems is expected to be inversely proportional to temperature. This behavior has

previously been observed in water and gas mixtures, and in methane hydrate systems. Different nucleation types will also be studied. In terms of increasing work of formation, it is expected that film-shaped heterogeneous nucleation will be first and thus lowest, followed by cap- and then lens-shaped, helping determine which type is most favorable. The same order would be valid for decreasing nucleation rate as a function of nucleation type at given conditions. This information will yield data to determine which conditions favor or hinder hydrate formation in carbon capture and storage, removing methane from the atmosphere, and avoiding methane release into the atmosphere. The predictions and computational platform contribute tools and new understanding to the energy-environmental nexus.

12:15 PM EN13.06.05
The Rheology of Methane and Carbon Dioxide Hydrates at Extreme High Pressures for the Development of Climate Change Mitigating Technologies Andre Guerra, Phillip Servio, Alejandro Rey and Milan Maric; McGill University, Canada

Gas hydrates are inclusion type compounds, in which gas molecules are trapped inside the solid phase of water. In the transition from liquid to solid phase, water molecules form a lattice structure that arises from hydrogen bonds between adjacent molecules. If the phase transition occurs at high enough pressures and in the presence of dissolved gas species in liquid water, the gas molecules can become trapped in “cages” as the solid lattice structure forms. Gas hydrates have been an active research topic due to their occurrence in the oil and gas industry. As a result, much of the body of knowledge focuses on water-in-oil emulsion gas hydrate systems. Recently, however, technologies that take advantage of gas hydrate properties have sparked new research motivation. Gas hydrates are stable, cage structures trap specific types and sizes of gas molecules, and one unit volume of gas hydrate can contain up to 180 times the unit volume of gas as required under standard conditions. These properties make gas hydrates good candidates in the development of new climate change mitigation technologies such as post-combustion carbon capture from flue gas, natural gas transport and storage, or the desalination of seawater. Most of these technologies require flow systems and do not involve oil-based systems. Based on these facts, the need for the characterization and elucidation of the shear rheology of gas hydrate systems from pure water systems is apparent.
This study explores pure water hydrate systems of methane and carbon dioxide at extreme high pressures (0 to 30 MPag). The viscosity of the system was measured at a constant 400 s^{-1} shear rate and at temperatures between 0 and 10C using a double-gap measurement geometry in an Anton Paar MCR302 high-pressure rheometer. The effect of temperature on the viscosity of methane hydrate systems was one order of magnitude larger than the pressure effect on viscosity in most of the pressure range: from about 0.01 mPas/C to 0.001 mPas/MPag. This difference was especially prevalent at lower temperatures. The pressure effect on the viscosity of carbon dioxide hydrate systems was up to one order of magnitude larger than that of the methane hydrate system, likely as there was more gas present in solution due to carbon dioxide’s higher solubility in water. During hydrate formation, a liquid-to-slurry phase transition occurred characterized by a progressive increase in viscosity up to a maximum value where the greatest amount of hydrate crystals was present. The time to reach maximum viscosity in methane hydrate systems was found to decrease by at least a factor of two as pressure increased from 10 to 15 MPag. For instance, it decreased from about 20 to 10 minutes at 2C. Further increases in pressure had diminishing reductions in the time required and the fastest time to reach maximum viscosity was 1.35 minutes at 30 MPag and 0C. Several systems with high driving forces for hydrate formation did not form gas hydrates within the 24-hour maximum experimental timeframe. The driving forces present in these systems were up to 4.1 MPag and 2.07 MPag for the methane and carbon dioxide systems, respectively. The key system limitations to the formation of hydrates were categorized as either arising from kinetic, mass diffusion, and/or heat of crystallization effects and were used to rationalize the main features of the experimental data. The presented data and analysis are a significant contribution to the currently sparse characterization of high pressure-low temperature shear rheology of these energy materials, which is crucial to the design and development of climate change mitigation technologies.

SESSION EN13.07: Climate Change Mitigation Technologies VII
Session Chairs: K. John Holmes and Mihrimah Ozkan
Monday Afternoon, December 6, 2021
EN13-Virtual

1:00 PM *EN13.07.01
The Role of Carbon Capture in Meeting Net-Zero Carbon Goals Jennifer Wilcox; U.S. Department of Energy, United States

President Biden has laid out a bold and ambitious goal of achieving net-zero carbon emissions in the U.S. by 2050. The pathway to that target includes cutting total greenhouse gas emissions in half by 2030 and eliminating them entirely from the Nation’s electricity sector by 2035. Research, development, demonstration, and deployment (RDD&D) will be required to achieve the president’s objectives, including investments in both point source carbon capture and carbon dioxide removal approaches that target the accumulated pool of carbon in the atmosphere. Both will be required to achieve net-zero carbon emissions in time and they will require increased deployment on an accelerated timeline in order to move down the cost curve. These efforts, combined with effective policy, will improve the economic viability of the implementation of these critical approaches.
Deployment of these technologies at the scale required will necessitate the use of resources including land, water, and low-carbon energy, while ensuring the secure and reliable storage of carbon dioxide (CO_2) on a timescale that impacts climate. Therefore, CCS and CDR deployment must be implemented strategically in terms of regional goals and requirements.
The Office of Fossil Energy and Carbon Management and the National Energy Technology Laboratory will play an important role in the transition to net-zero carbon emissions by reducing the environmental impacts of fossil energy production and use. This includes helping decarbonize other hard-to abate industrial sectors through investments in approaches like CCS, direct air capture, and technologies to produce low-carbon products and fuel - including hydrogen.

1:30 PM *EN13.07.02
Scaling Deep Decarbonization Technologies K. John Holmes; National Academies of Sciences, Engineering, and Medicine, United States

This is an unprecedented opportunity to address climate change in the United States. Moving to net-zero greenhouse gas emissions by 2050 requires greatly scaling up decarbonization technologies that do not emit carbon dioxide and the continued development, demonstration, and deployment of technologies that remove carbon dioxide directly from the atmosphere. It also requires eliminating or greatly reducing emissions of other greenhouse gases, including methane, nitrous oxide, and fluorinated gases. Eliminating energy sector carbon dioxide emissions, the most important greenhouse gas within the largest emissions sector, is required for approaching net-zero emissions. Optimistically, the United States’ large renewable resource base coupled with decreasing costs for electrification technologies can catalyze rapid progress over the first decade of this energy system transition. The United States also has an extremely rich base of scientists, engineers, social scientists, policy makers, and support within civic society to make progress on the other technological solutions. However, the country also faces rapidly emerging impacts from climate change that will not abate without decades of effort. In order to be successful, deep decarbonization cannot occur without broad support within society and therefore must be done in a way that not only accomplishes the

net-zero emissions goal but does so in a manner that meets wider societal goals and aspirations.

This talk addresses technology, societal, and policy issues for scaling deep decarbonization technologies. It is based on two recent activities at the National Academy of Sciences, Engineering, and Medicine (NASEM), a 2018 workshop that resulted in the proceedings Deployment of Deep Decarbonization Technologies and a consensus study that produced Accelerating Decarbonization of the U.S. Energy System in 2021. There is widespread consensus on the implementation of no-regrets, deployment-ready technologies aimed at decarbonizing electricity and electrifying end uses that make significant progress towards achieving mid-century decarbonization while preserving optionality. However, to accomplish these elements of decarbonization, existing solar and wind electricity generation technologies must be deployed by greater than four times their current highest annual rates. Electrification of vehicle sales and other end uses will require similar increases in technology deployment rates as renewable electricity. The increased challenge for decarbonization technologies involves addressing hard-to-decarbonize sectors such as heavy industry and air, rail, and shipping. This involves expanding the innovation toolkit. Examples include research, development, and demonstration for clean-firm electricity resources, long-duration energy storage, net-zero carbon fuels, electrolysis to make fuels from renewable power, low-carbon process heat solutions, and more efficient carbon dioxide capture technologies. It also involves development and deployment of negative emissions technologies that will compete as mitigation options. All of these strategies not only face the question of whether they can provide effective decarbonization options, they also face similar scaling issues as with decarbonizing electricity and electrifying end uses.

Reaching net-zero emissions is a transformation of society that will occur over decades, not years. Consideration of the societal aspects of decarbonization involves developing a social compact around the need to decarbonize and benefits that will accrue from it. Policy elements encompass the roles of federal, sub-national, economic, and regulatory approaches. Because political fortunes and societal opinions will change over this timeframe, consensus-building scientific institutions including the National Academies to facilitate the independent technical and policy advice needed.

2:00 PM *EN13.07.03
U.S. Department of Energy's Fossil Energy and Carbon Management R&D Program—Carbon Dioxide Removal Overview Andrew Jones; DOE/NETL, United States

The U.S. Department of Energy's Fossil Energy and Carbon Management (DOE-FECM) R&D Program is supporting the development of transformational cost-effective carbon dioxide (CO_2) capture technologies throughout the power-generation and industrial sectors as well as carbon dioxide reduction (CDR) technologies. Since 2001, DOE-FECM's Carbon Capture Program has been identifying and advancing technologies with the goal of decreasing the cost and improving the efficiency of carbon capture. Technologies developed to date have primarily focused on the capture of CO_2 directly from large point sources, such as industrial sources and fossil fuel power plant flue gas streams. The Carbon Capture Program is leveraging this past research in materials, equipment and process development for both current and transformational CDR technologies, such as direct air capture (DAC) and bioenergy with carbon capture and storage (BECCS), while evaluating the opportunities in direct ocean capture and enhanced weathering. More research is needed to develop efficient processes and components utilizing the transformational materials to lower the cost of these systems. At the same time, DOE-FECM aims to better understand system costs, performance, as well as business case options for the existing technologies, to better focus its research and development program. Accelerating the development and deployment of these climate-critical technologies will support the U.S. goal to achieve a carbon pollution-free electricity sector by 2035 and zero-carbon economy by 2050.

2:30 PM *EN13.07.04
Diminishing the Gigaton Carbon Giant Through Hybrid Material Strategies for Capture and Conversion Michelle Kidder[1], Luke L. Daemen[1], Yong Joo[2] and Alissa Park[3]; [1]Oak Ridge National Laboratory, United States; [2]Cornell University, United States; [3]Columbia University, United States

Energy generated from fossil fuels dominate the global use portfolio which now has reached an all-time high emission of approximately 40 $GtCO_2$. Undoubtedly this has had consequential impacts on our climate and environment, and sadly emissions are expected to rise. This has brought the urgent need to remove carbon from the atmosphere to reverse the rising atmospheric CO_2 concentrations with effective carbon negative technologies. However, many strategies to capture or convert carbon dioxide have been met with challenges with standalone materials. Hence, we have developed hybrid materials that employ a polymer with intrinsic microporosity (PIM) which has superior CO_2 selectivity with tunable functional and structural characteristics to enhance its effectiveness for both capture and conversion pathways. Here we show the development of hybrid PIM materials for both (1) direct air capture (DAC) and (2) utilization processes. Our first example is of a hybrid fiber mat composed of a silica bound polyethyleneimine (PEI) nanoparticle core (NOHM) encapsulated with a PIM sheath for DAC applications. NOHMs have demonstrated CO_2 sorbent qualities such as low volatility and high selectivity, however their viscosity and water retention have impeded their effectiveness for DAC. PIM encapsulation of NOHMs allows for selective rejection water and other air pollutants to reduce the parasitic energy consumption effects of significant mass transport limitations, yet maintain high gas permeability and selectivity. Secondly, we will present our catalytic PIM for the simultaneous capture and conversion of CO_2 to chemicals. Initial experiments show that this hybrid catalyst can overcome high temperature and pressure conditions normally needed for catalytic CO_2 reduction. From these initial findings of hybrid PIM materials, we learn key material properties such as stability, capacity, and recyclability that will help to provide insight into the technical feasibility of large scale applications needed for DAC and CO_2 conversion.

SESSION EN13.08: Climate Change Mitigation Technologies VIII
Session Chair: Sue Carter
Monday Afternoon, December 6, 2021
EN13-Virtual

4:00 PM *EN13.08.01
Power-Generating Greenhouses for Supplying the Worlds Energy, Water and Food Needs Sue Carter; University of California, Santa Cruz, United States

The increase if the world population and qualify of life over the next few decades is anticipated to increase the demand for food, water and energy by nearly 50%, Supplying these necessary life resources will become even more challenging with the increases in drought and temperatures brought on with climate change, as we have seen this year with the devistation of agricultural communities in the western United States. However, the same agricultural lands that are being detroyed by drought can also be part of the solution if they can be utilized more effectively. For example, covering less than 10% of the worlds agricultural lands with power-generating greenhouses would, in theory, be able to meet the increased global demands for fresh water, healthy food and clean renewable electricity due to the a potential for an order of magnitude reduction of water consumption and increase in crop yields that carefully

designed greenhouses can provide. This promise has spawned the new field of agrivoltaics, namely the co-location of PV with agriculture, as a climate change mitigation technology.

In this talk, I will give an overview of agrivoltaic technologies and critical economic, technology, and social challenges that exist for their wide-scale deployment. I will then discuss the basic science behind the agrivoltaics created by our laboratory at UCSC, in collaboration with Soliculture, consisting of luminescent photovoltaic (PV) panels that enhance the wavelenths of light that plants need while utlizing the wavelengths that plants do not need for renewable power generation, all while providing wavelength selective shading to reduce water consumption and overheating without negatively impacting crop yields. I will discuss the technology advances in moving this technology from small prototypes in the laboratory to full 1 meter by 2 meter agrivoltaic panels that can fit into standard greenhouse frames, including the challenges of demonstrating 20 years lifetimes and maintaining a competitive price with standard ground-mounted Si PV technology. In addition, I'll share our stories and results over the last 5 years of installing these greenhouses over acres of agricultural lands in Canada and California and working with farmers to measure the impact of the panels on crop yields. Having shown the promise, I'll end with potential ptifalls that agrivoltaics will still need to address to become widely deployed solutions for climate change mitigation.

Cement as a Negative Emissions Technology Paul S. Fennell, Mark Sceats and Justin Driver; Imperial College London, United Kingdom

Cement fulfils many important roles within society today. However, its production is highly CO2 intensive. We will consider a number of potential methods to incorporate the combination of biogenic material (including Municipal Solid Waste, but also considering waste woods, etc) within a cement plant which includes Carbon Capture and Storage. This will include the integration of a novel direct separation reactor within the cement production process. We will show that it is possible to produce significant net negative emissions from the production of cement, not including the subsequent uptake of CO_2 by the cement as it remains in place. We will consider the impact of different methods to cure the cement, including technologies such as those proposed by CarbonCure, and how these overall can add up with CCS, fuel selection and clinker substitution, to produce traceable net negative emissions from an industry that currently emits around 7 % of global CO_2.

5:00 PM *EN13.08.03
Contributions of Fellows and Senior Members of the National Academy of Inventors (NAI) Towards Climate Change Mitigation Technologies Kalliat T. Valsaraj[1,2] and Paul Sandberg[2]; [1]Louisiana State University, United States; [2]National Academy of Inventors, United States

Since the dawn of the industrial era, anthropogenic factors have contributed to an acceleration of climate change that is well documented in the literature. The human-induced factors presently overwhelm natural fluctuations and, global efforts to combat the effects of the same are underway. To this extent, several climate change mitigation technologies have been proposed on a global scale and reports published by the National Academies of Sciences, Engineering and Medicine (NASEM). Apart from the global efforts, it is also clear that regional efforts have to be undertaken to limit the adverse effects. Fellows and Senior Members of the National Academy of Inventors (NAI) have been at the forefront of developing and commercializing several related technologies. This relates to the overall mission of NAI in promoting innovation and technology commercialization for the benefit of humankind. This invited talk will summarize some of the technologies that are presently being considered for combating climate mitigation challenges in various parts of the world.

5:30 PM *EN13.08.04
Recent Advancement of Synthetic Oxygen Carriers for the Chemical Looping Combustion Technology Nader Mahinpey, Amr Abdalla and Mohanned Mohamedali; University of Calgary, Canada

The continuously rising concentrations of CO_2 in the atmosphere have led to significant negative impacts on the environment, which has propelled research efforts to replace fossil fuel-based energy with clean energy sources. Chemical looping combustion (CLC) has emerged in recent years as a promising technology for CO_2 capture in power plants and other CO_2 intensive industries. One of the main components of CLC is the oxygen carrier (OC) that is circulated between air and fuel reactors. The evolution of effective OCs with the desired properties for CLC application is deemed to be very significant for the commercialization of CLC. The research in this field is rapidly growing to tackle the major materials and operational challenges to advance the knowledge toward an industrial scale CLC application. This study provides a review of the advancements accomplished over the past five years in the progress of synthetic single oxide-based OCs. A summary of key performance indicators used to evaluate OCs is presented in this study to enable a systematic assessment of the OCs properties and performance. A focused and critical literature review over the last 5 years (2016-2021) on the OCs development was summarized. Moreover, the role of supports, synthesis protocols, promoters and other aspects affecting the OCs performance in CLC were outlined. This talk summarizes the main challenges, research needs and opportunities for future progress to highlight the potential pathways to develop synthetic single oxide OCs in an environmentally friendly, and cost-effective manner.

Stability Limits and Mechanical Behaviors of Methane Gas Hydrates for Use in Greenhouse Gas Mitigation Technologies Xiaodan Zhu, Alejandro Rey and Phillip Servio; McGill University, Canada

With the increasing crises of the global warming phenomenon, greenhouse gas mitigation technologies are essential to maintain the world's sustainability. Carbon dioxide (CO_2) sequestration is an inevitable component during this development. It aims to capture and store the CO_2 gases in the atmosphere to mitigate or reverse global warming. However, the selection of places to store the CO_2 gases is always a challenging process. The CO_2 storage in soil and ocean leads the sites to become acidic and threatens human life. To avoid potential problems like these, gas hydrates are potential material for CO_2 sequestration due to their excellent storage capacity.

Gas hydrates are guest-host crystalline materials formed by water cages and host gases such as methane and carbon dioxide. Regarding this structural feature, 1 m^3 gas hydrate can contain approximately 160 m^3 gases.

The CO_2 sequestration process is based on SI methane gas hydrates; methane is replaced by carbon dioxide. During this process, the pressures and temperatures surrounding the gas hydrates change, making the hydrate structure unstable. Jendi et al. reported that material properties of gas hydrates associated with structural stabilities change along with pressures and temperatures. Jia, J. et al. demonstrated the role of the guest molecules (methane and carbon dioxide) on the gas hydrates' stability. However, although the performance of the gas hydrates under different pressures and temperatures was demonstrated, little attention has been paid to the description and characterization of their stability limits.

This contribution will present the pressure stability limits of monocrystal defect-free methane gas hydrates, using accurate density functional theory (DFT) to simulate the hydrate's performance under varying pressure. The effects of pressure on the geometric and atomic bonding feature of this guest-host crystal are presented and analyzed using various atomic angle and bond length distribution functions. Important gaps or forbidden zones are identified and related to potential stability mechanisms as pressure increases. Locations of concentrated distortions in the crystal lattice are identified. Comprehensive characterization of the elastic properties with pressure is presented and related to the crystal geometry changes. Validation and accuracy are determined using available simulations, theory, and experiments. Taken together, these results contribute to understand the methane gas hydrate stability under a great range of pressures and provide a comprehensive prediction on the hydrate's performance during CO_2 sequestration.

6:45 PM EN13.09.02
Direct Air Capture of CO_2 with Aqueous Amino Acids/Peptides and Crystalline Guanidines Radu Custelcean; Oak Ridge National Laboratory, United States

Negative emission technologies, including direct air capture (DAC) of carbon dioxide, are now considered essential for mitigating climate change, but existing DAC processes tend to have excessively high energy requirements, mostly associated with solvent/sorbent regeneration. Recently, we have developed a promising approach to DAC that combines atmospheric CO_2 absorption by aqueous amino acids or peptide (e.g., glycine, glycylglycine) with (bi)carbonate crystallization by simple guanidine compounds. In this phase-changing system, the amino acid/peptide and the guanidine compounds work in synergy, and the cyclic CO_2 capacity can be maximized by matching the basicity of the two components. The resulting DAC process has a significantly lower regeneration energy compared to state-of-the-art solvent-based DAC technologies.

This research was sponsored by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, Chemical Sciences, Geosciences, and Biosciences Division.

7:00 PM EN13.09.03
Development of the Membranes for the CO_2 Separation from Air Based on the CO_2 Selective NbOFFIVE-1-Ni Metal-Organic Framework Roman Selyanchyn and Shigenori Fujikawa; Kyushu University, Japan

The membrane-based gas separation proved to be energy efficient in industrial processes and is also studied for the post- and pre-combustion CO_2 separation from N_2 and H_2 respectively. Meanwhile, direct capture of CO_2 from air represents a tougher challenge for the membrane approach due to the significantly lower concentration and very low driving force needed for gas transport. Advances in the membranes design, membrane processes, combination with CO_2 conversion are important to enable the energy competitive CO_2 extraction from low concentrated environmental mixes.

Metal-organic frameworks (MOFs) are novel microporous and tunable materials that suggested for separation processes, due to ability to precisely design the internal pores' size or chemical affinity via reticular chemistry. NbOFFiVE-1-Ni is among the recently discovered MOFs that demonstrated a peculiar CO_2 sorption property. Namely, in addition to its relevant sorption capacity of ~2.2 mmol CO_2 per gram of MOF, the sorption to full capacity undergoes at very low partial pressures. This causes the material to be filled with CO_2 when exposed to concentrations as low as 400 ppm. This property of NbOFFiVE-1-Ni and several other similar ultramicroporous materials suggested their use as solid sorbents in DAC application. However, the complexity of solid adsorption-based capture, tough requirements for the material regeneration (ultra-low vacuum), and even cost and scale make this approach impractical. To utilize the unique properties of NbOFFiVE-1-Ni we speculate that instead of solid adsorption it is possible to design the membranes and use the material in form of nanofillers in the mixed matrix architecture. It is known that fillers can improve membrane performance by increasing selectivity, permeability, or even both properties.

Here we report the fabrication, structure, and gas transport properties of mixed matrix membranes (MMM) composed of the fluorinated MOF (NbOFFIVE-1-Ni) and CO_2 selective polyether-polyamide block copolymer (Pebax-1657). The performance of MMM with different amounts of fillers (10-40 wt%) for CO_2, N_2, O_2, and H_2 gas permeation was studied with particular focus on the mixed CO_2/N_2 formulations (with concentrations as low as 1000 ppm CO_2). For better performance, MMMs should have well-dispersed fillers in matrix polymer without interfacial gaps or blocking interfaces between them. As such, the hypothesis of this study was that if NbOFFiVE-1-Ni material is optimally incorporated in the polymer it could provide better CO_2 separation from the matrices with low concentration.

It was found that the particles of as-synthesized NbOFFIVE-1-Ni MOFs have very large sizes, not suitable for uniform membranes fabrication. Therefore, planetary ball milling was used to reduce particle sizes reaching well below the sub-100 nm size range. The presence of ultramicroporous fillers of smaller size in Pebax-1567 made a significant impact on gas transport. In particular, the increased CO_2/N_2 selectivity (from ~60 in polymer to >100 in MMMs) was observed with the increase of filler loading. These results suggest the manifestation of the ultra-CO_2-selective nature of the NbOFFIVE-1-Ni. The highest CO_2/N_2 selectivity and CO_2 permeability of MMMs was observed when a 1000 ppm CO_2 mixture was used as a feed gas. The performance of MMMs at higher temperatures (40-60 °C) allowed us to achieve even better separation results matching the sorption performance of MOF in similar conditions and significantly overcoming the performance of pure polymer used as a matrix.

While the improvement in selectivity is important for the efficient membrane-based CO_2 capture processes, especially for the post-combustion and direct air capture, further efforts on the particle size reduction and mixed matrix membrane thinning for effective utilization of the excellent molecular sieving properties of NbOFFIVE-1-Ni are necessary. These experiments are underway, and results will be also reported.

7:15 PM EN13.09.04
Upcycling of Waste Materials for Sustainable and Scalable Energy Storage Cengiz S. Ozkan; University of California, Riverside, United States

Great many tons of waste glass and plastics end up in landfills without proper recycling, which aggravates the burden of waste disposal. Plastic pollution is especially harmful to the Earth's ecosystem, and impacts the quality of life all around. Plastics and glass are used on a massive scale in various sectors of industry, including the automobile, textile, and packaging industries. The conversion from waste glass or plastics to favorable materials is of great significance for sustainable strategies. In this talk, I will describe recent advancements in upcycling polyethylene terephthalate (PET) waste and glass waste bottles into active electrode materials of nanocarbon fibers and nanostructured silicon particles, respectively. Compared to other quartz sources obtained via pre-leaching processes that apply toxic acids and require high energy-consuming annealing, an interconnected silicon network is directly derived from

waste glass bottles via magnesiothermic reduction. In the case of PET waste plastic, materials are first dissolved in a mixture of trifluoroacetic acid and dichloromethane, followed by carbonization under an argon/hydrogen atmosphere. Nanocarbon electrodes derived from waste PET have been successfully employed in electric double layer supercapacitors. Glass bottles are directly utilized for magnesiothermic reduction without pre-leaching and annealing, which offers a more environmentally-benign, energy-saving and efficient route to prepare silica source materials. Their abundance in silica without any loss due to the non-etching process result in high silicon yield towards fabricating Li-ion battery anodes with excellent electrochemical performance with a capacity of over 1400 mAh/g at C/2 after 400 cycles. Both conversion processes for waste glass and plastics are highly scalable with environmental and economic advantages, and our methodologies could provide the means for achieving a circular economy involving the upcycling of sustainable waste materials integrated to manufacturing of scalable energy storage technologies.

7:30 PM *EN13.09.06
Climate Change Mitigation Technologies Ken Caldeira[1,2]; [1]Carnegie Institution for Science, United States; [2]Breakthrough Energy, United States

Climate change is one of the central challenges facing the world today. One of the basic ways to reduce risks from climate change is to reduce emissions of the greenhouse gases that are causing our planet to warm. In climate change jargon, efforts to reduce emissions have come to be known as “climate change mitigation”.
The three main ways to reduce greenhouse gas emissions are to: (1) reduce consumption; (2) reduce amount of energy used per unit consumption (efficiency); and (3) reduce the amount of net greenhouse gas emissions per unit energy used (carbon-emission-free energy).
Most national governments are working hard to increase abilities of populations to consume, so most mitigation efforts center on improving efficiency and powering systems with carbon-emission-free energy.
Efficiency can be improved through a change in systems (e.g., a shift from manufacturing to service sector) or through a change in devices (e.g., a more efficient engine).
There are only a small number of possible energy carriers and a finite number of technologies that could in principle convert energy from one carrier to another at scale without releasing greenhouse gases into the atmosphere. These include wind, solar, hydropower, nuclear and perhaps power from the oceans. Fossil fuels and bioenergy could perhaps be made carbon neutral through some combination of flue gas and direct air carbon capture and storage. While some non-emitting technologies are cost competitive with fossil-fuel alternatives in some settings, at today’s costs, near-zero emission energy systems have higher direct costs today than would a CO2-emitting system with similar characteristics. Therefore, substantial effort is being invested in lowering the “Green Premium” that must be paid to avoid greenhouse gas emissions.
This talk will present a taxonomy of mitigation technologies and approaches, with attention given to areas in which materials science might hopefully contribute to addressing important societal needs.

SESSION EN13.10: Climate Change Mitigation Technologies X
Session Chair: Ronaldo Giro
Monday Afternoon, December 6, 2021
EN13-Virtual

9:00 PM EN13.10.01
Accelerate Polymer Membrane Discovery for CO2 Separation with Graph-Based Generative Model and Molecular Dynamics Simulation Hsianghan Hsu[1], Akihiro Kishimoto[1], Ronaldo Giro[2], Mathias Steiner[2], Seiji Takeda[1] and Lisa Hamada[1]; [1]IBM Research-Tokyo, Japan; [2]IBM Research - Brazil, Brazil

Polymer membranes are potent materials for exhaust gas separation in energy production and transportation. Separating off carbon dioxide (CO2) from flue gases could help to mitigate climate change which is mainly driven by greenhouse gas emissions. Due to the trade-off between a membrane’s CO2 permeability and its selectivity with regards to CO2 and nitrogen (N2), and because of the harsh operation conditions, only very few polymers are actually used at industrial scale. In this study, consider the complexity of the process conditions and complicated interaction when flue gases permeate the membrane, we develop a simplified end-to-end framework and target to homopolymer type membranes first. Powered by the less data hungry artificial intelligence algorithms and physical validation, a similar trend compared to the literature values is observed. The results and challenges which include small number of the dataset, molecule generation efficiency, and validation with molecular dynamics (MD) are discussed.

The dataset is mostly acquired from the review article [1] and then converted to their corresponding SMILES. The target is to find membrane materials perform superior to Robeson's 2008 upper bound. Within the selected 150 samples none of them perform over the boundary. With the small data size, we tested the performance of three linear models (Lasso, Ridge and elastic net) and three non-linear models (random forest, kernel ridge and support vector machine). By performing grid search the best hyperparameter sets are configured automatically. For the linear models, we selected important features based on the Lasso penalty available in the scikit-learn library. For the non-linear models, we performed a combination of greedy search with local search that attempts to bypass the local optimum of the R^2 score. This benefits to the final CV scores improve at least 0.1 and finally random forest is used for doing structure generation. In the generation step, our strategy is to involve prescribed sub-structures embed in those samples close to the boundary rather than decided by exhaustive generation algorithm. The newly generated SMILES are clustered by Murcko scaffolds first and those predicted over the boundary are selected for MD validation.

The newly generated structures lack of clear identification for the atom charge and bond type information. The purpose of the MD validation is to efficiently observe the trend rather than to reproduce the literature values. An automation process is developed to convert generated SMILES to polymer slabs with MD input format. Since most experimental observations are performed at constant temperature and pressure, we realize the permeability calculation with a isothermal-isobaric (NPT) based methodology in which constant pressure difference is kept during the gas injection. According to the benchmark results under available options, polymer slabs with 800 heavy atoms per chain, 6 nm in thickness, and DREDING force field are selected. The benchmark results shows that the CO2 permeability is in the same order between predicted and calculated values. Instead, the selectivity is less comparable to the original values which is because that N2 permeability usually 10 to 40-fold smaller and a long enough simulation time (ex: 100 ns) is necessary.

The overall fitting results we have obtained are encouraging, considering the limitations of the training dataset and the membrane formation method. The automated process allows to put innovation on structure generation and MD methodology. Based on the results obtained, we are now analyzing the newly generated structures with highest predicted CO2 permeability. The inclusion of additional physical parameters such as adsorption energy, free volume, and gyration radius in the optimization could help further improve our material discovery results for polymer separation membranes.

9:15 PM EN13.10.02
Effect of Pore Expander on Pluronic Block Copolymer-Alumina Co-Assembly Geok Leng Zoey Z. Seah[1,2], Adam K. Usadi[3], Jonathan McConnachie[3] and Kwan Tan[1]; [1]Nanyang Technological University, Singapore; [2]KAIST, Korea (the Republic of); [3]ExxonMobil Research and Engineering Company, United States

Co-assembly of a structure-directing block copolymer and aluminium tri-sec-butoxide derived sols enables formation of highly ordered mesoporous alumina structures that are appealing for various applications such as carbon capture, separation and catalyst supports. We found that the addition of trimethylbenzene further induced an order-disorder-order mesophase transition in the F127-Al_2O_3 system. Thermal annealing resulted in the formation of micro-and mesoporous alumina structures with enhanced carbon dioxide adsorption capacity.

9:30 PM EN13.10.03
Automated AI-Driven Screening of Nanoporous Materials for Enhanced Carbon Dioxide Adsorption Rodrigo Neumann[1], Fausto Martelli[2], Binquan Luan[3], Ronaldo Giro[1], Tonia Elengikal[3], Nicholas Yankey[3], Anshul Gupta[3], Guojing Cong[4], Mathias Steiner[1], Tom Peters[5], Amir Farmahini[6], Joseph Manning[6], Conor Cleeton[6], Flor Siperstein[6], Lev Sarkisov[6] and Breanndan O Conchuir[2]; [1]IBM Research Brazil, Brazil; [2]IBM Research Europe, United Kingdom; [3]IBM T.J. Watson Research Center, United States; [4]Oak Ridge National Laboratory, United States; [5]University of Connecticut, United States; [6]The University of Manchester, United Kingdom

Millions of crystalline nanoporous materials have been identified for carbon capture, making the task of measuring the adsorption performance of each individual nanopore using computer simulations wholly unfeasible. Furthermore, experimentally synthesising and calculating the adsorption properties of each sample is even more impractical. A screening framework is thus required to identify a smaller number of promising candidates for further investigation. In this presentation, we introduce our work which deploys several distinct mathematical techniques to efficiently characterize nanopore structures, leading to a rapid high throughput nanopore screening mechanism.

Our automated cloud-based materials screening tool is composed of two distinct parts. Firstly, several computational geometric and topological descriptors are determined for each individual nanopore, allowing us to immediately discount samples with unfavourable structural properties. Next, Grand Canonical Monte Carlo (GCMC) simulations are deployed to calculate the target adsorption figures of merit. The computed results can be ingested into machine learning algorithms to produce a surrogate model to the original simulations, thus accelerating the estimation of desired adsorption properties of the candidate nanoporous materials.

9:45 PM EN13.10.04
Evaluating Classical Molecular Dynamics Methods for the Validation of Carbon Dioxide Separation Performance in Polymer Membranes Ronaldo Giro[1], Hsianghan Hsu[2], Akihiro Kishimoto[2], Seiji Takeda[2] and Mathias Steiner[1]; [1]IBM Research - Brazil, Brazil; [2]IBM Research - Japan, Japan

Climate change is mainly due to CO2 emissions occurring in energy production and transportation. A set of technologies are being developed to separate and sequester CO2 from point sources. Among these are liquid and solid adsorbents as well as membranes and hydrates. Polymer membranes show certain advantages with regards to their storage and disposal properties, they allow for passive operation, have high tolerance to SOx and NOx content and can be integrated within an existing power plant steam cycle (post combustion application).

Candidate materials for application in polymer separation membranes must fulfill two key requirements: high CO2 permeability and high CO2/N2 selectivity. Many candidate materials exist today or can be computationally designed; however, the time and cost of experimental lab validation is the principal limitation in materials discovery applications. In this contribution, we investigate the potential of Classical Molecular Dynamics (CMD) simulations as a time- and cost-efficient validation option for suited polymer candidates.

CMD simulations have been employed successfully for calculating permeation in glassy polymers [1], however, significant uncertainties with this approach remain. We have reviewed a set of available CMD methodologies and analyzed their strengths and weaknesses in application to the polymer membrane use case. Specifically, we have investigated effects related to number of atoms, membrane thickness and area, size of polymeric chain and membrane composition, respectively, on both CO2 permeability and selectivity. We show quantitative results for representative polymers that lead to the conclusion that Constant Pressure Difference Molecular Dynamics (CPDMD) [2,3] is the most appropriate methodology.

Simulating Fluid Flow at Pore Scale with Carbon Dioxide in Digital Rock Jaione Tirapu Azpiroz[1], Rodrigo Neumann[1], Ronaldo Giro[1], Adolfo Emmanuel Correa Lopez[1], Ricardo Luis Ohta[1], Abel Cabral Arruda[1], Matheus Esteves Ferreira[1], Ademir Ferreira Silva[1], Benjamin Wunsch[2] and Mathias Steiner[1]; [1]IBM Research-Brazil, Brazil; [2]IBM T.J. Watson Research Center, United States

Carbon dioxide capture and storage technologies will be required to reduce emissions into the atmosphere and limit global warming in the coming decades. Geo-sequestration involving the injection of CO2 directly into the pore space in sedimentary rocks, saline formations or abandoned oil fields may present a permanent storage solution. More scientific research is needed to understand and optimize CO2 injection process and long-term storage at the pore scale of these underground geological formations.
In our research, we model the rock pore space as a network of capillaries with spatially varying radii and the flow rate in each capillary is modelled as laminar flow. The capillary network representation is extracted from high-resolution X-ray microtomography images of suitable rocks [1]. This fined-grained capillary network representation allows for both single- and two-phase flow simulations with a high level of geometric accuracy at microscale. The two-phase flow simulations employ a time-dependent interface tracking approach for simulating displacement experiments that results in a system of differential-algebraic equations. Solving these time-dependent equations on the high-resolution three-dimensional geometrical representation of the rock sample obtained from the X-ray microtomography remains very time and computationally intensive. Alternatively, analysis is carried out on the aggregate

results of multiple two-phase flow simulations, each applied to a different simplified capillary network model of the rock sample. These simplified network models are generated algorithmically and allow for a higher level of control on the number of capillaries and their properties. The resulting networks are optimized to match the physical properties of permeability and porosity of the original sample at a significantly lower computational cost.
In this work we present results from the accuracy benchmark of the single-phase flow simulations against other known network methods from the literature and with respect to measurements of permeability performed at lab scale in the same rock samples. We then apply the methodology described to simulate two-phase flow on capillary network representations of porous sandstone rock samples extracted from the geometric boundaries of the connected pore space from x-ray microscale computer tomography data. In order to understand the physics of carbon dioxide trapping at the pore scale, we simulate two-phase fluid flow scenarios under varying conditions of temperature, pressure and fluid properties, and present our findings in optimizing parameters that maximize fluid saturation of the rock.

10:15 PM EN13.10.06
Rapid Thermal Swing Adsorption Gas Separation for Carbon Capture Emanuele Piccoli[1,2], Patrick Ruch[1] and Bruno Michel[1]; [1]IBM Research - Zurich, Switzerland; [2]EMPA, Switzerland

The large column inventory enforced by the long regeneration times prevented the use of thermal swing adsorption for gas separation. But with shorter regeneration times the technology would have a good potential due to the low operation cost enabled by the use of low grade waste heat. The key to shorter regeneration times is a **rapid thermal swing adsorption (RTSA) process.** This process has been developed in adsorption heat pumps that offer a clean technology for cooling or heating utilizing waste or renewable heat as driving energy. RTSA constitutes a similar step improvement as the rapid pressure swing process that reduced the investment cost for many gas purification and separation processes including oxygen separators used in treating COVID patients. A crucial component to reduce cycling times is the use of hierarchically structured sorbents. As part of the development of better adsorption heat pumps we have devised an inexpensive and scalable magnetic alignment route for the fabrication of adsorptive coatings with vertically open channels and thermal bridges improves mass transport more than threefold [1]. This combined with methods to improve thermal transport accelerate the thermal swing process strongly reducing column inventory and cost.
A novel controlled fast temperature jump setup (TJS) accurately measures temperatures and sorption processes based on chamber pressure as function of time following temperature steps. The sorption material is mounted as beads or layers onto aluminum carries that are temperature controlled with high performance microchannel heat exchangers. The TJS allows fast acquisition of cycled mass, thermal resistance and mass transport resistance to screen and optimize material and process libraries. Measurements were carried out as function of wide choice of sorbent materials, gas type (CO2, N2, H2O) including mixtures, gas pressure, cycling time, temperature gradient, layer thickness, and layer structuring. A selection parameter was defined that contains exchanged mass per cycle, adsorption and desorption speed as well as layer thickness: Parameters that maximize the performance of an RTSA gas separation process.
The maximum achievable specific exchanged mass per cycle could be determined by gravimetric method through Dynamic Vapor Sorption experiments. All adsorbents were tested in both mono and multicomponent gases showing that maximum CO2 adsorption capacity alone does not sufficiently represent the potential of a material, as residuals of adsorbed water in the pore can significantly decrease the cycling capacity. The same methods, as well as full adsorption isotherms, were applied to the adsorber coating materials (including binders, surfactants and thermally conductive materials) to provide a benchmark for the evaluation of the enhanced coatings tested with different cycle times.
According to the results obtained with the TJS experiments, the initial coating formulation and process was improved aiming to increase the active mass use and the CO2 cycled per unit area, and to decrease the adsorption and regeneration times. As a result, a protocol ensuring good adsorbent adhesion, good thermal contact and fast kinetics was obtained.
It was demonstrated that a proper integration strategy of pore formation by magnetically aligned emulsions is as significant as the choice of the adsorbent material itself, leading improvement factors between 2 and 10. The material screening and integration tailoring methods proposed proved to quickly highlight the most promising direction on which to build on scale-up and further research activities. We thus can quickly select best materials and structuring processes to establish RTSA as a viable alternative to other carbon capture processes.

10:30 PM EN13.10.07
Novel Gas Hydrate Systems with Plasma-Functionalized Graphene Nanoflakes for Emerging Methane Storage and Transport Technologies Adam McElligott, Jean-Luc Meunier and Phillip Servio; McGill University, Canada

Natural gas is composed primarily of methane, a potent greenhouse gas, and is a quickly-growing non-renewable energy source worldwide. To mitigate pipeline emissions, transport has moved towards using pressure vessels with liquefied (LNG) or compressed (CNG) natural gas. Gas hydrates are crystalline compounds formed when a gas is enclosed in and stabilizes a lattice of hydrogen-bonded water molecules. They require less severe conditions for formation: lower pressures than CNG and higher temperatures than LNG. Also, 1 L of methane hydrate is estimated to store 160 L of gas. Due to the high storage capacities and reduced transportation costs, gas hydrate technologies are now being developed for natural gas transport and storage applications. Methane hydrate technologies could also be used for direct air capture of methane from pipeline leaks and could equally extend to removing atmospheric carbon dioxide using CO_2 hydrates, which have the same structure as their methane counterparts.
The study of materials that assist in the formation of hydrate structures has focused on kinetic promoters that induce the nucleation of stable gas hydrate crystals and enhance hydrate growth rates as well as gas storage capacities through higher cage occupancy. Improved gas dissolution in water at the liquid-vapor-hydrate equilibrium point has also been examined. Recently, this class of promoters has expanded to include graphene nanoflakes (GNFs) which have already been shown to increase the yields of many hydrate compounds. They are made through a plasma decomposition process wherein critical carbon clusters form homogeneously from carbon vapors. GNFs are hydrophobic as they consist of sheets of carbon atoms, so they agglomerate in and settle out of aqueous solutions. Stability improvement methods have included the addition of surfactants, though this reduces the system purity, and chemical additions on the graphene surface. Recent advancements have allowed for the GNF surface to be functionalized with oxygen-containing groups. Here, the CH_4/N_2 feed used initially to form hydrophobic GNFs is changed to air, and the oxygen forms an active species and interacts with the GNF surface. Through covalent bonding with these oxygenated functionalities (such as carboxyl, hydroxyl, and ether oxide groups), a stable nanofluid of aqueous GNFs was achieved. These hydrophilic GNFs, called O-GNFs, have in-plane dimensions of roughly 100 x 100 nm^2 and are between 5 and 20 atomic layers thick. The atomic composition of their surface is approximately 14.2% oxygen.
The growth rates of methane hydrates were measured in the presence of plasma-functionalized GNFs at 2 °C and 4646 kPa, a 1500 kPa driving force. Improving growth rates furthers the efficacy of hydrate technologies by increasing gas capture rates. Enhancement occurred due to improved mass transfer resulting from high GNF specific surface area and additional gas-liquid interfacial area. Enhancement by O-GNFs rose linearly and rapidly at low concentrations, peaking at 1 ppm at nearly quadruple the growth rate (288% enhancement): the most significant enhancement of a hydrate system currently demonstrated. At 5 ppm, enhancement dropped to 215% due to limitations on the mean free path of the nanoparticles. At 10 ppm, enhancement rose again

to 247% due to further increases in surface area.
The dissolution rates of methane in hydrophilic GNF nanofluids at 2 °C and 3146 kPa (three-phase equilibrium) were also measured. These rates improved with loading and were at most 44% faster at concentrations of 5 ppm. Mean free path limitations may have restricted further dissolution rate enhancements beyond this point. The maximum dissolution rate for the specific system may also have been achieved. The amount of methane dissolved in the solution did not change with any GNF loading. This finding indicates that GNFs do not affect system thermodynamics: these additives may not affect how much gas can be stored in the hydrate.

SESSION EN13.11: Climate Change Mitigation Technologies XI
Session Chair: Susan Rempe
Wednesday Morning, December 8, 2021
EN13-Virtual

8:00 AM EN13.11.02
Ultra-Thin and Robust Liquid Membrane for CO2 Capture from Gas Mixtures Susan Rempe[1], Ying-Bing Jiang[2], Yongqian Gao[3], Ron Chiang[3] and Chris Beamis[3]; [1]Sandia National Laboratories, United States; [2]The University of New Mexico, United States; [3]Memzyme, LLC, United States

Current carbon dioxide membranes suffer from limited flux and selectivity while conventional absorption-based CO_2 sequestration are associated with high temperatures and high costs, calling for alternative CO_2 separation approaches. Here, we describe an ultra-thin and robust liquid membrane that enables both high flux and high selectivity for CO_2 separation and capture at ambient temperatures and low costs. The membrane comprises 18-nm thick arrays of 8 nm diameter hydrophilic pores that stabilize water by capillary condensation and precisely accommodate the metalloenzyme carbonic anhydrase (CA). CA catalyzes the rapid interconversion of CO_2 and water into carbonic acid, promoting uptake and release of CO_2. By minimizing diffusional constraints, stabilizing and concentrating CA within the nanopore array to a concentration 10× greater than achievable in solution, our thin, liquid membrane separates CO_2 at the highest combined flux and selectivity yet reported for ambient condition operation.

The Value of Negative Emissions Technologies for Mid-Century Transitions to a Net-Zero Economy Chris Greig[1] and Sam Uden[2]; [1]Princeton University, United States; [2]Conservation Strategy, LLC, United States

Negative emissions technologies (NETs) are often viewed as a 'risky backstop' technology for climate change mitigation. This view stems from IAM-based assessments of NETs which require very large-scale deployment of NETs in the second half of the century, to compensate for a mid-century emissions overshoot. In this presentation, we challenge this limited view of NETs. Taking Princeton's recent report, Net-zero America as a case study, we show the crucial role that negative emissions technologies plays in the economy-wide transitions to net-zero emissions by 2050 for the United States. The second part of the presentation proposes a fresh take on the value of NETs, and explores NETs via a bottom-up analysis. A decision-making framework is offered to determine the circumstances under which NETs could provide *value* as a mitigation option at jurisdictional scales. This framework is then applied to localized case studies to highlight how NETs could overcome socio-technical obstacles and/or unlock a variety of environmental and social co-benefits as part of the technology portfolio for achieving time-bound mitigation goals. Overall, the presentation aims to cut through what we see as a noisy discourse on NETs, which is wrapped-up in concerns that are dependent on scenario modeling, and offer a plain evaluation of NETs as a potential climate change mitigation option.

8:45 AM EN13.11.04
Synthesis of Hybrid Carbon Materials for CO_2 Capture Bashir E. Hasanov[1], Amira Alazmi[2,1] and Pedro Costa[1]; [1]King Abdullah University of Science and Technology, Saudi Arabia; [2]University of Hafr Albatin, Saudi Arabia

The continuous use of fossil fuels, along with other urban human activities, are behind an excessive emission of greenhouse gases. The intergovernmental panel on climate change (IPCC) stated that global greenhouse gas emissions must be reduced by 50-80 per cent by 2050 to mitigate climate change[1]. From the list of greenhouse gases, carbon dioxide (CO_2) has been considered a key contributor to the current state-of-affairs[2]. Therefore, there is a pressing demand for carbon capture and storage (CCS) technologies that allow for the capture and storage of CO_2 produced from fossil fuels. Solid porous adsorbent materials are the most competitive and promising candidates for CCS technologies, offering a high uptake capacity and tailored selectivity towards specific gases[3-5]. Among these materials, biomass and microporous carbons have come into prominence due to a set of desirable characteristics such as high availability of source precursors, ease of preparation, low-cost production, highly developed porous structure, moderate adsorption heat and the possibility to induce an abundance of functional groups.
In this communication, we report a porous carbon-carbon powdered mixture designed to perform CO_2 capture. The hybrid powder is constituted by KOH activated hydrothermally carbonised palm date seeds (HTC-PDS) and reduced graphene oxide (rGO). Previous work with the KOH activated HTC-PDS component showed interesting results for CO_2 uptake[6]. In the present case, we mixed HTC-PDS with rGO in different ratios before activating the powder with alkaline KOH. The oxygen functional groups (remainders in the rGO) could assist in optimising the CO_2 heat of adsorption in the hybrid material, enhancing the selectivity compared to the activated biochar. The approach was also designed to test if, beyond the porous development, the structure of the graphite building units in the two carbon components could be controlled and influence the adsorption of the greenhouse gas. The structural analysis, by Raman and X-ray diffraction, confirms the development of a more ordered structure. The optimised activated mixture had a specific surface area of 845 m^2/g, with 92% of the total surface area being microporous. The CO_2 adsorption capacity (at 1 bar, 273 K) was 3.40 mmol/g.

Redox-Active Metal Oxide Materials for Thermochemical Cycles—Key Thermodynamic Principles Ellen B. Stechel, Alberto de la Calle, Ivan Ermanoski and James E. Miller; Arizona State University, United States

High-temperature endothermic reduction of redox-active metal oxides, which can exchange oxygen between the solid and the gas phase at achievable conditions (where what is achievable remains an open question for the field), converts thermal energy to stored chemical energy. A subsequent re-oxidation step either recovers the stored energy as heat or utilizes it to drive other chemical reactions. If the re-oxidation step restores the material to its original state so that the two steps can repeat indefinitely, the sequence of reactions constitutes a thermochemical cycle. Two related processes (reversibly re-oxidizing with oxygen or affecting bond breaking by re-oxidizing with CO_2 and/or water) are somewhat analogous; the production of energized carriers (H_2 and/or CO) is significantly more constrained by thermodynamics and hence subject to greater challenges to objectives for high efficiency and low cost. Nonetheless, both chemistries have been of increasing interest due to their potential for high utilization of the sunlight in high direct normal irradiance (DNI) regions and economic competitiveness for clean energy, and most recently as a role in achieving negative emissions and closing the carbon cycle.

This presentation will discuss new revelations in the thermodynamics of the redox-active metal oxide and the operating conditions of a cycle. We will show recent progress towards developing high-performing materials and cycles for thermochemical energy storage and CO_2/H_2O splitting.

A Tale of Two Surface Terminations—Microscopic Insights into the Interaction of $BiVO_4$ with Water in Photoelectrochemical Applications Wennie Wang[1], Adam M. Hilbrands[2], Chenyu Zhou[3], Emily Chen[1], Marco Favaro[4], David Starr[4], Kyoung-Shin Choi[2], Mingzhao Liu[3] and Giulia Galli[1,1,5]; [1]The University of Chicago, United States; [2]University of Wisconsin–Madison, United States; [3]Brookhaven National Laboratory, United States; [4]Helmholtz-Zentrum Berlin, Germany; [5]Argonne National Laboratory, United States

Extracting hydrogen fuel from water splitting will require identifying and optimizing materials for the oxygen evolution reaction, as it is a major bottleneck in water splitting reactions. Photoelectrochemical cells have been at the forefront of technologies with the potential to realize a hydrogen economy at scale, and transition metal oxides in particular have garnered significant interest as photoelectrodes. Bismuth vanadate ($BiVO_4$) is one such oxide with numerous advantageous optoelectronic properties that make it amenable as a photoanode for oxygen evolution. However, progress towards achieving the optimal photocurrent densities and performance of $BiVO_4$ as a photoanode has not been systematic, thus necessitating the need to mechanistically understand its material properties, especially at the surface/interface.

Here, we present a combined experimental and computational study aimed at an atomic-level understanding of the $BiVO_4$ (010) surface with water. Our previous work [1] demonstrated that the surface composition plays a critical role in the photoelectrochemical performance and identified that the relevant surface is actually Bi-rich, not a 1:1 Bi:V ratio as previously thought. Building on this understanding, we performed first-principles calculations with Quantum ESPRESSO (https://www.quantum-espresso.org/) and Qbox (http://qboxcode.org/), and used resonant PES and XPS to elucidate the microscopic interactions between the $BiVO_4$ surface and water while varying the surface termination. In this presentation, we will compare and contrast the changes in surface energetics between different surface terminations of the $BiVO_4$ (010) surface upon immersion in water and discuss ways in which this could impact photoelectrochemical performance.

Fractal Exfoliation—Mechanisms of Rapid Hydrogen Generation From Liquid-Metal-Activated Aluminum Water Reactions and Their Practical Implications Peter Godart and Douglas P. Hart; Massachusetts Institute of Technology, United States

Aluminum is a promising energy carrier due to its abundance, low cost, and ability to react with water to produce hydrogen gas at a high volumetric energy density (up to 36.3 MJ/L Al). Ordinarily, aluminum's passivating oxide layer that rapidly forms upon exposure to oxygen prevents its reaction with water; however, in recent years, numerous promising approaches to disrupting this oxide layer have been developed that utilize a variety of room-temperature-liquid metal alloys containing some combination of gallium, indium, and tin, for example. In this work, an activating alloy composed of eutectic gallium and indium ($eGa_{0.8}In_{0.2}$) was studied due to its ability to activate bulk aluminum particles at added mass ratios below 5%. Prior research had shown that surface-treating bulk aluminum pellets (>5 mm in diameter) with this alloy results in complete penetration of the liquid metal along the aluminum grain boundary network, enabling near-unity theoretical hydrogen yield fractions in subsequent reactions with water. Despite the efficacy of this approach for producing hydrogen, however, numerous questions remain about the nature of the underlying reaction mechanism, in particular what happens to the eGaIn throughout the reaction.

In this work, experimental techniques were developed to carry out the aluminum-water reaction at arbitrarily slow reaction rates via controlled exposure to water vapor at room temperature. By starting and stopping the reaction at various stages in the absence of liquid water, standard SEM-EDS and XRD techniques could be used to study the reaction mechanism in significantly greater detail than before. The results of these experiments show that the aluminum-water reaction occurs in two primary stages: (1) rapid disintegration of the bulk aluminum along its grain boundaries via a fractal-like exfoliation process, and (2) the subsequent reaction of water at unoxidized sites on the freshly exposed aluminum grain surfaces. The phase of the activating eGaIn was also tracked and imaged at various stages of the reaction for the first time, showing ultimately that during the bulk disintegration process, reactions between gallium and ambient water and oxygen lead to the dealloying of the initial eGaIn, leaving behind micron-scale solid indium spheres. Given the high cost of the eGaIn relative to the input aluminum, their recovery is important for many practical applications. The operational implications of these results are discussed, and methods for recovering the activating metals are proposed.

Modulating Interfacial Charge Density of NiP_2–FeP_2 via Coupling with Metallic Cu for Accelerating Alkaline Hydrogen Evolution Ashwani Kumar and Hyoyoung Lee; Sungkyunkwan University, Korea (the Republic of)

Developing efficient earth-abundant electrocatalysts to replace high-cost Pt for alkaline hydrogen evolution reaction (HER) is crucial for sustainable hydrogen production. However, an additional sluggish water dissociation step associated with alkaline HER poses a major bottleneck for real applications. Recently, developing heterostructures catalysts with an electronegative atom (P, N, O, and S) acting as a base to trap the H* has emerged as a paramount strategy to boost HER activity. However, the alkaline HER activity of most of the heterostructure-based catalysts cannot surpass the commercial Pt, due to inadequate H* adsorption energy (ΔG_{H^*}) and high kinetic barrier for water dissociation, mainly determined by the electronic structure and localized charge-density at the interface-region.

Herein, density functional theory (DFT) predictions reveal that the electronic structure and localized charge density at the heterointerface of NiP_2–FeP_2 heterostructure can be significantly modulated upon coupling with metallic Cu, resulting in optimized proton adsorption energy and reduced barrier for water dissociation, synergistically boosting alkaline HER. Motivated by theoretical predictions, we developed a facile strategy to fabricate interface-rich NiP_2–FeP_2 coupled with Cu nanowires (Cu_{NW}) grown on Cu foam (NiP_2– FeP_2/Cu_{NW}/Cu_f). Benefiting from the superior intrinsic activity, conductivity, and copious active sites, the obtained catalyst exhibited exceptional alkaline HER activity requiring a low overpotential of 23.6 mV at −10 mA/cm^2, surpassing the state-of-the-art Pt. Additionally, a full electrolyzer required a cell voltage of 1.42/1.4 V at 10 mA/cm^2 in alkaline water/seawater with promising stability. This work highlights the importance of optimizing HER kinetics and offers a novel strategy for designing advanced electrocatalysts for various catalytic reactions (CO_2RR, ORR, OER, NRR, and so on).

11:45 AM EN14.01.05
Stabilizing OOH* Intermediate via Pre-Adsorbed Surface Oxygen of Single Ru Atom-Bimetallic Alloy for Ultralow Overpotential Oxygen Generation Jinsun Lee, Ashwani Kumar and Hyoyoung Lee; Sungkyunkan University, Korea (the Republic of)

Designing an efficient oxygen evolution reaction (OER) electrocatalysts based on single-atom catalysts is a highly promising option for cost-effective alkaline water electrolyzers. The main bottleneck in the practical water electrolysis system is the sluggish oxygen evolution reaction (OER) due to multiple proton/electron-coupled steps. Current technologies involve noble metal (Ir, Ru) or earth-abundant hydroxides/oxides as anodes; however, the scarcity and semiconducting nature, respectively, of these materials limit their activity. Unfortunately, earth-abundant metallic alloys have not been employed for OER. Recent work showed that single-atom catalysts (SACs) possess peculiar electronic features and near-unity atom economy, yet poor intrinsic activity and stability hinder their practical applications.

Overall, the instability of the OOH* intermediate and the high energy barrier for the rate-determining step (RDS) (O* to OOH*) on pure bimetallic alloy surfaces represent serious challenges and must be overcome for replacing Ir/Ru as anode materials based on an atomic level of understanding.

In this work, we introduce a simple approach to stabilize OOH* intermediates on a surface oxygen-rich $CoFe_2$/G alloy with homogeneously anchored Ru single atom (0.1 at.% of Ru) sites to boost the intrinsic activity via a facile micelle incorporated sol-gel and carbothermal reduction method. State-of-the-art characterizations including XANES, EXAFS, AC-TEM, and XPS supported by theoretical calculations confirmed the anchoring of isolated Ru atoms into the surface oxygen-rich $CoFe_2$ alloy. Remarkably, the resulting $Ru_{SA}CoFe_2$/G delivered excellent OER activity with an overpotential as low as 180 mV at a current density of 10 mA cm^{-2} and a reasonable Tafel slope of 51 mV dec^{-1} in a 1 M KOH aqueous solution. These results surpassed reported literature and state-of-the-art Ru-based electrocatalysts (RuO_2 and 5% Ru/C). Density functional theory (DFT) calculations revealed that the pre-adsorbed oxygens on $Ru_{SA}CoFe_2$ (110) efficiently stabilized the OOH* intermediates and the isolated Ru sites further dramatically reduced the Gibbs free energy for the RDS (O* to OOH*), thereby accelerating the OER process in alkaline medium. To meet the industrial standards of alkaline water electrolysis, we constructed a Ni_4Mo (-) // $Ru_{SA}CoFe_2$/G (+) alkaline electrolyzer demanding a very low cell voltage of 1.48 V at a current density of 10 mA cm^{-2}, which was much lower than those values for a commercial Pt/C-RuO_2 couple (1.65 V at 10 mA cm^{-2}).

SESSION EN14.02: Hydrogen Production II
Session Chairs: Ming Dao and T. Venkatesh
Tuesday Afternoon, November 30, 2021

1:30 PM EN14.02.01
Composite and Structured Electrodes for High-Performance Water Photooxidation Maxime Dufond[1], Sandra Haschke[2], Chiara Cozzi[3], Giuseppe Barillaro[3], Gabriel Loget[4], Julien Bachmann[2] and Lionel Santinacci[1]; [1]CNRS - Aix-Marseille Univ., France; [2]Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany; [3]Università di Pisa, Italy; [4]CNRS - University of Rennes 1, France

Among numerous semiconductors that can be used for water photosplitting, Si is highly interesting because it absorbs light in the visible range and its electronic structure is suitable to drive water photooxidation [1]. However, Si corrodes strongly in KOH and it is highly reflective.
The concept, presented, here, consists of successively depositing a protective layer and a catalyst onto the Si surface to extend the lifetime and the efficiency of the photoelectrode. To further improve the performances, various surface structuring methods are used to enhance the light absorption, enlarge the active area, and improve the charge collection. Various electrochemical structuring methods have been used to fabricated three different surface geometries: macropores (SiMP) [2], nanospikes (SiNS) [3], and micropillars (SiPillars) [4]. Those different morphologies show a large active area and a low reflectivity. Atomic Layer Deposition (ALD) is a well-adapted method to coat such tortuous surfaces. Thus, it has been applied to grow thin protective oxide layers (TiO_2 or Fe_2O_3) onto Si and SiMP, SiNS and SiPillars. To enhance the photocurrent and to lower the overvoltage corresponding to water photooxidation, metallic Ni has been deposited onto TiO_2-covered Si through a two-step process: (i) conformal ALD of NiO from Ni(CpEt)2 and O3 and (ii) the reduction to Ni by annealing under H_2 atmosphere. Ultra-low loads of IrO_2 have been deposited on Fe_2O_3-covered Si and ultra-thin TiO_2 capping allows for stabilizing the catalyst in an alkaline medium.
A detailed electrochemical study has been performed to assess the stability of the composite electrodes and to measure the water photooxidation performances. The TiO_2 dissolution at open circuit potential under a low illumination mechanism is identified. It proceeds through the insertion of H into the TiO_2 [5].
The efficiency of such multilayered and structured photoelectrodes is drastically improved using significantly fewer catalysts and the photoanodes exhibit long-term stability. The SiNSs covered by Fe_2O_3 and IrO_2 show, indeed, a photocurrent improved by a factor. It demonstrates that the appropriate combination of materials on the surface exhibiting the optimized geometry leads to high-performance photoanodes.

Enhanced Photoelectrochemical Water Splitting *via* Engineered Surface Defects of $BiPO_4$ Nanorod Photoanodes Nageh K. Allam; American University in Cairo, Egypt

Herein, we report on the defect engineering of $BiPO_4$ nanorods (NRs) *via* a facile room-temperature template-free co-precipitation method, followed by hydrogen treatment. The hydrogen treatment temperature determined the type of induced defects in the fabricated $BiPO_4$ NRs and consequently their photocatalytic performance. Upon varying the annealing temperature, the x-ray diffraction (XRD) analysis showed phase transformation and x-ray photoelectron spectroscopy (XPS) analysis revealed variation in the oxygen vacancy content. At moderate treatment temperatures (200-300ºC), shallow defects were predominant, which extended the optical activity of the material to the visible region and increased the photocurrent 3 times when compared to that of bare $BiPO_4$ NRs. However, treatment at higher temperatures completely altered the crystalline structure, destructed the morphology of the $BiPO_4$ NRs, and severely affected the photoelectrochemical performance.

2:00 PM EN14.02.05
Optimization of Functionally Graded Titanium Oxides Through Soft Chemistry Larissa S. Chaperman, Fayna Mammeri and Souad Ammar; Université de Paris, France

Within the current context of energy crisis and climate changes, the search for versatile, clean and sustainable energy sources is vital to reduce our dependency on fossil fuels. As such, photoelectrochemical (PEC) water-splitting arises as an ideal route for the obtention of hydrogen: by using sunlight as power input, it is possible to obtain a high-energy, carbon-free fuel.
In this work, we propose the elaboration of functionally graded photoanodes based on titanium oxides through a simple and fast soft chemistry route. The resulting photoanode presents an external mixed-phase TiO_2 layer that transitions to titanium suboxides (including Magnéli phases) allowing prompt charge separation and transport of the photogenerated electrons towards the metallic Ti support for current collection.
Two main factors enable the superior performance of the photoanode: an increased light absorption (due to the synergy between anatase and rutile domains in intimate contact at the outmost layer, and to Ti^{3+} species present at the oxygen deficient subjacent layers) and a more effective charge separation and transport (facilitated by the alignment of the bandgaps within the specific regions and by the increased conductivity of the titanium suboxides). [1, 2]
Such unique features are achieved by using chelating agents to direct the formation of the different TiO_2 phases, and subsequently enable the pore generation and localized reduction of TiO_2 during the calcination step. We explored variety of experimental conditions in order to optimize our process and to determine the influence of each parameter on the resulting material.
The obtained photocurrent densities (ranging from 0.25 to 0.80 mA cm^{-2} at0 and 1.2V vs. Ag/AgCl respectively, in 0.5 mol L^{-1} Na_2SO_4) are comparable or superior to doped, sensitized and/or nanostructured anatase photoanodes [3, 4], while not requiring the use of toxic components and while undergoing a much simpler, cheaper and environmentally benign productive process. As such, we envision a great potential for the development and up-scaling of adaptable, cheap and robust devices for hydrogen generation through water-splitting.

Non-Noble Metal MoS_2-CNO Heterostructure for Highly Efficient Electrocatalytic Hydrogen Evolution Reactions Jae-Jin Shim, Muhammed Shafi

Parasseeri and Mostafa Saad Sayed Mohamed; Yeungnam University, Korea (the Republic of)

Electrochemical water splitting is one of the most efficient techniques to produce hydrogen, which provides clean and sustainable energy. Developing an efficient catalyst for hydrogen evolution reaction (HER) based on 2D molybdenum disulfide is a challenge because of restacking of MoS_2 layers that leads to insufficient access to active sites. In this study, the drawbacks of 1T MoS_2 catalyst were overcome by employing carbon nano-onion (CNO). The unique CNO-MoS_2 heterostructure formed by growing few-layered 2D 1T MoS_2 on the CNO core facilitated smooth and barrier-free charge-transfer through the heterojunction formation. This heterostructure not only mitigates restacking but also maintains the structural stability, providing a long-term high performance catalyst. This CNO-MoS_2 exhibited an excellent HER performance with an overpotential of 53 mV *vs.* RHE and Tafel slope of 40.8 mV dec^{-1} for over 25 h, showing it one of the best HER catalysts next to platinum. This study highlights a new highly stable highly performing non-noble metal catalyst for electrochemical water splitting applications.

2:30 PM EN14.02.07
Surface Engineering to Improve Hydrogen-Evolving Electrode Performance Jack R. Lake[1], Alvaro Moreno Soto[1,2] and Kripa K. Varanasi[1]; [1]Massachusetts Institute of Technology, United States; [2]Universidad Carlos III de Madrid, Spain

Gas evolution at electrochemical electrodes is important for many industrial applications. Perhaps the largest activities where electrochemical bubble generation is critical are the chlor-alkali (chlorine gas production) and Hall-Héroult (electrochemical aluminum smelting) processes. Significant effort goes towards mitigating the “anode effect” of the Hall-Héroult process, where carbon dioxide gas inactivates the carbon anode, causing catastrophic increases in overpotential. Similar inefficiencies and problems are caused during water electrolysis when bubbles adhere to or flood electrodes. The limiting effects of bubbles no doubt limits the adoption of traditional, low-temperature electrochemical methods for hydrogen generation from renewable electricity, leaving natural gas reforming as the dominant form of hydrogen production in the US currently. In this way, both understanding and mitigating the negative impacts that bubbles have on electrode performance offers a unique path to enable low-temperature alkaline water electrolyzers to become a commercially viable route of hydrogen production from renewable electricity.

A key disadvantage for alkaline electrolyzers is that while their porous electrodes can increase the active area of the catalyst, the nature of the catalyst material, like nickel-foams, causes the evolved bubbles to stick, inactivating the catalyst surface and causing significant ohmic and activation losses. The extent to which these bubbles can restrict electrochemical performance is significant. For example, even for the well-established chlor-alkali process, the attachment of bubbles to electrode surfaces accounts for approximately 20% of the overpotential at industrially relevant current densities.

These problems motivate this work as we investigate the way that bubble inefficiencies manifest themselves for different types of electrode configurations for hydrogen-evolving electrodes. While previous research has characterized the impacts of electrochemical bubbles, approaches to mitigate bubbles are limited and typically focus on novel cell design, rather than the design of the electrode itself. Here, we will focus on how different architectures of the electrodes affect the performance of the electrode while systematically studying the differences that arise from a bubble perspective. In general, many approaches for improving the performance of non-gas evolving electrodes are currently used in gas-evolving systems as well. However, we will show that the inherent tradeoffs between traditional methods for improving electrode performance, and those that should be adopted for gas-evolving electrodes are distinct. As a result, we provide a novel framework for designing hydrogen-evolving electrochemical electrodes. Furthermore, implementations of the novel electrode motifs based on this new design perspective are also envisioned to improve the performance of water electrolyzer systems.

2:45 PM EN14.02.09
Dense Hydrogen Separative Membrane Fabricated by Atomic Layer Deposition Badie Clemence[1], Christophe Charmette[2], Martin Drobek[2], Anne Julbe[2], Jean-Manuel Decams[3], Mikhael Bechelany[2] and Lionel Santinacci[1]; [1]Aix-Marseille Université, France; [2]Université de Montpellier, France; [3]Annealsys, France

To provide affordable H_2 with high purity for energy applications, new strategies as H_2-selective membranes gained in interest. This technology presents interesting benefits as it is cost-effective and have a reasonable environmental impact. In addition, a large variety of materials is available, thus, the composition of the membrane can be adapted to the working temperature. This study focuses on the fabrication of dense membranes able to operate at the high temperatures required in industrial processes (400-800°C). The specificity of the present approach is to fabricate new nanocomposite devices that combine the stability of a ceramic matrix, titanium nitride, with the catalytic effect of palladium nanoparticles used as nanofillers. Both TiN films and Pd nanoparticles are deposited onto a hetero-porous alumina tubular membranes by Atomic Layer Deposition (ALD). The composite membrane is optimized to reach the highest H_2-selectivity and permeation (flow), by finely tuning the thickness and the chemical composition of the TiN/Pd coating. ALD is an original technique in this field, but it is well adapted because it allows for coating nanostructured substrates with an excellent control of the thickness and composition.
The fabrication of the membrane follows two steps. First, the TiN deposit must fill the alumina porosity. The coating forms a dense layer on the nanoporosity at the inner part and penetrates into the macroporosity of the outer part, covering the alumina grains. Afterwards, the Pd nanoparticles are deposited. The selectivity and the permeation of the TiN-Pd membrane are assessed using H_2 and N_2. The increase of the temperature up to 400°C allows for achieving an encouraging dihydrogen ideal selectivity and permeance of 35 and 258 GPU (Gas Per Unit), respectively. Moreover, these values increase during the measurement: the selectivity and the permeance rises up to 109 and 7018 GPU, respectively, after 4.5 h at 400°C. These performances are promising as a similar pure Pd membrane presents an ideal selectivity of 23 and a permeance of 991 GPU at 188°C [1]. The investigation of the thermal evolution and the stability of the present membrane is then required. Complementary results will therefore be presented. In another hand, a Pd-based membranes issue is their poisoning in presence of CO and sulfides gases that are present in industrial processes. The ALD of both TiN and Pd can be optimized to encapsulate the Pd nanoparticles within the TiN matrix. This could be a future route to take up the poisoning obstacle and to improve the performances.

Nucleation and Growth of Electrodeposited Cu_2O on FTO Substrates Akhilender J. Singh, Garima Aggarwal, Balasubramaniam Kavaipatti and Sushobhita Chawla; Indian Institute of Technology, Bombay, India

Nucleation and growth mechanism studies of functional oxide films are essential to gain an understanding and thereby control their morphologies. Towards this, we study the effect of solution pH and deposition potential on the nucleation and growth (NG) of the technologically important material Cu_2O as a thin film on the FTO substrates. The Cu_2O films electrodeposited at a low potential value of -20 mV (vs. Hg/HgO) at pH 9 exhibit a slow layer-by-layer NG mode where the 2-D instantaneous nucleation (IN-2D) is identified as the primary contributor. The NG mechanism, however, switches to 3-D diffusion-controlled instantaneous and progressive ($IN\text{-}3D_{diff}$ & $PN\text{-}3D_{diff}$) mode at the moderate potential value of -100 mV. Further raising the potential to -180 mV results in a complex process involving multiple contributions from $IN\text{-}3D_{diff}$ & $PN\text{-}3D_{diff}$ which would result in an island type morphology. In contrast, the films deposited at pH 12 show a minimal contribution from the 2-D type NG mechanism even at low potential values. At a low potential of -170 mV, the major contribution comes from the diffusion-controlled 3-D type progressive ($PN\text{-}3D_{diff}$) NG process. An additional contribution; the charge transfer controlled instantaneous ($PN\text{-}3D_{ct}$) NG process runs in parallel with previous processes when films are subjected to a moderate potential of -210 mV. At high potentials, however, the situation becomes similar to pH 9 having multiple contributions from both charge transfer and diffusion controlled IN and PN processes. The modeling of experimental data reveals that electrodeposition in a low pH, as well as low potential, is preferable to obtain a layer-by-layer deposition of Cu_2O thin films whereas a 3-D island type NG occurs at high potentials. These results pave the pathway to tailor the morphology of other technologically important metal oxides in a similar fashion.

EN14.03.04
Multiple Synergistic Effects of Zr-Alloying on the Phase Stability and Photostability of Black Niobium Oxide Nanotubes as Efficient Photoelectrodes for Solar Hydrogen Production Nageh K. Allam; American University in Cairo, Egypt

Niobium oxides exist in a plethora of metastable, stoichiometric, nonstoichiometric, and mixed phases, rendering the Nb-O systems very complicated and hard to study. These structures significantly differ in their catalytic activity, electrical conductivity, and photoresponse. Herein, we demonstrate the ability to selectively fabricate pure T-Nb_2O_5 *via* the addition of small amount of Zr as a phase stabilizer. Moreover, we were able to tune the photoactivity of the material *via* hydrogen annealing. The photoactivity and stability of the fabricated black Zr-doped Nb_2O_5 nanotubes were correlated with the nature of induced defects upon hydrogen annealing and Zr doping. The H_2-treated nanotubes showed extraordinary and remarkable stability and photoactivity upon their use for solar water splitting. This was accompanied by a noticeable reduction in the bandgap energy from 3.23 eV to 2.5 eV, which is mainly correlated with the introduced oxygen vacancies within the lattice with a remarkable conductivity. Most importantly, the black-defective nanotubes exhibited a photocatalytic activity that is ~ 65 times that of the air-annealed counterparts. The optimized photoanodes attained a hydrogen production rate of ~ 496 µmol h^{-1} cm^{-2} in 1 M KOH, revealing increased charge carriers transport and separation. The Mott-Schottky and valence band XPS analyses confirmed the increased charge carriers' concentration and the appropriate band positions of the fabricated black nanotubes relative to the redox potentials of the water.

EN14.03.05
Structural Engineering of Ti-Mn Bimetallic Phosphide Nanotubes for Efficient Photoelectrochemical Water Splitting Nageh K. Allam; American University in Cairo, Egypt

Designing next-generation advanced electrode materials by engineering their structural and compositional features can provide a feasible strategy to enhance the electrochemical performance of energy conversion devices. In this study, the rational pathway to design and fabricate nanotube arrays of titanium manganese phosphide via etching of titanium-manganese alloy followed by plasma phosphidation in PH_3 environment is presented and discussed. The structural and elemental analyses of the air-annealed electrodes before plasma treatment confirmed the presence of different binary oxides; TiO_2, MnO, and Mn_2O_3. However, the XPS fitting showed the presence of Ti^{3+} and higher ratio of MnO when annealed in hydrogen atmosphere. The presence of composite oxides resulted in a band gap reduction, which increased the light harvesting capability of the material. This synergetic effect resulted also in a shift in the open-circuit voltage (V_{OC}) and almost 10-fold increase in the photocurrent density compared to the performance of the nanotubes annealed in air. Mott-Schottky analysis showed a four-orders of magnitude enhancement in the carrier density for the electrodes annealed in Hydrogen and treated in PH_3-plasma compared to those annealed in O_2 or air, ascribed to the creation of Ti^{3+} defects and phosphidation. Our study thus paves the way to a new approach for creating high-performance hybrid electrodes for PEC water splitting.

EN14.03.06
Novel Bi-Based Photocatalysts with Unprecedented Visible Light-Driven Hydrogen Production Rate—Experimental and DFT Insights Nageh K. Allam; American University in Cairo, Egypt

Green and efficient energy technologies are a key point where nanoscience could make a difference in the paradigm shift from fossil fuels to renewable sources. One attractive possibility is the utilization of solar energy to obtain electricity or chemical fuel based on the ability of semiconductor nanomaterials to function as photocatalysts promoting various oxidation and reduction reactions under sunlight. We report on a novel class of Bi-based photocatalysts for hydrogen production via water splitting. A screening DFT investigation was performed on the $Bi_2(MO_4)_3$ (M = Cr, Mo, and W) systems. The $Bi_2(CrO_4)_3$ system exhibits the smallest band gap energy, the highest dielectric constant, and the highest absorption in visible region among the other counterpart materials. Consequently, $Bi_2(CrO_4)_3$ nanoparticles were synthesized via a simple one-pot method at room temperature and characterized by XRD, XPS, DRS, FE-SEM, HR-TEM, and Raman spectroscopy. The as-prepared yellow $Bi_2(CrO_4)_3$ nanoparticles exhibited a direct band gap energy of 2.45 eV. The photoactivity of the as-prepared $Bi_2(CrO_4)_3$ nanoparticles was tested toward the photocatalytic hydrogen production, where reasonable rates of 522.44, 174.15, and 88.24 µmol/g/h were achieved under UV, AM 1.5, and visible irradiations, respectively in the absence of any hole scavengers. Those rates are higher than those reported for Bi-based photocatalysts.

EN14.03.07
10-Fold Enhancement in Light-Driven Water Splitting Using Niobium Oxynitride Microcone Array Films Nageh K. Allam; American University in Cairo, Egypt

We demonstrate, for the first time, the synthesis of highly ordered niobium oxynitride microcones as an attractive class of materials for visible-light-driven water splitting. As revealed by the ultraviolet photoelectron spectroscopy (UPS), photoelectrochemical and transient photocurrent measurements, the microcones showed enhanced performance (~1000% compared to mesoporous niobium oxide) as photoanodes for water splitting with remarkable stability and visible light activity.

EN14.03.08
Computational Fluid Dynamic Modeling of Methane-Hydrogen Mixture Transportation in Pipelines Kun Tan, Devinder Mahajan and T. A.

Venkatesh; Stony Brook University, United States

Replacing fossil fuels and natural gas with alternative fuels like hydrogen is an important step towards the goal of reaching a carbon neutral economy. As an important intermediate step towards utilizing pure hydrogen, blending hydrogen in an existing natural gas network is a practical choice for reducing carbon emissions in the near future. A computational fluid dynamic (CFD) model is developed to quantify frictional losses and energy efficiency of transport of methane/hydrogen blends across straight pipe sections. The CFD model developed in the present study is first validated by verifying that the results obtained in the present study (for pressure drops, numerical friction number (f_N), and energy specific toll (EST) agree well with those obtained in an earlier study when identical boundary conditions and model parameters such as Redlich-Kwong equation of state, k-ε turbulence model and pipe wall roughness, are invoked. Furthermore, additional CFD models are developed to assess the effects of other factors such as 1) hydrogen concentration, 2) pipe surface roughness of common pipe materials, and 3) pipe diameter on the dynamics of blended gas flows. The principal conclusions from the present study are as follows: (i) High hydrogen concentration in the gas blends (i.e., greater than 25% and 50%) require higher energy for transporting the blended gases in the pipelines. (ii) Polyethylene (PE) or PE coated pipes, with smoother walls, are 33-40% more energy efficient in transporting gas blends than uncoated stainless steel pipes, which are 17-31% more energy efficient than the uncoated cast iron pipes. (iii) Due to relatively fewer gas interactions with wall surfaces which result in frictional losses, than in the case of smaller diameter pipes, it requires lesser energy to transport blended gases in larger diameter pipes. The CFD model and the simulation results provide valuable operational guidelines for transitioning natural gas networks to transport greener blends of methane and hydrogen.

EN14.03.09
Enhancing Photovoltage of Metal-Insulator-Semiconductor (MIS) Photoanode by Coordination Polymer via Chemical Deposition Ponart Aroonratsameruang[1], Gabriel Loget[2] and Pichaya Pattanasattayavong[1]; [1]Vidyasirimedhi Institute of Science and Technology, Thailand; [2]Université de Rennes 1, CNRS, France

One of the remaining challenges for the development of efficient photoelectrochemical water splitting systems is related to the photoanode, which requires a high-performance light absorber with an excellent catalyst to drive oxygen evolution reaction that needs high potential [1]. The metal-insulator-semiconductor (MIS) architecture employing Si as the photoanode is an attractive system due to the wide light absorption range of Si (E_g 1.1 eV) and high OER catalytic activity of metal [2]. For the latter, metal nanoparticles can be dispersed on the semiconductor surface via electrodeposition in Si MIS photoanodes [3]. Furthermore, surrounding the metal nanoparticles and the uncoated Si with a higher-work-function material leads to significant improvement of photovoltage due to the pinch-off effect [3]. Up to this point, the surrounding layer is generally the oxidized phase of the base metal, such as its oxide or oxyhydroxide, and the fabrication techniques used to introduce the surrounding layer are limited to a few choices, i.e., electrodeposition, photodeposition, or annealing methods [4]. Copper(I) thiocyanate (CuSCN) is a coordination polymer which can be prepared by a simple chemical deposition through conversion of Cu [5]. Because Cu and CuSCN have work functions of 4.5-4.9 [6] and 5.4 eV [7], respectively, the Cu/CuSCN junction on n-Si is expected to develop the pinch-off region and increase the performance. In this talk, we aim to highlight two key developments of Cu-based MIS Si photoanodes prepared by facile methods. Firstly, we employed electrodeposition to coat 30-nm Cu nanoparticles on n-Si, resulting in a photoanode with a low OER onset potential of 1.37 V vs reversible hydrogen electrode (RHE). Secondly, we added CuSCN on the n-Si/SiO_x/Cu photoanode via a chemical deposition in an aqueous bath containing ammonium thiocyanate. The presence of CuSCN on n-Si/SiO_x/Cu was confirmed by X-ray photoelectron spectroscopy and scanning electron microscopy. The optimal n-Si/SiO_x/Cu/CuSCN with a short CuSCN deposition time showed a 100-mV improvement in the onset potential relative to the unmodified n-Si/SiO_x/Cu. Based on open-circuit-potential measurements, the CuSCN-modified photoanode exhibited a high photovoltage of 460 mV. We believe that the findings can provide a new strategy for further surface modification of PEC devices to achieve low-cost solar harvesting technology.

EN14.03.10
HR-TEM Study of U Hydrides Mayerling Martinez[1,2], Miroslav Cieslar[2], Peter Minarik[2], Oleksandra Koloskova[2], Evgeniya Tereshina-Chitrova[2], Milan Dopita[2], Lukas Horak[2], Thomas Gouder[3] and Ladislav Havela[2]; [1]CRISMAT/Normandie University/CNRS, France; [2]Charles University, Czechia; [3]European Commission Joint Research Centre, Germany

U as interesting hydrogen storage medium forms with hydrogen the hydride UH_3, which has two allotropic cubic phases, known as α- and β-UH_3. While the transient phase α-UH_3 (*bcc* lattice of U filled with H) can be stabilized by alloying of Zr, other alloyed hydrides appear as nanocrystalline β-UH_3 phase (more complicated cubic with two different U positions), the grain size of which can be as small as 2-3 nm. Conventional XRD analysis, based on several very wide diffraction peaks, does not give in such case sufficient information e.g. about possible segregation of alloying elements. That is why methods like total scattering with PDF analysis have been applied [1].
Another method applied is Transmission Electron Microscopy, which allows structural characterization at the atomic level. The TEM study became even more important in the thin film research, in which it proved feasible to synthesize the hydride films by reactive sputter deposition of metals in H_2 containing Ar working gas [2,3]. Such synthesis requires typically low temperatures, which allow H to be embedded into the deposited material. Also this synthesis yields very small grain size, which is often accompanied by a pronounced texture. The information from glancing angle XRD is also in such situation limited.
Here we present results of High-Resolution TEM study both on the bulk alloyed UH_3 and on various U-H films. While crushed fine powder can be used as TEM sample in the former case, the films require the focused ion beam lift-out technique, which allows to obtain cross-sectional thin lamellae giving information on film thickness, individual interfaces to the substrate or possible capping layer, as well as on U phases in the main layer. In particular, despite of nanometer grain size it allows to distinguish well the β-UH_3 type phase from the UH_2 phase, which does not exist as a bulk phase but can be prepared in

the thin film form [4]. The study helped to exclude any possible segregation of Mo as alloying element and proved that spurious UO_2 remains on a very low level. The analysis is based on structural analyses using STEM and HR-TEM with subsequent Fourier analysis. The TEM micrographs were compared with simulated images using the JEMS software.
The work was supported by the Czech Science Foundation under the grant No. 21-09766S.

Experimental Investigation of Surface Resistivity of Yttrium Stabilized Zirconium as a Thin Film Matthew Melfi, Vincent De Castro and Mehmet A. Sahiner; Seton Hall Univ, United States

Solid Oxide Fuel Cells are devices that use electrochemical reactions to convert chemical energy from fuel to electricity. Solid Oxide Fuel Cells typically have three different layers, an anode, electrolyte, a cathode layer. In comparison with coal power plants, a Solid Oxide Fuel Cell, produces a higher electrical conversion efficiency. In the last couple of years, the electrical efficiency has increased from 40 to 60%. Solid Oxide Fuel Cells are modular in nature making the power output even greater. When combined with another form of energy the efficiency increases even more. However, Solid Oxide Fuel Cells typically operate at high temperatures (800-1000 degrees Celsius) which hinders the usability. At this high operating temperature, the materials that can be used are also limited. When lowering the operating temperature, the ohmic resistance increases. There are two ways to prevent this increase is to either to change the material used for the electrolyte layer or to make the electrolyte layer into a thin film. Typical Solid Oxide Fuel Cells use Yttrium Stabilized Zirconium as the electrolyte layer. In this research, the electrolyte layer will be a thin film of various concentrations, 1-10%, of the Yttrium Stabilized Zirconium. This layer is produced from a fine dimple grain structure allowing high flow of oxygen mobility. This mobility increases ionic conductivity and decreases the ohmic resistance. The goal of this research is to optimize the experimental film deposition parameters that will lead to minimum surface resistivity. These thin films are produced are produced by the Pulsed Laser Deposition method. This method of production has shown to produce a specific thin film thickness with repetition. With this method there are numerous parameters that can be adjusted. The pressure, frequency, laser energy, etc. The Yttrium Stabilized Zirconium is deposited onto Polished Zirconium, Sapphire, and Silicon. The differences of substrates were used to compare the different characteristics of Yttrium Stabilized Zirconium layer on different materials. An ellipsometer will be used to ensure the thickness of the Yttrium Stabilized Zirconium layer. These thin films will be characterized through electrical measurements such as 4-point probe resistivity measurements as well as Scanning Electron Microscopy, for the structural characterization.

EN14.03.12
$BaZr_{0.80}Y_{0.20}O_{3-d}$ - $SrCe_{0.95}Yb_{0.05}O_{3-d}$ Heterostructures for Proton Conducting Membranes Taner Ozdal, Gaye Ozdemir, Gulhan Cakmak, Berke Piskin and Fatih Piskin; Mugla Sitki Kocman University, Turkey

Separation membranes allow purification of hydrogen from gas mixtures produced by various methods, such as the reformation of natural gas, coal gasification, or the gasification of municipal waste. Hydrogen separated in this way may be used in fuel cells to generate electricity or may be fed directly to the natural gas grid to temporarly storage. It is likely that the current network of natural gas will soon be transformed into a “gas” grid where hydrogen would be an essential ingredient. All these require the use of efficient separation membranes, which would make the easy availability of hydrogen possible as is currently the case for natural gas. Thus, the separation membranes would have a much wider scope than normally anticipated and therefore there would be a need for separation membranes that are more efficient and in particular of low cost.

The current study concentrates on proton conducting oxides that can operate at temperatures higher than 450 °C and applicable to the steam reformation of natural gas including the water-gas shift reactions. Proton conducting oxides used for this purpose are quite attractive due to their high hydrogen selectivity and superior tolerance to possible toxic gases (e.g. CO, H_2S, etc.) that may be present in the gas mixtures.

The current study adopts a membrane design methodology based on combinatorial material science. This approach makes use of a magnetron sputtering system whereby a material library of thin-film membranes is produced in a single experiment. The library is then screened by four-probe resistivity and electrochemical impedance measurements so as to identify the compositions that are highly reactive with hydrogen. A map of reactive index prepared in this way is used to determine candidates for hydrogen separation. The membranes are then fabricated in the form of discs and tested for hydrogen permeability. In the current study, $BaZr_{0.80}Y_{0.20}O_3$-$SrCe_{0.95}Yb_{0.05}O_3$ heterostructures are investigated using the above methodology.

Bimetallic Nitrides on 3D Porous Nickel Foam as a Bifunctional Binder Free Electrode for Electrochemical Water Splitting Yamini Kumaran, Haralabos Efstathiadis and Iulian Gherasoiu; State University of New York Polytechnic Institute, United States

The rising need for renewable energy storage and conversion serves as the cause to explore suitable approaches to produce hydrogen. Among the different methods, electrochemical water splitting can produce hydrogen at low cost and high efficiency with non-noble metal catalysts, that can be used to accelerate the reaction. Until now, Pt/C and IrO_2 are found to be the best-known catalyst with very low overpotentials for hydrogen and oxygen evolution reaction, respectively. Yet, these are very costly and impractical for large scale industrial use. Hence, design and fabrication of low cost and highly efficient electrode is of utmost importance to produce hydrogen and oxygen with low overpotential thereby increasing the efficiency of overall water splitting. Transition metal oxides, nitrides and sulfides have been widely explored as catalysts for both HER and OER. Transition metal nitrides are found to have good electronic conductivity and superior corrosion resistance. In particular, Mo_2N exhibits high electrochemical stability and good activity towards HER in which the presence of nitrogen in the metal lattice increases proton adsorption. From the volcano plot which shows the activity of HER as a function of M-H bond strength it can be inferred that a nitride material combining Nickel which binds H weakly, along with molybdenum which binds H strongly, will have an activity as that of Pt. Further, VN has been reported to have good performance towards oxygen evolution reaction owing to its high density of states and good chemical stability. In this work, we introduce and study bimetallic nitrides (MoVN) on 3D porous Nickel foam for catalyzing water splitting reactions. Compared to electrodes with planar surfaces, the Nickel foam offers the advantage of a much larger reactive surface per unit of volume and weight, having the potential to increase the generation rate of H_2 and O_2 of the electrolysis cell. Further, the structural characterizations such as XRD, SEM is performed for the mirror samples. The performance of the electrode is tested in N_2/O_2 saturated 1M KOH solution. Hence, we report the synthesis of novel MoVN on Nickel foam using RF Magnetron co-sputtering as an efficient, bifunctional, binder free electrode for overall water splitting.

The Effect of Strontium Doping on Hydrogen Production of $La_{1-x}Sr_xMn_{0.6}Al_{0.4}O_3$ (x=0.2, 0.4 and 0.6) Perovskite Oxides via Thermochemical Water Splitting Seyfettin Berk Sanli, Ihsan E. Yigiter, Gulhan Cakmak, Fatih Piskin and Berke Piskin; Mugla Sitki Kocman University, Turkey

Hydrogen has a very important place for green-energy applications. In this context, thermochemical methods based on solar energy come to the fore in hydrogen production. It is possible to produce hydrogen without the need for purification via the two-step thermochemical water splitting (TWS) method. TWS uses metal oxides as redox materials allowing to produce of pure hydrogen at lower temperatures as compared to thermolysis. Therefore, the thermodynamics and kinetics of redox reactions are one of the important factors that determine hydrogen production efficiency and influenced by the structural properties of active materials used in these reactions. For this purpose, perovskite-oxides draw attention to be able to use in TWS reactions due to providing higher structural stability with allowing compositional diversity.

We focused on the structural properties in terms of morphology and surface area, investigating the compositional dependence of $La_{1-x}Sr_xMn_{0.6}Al_{0.4}O_3$ (x=0.2, 0.4 and 0.6) perovskite oxides to provide higher hydrogen production by TWS.

In this study, $La_{0.6}Sr_{0.4}Mn_{0.6}Al_{0.4}O_3$ (LSMA6464), $La_{0.5}Sr_{0.5}Mn_{0.6}Al_{0.4}O_3$ (LSMA5564), and $La_{0.4}Sr_{0.6}Mn_{0.6}Fe_{0.4}O_3$ (LSMA4664) were synthesized by Pechini method. As a precursor, $La(NO_3)_2\bullet 6H_2O$, $Sr(NO_3)_2$, $Mn(NO_3)_2\bullet 4H_2O$, and $Al(NO_3)_3\bullet 9H_2O$were used. After pre-calcination at 250 °C for 2 hrs, calcination was carried out at 1300 °C for 6 hrs to obtain desired crystal structure. The crystal structure of perovskite-oxide materials was analyzed by an X-Ray Diffractometer (XRD, Bruker D8 Advance) using Cu-Kα radiation. It was determined that synthesized LSMA6464, LSMA5564, and LSMA4664 perovskite oxides have a cubic structure. The morphology of LSMA6464, LSMA5564, and LSMA4664 was observed by scanning electron microscopy (SEM) and average particle size, as ca. 0.1 μm. BET analysis results confirmed that the increased A-site dopant, Sr, ratio decreased the surface area as 35 m^2/g, 28 m^2/g and 25 m^2/g for LSMA6464, LSMA5564, and LSMA4664, respectively. Correlated with the structural effect of Sr, two-step water splitting results show that increases in the amount of Sr dopant, causes less hydrogen production for LSMA6464, LSMA5564, and LSMA4664 perovskite oxides as 257 μmol/g, 170 μmol/g and 115 μmol/g, respectively.

Overcome the Dilemma between Low Loading and High Power Density for PEMFCs Using Ultrathin 1D PtCo Nanowire Catalyst Jin Huang[1], Bosi Peng[1,1], Qingying Jia[2], Xiangfeng Duan[1] and Yu Huang[1]; [1]University of California, Los Angeles, United States; [2]Northeastern University, United States

Platinum (Pt) group metals (PGMs) remain the best catalyst choice to speed up the sluggish oxygen reduction reactions (ORR) at the cathode of proton-exchange membrane fuel cells (PEMFCs). However, the requirement of a large amount of PGM catalysts has prevented the widespread adoption of PEMFCs. To address this challenge, it is central to achieve low PGM loading PEMFCs with high performance. However, using low PGM loading inevitably compromises the performance at the high current density region. To overcome this dilemma, we demonstrate an ultralow Pt loading and high-performance membrane electrode assembly (MEA) using ultrathin platinum-cobalt nanowires (PtCoNWs) as the cathode catalysts. The PtCoNWs showed an exceptional high electrochemically active surface area (ECSA) and exhibited a record-high mass activity (MA), far surpassing the Department of Energy (DOE) 2020 beginning of life (BOL) target (0.44 A/mg_{PGM}). In addition, PtCoNWs displayed an ultrahigh total Pt utilization, surpassing all state-of-the-art Pt-alloy catalyst performance in MEA. *In-situ* XAS studies suggest that the high atomic ordering core of the PtCoNWs contributes to the high ORR activity and stability of PtCoNWs in PEMFCs.

Nickel, Cobalt and Copper Electrodeposition on Vulcan XC-72R Via the Rotating Disk Slurry Electrodeposition (RoDSE) Technique for the Oxygen Evolution Reaction (OER) and Oxygen Reduction Reaction (ORR) in Alkaline Medium Joesene Soto-Perez[1], Carlos R. Cabrera-Martinez[1], Armando Pena-Duarte[2] and Pedro Trinidad[1]; [1]University of Puerto Rico, Río Piedras, United States; [2]University of Puerto Rico at Río Piedras, United States

Since the start of fuel cell research, electrocatalysts based on Pt have shown remarkable ORR performances. However, the high cost and low abundance of Pt limits their practical applications in the vehicle industry. The combination of Pt with first-row transition metals lowers the cost and enhances the electrocatalyst activity in the cathode compartment where the Oxygen reduction reaction (ORR) occurs. Additionally, when using an alkaline medium, the ORR is enhanced, metal oxides are more stable and non-noble metal could be used. In this study, we synthesized first-row transition metal catalysts (M= Ni,Co and Cu)—with the Rotating disk slurry electrodeposition (RoDSE) technique—supported on Vulcan XC-72R. We were able to electrodeposit Ni and Co on Vulcan XC-72R using an electrochemical potential of -0.75V vs. RHE and -0.80V vs. RHE to electrodeposit Cu on Vulcan XC-72R applying the RoDSE methodology in 0.1M $KClO_4$. These M/Vulcan XC-72R catalysts were modified with a Pt precursor via spontaneous galvanic displacement (SGD) and we obtained Pt-M/Vulcan XC-72R to catalyze the ORR in an alkaline medium. First, we tested the M/Vulcan XC-72R for the oxygen evolution

reaction (OER) and Ni/Vulcan XC-72R provided the lowest overpotential with 450 mV vs. RHE at 10 mA/cm^2_{disk} in 0.1M KOH. We also performed oxygen polarization to characterize the electrochemical activity towards oxygen reduction in an alkaline medium. Our results indicated that under controlled temperature (25.0°C), a mass loading of 100 mg/cm^2 on a glassy carbon rotating electrode and at 1,600 rpm the electrocatalysts revealed good performance. The PtNi-Vulcan XC-72R, PtCo-Vulcan XC-72R and PtCu-Vulcan XC-72R catalysts obtained half-wave potentials ($E_{1/2}$) of 0.88 V, 0.88 V and 0.82 vs. RHE, respectively, under an oxygen atmosphere in 0.1M KOH, compared with commercial Pt/Vulcan XC-72R $E_{1/2}$ = 0.83 V. The particle sizes of the catalysts were obtained using the X-ray diffraction (XRD) diffractograms of the nanoparticles and the Scherrer equation analysis, suggesting sizes between 2-10 nm. Upcoming studies will focus on evaluating the durability of the catalysts under electrochemical cycling and the electronic properties of the samples using X-ray Absorption Spectroscopy (XAS) techniques to determine their atomic states and coordination environments. Quantifying the Relationship Between Microstructure and Performance Improvements in Ni-infiltrated NiYSZ Anodes Jillian Rix, Hector Grande, Uday Pal, Srikanth Gopalan and Soumendra Basu; Boston University, United States

Infiltrated nickel nanocatalysts have been shown to improve the performance of NiYSZ fuel cell anodes, especially at low temperatures, by decreasing feature size and increasing triple phase boundary (TPB) density. However, estimating infiltrated TPB density by microstructural characterization and relating deposited nanocatalyst morphology to performance improvements is difficult because of the complexity of the deposited nanoparticle and scaffold microstructure. In this study, performance improvements in Ni-infiltrated NiYSZ anode symmetric cells are quantified by electrochemical impedance spectroscopy (EIS) and distribution of relaxation times (DRT) analysis, and the microstructure characterized by focused ion beam/scanning electron microscopy (FIB/SEM) analysis and cross-sectional SEM. A relationship between infiltrated microstructure and performance improvements is discussed.

11:15 AM EN14.04.05
Laser-Fabricated Tantalum-Based Nanomaterials as Bifunctional Catalysts for Direct Peroxide-Peroxide Fuel Cells Nathalie Herlin-Boime[1], Xiaoyong Mo[2] and Edmund Tse[2]; [1]CEA Saclay, France; [2]City University of Hong Kong, China

Efficient and durable electrocatalysts are instrumental to enabling next-generation fuel cell technologies. At present, costly precious metals are used as state-of-the-art catalysts. In this report, cost-effective tantalum-based alternatives are synthesized via a green and scalable laser pyrolysis method as bifunctional catalysts for direct peroxide-peroxide fuel cells. By varying the laser power, reactor parameters, and ammonia flow rate, five Ta/N/O nanomaterials are prepared containing Ta_2O_5, Ta_4N_5, Ta_3N_5, and TaN in tunable ratios. Electrochemical studies in neutral and alkaline conditions demonstrate that Ta_4N_5 is the active component for H_2O_2 oxidation and reduction. Kinetic isotope effect (KIE) studies show that protons are involved at or before the rate-determining step (RDS). Long-term stability studies indicate that Ta_3N_5 grants Ta/N/O nanomaterials their enhanced longevity during electrocatalytic operations. Taken together, Ta/N/O can act as active and robust electrocatalysts for H_2O_2 reduction and oxidation. Laser pyrolysis is envisioned to produce refractory metal nanomaterials with boosted corrosion resistance for energy catalysis.

Self-Assembling Amine-Borane Adducts to Nanostructure Ammonia Borane as Precursor of Nanostructured Boron Nitride for Hydrogen Storage Kevin Turani-I-Belloto, Johan Alauzun and Umit Bilge Demirci; University of Montpellier, France

Ammonia borane NH3BH3 (AB), a remarkable hydrogen storage material carrying 19.6 wt% of hydrogen, owns attractive properties [1]. It (in thermolytic conditions) has been understandably much investigated within the past two decades leading to destabilization strategies in order to decrease the onset dehydrogenation temperature (<100°C). Nanosizing AB is an attractive approach to make it suitable for solid-state hydrogen storage. The destabilization of the borane (i.e. modified thermal stability and reactivity) has been anticipated via changed atomic charges of the NH3BH3 molecule, perturbed intermolecular N−H H−B network and lowered activation energy. The nanoconfinement of AB has then shown new pathway to dehydrogenation properties. With this knowledge, it was demonstrated that different porous structures so called scaffolds can be used to improve dehydrogenation properties of AB, such as silica (ex. SBA-15) [2], MOF (ex. Mg-MOF-74) [2] or polymers (ex. PMMA) [2]. In regards to efficiency, sustainability and disruption, AB has been nanosized without scaffold. Inspired from the nanosized AB using cetyltrimethylammonium bromide (CTAB) as surfactant [3], and obtained via an anti-precipitation method in solution, we used amine-borane adducts to produce nanosized AB particles (60 to 200nm). Adducts are the keys for shaping. Different adducts R-NH2-BH3 with R a carbonaceous group have been successfully synthesized and characterized. We have produced adducts such as tetradecylamineborane (C16H33NH2BH3AB) and biphenylamineborane (C12H11NH2BH3). The self-assembling properties of adducts have allowed nanostructuring of AB in solution; spherical, lamellar and polyhedral shapes have been observed. We accordingly synthesized nanoparticles of AB without a scaffold, which opens new perspectives for elaborating from these nanostructured new C-doped B-N-based materials. Recent computational works support that such materials would be the most attractive solutions for reversible H2 storage at ambient conditions [4]. However, there is to our knowledge a lack of experimental evidence yet. The present project aims at confirming the potential of high reversible H2 storage in the field of B-based ceramics.

Nickel Hydride Performed Under Cold Ar/H2 Plasma Treatment—Material Processing and Mechanism Marie-Charlotte Dragassi[1,2], Alicia Oussaidi[1], Souad Ammar-Merah[1], Michaël Redolfi[2] and Laurent Royon[1]; [1]Université de Paris, France; [2]Université Sorbonne Paris Nord, France

Solid hydrogen storage is a technological obstacle for the hydrogen economy broadening. Various materials and methods have been studied under the scope of the industrial purpose such as complex metal hydrides made by the Sievert's method. Lanthanum-Nickel hydride, LaNi5 had been chosen for its high volumetric (117kgH2/m3) and gravimetric (1,5wt.%) hydrogen capacity. Notwithstanding, this technique requires expensive high purity materials (99,99%) and the process is performed at high temperature (300K) and high pressure (2bar). To overcome these drawbacks, we decided to go through the hydroxide-plasma path. It consists in synthesising by soft chemistry the hydroxide of the selected metal and reducing it under hydrogen plasma. For this study we chose Nickel as the matrix carrier. Three soft chemistry protocols were chosen : (i) coprecipitation and water washing, (ii) polyol and water washing (iii) polyol and ethanol washing. By coprecipitation, the obtained nanopowder is of a controlled dense structure and composition, while by polyol the composition is sensitive to ambient CO2 pollution and washing. Polyol-made nanoparticles have a non-denses lamellar structure sensitive to washing : water can enter between the layers and leads to delamination. It leads to low mechanical strength. For the hydrogen plasma treatment, the main goal was to study the kinetic of the reduction and the composition evolution of the plasma by mass spectrometry. For both nano-nickel hydroxide made by coprecipitation and made by polyol and washed with water, the mechanism followed was : Ni(OH)2>NiO>Ni (solid solution). Under plasma, the phase change lasted 1-2h. But for the nano-nickel hydroxide made by polyol and washed by ethanol, the mechanism was rather different : Ni(OH)2>Ni2H>Ni (solid solution). This shows that nano-nickel hydroxide can be reduced under plasma up to the unstable nickel-hydrogen solid solution. Further work around plasma parameters must be done to overcome this last step of hydration.

Uranium and U-Alloys in Hydrogen Storage and Magnetism of the U Hydrides Ladislav Havela[1], Dominik Legut[2], Jindrich Kolorenc[3], Volodymyr Buturlim[1], Oleksandra Koloskova[1], Evgeniya Tereshina-Chitrova[1] and Thomas Gouder[4]; [1]Charles University, Czechia; [2]VSB - Technical University of Ostrava, Czechia; [3]Institute of Physics, Academy of Science of the Czech Reoublic, Czechia; [4]European Commission Joint Research Centre, Germany

Violent reaction of Uranium metal hydrogen can be detrimental for mechanical integrity of devices containing this actinide element. The product of such reaction, UH_3, appears usually as a very fine powder, which burns spontaneously if exposed to air. This was a prohibitive feature in considerations of U for hydrogen storage in stationary applications. (Automotive applications were never considered due to the high mass of U). On the other hand, there are some pros. U absorbs H at very low pressures, working essentially as a getter, and all H is released above T = 450 ºC. Eventually U started to be used as tritium storage medium in prospective nuclear fusion devices.
Our aim is to explore modifications of U hydrides by small substitutions of U by transition metals, which turned out possible using U-T alloys (T = Mo, Zr, V, Nb...) as precursors. It turned out that surface reactivity can be suppressed, H_2 pressure needed for hydrogenation increases and such hydrides adopt the form of brittle but monolithic pieces stable in air, while maintaining the H sorption capacity. It allowed a comfortable study of basic characterictics (magnetic, electrical resistivity, heat capacity), the results of which can be confronted with ab-initio calculations. The effort revealed a bit surprizing fact that UH_3 is not simply the U metal expanded by 60% due to H absorption, but the polar character of U-H bonds is more important for the bulk properties than the overlap of 5*f* wave functions between nearest neighbours. UH_3 is ferromagnetic below $T \approx 165$ K, and one of striking features observed is the enhancement of the Curie temperature for any kind of dopant up to the concentration of 15 at.% [1].
For spectroscopic studies by XPS, UPS, BIS, XMCD, and XAS, we developed the technique of synthesis of U-H films by reactive sputter deposition. The films exhibit a similar properties as bulk U hydrides, but their composition and microstructure can be varied in a broader range, not being constrained by equilibrium thermodynamics. In a certain regime a di-hydride with CaF_2 structure type, not known before and analogous to rare earth dihydrides, could be obtained [2]. The sputter deposition technology opens a possibility for manufacturing sandwich devices, combining ferromagnetism of U hydrides with paramagnetism (and superconductivity) of U-T alloys on a nanoscopic scale, which can give, due to stron spin-orbit coupling, functionalities relevant in spintronics. The spectroscopies applied [3] confirm the effect of polar bonds, based on a charge transfer towards H and strong 6*d*-1*s* hybridization, which leaves behind the 5*f* states, responsible for magnetism. The reduction of the 5*f*-6*d* hybridization allows for pronounced magnetic properies of all hydrides studied (UH_2, α- and β-UH_3).

Limiting Ingress While Maximizing Desorption—Exploring New Hydrogen Solutions for Pipeline Steels Cem Tasan, Jinwoo Kim, Xiahui Yao, Ju Li and Bilge Yildiz; Massachusetts Institute of Technology, United States

Regulating hydrogen transport in structural metals is one of the key challenges for hydrogen related technologies. Here, we will discuss two new technologies that aim to regulate hydrogen ingress and hydrogen desorption. The former is a novel hydrogen barrier coating with multilayer composite structures of metal and oxide. This structure provides (i) enhanced resistance to delamination, (ii) formation of extended space-charge zones at oxide/metal interface that improves H-permeation barrier performance, and (iii) strong micro-cracking resistance and the self-healing potential to retain hydrogen barrier performance even after mechanical damaging. The latter method aims for recovering steels from hydrogen embrittlement at room temperature by accelerated electrochemical desorption of hydrogen. We confirmed that the method can effectively help several commercial steels to recover from the hydrogen damage, by comparing the mechanical behavior of H-precharged specimens after uncontrolled desorption and controlled electrochemical desorption experiments. Several case studies in different steels will be introduced in this presentation to discuss the influence of trapping sites on the effectiveness of this recovery approach.

11:00 AM EN14.06.02
Microstructural Engineering of Mn-Alloyed Duplex Steels and Accelerated Test Method Development to Achieve Low Cost, High Performance Solutions for Hydrogen Storage and Delivery Yuran Kong[1], Pawan Kathayat[1], Lawrence Cho[1], Kip O. Findley[1], John G. Speer[1], Brian Kagay[2], Christopher San Marchi[2] and Joseph Allen Ronevich[2]; [1]Colorado School of Mines, United States; [2]Sandia National Laboratories, United States

Two major obstacles to the broader use of hydrogen energy technologies include (1) cost and reliability of hydrogen storage and delivery infrastructure; and (2) cost and complexity of evaluating materials in hydrogen environments. In particular, the ferrous alloys known to have high resistance to hydrogen embrittlement, e.g., high Ni-containing austenitic stainless steels, are relatively expensive. The current study aims at designing Mn-alloyed ferrite-austenite steels as economical materials for hydrogen service, as an alternative to high Ni stainless steels. The alloy design was guided by a literature review on the effects of alloying on austenite stacking fault energy (SFE), which is established to be correlated with the mechanical stability of austenite and hydrogen embrittlement resistance. The composition of a high Mn duplex steel was designed considering SFE and equilibrium volume fraction of austenite in duplex microstructures, obtained through thermodynamic calculations. Moreover, various thermomechanical processing routes are being explored to obtain desirable combinations of austenite stability, volume fraction, and deformation mechanisms and to enhance fracture toughness of the high Mn duplex steel in hydrogen at given or higher strength levels. In addition to reducing the cost of alloys, the present study also focuses on develop and validate a cheaper and easily accessible method to test alloys in hydrogen environments. Electrochemical hydrogen charging methods are being developed in parallel utilizing a 255 duplex stainless steel. The electrochemical charging method is intended to be a surrogate for testing in gaseous hydrogen at a pressure of approximately 103 MPa. The hydrogen embrittlement characteristics of the 255 duplex stainless steel were evaluated as a function of the hydrogen environment (electrochemical variables compared to testing in high-pressure gaseous hydrogen) and the geometry of circumferentially notched tensile specimens.

Hydrogen Detection and Discrimination Using ZnO Nanostructures Ionut Nicolae, Razvan Mihalcea, Bogdan Calin, Cristian Viespe and Aurelian Marcu; NILPRP, Romania

Hydrogen technologies are a very promising option among the green energy sources. However, safety precaution have to be taking care while using, handling and storing it and sensors are a key issue in the present technological development. All existing sensors are known to have specific issues and gas discrimination and ambient factors influences are among the most frequent issues.
Surface Acoustic Wave (SAW) sensing is one of the development directions using acoustic waves propagating over a piezoelectric surface and are basing their functionality on the mechanical properties change of an ‘active layer’ material, which the wave is passing through in the presence of the detected gas. Nanostructure or nanostructured materials present a series of enhanced properties compared with the bulk materials, due to their high surface-to-volume ration, but their specific parameters need to be controled for optimizing sensor performances. For SAW sensor fabrication we use ZnO material as a versatile wide bang-gap semiconductor, which is having a good absorption of hydrogen isotopes and various other gases. We use Pulsed Laser Deposition (PLD) - Vapour-Liquid-Solid (VLS) techniques to grow ZnO single crystal [0001] nanowires on sensor surface as an active leyer.
By controlling experimental ZnO growing parameters we are able to control VLS grow elementary processes and respectively nanostructure morphology, optimizing the sensor sensibility. By monitoring sensor response to various propagation frequencies we are able to distinguish several (known) gases presence. Some correlations between experimental parameters and sensor response are presented as well as sensor performances on hydrogen isotopes and few other gases detection.

Hydrogen Embrittlement in Steels and High Entropy Alloys William A. Curtin and Xiao Zhou; Ecoloe Polytechnique Federale Lausanne, Switzerland, Switzerland

The urgent need for clean energy coupled with the exceptional promise of hydrogen (H) as a clean fuel is driving development of new metals resistant to hydrogen embrittlement. Experiments on new fcc high entropy alloys (HEAs) present a paradox, absorbing more H than Ni or austenitic 304 stainless steel (SS304) but more-resistant to embrittlement. Here, a new theory of embrittlement in fcc metals is presented based on the role of H in driving an intrinsic ductile-to-brittle transition at a crack tip. The theory quantitatively predicts a hydrogen concentration at which a transition to embrittlement occurs, and good agreement with experiments is found for the alloys SS304, SS316L, CoCrNi, CoNiV, CoCrFeNi and CoCrFeMnNi. The theory rationalizes why CoNiV is the most-resistant alloy and why SS316L is more resistant than the HEAs CoCrFeNi and CoCrFeMnNi. The theory opens a path for computationally-guided discovery of new embrittlement-resistant alloys.

2:00 PM EN14.07.02
Microstructural Basis of Mechanical Behavior of Hydrogen Resistant Austenitic Steels Po-Cheng Kung, Hoon Lee, Quinten Yurek, Jessica A. Krogstad and James F. Stubbins; University of Illinois at Urbana-Champaign, United States

The development of hydrogen-resistant steels depends directly on the understanding of the role of alloy composition and microstructure on mechanical behavior. In this work, we describe the progress toward developing elevated strength, cost-effective alloys through the employment of nano-level strengthening features including short range order (SRO). The intent is to develop microstructures that are sufficiently strong, compared to the current generation stainless steels, that they could be used in hydrogen handling applications with reduced section sizes, and thus reduced cost. The alloy development effort derives from features of the 21-6-9 (Nitronic 40) alloy which has been the focus of multiple hydrogen effects studies over the years. The appeal comes from the relatively high strength, depending on the processing, and the use of Mn in place of some level of Ni. A series of developmental alloys in which the Ni/Mn ration is varied across a wide range are also analyzed. From a microstructural standpoint, the Ni/Mn balance can affect several critical materials parameters including alloy phase stability during deformation, stacking fault energy and the tendency for slip-induced twinning. This work covers the connection between the compositional and microstructural differences in these alloys and the associated mechanical behavior. In particular, the study includes the evolution of microstructure during deformation in both hydrogen charged and uncharged specimens to understand the dislocation-strengthening particle/SRO. Interactions, the tendency to transform from cross-slip to planar slip based, and the tendency for twinning, all of which influence performance in hydrogen atmospheres.

4:00 PM EN14.08.01
Effect of Various Rare Earth Doped Ceria Barrier Layers in Reversible Solid Oxide Cell Technology Ayesha Akter and Srikanth Gopalan; Boston University, United States

Renewable energy from wind turbine or photovoltaic cells will be abundant in future. We have a need for a clean, efficient system that can act as both energy conversion and storage device. A reversible solid oxide cell (RSOC) is such kind of a device that can convert electricity to fuel during the electrolysis mode by conversion of steam to hydrogen and using that hydrogen later as fuel to generate electricity during the fuel cell mode. Hydrogen is always a fuel of interest due to environmental considerations, increasing oil price and limited supply of fossil fuel. However, when operating in the SOEC mode, pressure builds up in the electrolyte-oxygen electrode interface due to the accumulation of molecular oxygen in the pores near the interface. As a result, the oxygen electrode particularly, suffers delamination in the SOEC mode causing serious performance degradation and failure of the system. To mitigate delamination of the oxygen electrode, the Ruddlesden-Popper structure based mixed ionic electronic conductors (MIEC) in the rare earth nickelate family are an attractive option. However, rare earth nickelates have the tendency to react with the YSZ electrolyte and form undesirable phases. To prevent this, a barrier layer is used between the oxygen electrode and electrolyte to prevent any kind of chemical interaction between the oxygen electrode and the electrolyte. In this work, various rare earth doped ceria have been evaluated as barrier layers and their effect on electrochemical polarization has been systematically studied. Symmetrical cells with various doped ceria barrier layers and nickelate-doped ceria composite electrode have been screen printed and EIS data has been obtained at varying temperatures and oxygen partial pressures. DRT analysis of the impedance spectra has provided insights into the reaction mechanism, and identify the rate limiting steps.

4:15 PM EN14.08.02
Comparison of Chromium Removal via Electrochemical Cleaning Technique between Predominantly Electronically Conducting versus Mixed Ionic/Electronic Conducting Solid Oxide Fuel Cell Cathode Materials Michelle A. Sugimoto, Zhikuan Zhu, Ayesha Akter, Srikanth Gopalan, Soumendra Basu and Uday Pal; Boston University, United States

Chromium poisoning remains a major obstacle to wide-spread solid oxide fuel cell (SOFC) employment. A mitigation strategy, electrochemical cleaning, has been proposed in which the Cr deposition reaction is reversed by applying a mild electrolytic current. The method has been shown to reverse chromium deposition and performance loss on cells with $(La_{0.8}Sr_{0.2})_{0.9}MnO_{3-\delta}$ (LSM) air electrodes. Here we demonstrate the applicability of electrochemical cleaning using more Cr-tolerant electrode materials: $La_{0.6}Sr_{0.4}Co_{0.2}Fe_{0.8}O_{3-\delta}$ (LSCF) and $Nd_2NiO_{4+\delta}$ (NNO). Three cells with LSM, LSCF, and NNO cathodes were exposed to accelerated poisoning conditions followed by electrochemical cleaning, i.e., mild electrolytic bias and increased fuel humidity. Performance recovery due to electrochemical cleaning is recorded using current-voltage and EIS measurements. Three additional cells were exposed to the same poisoning condition, but not cleaning for post-test Cr content comparison. Cell cross-sections were analyzed using energy dispersive x-ray spectroscopy (EDS). Cells that were poisoned and cleaned compared to their respective baseline poisoned cell demonstrate a decrease in overall Cr content. Whereas, the location of Cr deposition during poisoning is different between LSM and LSCF or LNO air electrodes. Due to the mixed ionic/electronic conductivity of LSCF and NNO electrodes, the effect of Cr deposition on cell performance is less pronounced compared to LSM. Therefore, when using more Cr-tolerant air electrode materials, electrochemical cleaning is effective in Cr removal and performance recovery and is required at a lower frequency compared to cells with primarily electronically conductive air electrodes.

Theory of the Electrostatic Surface Potential and Non-Equilibrium Thermodynamics at the Mixed Ionic Electronic Conductor (MIEC)–Gas Interface Nicholas Williams, Ieuan D. Seymour and Stephen Skinner; Imperial College London, United Kingdom

The catalytic and transport properties of mixed ionic-electronic conducting (MIEC) electrodes for solid oxide fuel cells (SOCs) are well documented and utilised, yet poorly understood. In the current study, a novel kinetic framework for the electrochemical behaviour of hydrogen at the MIEC-gas interface will be discussed for three parallel treatments: as an ideal gas, as an adsorbate on the electrode surface and as a charge carrier dissolved in the oxide lattice. This model gives a physically meaningful reason for the enhancement in electrochemical activity of a MIEC electrode as the steam pressure is increased in both fuel cell and electrolysis modes, and is ubiquitous for any electrochemical system where the electric double layer is described as a Heaviside step function.

The process of charge transfer at the MIEC electrode/gas interface comprises of ambipolar exchange of ions and electronic species. The result of such a process causes charge separation and an associated dipole moment at the electrode surface. By applying an overpotential η to the MIEC electrode, an electrostatic surface potential shift away from equilibrium may be established where an effective double layer is formed between the electrode surface and the adsorbed species. Although no net charge transfer occurs, this surface potential shift modifies the surface chemistry and is the driving force for the ambipolar exchange of ions and electronic species.

Density Functional Theory (DFT) calculations were used to study the electrostatic potential at the ceria [111] surface, where we were able to calculate the dipole moment and adsorption energy as a function of hydroxyl coverage. The theory of the electrostatic potential at the MIEC-gas interface was then applied to predict the surface electrochemical properties as a function of local overpotential. [1]

Finally, we extend this model to show the effects of non-equilibrium thermodynamics on the bulk defect concentration and adsorbate induced electrostatic surface potential in MIEC electrodes. This methodology is used to model the current-overpotential characteristics of water electrolysis mechanism at 2 phase and 3 phase boundaries present in cermet electrodes.The mechanistic understanding gained from this model is widely applicable to a range of MIEC systems and provides a basis upon which the operating conditions can be tailored.

[1] Williams, N.J., Seymour, I.D., Leah, R.T., Mukerjee, S., Selby, M. and Skinner, S.J., 2021. Theory of the electrostatic surface potential and intrinsic dipole moments at the mixed ionic electronic conductor (MIEC)–gas interface. doi.org/10.1039/D1CP01639C

4:45 PM EN14.08.04
Oxygen and Sulfur Reduction Activities of Mesoporous N- & Fe,N-Carbon Electrocatalysts Correlate with Atomic-Scale Compositions and Structures Shona M. Becwar[1], Ziyang Wei[2], Rongli Liu[2], Xiangfeng Duan[2], Philippe Sautet[2] and Brad Chmelka[1]; [1]University of California, Santa Barbara, United States; [2]University of California, Los Angeles, United States

Mesoporous N- and Fe,N-carbons exhibit high and stable activities for oxygen and sulfur reduction that are comparable to or surpass those of standard Pt-activated-carbon electrocatalysts. Favorable properties include high nitrogen contents (>15 atom%), high fractions of N moieties at surface sites, 3-nm mesopores to promote diffusion, and electron conductivity to surface N environments where the reduction reactions occur. The types, quantities, and distributions of N-heteroatom environments, especially those at surface sites, are shown to strongly influence macroscopic reduction activities. N- and Fe,N-mesoporous carbons synthesized using difference mesopore templates (e.g., salt versus silica) are explored to understand the atomic level differences that correlate with increased reduction activity, and how they can be optimized. Compared to 20 wt% Pt supported on activated carbon, the salt-templated mesoporous Fe,N exhibits the highest reduction activity, exceeding even that of the commercial Pt-carbon catalyst.
While inclusion of N-heteroatoms improves carbon-based electrocatalyst reduction activity,[1] the atomic-level origins of such properties have remained elusive. Nevertheless, two-dimensional ^{13}C-^{15}N NMR spectra resolve signals from four distinct types of N-heteroatom environments: pyrrolic, graphitic, edge/isolated pyridinic, and pyrazinic/pyridinic moieties, the quantities of which vary by porogen and account for different O_2 reduction activities.[2,3] Chemical shift assignments are corroborated by DFT, with points corresponding to different structural motifs overlaying the spectrum. Importantly, ^{15}N-^{1}H NMR spectra enable surface N species to be selectively distinguished from interior moieties via interactions with adsorbed water. These analyses establish that certain types of N-carbon moieties are more important to electrocatalytic performance than others. The incorporation of non-precious transition metals (e.g., Fe) significantly increases electrocatalytic activity, which have been challenging to explain.[4,5] Nevertheless, ^{57}Fe Mössbauer spectroscopy and solid-state ^{15}N NMR and spin-lattice relaxation-time analyses resolve signals from ^{15}N species that are proximate to paramagnetic Fe-heteroatoms, from which ^{15}N-Fe distances are estimated. XRD, XPS, XRF, Raman spectroscopy, STEM, and EXAFS are used to characterize the materials and corroborate the hypotheses. Understanding the roles of Fe and N-carbon moieties in electrocatalytic reduction yields new design criteria for syntheses of high performance non-precious-metal electrocatalysts with diverse fuel cell and battery applications.

SESSION EN14.09: Hydrogen Compatibility of Materials III
Session Chairs: Christopher San Marchi and T. Venkatesh
Monday Morning, December 6, 2021
EN14-Virtual

8:00 AM *EN14.09.01
U.S. Department of Energy Hydrogen and Fuel Cell Technologies Office Overview Neha Rustagi; U.S. Department of Energy, United States

The U.S. Department of Energy's (DOE) Hydrogen and Fuel Cell Technologies Office (HFTO) funds research, development, and demonstration (RD&D) activities to enable decarbonization across sectors. HFTO's R&DD portfolio includes hydrogen production, infrastructure, storage, fuel cells, and a wide range of end-uses for hydrogen, including industrial processes (e.g. steelmaking, data centers), energy storage, hydrogen blending with natural gas, and transportation. The Office's materials R&D activities are conducted largely through national laboratory consortia within the DOE's Energy Materials Network. These consortia include: H-Mat, focused on materials compatibly with hydrogen; HyMARC, focused on materials-based storage of hydrogen; HydroGEN, focused on advanced water splitting materials; and ElectroCat, focused on platinum group metal (PGM)-free catalysts for fuel cells. The current presentation will provide an overview of the HFTO RD&D portfolio and EMN consortia, including recent accomplishments and future priorities.

8:30 AM EN14.09.02
Evaluation of Tensile Behaviour of Structural Steels in High Pressure Gaseous Hydrogen Using Tubular Specimen Thorsten Michler, Fabien Ebling, Ken Wackermann and Heiner Oesterlin; Fraunhofer Institut für Werkstoffmechani, Germany

Quasi-static tensile properties are the base for any component design. Often, wall thickness are set based on such data. A cost effective test method to acquire the required data for high pressure hydrogen applications is tensile testing using tubular specimen, where the hydrogen pressure is applied to the inner cavity of the specimen. Several structural steels were tested with this method and this study compares the results of tubular specimens with those of conventional specimens tested in a high pressure hydrogen autoclave. Commonalities and differences will be presented and discussed by means of FEM analysis and hydrogen failure modes.

8:45 AM *EN14.09.03
Decompression Failure Mechanisms in Hydrogen-Exposed Rubbers—Insights from *In Situ* 3D Tomography Using Synchrotron Source Sylvie Castagnet[1,2,3], Azdine Nait-Ali[1,3], Mahak Fazal[1,3], David Mellier[1], Guillaume Benoit[1], Yannick Pannier[1], Mario Scheel[4] and Timm Weitkamp[4]; [1]Pprime Institute (CNRS-ENSMA-Univ. Poitiers), France; [2]Fédération de Recherche CNRS Hydrogène (FR2044 FRH2), France; [3]LABEX Interactifs (ANR-11-LABX-0017-01), France; [4]Soleil Synchrotron, France

Exposure of rubber materials to diffusive gases at high pressure and subsequent decompression may lead to cavitation and cracking depending on the exposure conditions. This phenomenon has been studied for different gas polymer systems in the past, but the interest in hydrogen as an alternative energy carrier and the application of rubber materials in Fuel Cell Vehicles and equipment for storage and transportation of hydrogen makes it important to study the compatibility of these materials with hydrogen. The relatively high pressures in use, combined with the safety measures required for the usage of hydrogen itself pose serious challenges in terms of material and design. In particular, the safety risk associated with hydrogen leakage makes specific demands on the rubber materials used as seals in terms of durability.
Decompression failure can be addressed at two different scales. At the macroscopic scale of the component, the main challenge is to capture the statistics of cavity fields (known to depend on the mechanical loading, decompression conditions and material properties), the gradients and the full diffuso-mechanical couplings, in order to model the residual mechanical and permeation properties. The question of a Representative Volume Element over which to develop modelling is a key one.
At the cavity scale, the existence of full diffuso-mechanical couplings is a key issue too: the expansion and deflation of the cavity depends on the balance between the external hydrostatic pressure and the internal pressure (which depends itself on the volume of the cavity and the gas content inside it, possibly varied by the gas flux at the cavity wall) but also on the intrinsic properties of the rubber at large strains at the cavity wall, and on the global gas content field. The type of mechanisms responsible for cavitation is another issue, for soft matters in general, regardless of the specific decompression failure

context.
The experimental works reported here aim at better understanding of the mechanisms of cavity growth, some possible interaction effects at variable range, with a free surface or between close cavities. The work was based on a very recent 3D time-resolved quantification of the kinetics and morphology of the damage, from an in-situ X-ray tomography experiment initially developed on a laboratory source (spatial resolution 16µm, temporal 100s) and extended under a synchrotron environment on the Anatomix beamline at SOLEIL synchrotron (France).
The gain in spatial (3µm) and temporal (4s) resolution made it possible to access the very first stages of growth, to properly quantify anisotropy and to detect residual damage. These different elements showed the existence of a first rapid spherical growth regime which then evolved into an anisotropic regime which reflected an underlying mechanism of cracking. The correlation with the intrinsic fracture properties of the rubber are considered more in-depth.
Then, the evolution of this damage during successive pressure cycles was investigated, raising the question of non-trivial cumulated effects.
Results mainly concern a series of unfilled EPDM, with low variable degrees of cross-link density. However, this microstructural parameter alone did not appear discriminating.

9:15 AM EN14.09.04
Morphological Changes and Their Effects on Material Properties in Natural Gas Medium Density Polyethylene Pipe in Low Pressure Hydrogen Kevin Simmons[1], Lisa Fring[1], Wenbin Kuang[1], Yongsoon Shin[1], Rakish Shrestha[2] and Christopher San Marchi[2]; [1]Pacific Northwest National Laboratory, United States; [2]Sandia National Laboratories, United States

As the energy sector decarbonizes, hydrogen is being considered as a medium to store and convey renewable energy, for example in the natural gas networks. Therefore, the interactions of hydrogen with structural materials in existing energy infrastructure is needed. Medium density polyethylene (MDPE) pipelines are commonly used in distribution gas networks to deliver natural gas from the transmission system to the end user. The open literature contains limited information on the effects of hydrogen (either pure or blended into natural gas) on these commonly used materials. In this research, the morphological changes, transport and mechanical properties associated with exposure to hydrogen were evaluated. Test specimens of PE2708 medium density polyethylene pipe were saturated with hydrogen at pressures ranging from 0.7 to 3.4 MPa for up to 72 hours, prior to evaluating morphological changes in the polymer, equilibrium hydrogen content, hydrogen diffusivity, nano-indentation properties, and burst behavior. In addition, fatigue life tests were conducted in-situ in the presence of low-pressure gaseous hydrogen. The material shows a decrease in the degree of crystallinity by up to 6% using X-ray diffraction and differential scanning calorimetry after exposure. The reduction in the diffusion coefficient was observed using thermal desorption spectroscopy, and nano indentation testing revealed up to a 30% decrease in hardness and modulus immediately following hydrogen exposure. Burst pressures test results were not significantly reduced. The fatigue life, however, was greater in hydrogen than in air. The implication of these property changes on the structural behavior of MDPE pipelines in hydrogen service are discussed.

9:30 AM EN14.09.05
Advanced Imaging to Study Hydrogen Compatibility of Polymers for Hydrogen Infrastructure Wenbin Kuang[1], Kevin Simmons[1], Yongsoon Shin[1], Bruce Arey[1], Alice Dohnalkova[1] and Nalini Menon[2]; [1]Pacific Northwest National Laboratory, United States; [2]Sandia National Laboratories, United States

The U.S. Department of Energy Hydrogen and Fuel Cell Technologies Office launched the H2@Scale program to improve the durability and reliability of materials for hydrogen infrastructure to facilitate widespread utilization of hydrogen. Pacific Northwest National Laboratory leads a multi-lab effort to understand the mechanisms of hydrogen-polymer interactions with the goal of developing polymers with improved resistance to hydrogen degradation. Model nitrile butadiene and ethylene propylene diene rubber compounds were formulated collaboratively with Kyushu University to investigate how each constituent responds to high-pressure hydrogen exposure in such complex systems. Advanced imaging techniques offer unique advantages to visually study possible changes in polymer morphology associated with hydrogen effects at different length scales. X-ray computed tomography research revealed formation of more voids in plasticized systems after static exposure to 90 MPa hydrogen than unplasticized. Surface damage and plasticizer migration at the submicron level were captured by helium ion microscope. Transmission electron microscopy combined with energy dispersive spectroscopy highlighted hydrogen-induced voids formation around accelerator particles along with sulfur coalescing.

9:45 AM EN14.09.06
Atomistic Modeling of Elastomer Performance During Exposure to High-Pressure Hydrogen Matthew P. Brownell, Amalie L. Frischknecht and Mark Wilson; Sandia National Laboratories, United States

Elastomeric rubber materials serve a vital role as gas barriers in the hydrogen storage and transport infrastructure. With applications including O-rings and hose-liners, these components are exposed to pressurized hydrogen at a range of temperatures, cycling rates, and pressure extremes. High-pressure hydrogen exposure often rapidly leads to cavitation, a hydrogen-induced failure mode following several (de)pressurization cycles. This type of failure is readily visible, occurring as a material rupture during decompression and is due to the oversaturated gas traversing the polymer matrix towards the outside of the rubber. Computational modeling in the Hydrogen Materials Compatibility Program (H-Mat), co-led by Sandia National Laboratories and Pacific Northwest National Laboratory, employs multi-scale materials simulation efforts to build a predictive understanding of cavitation damage. We aim to motivate material formulations that are less sensitive to hydrogen-induced failure. Here, we will discuss the use of atomistic molecular dynamics simulations to predictively assess compositional variations and resulting performance metrics of the commonly used elastomer, ethylene propylene diene monomer (EPDM). We perform systematic studies as a function of increasing crosslink density, which show indications of improved bulk material response to the depressurization of gas at higher crosslink density. However, this performance improvement comes with a tradeoff; microscopic analysis indicates an increase in free volume at higher crosslink density, a necessity for gas localization and the initiation of cavitation. We will also discuss the mobility of hydrogen through the polymer matrix leading up to gas localization. Our diffusion results reveal that the hydrogen molecules can be divided into two classes, one with high mobility and one with low mobility in which the hydrogen gas diffusion is impeded by atomic structural features of the polymer.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525. 10:30 AM *EN14.10.01
Cost Effective Alloy Design for Hydrogen Resistant Austenitic Steels—Understanding the Impact of Short Range Order Through Integrated Computational and Experimental Approaches Jessica A. Krogstad[1], Petros Sofronis[1], Tianyu Su[1], Po-Cheng Kung[1], Quinten Yurek[1], Hoon Lee[1], Huan Yan[1], Zahra Hosseinisarani[1], Mohsen Dadfarnia[2], Elif Ertekin[1], Katheryn Huff[1], Brian Somerday[1] and James F. Stubbins[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]Seattle University, United States

Development of robust, cost effective, reliable and safe hydrogen applications requires a new generation of low cost, high strength austenitic steels. In this talk we will review recent collaborative efforts to achieve this goal by intimately coupling experiments with modeling and simulation to establish how the intrinsic chemical composition, in concert with hydrogen, governs microstructural evolution and ultimately leads to fracture initiation and failure. Classical metrics of embrittlement (e.g. stacking fault energy and others) have proven to be insufficient on their own to explain failure and thus guide the design of optimum alloy composition. Several commercial and novel austenitic steels have been characterized via highresolution electron microscopy to reveal ubiquitous short range ordering (SRO) behavior, where SRO is defined as any local deviation from a random solid solution. Direct feedback between these experimental observations and our constitutive modeling framework suggests that such SRO domains significantly modify the mobility of nearby dislocations, whileatomistic simulations reveal that not only should such domains be expected but that the SRO domains may also impact the distribution of hydrogen within the lattice. In addition to these observations, we will present preliminary observations for our novel low-nickel austenitic alloys, which have been developed to suppress other known features associated with hydrogen embrittlement (phase transformation, twinning, etc) so as toexplicitly explore the relationship between the observed SRO domains, slip localization and ultimately the failure modes of austenitic steels in the presence (and absence) of hydrogen.

11:00 AM *EN14.10.02
Effect of Hydrogen on Tensile Properties of Stainless Steels at Cryogenic Temperatures Daniel R. Merkel[1], Ethan K. Nickerson[1], Robert J. Seffens[1], Kevin Simmons[1], Christopher San Marchi[2], Brian Kagay[2] and Joseph Allen Ronevich[2]; [1]Pacific Northwest National Laboratory, United States; [2]Sandia National Laboratories, United States

Safe and efficient hydrogen storage and distribution are key challenges to realizing hydrogen as an alternative energy carrier. To this end, cryogenic liquid and cryo-compressed gaseous hydrogen are considered high energy density alternatives to ambient temperature gaseous hydrogen. However, these alternatives have significant material demands: extreme temperature (20 K) and pressure (700 bar) as well as the insidious effects of hydrogen. Austenitic stainless steels are widely used for cryogenic pressure vessels owing to relatively high ductility even at 4 K. However, the influence of hydrogen on mechanical properties at cryogenic temperatures has rarely been studied. In this research, the tensile properties of 304L and Nitronic 50 (XM-19) stainless steel alloys with internal hydrogen were evaluated at 20 K, 77 K, and 113 K. Test specimens were saturated with internal hydrogen through thermal precharging at 573 K in 138 MPa H_2. In both 304L and Nitronic 50, reduced temperature increased strength properties and reduced elongation. The presence of hydrogen increased strength in both alloys but reduced ductility, as measured by reduction of area. Magnetic evaluation of the uniformly strained region of the 304L test specimens suggest that hydrogen mitigates the strain-induced transformation to α'-martensite in 304L, whereas the Nitronic 50 alloy remains stable with regard to transformation to α'-martensite. The effects of temperature and hydrogen were also explored in gas tungsten arc-welded 304L.

11:30 AM EN14.10.03
An Fe-Ni-Cr-H Interatomic Potential and Predictions of Hydrogen-Affected Stacking Fault Energies in Austenitic Stainless Steels Xiaowang Zhou[1], Chris Nowak[1], Skelton Richard Samuel[1], Michael E. Foster[1], Joseph Allen Ronevich[1], Christopher San Marchi[1] and Ryan B. Sills[2]; [1]Sandia National Laboratories, United States; [2]Rutgers, The State University of New Jersey, United States

While Fe-Ni-Cr austenitic stainless steels exhibit relatively good resistance to hydrogen embrittlement, they still suffer from significant degradation of ductility, fatigue and fracture properties in gaseous hydrogen environments. Experimental studies in the literature suggest that hydrogen reduces stacking fault energy in austenitic stainless steels. This phenomenon causes a large separation of partial dislocations and lower propensity for cross-slip. Whereas lower stacking fault energy does not correlate well with loss of ductility in the absence of hydrogen, when hydrogen is present lower stacking fault energy trends toward greater loss of ductility. Calculations of stacking fault energy are challenging for austenitic stainless steels. One main issue is that in alloys, stacking fault energy is not a single value but rather varies depending on local composition. Herein, we first report an Fe-Ni-Cr-H quaternary interatomic potential and then use this potential to perform time-averaged molecular dynamics simulations to calculate stacking fault energies for tens of thousands of realizations of local compositions for selected stainless steels alloys with and without internal hydrogen. From statistical analyses, our results suggest that hydrogen reduces stacking fault energy, which likely impacts deformation mechanisms of Fe-Ni-Cr austenitic stainless steels when exposed to hydrogen environments. We then perform validation MD simulation tests to show that hydrogen indeed statistically increases the stacking fault widths due to statistically reduced stacking fault energies.

Molecular Dynamics of Hydrogen Cottrell Atmosphere Formation in Aluminum—Influence of Non-Dilute Concentration at the Dislocation Core Chris Nowak[1], Catalin Spataru[1], Kevin Chu[2], Xiaowang Zhou[1] and Ryan B. Sills[3]; [1]Sandia National Laboratories, United States; [2]Georgia Institute of Technology, United States; [3]Rutgers, The State University of New Jersey, United States

Cottrell atmosphere formation occurs when solute atoms segregate to dislocations and is one of the most basic processes by which solutes alter mechanical properties of materials.
Hydrogen Cottrell atmospheres can contribute to hydrogen embrittlement. Using molecular dynamics simulations we study the formation of hydrogen Cottrell atmospheres around edge dislocations in aluminum. By pinning dislocations to one position and using coarse-graining techniques, we can resolve the time-dependent changes in the hydrogen concentration field. Comparing to previous Cottrell atmosphere formation and thermodynamics theories, we observe a surprising reduction in peak atmosphere concentration at the dislocation core. This was found to arise from a repulsive, concentration-dependent H-H interaction at the dislocation core that is absent in the bulk far away from dislocation. Since the essential physics of Cottrell atmosphere formation is accurately represented in molecular dynamics, our results provide important inputs to improve Cottrell atmosphere theories. Based on our findings, we propose next steps to study the interaction between dislocations and their associated hydrogen Cottrell atmosphere.

Hydrogen Effects on Short Range Order in Austenitic Steels—Cluster Expansion and Monte Carlo Investigation Tianyu Su, Brian Somerday, Petros Sofronis, Jessica A. Krogstad and Elif Ertekin; University of Illinois at Urbana-Champaign, United States

Hydrogen embrittlement, a process whereby metals suffer the loss of ductility in hydrogen environments, limits the choice of austenitic stainless steels that can be used for reliable hydrogen applications. Although several possible mechanisms for hydrogen embrittlement have been put forward, there is still no clear consensus on the precise ways that hydrogen affects microstructural evolution and leads to failure. In this work, we consider how alloy composition and hydrogen affect the presence or absence of short range order (SRO) in austenitic steels, and how these changes to SRO may ultimately affect microstructure evolution. We present a computational assessment of alloy chemistry, SRO, and hydrogen effects using first-principles calculation and cluster expansion-Monte Carlo (CE-MC) simulation in Fe-Cr-Ni binary and ternary alloys. The degree of SRO present in typical binary and ternary austenitic steels of varying Fe-Ni-Cr composition is estimated from the Warren- Cowley short range order parameters. The composition and temperature dependence of SRO agrees with experimental and other computational works. We then demonstrate the effects of interstitial H on SRO in these alloys using a multicomponent multisublattice CE-MC method. The model results indicate that introducing H modifies the SRO preference of typical Fe-Ni-Cr alloys. In particular, we observe a strong tendency to form Cr and H rich domains. It is broadly presupposed that SRO may cause localized slip since planar glide is frequently reported in alloys known to exhibit SRO. As embrittlement is often accompanied by a transition from homogeneous to localized slip, the interaction between chemistry, SRO, and hydrogen may play a role in the slip localization that takes place during embrittlement of austenitic alloys.

12:15 PM EN14.10.06
Study of Hydrogen Permeation Using Molecular Dynamics Guang Cheng[1], Xiaoli Wang[1], Shulei Han[1], Kaiyuan Chen[1], Yang Zhang[1] and Venkatesh T. A.[2]; [1]Beijing University of Chemical Technology, China; [2]Stony Brook University, The State University of New York, United States

We utilized molecular dynamics to study the hydrogen permeation in metallic materials such as pipeline steels, stainless steel, welding zones, and amorphous coatings. First, the nano/micro- structures and element distribution were obtained through experimental characterization. Then, the corresponding molecular dynamics models were established to represent the actual material structures within a small scale (i.e., 100 nm-1 um). Then, we investigated the effects of crystal defects, crystal structures, grain boundaries, interfaces, and surface roughness on hydrogen permeation. The correlation between pressure, temperature, and hydrogen permeation was also studied. The current study aims to understand the metallic materials compatibility used in pipelines and storage vessels. Meanwhile, the current investigation helps establish a method to accelerate hydrogen permeation to simulate the long-time service in hydrogen transporting and storage for mechanical properties tests. Finally, we would like to seek the possible approach to design materials with specific nano- and micro-structures for hydrogen barrier purposes considering different hydrogen pressure.

SESSION EN14.11: Hydrogen Compatibility of Materials V

Investigating the Microstructural Origins of Hydrogen Effects on Deformation and Fracture Coleman Alleman, Brian Kagay and Christopher San Marchi; Sandia National Laboratories, United States

The mechanisms of hydrogen-assisted fracture in stainless steels are superficially described in the literature. Here, we attempt to produce causal and quantitative evidence of hydrogen-affected deformation and fracture. We analyze oligocrystalline microstructures to isolate deformation mechanisms in physical samples and create computationally equivalent microstructures to simulate the experimentally-observed responses.

This talk focuses on the development of a framework to simulate stress-strain responses of these microstructures, consisting of a tool to assign a best-fit crystal orientation on a regular 2D grid, an application to simulate grain growth in a 3D volume with boundary conditions imposed by a 2D domain, and a crystal plasticity model to simulate mechanical response.

Sandia National Laboratories is a multi-mission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC., a wholly owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

1:30 PM EN14.11.02
Hydrogen Interaction and Storage in Transition Metal Carbides Christopher Weinberger[1], Xiaochuan Tang[1], Salehin Rofiques[1] and Gregory Thompson[2]; [1]Colorado State University, United States; [2]The University of Alabama, United States

The interaction between transition metal carbides and hydrogen is an important topic for both hydrogen trapping and hydrogen storage. There are reports that hydrogen can be trapped in carbide precipitates in steel, increasing their tolerance to hydrogen-induced delayed fracture. This trapping could result from hydrogen interaction with the surface or in the bulk. There is also evidence that hydrogen can be stored in transition metal carbides, notably $TiC_{0.6}$. This raises important questions regarding hydrogen interaction and storage in transition metal carbides and its dependence on chemistry. In this talk, we examine how hydrogen binds to carbide precipitate interfaces and in the bulk using a combination of density functional theory and elastic models as a function of chemistry, both the transition element and carbon concentration. Our results reveal that metal-rich transition metal group IVB carbides are superior at trapping and storing hydrogen in the bulk while trapping at coherent interfaces is a function of both lattice mismatch and elastic constants of the carbide precipitates.

1:45 PM *EN14.11.03
A Data-Driven Roadmap Towards Pareto Optimal Hydrogen Storage Alloys Matthew Witman[1], Sanliang Ling[2], Gustav Ek[3], Anis Bouzidi[4], Jorge Montero[4], Jeffery Chames[1], Sapan Agarwal[1], Justin Wong[1], Gavin Walker[2], David Grant[2], Mark D. Allendorf[1], Claudia Zlotea[4], Martin Sahlberg[3] and Vitalie Stavila[1]; [1]Sandia National Laboratories, United States; [2]The University of Nottingham, United Kingdom; [3]Uppsala University, Sweden; [4]Institut de Chimie et des Matériaux Paris-Est, France

After decades of research and success stories, an elusive question remains: have the truly “optimal” hydrogen storage alloys escaped discovery? The traditional approach to novel materials discovery has typically relied on researchers’ significant domain expertise and trial-and-error experimentation in order to narrow down the vast space of possible materials. A recent paradigm involves the use of machine/statistical learning (ML) techniques to form surrogate models that screen materials’ performance properties with many orders of magnitude greater efficiency and significantly cut the time and material costs of experimental search and validation. Focusing on materials-based hydrogen storage, we demonstrate that explainable machine learning

techniques can be used to elucidate simple, first-order design rules for predicting metal hydride thermodynamics. Trained purely on experimental data, the model does not rely directly on crystal structure and permits predictions on materials that otherwise lack well defined, computationally tractable unit cell representations. These developments are critical in order to apply these models to screen a novel chemical space of 672 high entropy alloys (HEAs), where we discover that we can finely tune the thermodynamic stability across many orders of magnitude within this set of materials. Afterwards we identify and experimentally validate two novel HEA compositions whose hydrides were significantly destabilized (up to 70x increase in equilibrium pressure) compared to the benchmark HEA hydride, thereby releasing hydrogen at much milder conditions. Exploring an even more comprehensive space of nearly 21,000 proposed HEA compositions, we are now using these ML models to optimize the competing objectives of thermodynamic stability, maximal volumetric/gravimetric capacity, and minimal cost (i.e., finding Pareto optimal materials). Our workflow takes seconds to predict the 138 Pareto optimal candidates, and a handful are currently undergoing laboratory validation within our international collaboration group. Assuming 1 month per HEA is required for synthesis and characterization, random sequential selection within this search space would consume an expected 17 years of experimental time before measuring the first Pareto material by chance.

2:15 PM *EN14.11.04
A Rational Strategy for Linking the Properties of Hydrogen Carriers with the Needs of Energy Storage Use Cases Mark Bowden, Ba Tran, Kriston Brooks and Tom Autrey; Pacific Northwest National Laboratory, United States

The successful deployment of hydrogen carriers requires careful consideration of chemical properties, engineering factors, and economic realities. The carrier effort in PNNL focuses on identifying and addressing the research needs of potential use cases that will benefit from large scale stable energy storage. The properties of the carriers must be matched to the needs of the use cases, which cover a wide range of scales, storage duration, and delivery rates. Hydrogen storage for stationary back-up or load-levelling applications poses different challenges from uses where the carrier must be transported over large distances between storage and release. We have determined the requirements of a range of representative use cases and used these to calculate operational performance parameters along with the thermodynamic, kinetic, and physiochemical properties of ideal carriers. We will discuss an example of a hydrogen storage system based on using ethanol to power a neighborhood microgrid. The lessons learned from the experimental research and associated engineering analysis are leading us to improved carrier systems for this and other applications.

2:45 PM EN14.11.05
Influence of Hydrogen on Kinetics of Dislocation Motion During Low Cycle Fatigue of 316L Stainless Steel Dayane M. Oliveira[1], Christopher San Marchi[2] and Jeffery C. Gibeling[1]; [1]University of California, Davis, United States; [2]Sandia National Laboratories, United States

The current work applies a framework of thermally activated dislocation motion to obtain fundamental information about the effect of hydrogen on the mechanisms of cyclic deformation in strain hardened 316L stainless steel, a common alloy used for hydrogen service. As-received and hydrogen-precharged specimens were deformed in plastic strain controlled low cycle fatigue tests at amplitudes ranging from 0.3% to 0.6% plastic strain, and a series of plastic strain rate change experiments were performed periodically at the peak tension stress. These tests represent constant temperature and dislocation structure experiments from which changes in operational activation area could be determined as the microstructure evolved. Specifically, operational activation areas were determined from the difference in stress associated with the logarithmic difference in plastic strain rate and then plotted as a function of the cumulative plastic strain. Both material conditions experienced a rapid increase in operational activation area during the first few cycles at all plastic strain amplitudes, followed by a region of steady state that coincides with the reduced rate of softening observed throughout most of the fatigue lifetime. The values of operational activation area were larger in the as-received than in the hydrogen-precharged condition, ranging from 100 to 150 b^2 and from 60 to 90 b^2, respectively. After the specimens had been cycled to one-half of the expected lifetime, additional tests were conducted at various plastic strain values around stable hysteresis loops to reveal information about the character of deformation and obstacles to dislocation activity in this stainless steel. Plots of the inverse of the normalized operational activation area as a function of the flow stress, also known as Haasen plots, were used as a first step in inferring the dominant deformation mechanism. The results indicated the presence of an athermal stress associated with the interactions between dislocations and the dominant glide obstacles for both material conditions, and the magnitude of this stress is reduced in presence of hydrogen. Although the operational activation areas are weakly dependent on the plastic strain amplitude for as-received and hydrogen-precharged specimens, the nature of the dominant obstacle to dislocation motion tends to be slightly more thermal than forest dislocations in the high amplitude regime. Values of operational activation area at this stage of fatigue life ranged from 100 to 300 b^2 and from 70 to 200 b^2 in the as-received and hydrogen-precharged conditions, respectively. Transmission electron microscopy was used to directly observe the differences in dislocation arrangements with and without hydrogen at half-life.

Predicting Hydrogen Storage in MOFs via Machine Learning Alauddin Ahmed and Donald Siegel; University of Michigan, United States

The H_2 capacities of a diverse set of 918,734 metal-organic frameworks (MOFs) sourced from 19 databases is predicted via machine learning (ML). Using only 7 structural features as input, ML identifies more than 8,000 MOFs with the potential to exceed the capacities of state-of-the-art materials. The identified MOFs are predominantly hypothetical compounds having low densities (<0.31 g/cm^{-3}) in combination with high surface areas (>5,300 m^2/g), void fractions (~0.90), and pore volumes (>3.3 cm^3/g). The relative importance of the input features are characterized, and dependencies on the ML algorithm and training set size are quantified. The most important features for predicting H_2 uptake are pore volume (for gravimetric capacity) and void fraction (for volumetric capacity). The ML models are available on the web (https://sorbent-ml.hymarc.org), allowing for rapid and accurate predictions of the hydrogen capacities of MOFs from limited structural data; the simplest models require only a single crystallographic feature. DOI: 10.1016/j.patter.2021.100291

4:30 PM EN14.12.02
Reversible Hydrogen Storage by Metastable Hydrides in Functionalized Porous Hosts Mark D. Allendorf[1], Vitalie Stavila[1], Sichi Li[2], Jonathan Snider[1], Joseph Reynolds III[1], Farid El Gabaly[1], Joshua Sugar[1], Brennan Dizdar[3], Eric Majzoub[3], Hendrik Schlomberg[4], Bettina V. Lotsch[4], Jeff Urban[5] and Brandon Wood[2]; [1]Sandia National Laboratories, United States; [2]Lawrence Livermore National Laboratory, United States; [3]University of Missouri–St. Louis, United States; [4]Max Planck Institute for Solid State Research, Germany; [5]Lawrence Berkeley National Laboratory, United States

Metal hydrides continue to be of interest for materials-based hydrogen storage. However, most research has focused on hydrides that are too stable, i.e. their enthalpy of H_2 desorption is too high for the residual heat of a PEM fuel cell to drive the release. In contrast, metastable hydrides, for which H_2 release is exothermic, have received less attention. Compounds such as alane (AlH_3) are so thermodynamically unstable that direct rehydrogenation following hydrogen release is thought to be impossible.[1] Multistep chemistry involving Lewis acid-base intermediates (e.g. alane-ether complexes) can be used but is impractical for many applications, including on-board vehicular storage. This is unfortunate because AlH_3 and another metastable hydride, $LiAlH_4$, have attractive gravimetric capacities (10.1 wt% and 8.0 wt%, respectively). Here we show that these hydrides can be thermodynamically stabilized by nanoconfinement using two types of porous hosts: nitrogen-functionalized porous carbon ($LiAlH_4$@NCMK-3) and bipyridine-functionalized Covalent Triazine Framework (AlH_3@CTF-bipyridine). $LiAlH_4$@NCMK-3 desorbs 100% of its hydrogen by 240 °C and >80% can be regenerated at <100 MPa H_2, bypassing the Li_3AlH_6 intermediate of bulk.[2] Even more surprisingly, AlH_3@CTF-bipyridine is reversible at 60 °C under 700 bar hydrogen, 36 times lower than the experimentally measured H_2 plateau pressure of bulk aluminum. DFT calculations and EPR spectroscopy support a radical-based mechanism via AlH_3 binding to bipyridine, resulting in single-electron transfer to form $AlH_2(AlH_3)_n$ clusters.[3] Together, our results reopen the case in favor of these high-capacity metastable hydrides for H_2 storage. They also suggest potential for using them in batteries, supercapacitors, and heterogeneous catalysis.

Interface Pinning Causes the Hysteresis of the Hydride Transformation in Binary Metal Hydrides Nicholas J. Weadock[1,2], Peter Voorhees[3] and Brent Fultz[1]; [1]California Institute of Technology, United States; [2]University of Colorado at Boulder, United States; [3]Northwestern University, United States

The absorption and desorption of hydrogen by hydride forming metals is well known to exhibit hysteresis, in which the partial pressure of hydrogen absorption is greater than desorption. We will demonstrate, by combined theoretical and experimental work, that a continuous barrier to interface motion is the origin of hysteresis. Hysteresis and elastic energies determined from high precision pressure composition isotherm and *in-situ* X-ray diffraction measurements on palladium hydride are found to be inconsistent with previous theories. Our experiments show that in bulk samples the hysteresis is present even in a partially transformed system, thus a stress-induced jump in volume fraction of hydride cannot be responsible for the hysteresis. Furthermore, we characterize the absorption and desorption kinetics stepwise and find that the equilibration time is constant within the two-phase region of the palladium-hydrogen phase diagram, indicating that there exists a persistent energy barrier.

First-Principles Elucidation of Initial Dehydrogenation Pathways in $Mg(BH_4)_2$ Liwen Wan[1], Tom Autrey[2] and Brandon Wood[1]; [1]Lawrence Livermore National Laboratory, United States; [2]Pacific Northwest National Laboratory, United States

Hydrogen is a promising technology for long-term energy storage and realization of zero CO_2 emission. However, utilizing hydrogen as a fuel presents practical challenges due to its low volumetric energy density and therefore requires development of advanced storage medium. Complex magnesium borohydride, $Mg(BH_4)_2$, possesses one of the highest gravimetric (14.8 wt.%) and volumetric (112 g/L) hydrogen storage density. Yet practical challenges remain due to kinetic limitations to realize full reversibility for de- and re-hydrogenations. Early theoretical work based on density functional theory predicts hydrogen desorption temperature between 20 and 75°C via reaction $Mg(BH_4)_2 \rightarrow MgB_2 + 4H_2$, however, in experiments, hydrogen release have only been observed above 200°C. It is speculated that this discrepancy is originated from the formation of various B_xH_y intermediates that act as a thermodynamic sink or a kinetic barrier during hydrogen desorption. In this work, we use first-principles methods to explore initial dehydrogenation, from BH_4 to B_3H_x, in bulk γ-$Mg(BH_4)_2$ and to identify the preferred reaction pathways for the formation of key B_2H_x and B_3H_x intermediates that limit the overall kinetics of BH_4 to B_3H_x transformation. Our results not only provide valuable thermodynamic and kinetic information regarding each of the elemental reaction steps during BH_4 to B_3H_x conversion, but also shed light on the long-standing contradiction between previous theoretical prediction and experimental observation about the existence of B_3H_8 intermediate.

This work was supported by the Hydrogen Materials Advanced Research Consortium (HyMARC), established as part of the Energy Materials Network by the U.S. Department of Energy, Office of Energy Efficiency and Renewable Energy, Fuel Cell Technologies Office and was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

Advanced Computational Modeling of Metal Hydrides for Vehicular and Stationary Hydrogen Storage Applications Brandon Wood, Tae Wook Heo, ShinYoung Kang, Liwen Wan, Nathan Keilbart, James Chapman, Sichi Li and Kyoung E. Kweon; Lawrence Livermore National Laboratory, United States

More efficient, compact storage of hydrogen represents a critical need for fuel cell vehicles and long-duration energy storage. Metal hydrides are promising materials to replace high-pressure tanks, offering high volumetric capacities at relatively low hydrogen pressures. However, these materials often suffer from kinetic limitations that incur undesirable energy cost under operation. Within the DOE Hydrogen Materials—Advanced Research Consortium (HyMARC), we are using multiscale models to model kinetic processes in hydrogen storage materials and identify key limitations for targeted engineering. This talk will present an overview of the materials modeling strategy within HyMARC, which incorporates and integrates atomistic simulations of complex interface chemistry, effective-medium approaches for transport and mechanical stresses, and continuum methods for microstructure evolution. Our aim is to go beyond thermodynamic models to understand harder-to-simulate kinetic processes under nonequilibrium cycling conditions. We will show how modeling coupled with high-fidelity experimental characterization has been employed to elucidate chemical reaction pathways at interfaces and to understand the formation and evolution of new solid phases. We will also present recent progress towards elucidating the interaction of hydrogen with native oxide films, which form on metal surfaces and play a key role in determining the activation temperatures and pressures for many metal hydrides. To this end, multiscale simulations and experiments are being combined with machine learning and graph-theoretic algorithms to simulate hydrogen transport through these polycrystalline and amorphous surface films. The talk will also review our recent efforts to improve kinetic predictions of hydrogen storage materials by incorporating additional physics into the simulations, which better approximates realistic operating conditions. Finally, we will discuss how modeling-derived understanding is being used within HyMARC to guide new improvement strategies, including nanoconfinement and compositional modification. Examples will be drawn from multiple materials systems, including complex light metal hydrides for vehicles and TiFe alloys for stationary energy storage.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

SESSION EN14.13: Fuel Cells III

Iron-Based Proton Exchange Membrane Fuel Cell Cathode Catalysts Deborah Myers, Magali Ferrandon, Jaehyung Park, A. Jeremy Kropf and Evan Wegener; Argonne National Laboratory, United States

The sluggish kinetics of oxygen electrocatalysis and the resulting high overpotentials necessary to achieve useful current densities limit the performance and efficiency of proton exchange membrane fuel cells (PEMFCs).(1) The best catalysts for the oxygen reduction reactions are based on platinum, leading to limitations in the cost effective implementation of this technology.(2,3) The development of alternative catalysts, with comparable or higher activity and durability to the platinum and derived from earth-abundant materials has thus been an active research area for decades.

Incredible progress has been made over the past decade in increasing both the ORR activity and durability of PGM-free PEMFC cathode catalysts.(4) The class of catalysts demonstrating the highest ORR activities are those typically denoted as “Fe-N-C” and synthesized by heat treating iron salts and zinc-based zeolitic imidazolate frameworks (ZIFs) and/or phenanthroline, as carbon and nitrogen sources, or by heat treating iron-substituted ZIFs. For this class of PGM-free materials, it has been determined that variables such as the metal and carbon-nitrogen macrocycle content, as well as the temperature and atmosphere in which the composites are heat treated are important in determining the activity and activity stability of the resulting catalysts.(5,6) Changing these variables and testing their effect on the resulting catalyst properties is a time-consuming process and only a limited portion of the composite composition and temperature space have been explored for this broad class of materials.

This presentation will describe the development and application of high-throughput methodology to accelerate exploration of the effects of composition and synthesis parameters on the activity of iron-carbon-nitrogen acidic electrolyte ORR electrocatalysts. The structural characterization of the materials using X-ray absorption spectroscopy (XAS) and correlation of the atomic structure with ORR activity will be described, as will the high-throughput testing and optimization of the electrode composition using a 25-electrode array fuel cell hardware.(7)

Surface Engineering of Platinum-Based Nanomaterials for Highly Efficient and Durable Oxygen Reduction Reaction Electrocatalysts Yanling Ma; Shanghai Jiao Tong University, China

The essence of the electrocatalytic reactions is a heterogeneous reaction process that occurs on the surface of a solid-phase catalyst, including the adsorption, diffusion and dissociation of reactants, electron transfer and the absorption and desorption of the intermediate/reaction products. The surface physical and chemical properties of the catalyst such as geometric morphology, atomic arrangement, element composition, hydrophilicity, etc. are closely related to the adsorption behavior of active species and play a critical role in determining the catalytic activity, selectivity and stability. Moreover, the surface structure of the catalyst is also affected by the chemical environment in which it is located, and then offer significant insights in catalyst design strategies.
Based on the relationship among design, surface structure, environment and activity in catalysis, here we focus on the cathodic oxygen reduction reaction in fuel cells and takes the design and synthesis of platinum-based nanocatalysts as the research object. Starting from the surface design and engineering of nanostructured catalysts, our work studies the effect of 1. surface diffusion behavior under different reaction environments, 2. surface atomic arrangement, 3. exposed crystal planes, and 4. surface charge and the corresponding structure-activity relationship. It aims to combine the influence of the chemical reaction environment on the surface structure of the catalyst and the influence of the surface structure of the catalyst on the catalytic performance to pave the way for the development of highly-efficient and stable platinum-based oxygen reduction catalysts.

8:45 AM EN14.13.03
Characterization of CeO_x-Decorated Pd/C Catalysts Synthesized by Controlled Surface Reactions for Hydrogen Oxidation in Anion Exchange Membrane Fuel Cells Richard Andres Ortiz Godoy[1], Ramesh Kumar Singh[2], Elena Davydova[2], Ana C. Alba-Rubio[3], Dario Dekel[2] and Jasna Jankovic[1]; [1]University of Connecticut, United States; [2]Technion–Israel Institute of Technology, Israel; [3]The University of Toledo, United States

The high cost and difficult task to eliminate platinum (Pt) catalyst in Proton Exchange Membrane Fuel Cells (PEM-FCs) are some of the main obstacles that thwart the wide adoption of fuel cells. For this reason, Anion Exchange Membrane Fuel Cell (AEM-FC) has been suggested as an alternative to the PEM-FC technology in which non-Pt metals may be employed. However, the common slow kinetics at the anode experienced during Hydrogen Oxidation Reaction (HOR) has been one of the challenges preventing the achievement of high-power density in the Pt-free AEM-FC. Here, our objective is to improve the efficiency of HOR catalysts by depositing various ratios of CeO_x/Pd catalysts onto carbon support using the Controlled Surface Reactions (CSR) process. It is expected that a homogenous distribution of CeO_x preferentially attached to Pd nanoparticles (NPs) can produce highly active CeO_x-Pd/C catalysts for HOR. In the present study, we offer a comprehensive characterization approach for the synthesized highly active catalyst and correlate the obtained structural/compositional parameters to its performance. The characterization of the catalysts was carried out using Inductively Coupled Plasma-Atomic Emission Spectroscopy (ICP-AES), X-ray Diffraction (XRD), High-Resolution Transmission Electron Microscopy (HR-TEM), Scanning Transmission Electron Microscopy (STEM) - Energy Dispersive Spectroscopy (EDS), Electron Energy Loss Spectroscopy (EELS), and X-ray Photoelectron Spectroscopy (XPS) to confirm the bulk composition, phases present, morphology, elemental mapping, local oxidation state and surface chemical states, respectively. The HRTEM micrographs indicated that Pd NPs were uniformly distributed on the carbon support with only some minor agglomeration. Additionally, the achieved high interfacial contact between CeO_x and Pd acquired on single Pd NPs was, for the first time, segmented and calculated using High-resolution STEM-EDS maps and Image J processing program by measuring the overlap intensities between Pd and Ce in the NPs. The intimate contact between CeO_x and Pd and the increase in their interfacial contact area with the addition of CeO_x in these NPs was observed. This interfacial contact area is higher than other previously reported for Pd-CeO_x catalysts system synthesized by other methods, suggesting that the CSR method can provide a more selective deposition of CeO_x on Pd. EELS was used to determine that the primary oxidation state of our oxide was in the form of CeO_2 and Ce^{4+} was predominantly present in the CeO_x. However, the presence of Ce^{3+} cannot be ruled out, especially near the surface of the NPs. The study also found that the already mentioned interfacial contact area was directly correlated to the electrochemical performance reflected on the HOR activity of the CeO_x-Pd/C catalysts. Additionally, to track the morphological, compositional, and structural changes at the nanoscale we used postmortem Identical location transmission electron microscopy (IL-TEM), to reveal the degradation mechanisms governing this new CeO_x-Pd/C catalyst material following Accelerated Stress Tests in a three-electrode electrochemical cell. The preliminary results have shown that CeO_x can act as a promising anchoring mechanism that prevents the mobility, agglomeration, and detachment of Pd at a considerably high degree when compared to samples without CeO_x.

9:00 AM EN14.13.04
Cathodic Nanocatalyst Development for Alkaline Fuel Cell Applications Merissa Schneider-Coppolino, Audrey Taylor and Byron D. Gates; Simon Fraser University, Canada

Alkaline fuel cells are a versatile, low-emission alternative energy source for use in transportation, as well as for portable and stationary power applications. These systems use chemical energy from the electrochemical conversion of hydrogen and oxygen gas to produce electrical energy, with only water and heat as by-products. They operate through two interdependent redox reactions within the cell consisting of oxidation of the hydrogen fuel at the anode and reduction of the oxygen at the cathode. One of the most significant barriers that fuel cells face is the sluggish nature of the oxygen reduction and its dependence on platinum, a rare and costly metal, as a catalyst for the reaction. Through the development and optimization of structures and materials, the amount of catalyst can be decreased without sacrificing performance and enabling an increase in the commercial viability of the device.

An alternative cathode material is palladium, which possesses similar chemical properties to platinum but is available in a greater abundance. Additionally, palladium has exhibited improved electrochemical properties in alkaline fuel cells. It has been shown that the activity of palladium-based catalysts can be further increased when alloyed with ancillary metals such as nickel. The incorporation of nickel, a more abundant transition metal, improves the properties of the catalyst and decreases the amount of palladium needed while increasing its utilization. This creates a more cost-effective solution to preparing catalysts. Furthermore, the use of nanoparticles as the basis for the cathode catalyst allows for a high surface area for the oxygen reduction reaction to take place. Nanoparticles allow for a more efficient use of the catalyst materials and, consequently, decreases the amount of metal required and the overall cost of the catalyst.

This study assesses the viability of palladium nickel nanocatalysts as an alternative cathode material for alkaline-based fuel cells. These nanoparticles are synthesized using a water-in-oil microemulsion method and characterized using a series of electron microscopy and electrochemical techniques. By adjusting the ratio of metal salt precursors, a series of nanocatalysts were prepared with various compositions of palladium and nickel. The analysis of these nanocatalysts included assessing the relationship between their composition, structure, and function to determine an optimal ratio of the palladium and nickel within these materials for increasing their catalytic performance. Initial tests demonstrate a promising activity of these nanocatalysts, although further studies will be needed to assess the durability and to better understand the stability of these catalysts.

9:15 AM EN14.13.05
Understanding the Role of Disorder in Materials Used in Catalysis and Fuel Cells Applications Kulbir K. Ghuman; Institut national de la recherche scientifique, Canada

The functionality of materials used for energy applications is critically determined by the physical properties of small active regions such as surfaces, interfaces, and grain boundaries. Although small, these regions in materials if well utilized can provide sustainable solutions to alleviate the energy crisis of today's world. In particular, the capability to manipulate disorder in materials, whether due to zero-dimensional defects (such as vacancies, dopants) or three-dimensional defects (such as pores, cracks, etc.), can bring innovation in designing sustainable technologies. Among various tools, computational materials science plays a significant role in understanding and manipulating disorder in energy materials. Hence, in this talk, I will provide a brief overview of our recent work on understanding and manipulating disorder in oxides such as TiO_2 and Yttria stabilized ZrO_2 for enhancing their performance. I will mainly focus on modeling of realistic materials with structural defects and disorder for next-generation solid oxide fuel cells electrolytes and sustainable heterogeneous catalysis. [1]

9:30 AM EN14.13.06
Synthesis and Characterization of Platinum on Carbon Nanoparticles Selectively Coated with Titanium Nitride (TiN) by Atomic Layer Deposition (ALD) Richard Andres Ortiz Godoy[1], Saidjafarzoda Ilhom[1], Mor Kattan[2], Necmi Biyikli[1], Yair Ein-Eli[2] and Jasna Jankovic[1]; [1]University of Connecticut, United States; [2]Technion - Israel Institute of Technology, Israel

The growing demand for clean and efficient energy sources has been a direct result of the serious effect on the climate and the environment associated with high emissions of pollutants that are mainly produced from fossil fuel-based energy generators. Currently, a green technology like Proton Exchange Membrane Fuel Cell (PEMFC) can produce zero-emissions energy power by primarily using the electrochemical reactions of hydrogen and oxygen to generate electrical energy. Additionally, due to their high activity, Platinum (Pt)/Platinum alloy nanoparticles distributed on a carbon (C) catalyst support

are considered the most efficient catalyst materials use in this technology. However, the main drawbacks from this technology are (i) the scarcity of Pt, making it very expensive for widespread fuel cell application and commercialization, as well as the fact that (ii) carbon support can be prone to corrosion and degradation when operating even at the most typical PEMFC conditions. This carbon corrosion can induce the loss of Pt nanoparticles (NPs) active surface area when Pt detaches from the carbon support or agglomerates into larger Pt NPs, which can lead to premature performance losses in a PEMFC. In this work, we propose a novel approach to prevent carbon corrosion by selectively depositing a corrosion-resistant layer (approximately 1.5 nm thickness) of titanium nitride (TiN) only on the surface of the carbon support while the Pt NPs catalyst centers are left uncoated and accessible for reagents reactions (oxygen O and H^+ protons). TiN was used as the coating material because of its attractive properties, such as its electronic conductivity, which is enough to enable the free movement of electrons from the current collector toward the catalytic centers. TiN would also act as an anchoring mechanism of Pt NPs, preventing their mobility on the carbon support and subsequent agglomeration. The deposition of TiN layers is carried out at 150°C with a Hollow-Cathode Plasma-Assisted Atomic Layer Deposition (HCPA-ALD) while using Tetrakis(dimethylamino)titanium (IV) (TDMAT) as the metal precursor in Ar/N_2 plasma, from which nitrogen was used as co-reactant. Before HCPA-ALD, to prevent TiN from depositing on top of the Pt NPs, the surface of Pt NPs is selectively coated with a thin film of oleylamine (OAm), a polymer that would only absorb onto Pt NPs, which is later removed from the catalyst and TiN system (after the HCPA-ALD process is finished), by heat treatment at 185°C. Here we will mainly focus on the TiN deposition process and the subsequent Transmission Electron Microscopy (TEM) characterization performed on these nanoparticles, which allows us to prove the successful formation of homogenous coatings and architecture characteristics of these nanoparticles after oleylamine application and TiN deposition. Electrochemical characterization, including Cyclic Voltammetry (CV) and Oxygen Reduction Reaction (ORR), were performed in a Rotating Disc Electrode (RDE) to further confirm the activity and effectiveness of our designed catalyst. Our preliminary results have shown that highly conformal TiN can be successfully grown onto Pt/C nanoparticles (as powders) by using HCPA-ALD with a custom-made agitator mechanism. The second phase of this research will be focused on inspecting the degradation mechanisms this novel catalyst system experiences after potential cycling in a Membrane Electrode Assembly (MEA).

9:45 AM EN14.13.07
Nanoporous Surface Modification of 316L Support Materials by Electrochemical Dealloying Seyfettin Berk Sanli and Fatih Piskin; Mugla Sitki Kocman University, Turkey

316L porous stainless steel (PSS) is a very suitable support material for particularly thin film Pd-based membranes due to its high thermal, oxidation resistance and having a thermal expansion coefficient similar to Pd. However, commercially available PSS have often very large surface pores that affect the final thickness of the membrane that could be deposited on it. The size of pores at the commercial PSS surface can be as large as 30 µm or more. That's why the membrane thickness deposited on the PSS can reach several tens of microns in order to create a porous-free membrane. Several studies focus on applying an interlayer between PSS and thin film membrane so as to reduce the size of pores at the PSS surface and thus reduce the thickness of the membrane. However, it is often not easy to control the size of surface pores and keep their size under a threshold. In addition, a non-homogeneous application of the interlayer to be formed on the PSS surface can cause formation of large pores that might be overlooked. The deposition of a thin film membrane on such an interlayer typically causes the formation of pin-holes at the thin film membranes. The presence of pin-holes in the membrane results in a reduction in hydrogen selectivity, even though fully dense metallic membranes principally offer infinite hydrogen selectivity. That's why modification of PSS surface has to be employed in a controlled manner and should be reproducible.

The current study concentrates on surface modification of PSS as a support material in order to enable thin film (<1µm) deposition on PSS. In this respect, 316L foil was used as a model system to determine the application parameters for the formation of a nanoporous Ni surface layer on the PSS. 316L foils were initially electroplated by Ni-Cu alloys using plating solutions with different Ni:Cu ratios. Subsequently, the Ni-Cu surface layers on 316L foils were subjected to an electrochemical dealloying process in order to dissolve Cu back into the plating solution and remain nano-porous Ni surface layer. In the study, different electroplating solutions were employed to determine the suitable alloy composition that yielded the desired pore size (<100nm) in the Ni surface layer formed after the de-alloying process.

This work was supported by TUBITAK (The Scientific and Technological Research Council of Turkey) with project Number 119M636, which the authors gratefully acknowledge.

Approach of Metal-Sulfides for Hydrogen and Fuel Cell Technologie by Molecular Building Blocks Veronika Brune, Wilhelm Michael, Khan Lê and Sanjay Mathur; University of Cologne, Germany

The unique physical properties of 2D van der Waals materials have attracted great attention to fulfill the demands of future nanoelectronics for sustainable developments and have recently attracted significant attention for addressing the current worldwide challenges of environmental pollution and energy shortage. The ultrahigh surface area in combination with and extraordinary physiochemical, electronic and optical properties offer the application in hydrogen and fuel cell technologies. The huge number of active sides of 2D van der Waals materials as well as their suitable band gap offer their application as photocatalyst. The lacking control of large-scale material synthesis corresponding to specific requirements in commercial material formation processes is still challenging, which motivated us to develop a unique synthetic approach to layered 2D materials MS_2 (M= Mo^{IV}, W^{IV}, Ti^{IV}, Sn^{IV}), MS (M=Sn^{II}, Ge^{II}). A uniform synthesis route of molecular building blocks for controlled formation of stable precursor classes $[M(SEtN(Me)EtS)_x]$ (M = Mo^{IV}, W^{IV}, Ti^{IV}, x = 2; M = Ge^{II}, Sn^{II}, x = 1) was developed. Following a simple synthetic protocol, the reaction of tridentate SNS donor ligand with suitable metal compounds resulted in (air)stable molecular precursors, which enabled the targeted formation of homogeneous crystalline 2D MoS_2, WS_2, TiS_2, SnS_2, SnS by thermal decomposition experiments as well as in wet chemical syntheses via microwave assisted decomposition resulting in SnS and SnS_2 particles.
These molecular building blocks provide an extraordinary synthetic approach to materials for hydrogen economy.

10:45 AM EN14.14.03
Physicochemical Properties and Low Relative Humidity Fuel Cell Performance of Pt/ECS™ Catalysts Richard Andres Ortiz Godoy[1], Michael Dzara[2], Alexey Serov[3], Madeleine Odgaard[4], Barr Zulevi[3], Svitlana Pylypenko[2] and Jasna Jankovic[1]; [1]University of Connecticut, United States; [2]Colorado

School of Mines, United States; [3]Pajarito Powder, LLC, United States; [4]IRD Fuel Cells, Denmark

Fuel cells are one of the most advantageous solutions for clean energy applications due to their near-zero-emission, high efficiency, low maintenance cost, and high energy density. However, the development of highly efficient and reliable versions of the current Polymer Electrolyte Membrane Fuel Cells (PEMFCs), mature enough to result in an increased application in the transportation and energy generation sectors, have been subjected to considerable scientific and industrial level effort. In general, PEMFCs produce electricity through the electrochemical reaction of hydrogen and oxygen (or air) taking place in the Membrane Electrode Assembly (MEA) by converting the chemical energy of the hydrogen oxidation and oxygen reduction into electrical energy with water as a byproduct. However, high performances (at scale) in oxygen reduction reaction (ORR) catalysts are a challenge that must be tackled to allow an increase in the energy generation of this technology. For this reason, tunability of the materials at the core of this technology is necessary to meet the demands of not only a specific application but also operating conditions. Here, we study commercially available ORR catalysts based on platinum nanoparticles (Pt-NPs) supported on nitrogen-functionalized carbon (Engineered Carbon Supports™, ECSTM) produced by Pajarito Powder, LLC at scale. The ORR performance of three MEAs made with different Pt/ECS catalysts, by IRD Fuel Cells, LLC was studied under low relative humidity conditions. At low Pt loading, 0.1 mg_{Pt} cm^{-2}, they displayed competitive performance, achieving current densities between 1.8 and 1.3 Acm^{-2} at 0.6 V. A comprehensive study of the physicochemical properties and structure of these Pt/ECS catalysts and their Pt-free equivalent ECSTM carbon support materials was also performed by using several characterization techniques, such: X-ray diffraction, Raman spectroscopy, and Transmission Electron Microscopy (TEM) to investigate structural and morphological properties, X-ray Photoelectron Spectroscopy (XPS) to determine the surface composition and chemical properties, Thermogravimetric Analysis (TGA) to evaluate thermal oxidation properties, and nitrogen sorption (Brunauer-Emmett-Teller (BET) and Barrett-Joyner-Halenda (BJH)) to determine the surface area and porosity, of these catalyst materials. This detailed study allowed us to conclude that the best performing catalyst in the conditions used in this work has the highest surface area and the highest concentration of surface dopants (nitrogen and oxygen). However, it is worth mentioning that catalysts supported on low surface area carbon with a high graphitic degree, exhibited competitive performance that can be used in applications where corrosion-resistant carbon is needed. We can also conclude that based on the highly competitive MEA performance for the three Pt/ECS catalysts these carbon supports, developed by Pajarito Powder LLC with engineered morphology and composition through the VariPore™ synthetic technology, can result in tunable properties suitable for a targeted application. These commercially available materials can be adapted through modification of the versatile synthesis platform to tune the physicochemical properties of carbons for other applications and conditions.

11:00 AM EN14.14.04
Development of LSC Based Amorphous/Nanocrystalline Composite Cathodes for Intermediate Temperature Solid Oxide Fuel Cells Ramin Babazadeh Dizaj and Tayfur Ozturk; Middle East Technical University, Turkey

There is a considerable interest in lowering the operating temperature of solid oxide fuel cells. In this respect, (La,Sr)CoO3-(La,Sr)2CoO4 dual phase oxides have attracted much attention as cathode materials due to their enhanced oxygen reduction reaction kinetics[1,2]. Moreover there is much interest to develop these cathodes in amorphous state which not only leads to significantly improved cathode performance, but also are associated with a strong resistance to Sr segregation making them as a suitable choice for IT-SOFCs[3]. In the current study so as to further improve the stability, a third oxide was introduced into the system. Over 20 cathodes compositions, all based on (La,Sr)CoO3-(La,Sr)2CoO4- (Gd,Ce)O2 ternary system, were sputter deposited in combinatorial geometry. A target operating temperature of 550ºC was selected and the full cell performances were measured in each cell so as to identify the best cathode composition. Scenarios how to best keep the amorphous structure at elevated temperatures and with prolonged use are discussed.

YSZ Mixed Grain Boundary Modeling—Understanding Its Structure, Yttrium Segregation and Its Effect on Oxygen-Ion Self-Diffusion Jose C. Madrid Madrid and Kulbir K. Ghuman; Institut National de la Recherche Scientifique, Canada

SOFC technology currently suffers from material interaction, insulating phase formation, and thermal stresses as it operates at high temperatures, which results in rapid degradation, low reliability, and high cost for commercialization. One of the approaches to reduce the operating temperature of SOFCs is the use of thin-film electrolytes to reduce the ohmic losses experienced at a reduced temperature while offering high thermal stability. That been said, the nanoscale thin films are generally polycrystalline and contain a high density of Grain Boundaries (GBs), which can substantially affect the ion diffusion in electrolytes. Experimentally, the atomistic structure of GBs can be analyzed and observe via high-resolution scanning STEM, but unfortunately, it does not provide sufficient information about the atomic-level structure of these boundaries. Molecular Dynamics (MD) simulations have been used for studying Grain Boundaries' atomic structure and oxygen-ions transport across YSZ electrolyte over the last decades. However, high symmetry GBs have been commonly targeted even though most boundaries found in polycrystalline samples are a mix of twisted and tilted denominations- commonly named "mixed" GBs. A mixed grain boundary (GB) was modeled at the atomic level using MD in this work. The structure was built from a TEM image of an 8YSZ thin film sample using the amorphization and recrystallization (A&R) technique. Oxygen-ion self-diffusion was studied for a range of temperatures between 700 K and 2300 K and Y_2O_3 concentration between 4-14 mol%. It was found that Y_2O_3 does not segregate toward the GB core for one of the grain orientations. On the contrary, Y^{3+} prefers to accumulate in this particular grain after the A&R process. As a result, it allows a better distribution of oxygen vacancies inside the grain interior what leads to obtain a higher oxygen-ion self-diffusion for this region.

Triple-Conducting Electrodes for Intermediate-Temperature Fuel Cells and Electrolysis Cells Meagan C. Papac[1], Jake Huang[2], Ryan O'Hayre[2] and Andriy Zakutayev[3]; [1]National Institute of Standards ad Technoology, United States; [2]Colorado School of Mines, United States; [3]National Renewable Energy Laboratory, United States

Performance of intermediate-temperature fuel cells and electrolysis cells is often limited by the high polarization resistance and low electrocatalytic activity of the positive electrode (i.e., positrode). Mixed ionic-electronic conducting electrode materials have been developed to improve device performance and, recently, triple ionic-electronic conducting oxides (TIEC) have provided a pathway for further improvement. Transport of each charge carrier in these materials depends on defect concentrations, which are moderated by cation concentrations and by operating conditions. Thus, it is important to understand mixed-species transport in single-phase TIEC materials, including discovery and design principles of TIECs, and high-priority areas for further TIEC materials development.[1]
Here, we describe a combinatorial experimental approach to investigate a family of TIEC materials, $Ba(Co,Fe,Zr,Y)O_3$ (BCFZY), which is of interest for

electrocatalytic applications in intermediate-temperature fuel cells and electrolyzers. Layered, half fuel-cell devices were deposited by pulsed laser deposition. An electrolyte layer ($BaZr_{0.8}Y_{0.2}O_{3-\delta}$) was topped with compositionally graded arrays of BCFZY thin film microelectrodes to investigate the effects of chemical composition on performance. An automated benchtop instrument was developed to measure spatially resolved impedance of these films at temperatures up to 500°C under localized dry or humidified gases (air or nitrogen).[2] Performance of the BCFZY thin films was evaluated as a function of temperature and gas atmosphere.[3] Distribution of relaxation times analysis was applied to disentangle individual fuel cell processes with distinct time constants in the frequency-dependent impedance spectra. The dependence of the polarization resistance of each of these processes on chemical composition, temperature, and gas atmosphere are reported.
The BCFZY impedance spectra show that a low-frequency process dominates under humid N_2, while the limiting process under dry air depends on the chemical composition of the electrode material. Total polarization resistance is low in Co-rich materials under both gas atmospheres. Low total polarization resistance is also observed in Y-rich materials under the humid N_2 atmosphere, suggesting a substantial proton-related impedance contribution at low frequencies in BCFZY. These results demonstrate a high-throughput experimental approach to studying triple-conducting materials as positive electrodes for intermediate-temperature electrolyzers and fuel cells.

Effects of Binary Oxide Additives on SOFC Cathodes- An EIS Study Anna F. Staerz[1], Han Gil Seo[1], Dino Klotz[1,2], Clement Nicollet[3] and Harry Tuller[1]; [1]Massachusetts Institute of Technology, United States; [2]Kyushu University, Japan; [3]Institut des Matériaux Jean Rouxel (IMN), CNRS, France

It was previously found that the Smith acidity scale is a powerful descriptor for predicting how binary oxide additives influence the oxygen surface exchange kinetics of the mixed ionic-electronic conductor $Pr_{0.1}Ce_{0.9}O_{2-x}$ (PCO10). By infiltrating various binary oxides, ranging from strongly basic (Li_2O) to acidic (SiO_2) onto the surface of PCO10, basic additives reportedly result in surface electron accumulation leading to enhanced oxygen exchange while acidic materials yield surface electron depletion, deactivating the surface. [1,2] These findings are extended by examining the impact of the relative acidity of additives on the polarization resistance of screen printed porous PCO10 electrodes applied symmetrically to YSZ single-crystal wafers by Electrochemical Impedance Spectroscopy (EIS). Chromia, an acidic oxide, is a common poison for cathodes that originates from the metal interconnects used in SOFC stacks. To validate the detrimental effects of chromia, each layer of PCO was infiltrated with a Cr concentration of 230 ppm. This value was selected based on the results of Menzler et al. on a SOFC stack after 3000 h of operation, who found a Cr-deposition amount of 0.8 $\mu g/cm^2$ on a cell cathode of similar morphology. [3] For comparison, the effect of an equivalent mass of lithia (1270 ppm), a basic oxide, was also examined. The area-specific resistance (ASR, Ωcm^2) increased over four-fold upon infiltration with of chromia, from approximately 124 to 532 Ωcm^2 when measured at 450 ˚C and in 0.1 atm O_2, while the ASR of the cell infiltrated with the lithia was lower than the pure cell. The semicircles in the Nyquist plot, are distorted as a result of several overlapping processes. Here, the distribution of relaxation times (DRT) method enables a clearer differentiation between electrochemical processes, e.g. low frequencies processes (LF) such as gas diffusion, surface oxygen exchange and high frequency (HF) processes such as charge transfer processes across electrolyte–cathode interfaces. [4,5] At 450 °C, the HF region remains largely unchanged by surface infiltration, while in the LF there are significant differences between samples. Upon chrome infiltration a new LF frequency peak forms, while after Li infiltration the peaks in the LF region largely disappear. By using a systematic temperature study under varying oxygen concentrations, the different peaks in the DRT will be attributed to specific electrochemical processes, allowing for more precise understanding of how the binary oxides influence the cathode reactivity.

Understanding Hydrogen Diffusivity in Amorphous Titania—Bridging Quantum and Classical Descriptions with Graph Theory James Chapman, Kyoung E. Kweon and Nir Goldman; Lawrence Livermore National Laboratory, United States

Understanding hydrogen transport is vital to a multitude of application spaces, including energy storage and corrosion mitigation. However, knowledge of the physical diffusion pathways of hydrogen is limited, with a serious gap existing with regards to how hydrogen transport is affected by the host material's underlying atomic structure and defects. For the case of polycrystalline materials, answering this question is non-trivial, as diffusion can occur through many structurally unique environments: (1) bulk regions (2) grain boundaries, (3) surfaces, etc. In this work we have chosen to study hydrogen diffusion through titania due to its importance in corrosion mitigation and energy storage. In particular, we aim to understand diffusion through titania grain boundaries, approximated by using amorphous phases due to similarities in their short-range atomic order. Density functional theory was used to generate these amorphous configurations via ab initio molecular dynamics. A spectrum of hydrogen binding energies was then calculated using a multitude of oxygen sites with varying coordination number. Classical molecular dynamics were then performed on larger amorphous systems using a machine learning force field. A graph-based order parameter was then used to characterize the classically derived amorphous phase space which was correlated with oxygen

coordination number. Our results qualitatively indicate that hydrogen diffusivity can be tailored to either inhibit or induce diffusion based on the specific local oxygen environments present in the amorphous phase.

Titanium Carbide MXenes with Specific Terminations as Platinum Supports Haeji Hong[1], Filipe Marques Mota[1], Nur Aqlili Riana binti Che Mohamad[1], Won Il Cho[2] and Dong Ha Kim[1]; [1]Ewha Womans University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

MXenes possess attractive hydrophilicity, high conductivity, and durability for application in electrocatalysis. Tailored Ti_3C_2 has been actively employed as active support candidates in Pt-loaded catalytic systems to drive the hydrogen evolution reaction (HER). It is noted that the effect of diverse surface functional groups, which may play an important role to optimize the interaction with loaded Pt nanoparticles, has not been deeply investigated to date. 3D wrinkled $Ti_3C_2(OH)_x$ and $Ti_3C_2O_x$ were prepared after the alkali-induced process. 3D MXene with high concentration of -F groups ($Ti_3C_2F_x$) were prepared by mixing with HF. The incorporation of different functional groups was confirmed by FT-IR spectroscopy. Collected XRD patterns of the MXene powders revealed that NaOH-based and subsequent treatments did not induce the formation of distinct phases. It can be clearly observed that all MXene have same structure even after subsequent treatments from evidenced by SEM and TEM images. Moreover, there is no substantial change in defect ratio. Specific electrochemical properties were obtained due to different termination groups on the surface of Ti_3C_2. In this work we direct our attention to the effect of these surface terminations on the resulting interactions with Pt to improve the electrocatalytic activity of Pt-loaded Ti_3C_2 materials toward HER.

Relation Between *d*-Orbital States and Oxygen Evolution Electrocatalysis in Perovskite Oxides Tae Gyu Yun and Sung-Yoon Chung; Korea institute of science and technology, Korea (the Republic of)

Numerous studies on oxide electrocatalysts for an efficient oxygen evolution reaction have been conducted to compare their catalytic performance and suggest new compositions. However, two significant constraints have been overlooked: One is the difference in electrical conductivity between catalysts and the other is the strong crystallographic surface orientation dependence of the catalysis in a crystal. Consequently, unless a comprehensive comparison of the oxygen-evolution catalytic activity between samples is made on a crystallographically identical surface with sufficient electron conduction, misleading interpretations on the catalytic performance and mechanism may be unavoidable. To overcome these limitations, we utilize both metallic (001) $LaNiO_3$ epitaxial thin films together with metal dopants and semiconducting (001) $LaCoO_3$ epitaxial thin films supported with a conductive interlayer. We identify that Fe, Cr, and Al are beneficial to enhance the catalysis in $LaNiO_3$ although their perovskite counterparts, $LaFeO_3$, $LaCrO_3$, and $LaAlO_3$, with a large bandgap, are inactive. Furthermore, semiconducting $LaCoO_3$ is found to have more than one order higher activity than metallic $LaNiO_3$, in contrast to previous reports. Showing the importance of facilitating electron conduction, our work highlights the impact of the near-Fermi-level *d*-orbital states on the oxygen-evolution catalysis performance in perovskite oxides.

Atomically-Dispersed Iridium on Haematite Photoanodes for Solar Water Splitting—Catalyst or Spectator? Qian Guo[1], Magdalena Titirici[2] and Ana Sobrido[1]; [1]Queen Mary University of London, United Kingdom; [2]Imperial College London, United Kingdom

Oxide semiconductors have been widely studied as photoanodes for solar water splitting to generate clean hydrogen as they are in principle inexpensive and stable [1]. To improve their solar-to-hydrogen efficiency, integration of photoanodes with suitable cocatalysts is an attractive strategy to lower reaction barriers thus boosting the photoelectrochemical water splitting ability [2-4]. Very recently, atomically-dispersed catalysts have gained significant attention for integration with semiconductors for solar-to-fuel conversion, due to their high atom utilization, superior catalytic activity, tunable physicochemical properties, and clear active sites [5, 6]. For example, atomically-dispersed iridium catalysts with superior oxygen evolution catalytic performance, have been demonstrated working efficiently on oxide semiconductors for solar water splitting [7, 8]. As the interest in atomically-dispersed catalysts on photoanodes is just rising since 2010, although the phenomenological advantages of pairing atomically-dispersed catalysts with semiconductors are now widely confirmed, the precise role of such cocatalysts, *i.e.* acting as a catalyst or playing a non-catalytic role on photoanodes, which is essential for future efficient photoanode design, are far from understood.

Haematite (α-Fe_2O_3) has long been targeted as a promising oxide semiconductor for solar water splitting in the photoelectrochemical (PEC) configuration due to its natural abundance, narrow bandgap to capture visible light, and excellent chemical stability. With the advances in improving the fundamental deficiencies of haematite over the past few decades, haematite is currently the leading performer among oxide photoanodes. Also, haematite serves as a prototype oxide photoanode in many ways. Therefore, in this research, atomically-dispersed iridium catalyst with excellent oxygen evolution catalytic activity was firstly synthesized followed by loading on hematite photoanodes. The photoelectrochemical measurements have shown a remarkable cathodic shift of the turn-on voltage and a significant increase in photocurrent. The detailed mechanism through which the atomically-dispersed iridium catalyst enhanced the photoelectrochemical performance of hematite was thoroughly investigated by in-situ transient absorption spectroscopy, in-situ Raman spectroscopy, and in-situ extended X-ray absorption fine structure analysis along with density-functional theory calculations. By doing this, we hope to unravel the mechanisms involved in the higher activity of atomically-dispersed iridium on hematite for the first time, and hence, to provide a guide to employ such cocatalysts for integrated solar-to-fuel conversion.

Liquid Metal Dealloying Toward Nanoporous Mo-Based Intermetallic Compounds for Efficient Hydrogen Production Ruirui Song[1,1], Jiuhui Han[1], Masayuki Okugawa[2], Takeshi Wada[1], Jing Jiang[1], Daixiu Wei[1] and Hidemi Kato[1]; [1]Tohoku University, Japan; [2]Osaka University, Japan

Dealloyed 3D nanoporous materials with bicontinuous open porous structure, large specific surface area, high electric conductivity, and superior catalytic activity are ideal monolithic electrodes for electrochemical devices. Molybdenum-based intermetallic compounds have been considered as promising low-

cost alternatives to noble platinum for the electrocatalytic hydrogen production, but they have rarely been developed into nanoporous structures due to the challenges in controlling the composition and chemical order during low-temperature chemical dealloying. Here, we report the direct fabrication of nanoporous Mo-based intermetallic compounds of Co_7Mo_6 and Fe_7Mo_6 by a liquid metal dealloying method at elevated temperatures. An unexpected derivation of the characteristic length of dealloyed nanoporous structures from the conventional linear trend in "ligament diameter *versus* inverse homologous temperature ($1/T_H = T_m/T_{dealloy}$)" is discovered, suggesting a unique intermetallic effect on the pore formation. Assisted by molecular dynamics simulation, this intermetallic effect is explained by the suppressed surface diffusivity of the ordered μ phases that retards the thermal coarsening. As a result, the nanoporous Co_7Mo_6 with a fine structure and correspondingly large surface area delivers excellent activity toward the electrochemical hydrogen production, together with high durability. This study sheds light on a previously unexplored intermetallic effect in dealloying and would promote the development of advanced nanoporous electrocatalysts for energy applications.

Crystalline PEDOT:PSS-Platinum Nanoparticle Composites for Volumetric Electrochemical Catalyst Da-Young Lee, Hye-Min Shin and Myung-Han Yoon; Gwangju Institute of Science and Technology, Korea (the Republic of)

Recently, poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) is a widely used as an active component for water-related electrochemical catalysis and photocatalysis due to its decent electrical conductivity, high optical transparency, and good mechanical flexibility. Nonetheless, its hygroscopic nature, intrinsic inhomogeneity, and poor catalytic activity have limited its broad impact on electrochemical catalyst research. In this research we developed the PEDOT:PSS-platinum nanocomposite electrode by electroplating platinum nanoparticles within the crystalline PEDOT:PSS nanofibrillar matrix and demonstrated its electrochemical catalytic function for hydrogen evolution reaction. We systematically investigated optical, structural, electrical, and electrochemical properties of crystalline PEDOT:PSS-platinum nanoparticle composites. The resultant nanocomposite electrode showed the uniform impregnation of platinum nanoparticles into the whole volume of PEDOT:PSS films, leading to the volumetric electrochemical catalyst with high aqueous stability, high reactant permeability, large electrochemically active surface area (20 m^2/g_{pt}) and enhanced catalytic activity for HER (overpotential of 54.7 mV at 10 mA/cm^2) compared to that of Pt nanoparticle-tethered electrode without PEDOT:PSS.
