In recent years A_2B_7-type RE-Mg-Ni hydrogen storage alloys have been investigated to replace the conventional AB_5-type negative electrodes due to the higher storage capacity (~400 mAh/g vs a theoretical capacity of 372 mAh/g for AB_5). Due to the high Mg vapour pressure, the exact composition of these A_2B_7 materials is challenging to control during production. At the same time, Mg is easily volatilized into ultra-fine powder particles, thus becoming a safety hazard. As a result, new production techniques have been developed. However, these are either expensive or complicated to reproduce [1]. Thus another option is to produce Mg free compositions. By replacing the Mg element with Y, a similar capacity (392.9 mAh/g) is found for $LaY_2Ni_{10}Mn_{0.5}$ [2]. Controlled studies into how Y is affecting the electrochemical capacity, stability and phase composition have been performed by Liu et al. [3] and Zhao et al. [4]. However, the effects on the gas storage properties are not well understood. In the current study, the effects of replacing La with Y on the thermodynamic and kinetic properties of $La_{6-x}Y_xNi_{19.5}MnAl_{0.5}$ (x = 3, 4, 5) are presented.

Statistical Analysis and Machine Learning Performed on a Large Electrocatalytist Dataset Generated by High-Throughput Experimentation Lars Banko, Olga A. Krysiak, Wolfgang Schuhmann and Alfred Ludwig; Ruhr-Universität Bochum, Germany

High-throughput experimentation (HTE) generates large, comprehensive datasets with reasonable efforts. In combination with efficient electrocatalytic screening, the corresponding datasets produced by HTE have a huge potential to generate improved understanding of the governing principles that drive electrocatalytic activity in compositionally complex alloys. The challenge is to identify viable combinations of elements and their mixing ratios out of millions of possible combinations and discover new electrocatalysts with advanced properties.

In this contribution, the electrochemical activity data of > 40 sputtered composition spread materials libraries are analyzed using statistical methods and machine learning. The dataset spans > 15000 different chemical compositions distributed in > 15 compositionally complex material systems from combinations of > 25 chemical elements. Electrochemical characterization was performed using a scanning droplet cell. The electrochemical dataset contains > 20 000 linear sweep voltammograms measured by the scanning droplet cell and covers relevant potential ranges for the hydrogen evolution reaction, the oxygen reduction reaction and the oxygen evolution reaction.

The results of statistical analysis and preliminary predictive machine learning models highlight the value of large experimental datasets generated by HTE for the data-driven development of high-performance catalysts.

Hydrogen Production using $LaNi_xCo_{1-x}O_3$ Perovskite Catalyst by Steam Reforming of Bio-Oil Model Compounds Piyush P. Singh, Neelkanth Nirmalkar and Tarak Mondal; Indian Institute of Technology Ropar, India

Now a days agriculture waste are very challenging as most of the residues burn, which deteriorate the environment directly. The conversion of agricultural waste into energy has twin benefits for society - utilization of waste and sustainable energy production. In this regard, catalytic steam reforming (SR) of bio-oil produces hydrogen, which is a clean and green source of energy having heating value 2.5 times to the petroleum products. In recent years, perovskite oxides have drawn tremendous attention for green hydrogen production due to their excellent catalytic properties. Reported study suggests that the presence of oxygen vacancies of A atoms and ability to break carbon-carbon and carbon-hydrogen bonds of B-site atom make it suitable for steam reforming processes. Here, we report a series of $LaNi_xCo_{1-x}O_3$ perovskite catalysts for the SR of a mixture of bio-oil model oxygenates to produce green hydrogen. The effect of variation of reaction temperature, Ni and Co species composition, steam to carbon molar ratio (SCMR), and weight hourly space-time (WHST) on gaseous products yield and bio-oil conversion were evaluated using fixed catalytic bed reactor unit. The $LaNi_{0.5}Co_{0.5}O_3$ exhibited the best

catalytic activity (83% hydrogen yield and 95% conversion) towards hydrogen production among all other combinations of $LaNi_xCo_{1-x}O_3$ catalysts. The catalyst deactivation study revealed that the deactivation was primarily due to two types of coke (amorphous and carbon nanotubes) deposition validate by the thermogravimetric analysis.

1:45 PM EN14.15.15
Transition Metal Chalcogenides as Electrocatalysts for Efficient Sea Water Splitting Rajarshi Kar[1], Jahangir Masud[2], Harish Singh[1], Umanga De Silva[1] and Manashi Nath[1]; [1]Missouri University of Science & Technology, United States; [2]University of North Dakota, United States

Designing a catalyst with high efficiency toward oxygen evolution reactions (OERs) through sea water splitting is a promising factor in recent times for hydrogen production from renewable sources which can consequently contribute towards energy sustainability. Seawater electrolysis possess a challenge of suppressing chlorine evolution reaction (CER), which leads to the undesirable formation of chlorine gas, while enhancing OER. In the current investigation, Nickel Telluride based electrocatalyst was synthesized through electrodeposition process directly on gold-coated glass substrate. When employed as an OER catalyst, the nickel telluride electrode exhibits a current density of 10 mA/ cm^2 at an OER overpotential of 180 mV with superior stability in a highly alkaline electrolyte which replicates original unfiltered seawater. More importantly, it was observed that nickel telluride did not lead to generation of Cl_2 through CER in simulated seawater electrolyte. To comprehend the admirable OER activity of the Nickel Telluride electrode, a Tafel plot was derived from the LSV curves. The Tafel slope was found to be 56 mV dec^{-1}, which surpass the revolutionary RuO_2 catalyst at 114.4 mV dec^{-1}, indicating superior kinetic performance of nickel telluride. The long term OER stability of the nickel telluride electrocatalyst in artificial seawater was confirmed through surface-sensitive analytical approaches such as XPS. The stability was reestablished through high resolution surface imaging techniques such as SEM and TEM, which confirms that the catalyst surface did not undergo any deterioration, or compositional change. The oxygen and hydrogen gas evolution for Nickel Telluride catalyst was collected over an electrode surface area of 0.5 cm^2 at a working potential of 0.6 V over a duration of 2 hours. The ratio between the hydrogen and oxygen gas evolved was 1.82:1 which is very close to the 2:1 ratio for electrocatalytic full water electrolysis. Nickel telluride was hence identified as an ideal catalyst to promote OER through seawater electrolysis with low overpotential and high stability while suppressing generation of toxic chlorine gas.

1:50 PM EN14.15.18
Visible Light-Induced Electrochemical Performance of CdS@WS_2 as an Oxygen Evolution Photoelectrode in Water Splitting Muthuraja A. V and Praveen Meduri; IIT Hyderabad, India

Photoelectrochemical water splitting (PEC) is a compelling approach to convert solar energy to chemical energy by liberating hydrogen, making it a possible solution to the worldwide energy crisis by eliminating all carbon dioxide emissions. In practice, no single electrode material can meet all PEC water splitting requirements. The major challenges for PEC are electron-hole pair recombination, stability, and reduced absorption of visible light. Transition Metal dichalcogenides (TMD) based heterostructures are being envisioned as novel electrode materials because of their exceptional electrical, chemical, mechanical, and thermal stability which include high electron mobility, highly exposed active sites, layer dependent bandgap, and higher ionic conductivity, etc. TMDs have higher electro conductivity resulting in significant enhancement of the electrochemical performance in PEC. Further, it also exhibits desirable electrochemical behavior through its oxygen evolution reaction (OER) and hydrogen evolution reaction (HER) as a photoelectrode for water splitting. However, due to poor absorbance and significant reflection at the grain boundaries, the light-harvesting ability of bulk or nanosized TMD materials is often limited. The charge carriers produced by light illumination will also reach the surface faster than bulk materials in the semiconductor, because of the lesser transport distance.
In the present work, heterostructures consisting of Tungsten disulfide (WS_2) and cadmium sulfide (CdS) were synthesized using a hydrothermal method and Successive Ionic Layer Adsorption Reaction (SILAR) deposition method. The presence of these nanostructures was confirmed by XRD, Raman, UV-Visible spectroscopy, SEM, TEM, and PL spectroscopy. The morphological study clearly indicates a homogeneous distribution of CdS nanospheres on WS_2 nanostructures, indicating close contact between them which helps in efficient charge separation and migration. Further, the continuous nature of the heterostructures of the two materials is not limited to any visible discrete entities. The porosity of the pristine WS_2 nanostructures allows CdS nanospheres to deposit inside the pores along with the entire thickness of the nanosphere, and hence, the highly homogeneous nature of the heterostructures is obtained as indicated by the physical characterization. Due to this unique structure, the obtained heterostructures showed excellent performance as photoanode. The CdS@WS_2 photoanode demonstrated a photocurrent density of 0.15 mA cm^{-2} at 1.23 V vs. RHE, which is over 20 times higher than that of the pure pristine materials. Further, CdS@WS_2 heterostructures, as compared to pure materials, have demonstrated longer emission-decay-life times and dramatically quenched the emission of fluorescence compared to pristine materials. In CdS@WS_2 heterostructures, the absorption edge of the WS_2 nanostructures also exhibits a considerable increase in light absorption in the total visible spectrum. This results in enhanced charge separation with proper band alignment leading to improvements in electrochemical performance of CdS@WS_2 photoelectrodes. Further, the low onset potential further eliminates the need for voltage bias in practical applications.

Ultrathin Palladium Nanowire-Based Chemiresistive Sensors on Paper Substrates for Room-Temperature Detection of Hydrogen Abhishek Kumar, Thomas Thundat and Mark T. Swihart; University at Buffalo SUNY, United States

Hydrogen (H_2) is often seen as a cleaner alternative to conventional fossil fuels with zero carbon emission. Its usage, however, is limited by its lower explosion limit (4%) and high permeability through many materials that make storage and handling of H_2 a challenging task. Hence, the development of low-cost, fast, and sensitive H_2 detection technologies is of paramount importance to the development of the future hydrogen-based economy. The United States Department of Energy (US-DOE) has set a target for the cost of H_2 sensors for fuel-cell-powered vehicles to be <$15 including the cost of electronics. Paper is an inexpensive, flexible, porous, adaptable, environmentally-friendly, and degradable material that has huge potential for the development of sustainable electronics. We report an ultra-low-cost paper-based sensor for room-temperature detection of hydrogen (H_2) using ultrathin palladium nanowires (PdNWs) and prepared by a simple drop-casting method. To gain insight into the sensing mechanism of ultrathin PdNWs, we compare the performance of polycrystalline PdNWs to that of single-crystalline PdNWs. The polycrystalline PdNWs showed a response (fractional resistance change) of 4.3% to 1% H_2 with response and recovery times of 4.9 s and 10.6 s, respectively. Similarly, the single-crystalline PdNWs showed an 8% response to 1% H_2 with slightly slower response and recovery times of 9.3 s and 13.0 s, respectively. The polycrystalline PdNWs show excellent

selectivity to H_2 with a limit of detection of 10 ppm of H_2 in air and good stability under repeated exposure to H_2 and after extended storage in air. We attribute the fast response and recovery times of the ultrathin polycrystalline PdNW-based sensors to synergistic effects of their ultrathin (< 5 nm) diameter, strain-coupled grain boundaries, and the porous paper substrate that facilitates rapid transport to exposed PdNWs. This paper-based sensor, using only ~100 μg Pd per device on a substrate of negligible cost, is one of the fastest chemiresistive H_2 sensors and could be orders of magnitude less expensive than the current state-of-the-art H_2 sensing solutions.

2:00 PM EN14.15.20
PLD and O_2 Annealing Synthesis of $La_{n+1}Ni_nO_{3n+1}$ Epitaxial Films for SOFC Cathode Material Shohei Hisatomi[1], Yuki Goto[1], Tomoaki Oga[1], Kenta Kaneko[1], Kazuki Watanabe[1], Satoru Kaneko[2,1], Mamoru Yoshimoto[1] and Akifumi Matsuda[1]; [1]Tokyo Institute of Technology, Japan; [2]Kanagawa Institute of Industrial Science and Technology, Japan

There is a strong requirement to establish a hydrogen energy system with the aim of realizing the sustainable society. Highly efficient solid oxide fuel cells (SOFCs) are capable of supplying both heat and electricity without precious catalytic metals, utilizing various fuels such as natural gas, ammonia, and biogas. SOFCs are expected to operate at low temperatures. Reduction of the operation temperature by couple of hundred degrees from conventional >800°C would expand options of surrounding materials and structures, that contributes to improved performances and cost-effective development of the systems. Thus, it has been of importance to improve conductivity of cathode materials to advance the low-temperature operation efficiency. Meanwhile, lanthanum nickelates $La_{n+1}Ni_nO_{3n+1}$ (n=1, 2, and 3) with layered perovskite structures, such as La_2NiO_4, have been developed and their mixed oxygen-ion/electron conductivity has been researched as an expected property for the cathode application in SOFCs [1–3]. Although, the electronic transport properties of the higher order (n≥2) phases still require further study to understand its correlation with their structures. It is also of significance to find an effect of impurity doping on modification of the structure and electronic properties. In this study, $La_4Ni_3O_{10}$ (n=3) thin films were epitaxially developed on single crystal substrates, and the effect of tetravalent doping on their structure and properties was investigated.
The pure and (Hf^{4+}, Sn^{4+}) co-doped lanthanum nickelate thin films were grown on single crystal $NdGaO_3$ (110) substrates by pulsed laser deposition (PLD) method using a KrF excimer laser (λ=248 nm) and sintered targets of pure and co-doped $La_4Ni_3O_{10}$ (0.625 at% for each dopant). The fluence and repetition of the laser beam were E~1.0 J/cm^2 and f=3 Hz, respectively. Deposition ambience was 10 Pa O_2-flow (base pressure ~3×10^{-6} Pa), and the substrate temperature was kept at 700°C. The grown lanthanum nickelate thin films were subsequently heat treated in atmospheric O_2-flow at 950°C for 10 hours.
The epitaxy of (Hf^{4+}, Sn^{4+}) co-doped $La_4Ni_3O_{10}$ (001) thin films on $NdGaO_3$ (110) substrates were obtained after the deposition, that XRD analyses using monochromated CuKα1-ray demonstrated {001} diffraction peaks in 2θ/ω-scan and planar four-fold symmetry in φ-scan detecting {208} diffractions. The co-doped epitaxial $La_4Ni_3O_{10}$ (001) thin film revealed resistivity of ρ=8.9×10^{-2} Ωcm at room-temperature, measured by four-probe DC method. Further development of $La_{n+1}Ni_nO_{3n+1}$ crystal phases other than the case of n=3 was available by modification of the O_2 pressure and deposition rate during the thin film growth. Further detailed structural analyses, physical properties including electric conductivity at raised temperature, and comparative study with pure films will also be presented.

Theoretical Insight into Absolute Surface and Interface Energies and Optoelectronic Properties of 2D Vertical Singularities for III-V/Si Heterostructure Applications Pedesseau Laurent, Ida Lucci, Lipin Chen, Jacky Even and Charles Cornet; FOTON Institute - INSA Rennes, France

Solar water splitting converting the solar energy into green hydrogen fuel is one significant milestone on the road to a sustainable energy future and has driven many researches in the past years [1]. III-V/Si heterostructure combining the good optical properties of III-V semiconductors with the low cost of Si substrates is considered as an attractive solution for efficient water splitting reactions [2-4].
Here, we first show that surface and interface energies play a central role during the epitaxy of III-V semiconductors on Si. We then demonstrate that the presence of 2D vertical singularities (antiphase boundaries) drastically modify the electronic properties of the heterostructure, yielding very promising photo-electro-chemical (PEC) device performances. The strong absorption of light by the bulk materials is the first requirement for the proper operation of the PEC. Next, it is also essential to efficiently extract and collect the carriers. Therefore, the atomistic studies based on the density functional theory have been dedicated to three different aspects: i) the optoelectronic properties of bulk materials, ii) the study of surface stability to understand III-V/Si heteroepitaxy, and iii) the study of interfaces and 2D vertical singularities used to collect charge carriers.

Semiconducting Polymers as Promising Materials for Photoelectrochemical Water Splitting Han-Hee Cho[1], Liang Yao[2], Dan Zhang[1], Jun-Ho Yum[1] and Kevin Sivula[1]; [1]EPFL, Swaziland; [2]Max Planck Institute for Solid State Research, Germany

Direct solar-driven water splitting into hydrogen (H_2) and oxygen (O_2) has emerged as a leading approach to reduce our dependence on fossil fuels as hydrogen can be converted into electrical energy using a fuel cell or transformed into chemical feedstocks. However, the identification of ideal light harvesting semiconductors that meet performance and cost requirements for industrialization still remains a main obstacle. Organic photoelectrochemical cells (OPECs) in which pi-conjugated organic semiconductors (OSs) are coupled with co-catalysts have recently attracted great attention as alternative photoelectrodes for solar water reduction (yielding hydrogen) and oxidation (yielding oxygen), considering unique features of OSs such as precisely

tunable optoelectrical properties and solution-processability at low temperature. Nevertheless, the conversion efficiency and stability of OPECs (both photocathode and photoanode) for the solar water splitting have remained particularly poor. Herein, we present high-performance and robust organic photoelectrochemical cells by employing a bulk heterojunction (BHJ) blend of semiconducting polymers as a photoactive layer. Our in-depth study using sacrificial agents for photoreduction and photooxidation unveils critical parameters that significantly affect the performance and operational stability of OPECs: (i) rational selection of semiconducting polymer donor and acceptor to generate free charges efficiently and ensure chemical stability upon illumination, (ii) large surface roughness of interlayers to improve interfacial adhesion, and (iii) mitigation of charge accumulation at the interfaces. By leveraging these insights, our optimized polymer BHJ photocathode and photoanode where the polymer BHJ layers are coupled with hydrogen and oxygen evolution catalysts, respectively, show outstanding performance and unprecedented robustness compared to previous OPECs, demonstrating a new benchmark of OPECs for solar fuel production. In particular, the polymer BHJ photocathode and photoanode exhibit initial 1 Sun photocurrent density values up to 8.7 mA cm^{-2} at 0 V vs RHE and 2.3 mA cm^{-2} at 1.23 V vs RHE for solar water reduction and oxidation with 100% Faradaic efficiency, respectively, which can rival the performance of their inorganic counterparts. More importantly, further engineering of charge transport layer to establish stability of polymer BHJ photocathodes in wide range of pH leads to the first demonstration of an organic tandem photoelectrochemical cell for complete solar water splitting in the same electrolyte in the absence of a membrane, which is a considerable advance in the field of OPECs. Consequently, our work coupled with the facile solution processability of the semiconducting polymers establishes the use of polymer BHJs as a promising path towards efficient, scalable, and economical photoelectrochemical cells for overall solar water splitting.

Enhanced Water Splitting Performance of MoS_2 and $PdSe_2$ Using Heterostructuring Edward A. Baker, Joe Pitfield and Steven Hepplestone; University of Exeter, United Kingdom

Two dimensional materials, such as the transition metal dichalcogenides (TMDCs) are a good candidate for water splitting catalysts [1,2], as they often have larger band gaps than their bulk counterparts. However, this had to be balanced by the thin layers having a small absorption cross section and difficulties in mounting on a suitable substrate. $PdSe_2$ is being suggested as a potential water splitting candidate [3]. However its bulk band gap is too small for water splitting [4]. We propose to use this structure as a surface coating to a second TMDC with a larger band gap such as MoS_2 and use this as an example of how such heterostructures could function.
Using density functional theory, implemented in the Vienna Ab-initio Simulation Package, we have investigated the surfaces of TMDC monolayers MoS_2 and $PdSe_2$, and a Hetero-bilayer of the two, for their potential application as photocatalytic water splitters. The different functional groups involved in the Hydrogen and Oxygen evolution reactions have been added to the monolayers and the hetero-bilayer to determine their energetics. In addition to this, we have looked at how stable these materials are, to both adsorptions and substitutions, in both air and water environments.

4:45 PM EN14.16.04
Optical and Scanning Electrochemical Microscopy for Facile Localized Photoelectrochemical Measurement Bhavana Gupta and Wojciech Nogala; Polish Academy of Science, Poland

For conducting localized photoelectrochemical analysis of photoanode, several *in-situ* electrochemical techniques have emerged. Scanning electrochemical microscopy (SECM) is one of the methods by which localized properties of the surface are analyzed with the help of a microelectrode probe. We present here a highly resolved photoelectrochemical property of α-Fe_2O_3 surface through a new and more straightforward approach in SECM set-up. Optical microscope objective is used to illuminate a localized surface from the bottom of the sample and a micro-electrode probe scan the sample from the top. The surface generation and tip collection mode of SECM is used to detect locally products of photoelectrochemical reaction at the sample. Recorded faradaic current is directly correlated to the oxygen evolution quantitatively on the surface of photoanode as the influence of light in terms of oxygen flux. Both qualitative and quantitative information of oxygen evolution will open new gateways in the field of photoelectrochemistry to understand the influence of dopants and hole scavengers by an easy and conventional approach.

5:00 PM EN14.16.05
Surface Engineering and Controlled Growth of 2D-3D In_2S_3 and ZnO Photocatalytic Heterojunction for PEC Water Splitting by Chemical Vapor Deposition Narinder Kaur and Bodh Raj Mehta; Indian Institute of Technology, India

Surface modifications and substrate effect growth of photoanode for heterojunction ZnO/In_2S_3 are achieved in this paper. 2D nanolayers of In_2S_3 and 3D ZnO have been synthesized using a two-step process physical vapor deposition (PVD) for ZnO, followed by chemical vapor deposition (CVD) for 2D layers of In_2S_3 for PEC application. Enhanced photocurrent density in heterojunction ZnO/In_2S_3 is reported due to uniformity in film growth, increased surface area, and efficient electron-hole separation at the heterojunction interface. A photocurrent density of 2.4 $mAcm^{-2}$ is produced for ZnO/In_2S_3 heterojunction, which is 2.5 and 1.4 times higher than pristine ZnO and In_2S_3 at 1.23V (vs. RHE). Transient photocurrent density plots at different wavelengths confirm that the enhancement in photoelectrical response of the interface at lower energy (2.4 eV) compared to ZnO (3.1 eV) is due to absorption in the In_2S_3 layers with energy 2.3 eV. The present approach can be extended to other heterojunctions with 2D materials having different optical and electronic properties.

5:15 PM EN14.16.06
Mitigating Voltage Losses in Scaling-up Photoelectrochemical Water Splitting Devices Keisuke Obata, Babu Radhakrishnan, Ciler Özen and Fatwa F. Abdi; Helmholtz-Zentrum Berlin, Germany

Significant progress has been reported in solar water splitting, with solar-to-hydrogen (STH) efficiency as high as 30% already demonstrated. However, two major challenges remain. First, these high-efficiency devices (> 15%) have only been achieved using expensive and non-scalable III-V semiconductors. Low-cost metal-oxide based devices, mainly using $BiVO_4$ as the absorber, have only achieved STH efficiency of < 10%. Due to stability limitations, many of these metal-oxide based devices are operated in near-neutral pH electrolytes, which poses an additional mass transport challenge. Second, the majority of the demonstrated devices are still at the laboratory scale. Reports on large-area devices are limited, and they typically show much lower efficiencies. This is best illustrated in a recent review:[1] even when III-V semiconductor-based devices are considered, there is no report of devices

with a semiconductor absorber area larger than 10 cm^2 and STH efficiency > 10%. In this talk, we will discuss the scale-up of our photoelectrochemical water splitting devices based on a complex metal oxide absorber. Factors other than the semiconductor itself are found to be responsible for a total voltage loss of > 500 mV and therefore limit the overall performance of the large-area device.[2] We use a combination of multiphase multiphysics simulations (2-D and 3-D finite element analysis models) and validation experiments (e.g., in-situ pH fluorescence, particle image velocimetry, shadowgraphy) to quantify and breakdown the different loss mechanisms (substrate and electrolyte Ohmic loss, concentration overpotentials, product crossover, bubble-related losses) while scaling-up photoelectrochemical water splitting devices.[3-6] Based on these insights, electrochemical engineering strategies to overcome the scale-up related losses are offered.

High-Throughput Experimentation and Artificial Intelligence for the Discovery of New Energy Materials Lars Banko, Olga A. Krysiak, Wolfgang Schuhmann and Alfred Ludwig; Ruhr-Universität Bochum, Germany

High entropy alloys (HEA) comprising four or more constituent elements, are an interesting new class of materials with tunable chemical composition providing the basis for catalytic or electrocatalytic activity towards many reactions. The high electrocatalytic activity of HEA is related to an abundance of active sites, resulting from the statistical distribution of the elements on the surface. With noble metal prices on the rise, noble-metal-free HEA have the potential to decrease the cost for electrocatalysts in various energy conversions technologies.

The challenge involved with both, the experimental and computational exploration of HEA, lies in the enormous number of possible combinations of chemical elements and their mixing ratios, leading to a huge option space for the development of new catalysts. With millions of possible element combinations and roughly 10^4 possible mixing ratios for each material system, fundamentally new research strategies are required.

In this contribution, a high-throughput experimentation strategy is reported, enabling rapid synthesis and screening of possible HEA catalysts materials for water splitting and fuel cells. Combinatorial co-deposition using magnetron sputtering is applied to cover substantial parts of the total composition space of quinary HEA material systems in materials libraries. Electrochemical high-throughput screening is applied to map the electrocatalytic activity over the chemical compositions.

It is demonstrated that within a HEA material system, the electrochemical activity can be increased significantly (e.g. by a factor of 10 as demonstrated in this contribution) by adjusting the mixing ratios of individual elements. The large electrochemical datasets generated by this approach enable the use of artificial intelligence methods (e.g. supervised and unsupervised) for the optimization of chemical composition and synthesis parameters with an enormous potential for understanding the driving forces of electrocatalytic activity and predicting advanced materials.

Material and Component Requirements for (Scaled) Photo-Electrochemical Hydrogen Processing Utilizing Concentrated Irradiation Sophia Haussener; Ecole Polytechnique Federale de Lausanne, Switzerland, Switzerland

Photoelectrochemical (PEC) approaches for the processing of solar fuels and materials are interesting, provided they can be efficiently, stably, scalably, and sustainably implemented. One way to increase the economic and sustainable competitiveness is the utilization of concentrated irradiation [1]. This pathway also allows for the thermal integration of the photoabsorbing and electrocatalytically active components, benefiting the performance as a whole [2]. Scaling of such a thermally integrated photo-electrochemical system keeps the interesting thermal dynamics while also indicating that co-generation of hydrogen and heat increase overall system efficiency [3].
I will discuss material challenges for PEC devices in terms of efficiency and longevity at the laboratory scale, specifically focusing on the unique challenges related to the utilization of concentrated radiation and thermal integration. Additionally, the transition from the laboratory scale (at ~100W power) to the demonstration scale (at ~10kW power) requires tackling alternative challenges related to different approaches for component integration and the design of a complete system, including the incorporation of fitting auxiliary components. I will discuss these integrational challenges at the larger scale, while also discussing requirements for the complete solar processing plant design, both informed by our recent large-scale outdoor and on-sun demonstration activities.

High-Performance $BiVO_4$ Photoanode Fabricated via Sputtering on Patterned FTO Sucheol Ju, Nakhyun Kim and Heon Lee; Korea University, Korea (the Republic of)

Bismuth vanadate ($BiVO_4$) is a promising photoanode material; however, its efficiency significantly changes depending on the atomic ratio of Bi/V, and

there is no suitable method for synthesizing large-area photoanodes. In this study, an efficient $BiVO_4$ photoanode was fabricated via sputtering, by manipulating the molar ratio of Bi/V with V solution annealing. V solution annealing not only adjusted the atomic ratio of Bi/V but also increased the number of O vacancies, thereby improving the charge-separation and charge-transport efficiencies. Consequently, the photocurrent density of the sputtered photoanode with V solution annealing (BVO-V) was 1.86 mA/cm^2, which is 23 times higher than that of the sputtered photoanode annealed under air conditions (BVO-A, 81.0 μA/cm^2). Furthermore, microcone-patterned fluorine-doped SnO_2 was fabricated to increase the active area and reduce the high reflectance, owing to the dense deposition because of the sputtering. Thus, the photocurrent density of the MC-BVO was 3.11 mA/cm^2, which is approximately 67% higher than that of BVO-V (1.86 mA/cm^2).

Parallel Water Photo-Oxidation Pathways in Hematite Photoanodes for Solar Water Splitting Anton Tsyganok[1], Paulino Monroy-Castillero[2], Yifat Piekner[1], Arik Yochelis[2] and Avner Rothschild[1]; [1]Technion, Israel; [2]Ben-Gurion University of the Negev, Israel

Hematite is considered as a promising candidate for photoanodes for water photo-oxidation for direct conversion of solar energy to hydrogen in photoelectrochemical (PEC) water splitting. The water photo-oxidation reaction on hematite surface attracts a lot of scientific interest. Different studies highlight the importance of surface states in the oxygen evolution reaction (OER) mechanism and attribute them various roles in the charge transfer and recombination processes that affect both the photocurrent and the photovoltage. In this work we report a study on the surface states by using time dependent cathodic discharge measurements (CDM) of preconditioned hematite photoanodes that were polarized under illumination and potential sufficient to drive oxygen evolution. We show that upon turning the light off, some of the charged (oxidized) surface states discharge spontaneously while others remain meta-stable in their charged state. When the potential is swept cathodically, in a suitable range and rate, double-peak cathodic discharge wave is observed. The magnitude and the shape of the discharge wave depends on the elapsed time between turning the light off and the cathodic sweep. Specifically, we show that the relative heights of the observed cathodic discharge peaks reverse after sufficient time interval. This observation indicates that the cathodic discharge mechanism involves parallel pathways with different relaxation times rather than a single pathway with consequent serial steps, suggesting parallel reaction pathways for the OER on the surface of hematite photoanodes. This conclusion is corroborated by a microkinetic model that is analytically solved for serial and parallel reaction mechanisms. Furthermore, the model predicts the evolution of the two reaction pathways as a function of time and applied potential.

9:00 AM EN14.17.04
Solution-Based Nickel Oxide Passivation on Silicon Photoanode by Light Irradiation Pre-Treatment Hye-Min Shin, Da-Young Lee and Myung-Han Yoon; Gwangju Institute of Science and Technology, Korea (the Republic of)

Photoelectrochemical cells (PEC) have drawn much attention due to their eco-friendly capability of light-to-hydrogen energy conversion. Silicon, a promising candidate for photoelectrode due to its low bandgap and high efficiency in photo water-oxidation, shows low stability during the alkaline-based photoelectrochemical reaction, which spurred the research on materials and deposition methods for thin passivation layer on silicon. Herein, we report on the formation of an efficient passivation layer on silicon photoanode using solution-processed nickel oxide in combination with light irradiation pretreatment. While the thickness of nickel oxide film and the condition for light irradiation pretreatment are systematically varied, the resultant passivation layer is characterized optically, morphologically, and electrochemically. The light irradiation pre-treatment used an excimer lamp ultra violet with a wavelength of 172 nm and was carried out under varying temperature conditions for 1 h at N_2 atmosphere. Thickness of film fabricated through light irradiation pre-treatment are about 50% thinner than that of conventional annealed films and film has a flat roughness. The nickel oxide film fabricated with light irradiation pre-treatment showed higher PEC efficiency with narrow band gap (3.41 eV), higher saturation current (36 mA/cm^2), and more left shifted overpotential (-0.3 V from on-set of conventional thermal annealing processing film) than those prepared by the conventional thermal annealing process.

9:15 AM EN14.17.05
First-Principles Study of the Effect of Transition Metal Dopants on Enhancing the Carriers' Concentration in Hematite Photoanodes Hoda E. El Gibally, Nageh K. Allam and Mostafa Youssef; American University in Cairo, Egypt

Hematite's intrinsic properties qualifies it to be one of the most effective photoanodes for photoelectrochemical water splitting (PEC). On the other hand, there are several limiting factors for hematite photoanodes that prohibit them from reaching their maximum theoretical efficiencies. One of the most important negatively affecting factors is the low conductivity in hematite, which results in fast recombination rates and hence the loss of the carriers required to perform the PEC process, which eventually results in low hydrogen production rates. Adding dopants to hematite was proven to be one of the best treatments for the low conductivity issue, since donor dopants can generate sufficient electrons to enhance the conductivity and the overall PEC performance. However, in many cases the desired enhancement in conductivity cannot be attained due to compensators for the donors other than electrons such as iron vacancies and other negatively charged defects. In this research, we investigate the effect of substitutional and interstitial defects resulting from the addition of 1% dopants in hematite to determine the optimal set of dopants that can result in a 1:1 dopant-to-electron ratio while maintaining accessible thermodynamic conditions for hematite sample preparation. The investigated dopants include the whole 3d transition metals, in addition to Zr, Nb and Mo from the 4d transition metals and Hf, Ta and W from the 5d transition metals. The formation energies of the dopant defects are calculated using density function theory simulations with Hubbard U corrections and the results are used to plot Kröger Vink diagrams (KVD) which allow us to determine the donors which results in 1% electrons at reasonably accessible oxygen partial pressures. Furthermore, the diagrams are utilized to highlight the dominant dopant defects, which compensate for the electrons and hence provide an insight about their dominant oxidation state in hematite. A further utility of our computations is investigating the possibility of finding a co-doping scenario that can enhance both electrons and holes simultaneously. Our results suggest that 1% doping with W, Ta, and Nb can achieve a 1:1 electron-to-dopant ratio at the atmospheric pressure. Similarly, 1% Ti, Hf, Zr, and Mo can achieve the same effect but at an oxygen partial pressure two orders of magnitude less that the atmospheric pressure. We also propose a W-Zn doped hematite as an optimal dopant strategy to balance enhancing both electrons and holes at a reasonable oxygen partial pressure. We believe that our computational results can narrow down the search space for performing experiments to test the optimal compositions for doped hematite with the goal of enhancing the hydrogen production rates from PEC.

Wasted Photons—Photogeneration Yield and Charge Carrier Collection Efficiency of Hematite Photoanodes for Water Splitting Yifat Piekner[1], David S. Ellis[2], Daniel A. Grave[2,3], Anton Tsyganok[2] and Avner Rothschild[2,1]; [1]Technion-Israel Institute of Technology, Israel; [2]Technion–Israel Institute of Technology, Israel; [3]BenGurion University of the Negev, Israel

Hematite (α-Fe_2O_3) is considered as a leading photoanode candidate, primarily due to its bandgap applicability to the solar spectrum. Its photocurrent is estimated to potentially reach 12.6 mA cm^{-2}, assuming every photon with above band gap energy is absorbed and produces hole-electron pair that contributes to the water splitting reaction. Since hematite's spatial collection efficiency is commonly perceived as the main cause preventing its photocurrent from reaching this value, extensive efforts were made to overcome this challenge by nanostructuring or light trapping routes. However, the

record photocurrent reported for hematite photoanodes reaches about 50% of the theoretical limit. This suggests that optical transitions that do not produce mobile charge carriers contribute to light absorption but not to photocurrent generation, and hence fundamentally limits hematite's performance. The photogeneration yield spectrum, defined as the wavelength-dependent ratio between the absorption that ultimately contributes to the photocurrent and the overall absorption, is elemental fundamental material property that provides a more realistic estimation of the maximum photoconversion efficiency of hematite photoanodes. A general method, that applies to thin and thick films, to extract the photogeneration yield spectrum and the spatial collection efficiency from optical and photoelectrochemical external quantum efficiency (EQE) measurements using minimal *a priory* assumptions regarding the charge carrier collection efficiency will be presented in this talk. Analyzing a 30 nm thick Sn-doped hematite film shows that the photogeneration yield drops from ~60% at short wavelengths (300-400 nm) to ~20-30% at long wavelengths (~550-600 nm), indicating that ~50% of the photons in the solar spectrum between 300 and 600 nm are lost for non-contributing absorption. This explains the difficulty in reaching high photocurrent in hematite photoanodes, even with optimal nanostructured morphologies and ultrathin films with high charge carrier separation and collection efficiency.

10:30 AM *EN14.18.01
Anode Catalyst Layer Durability in Low Temperature Electrolysis Shaun Alia[1], Kimberly S. Reeves[2], Elliot Padgett[1], Haoran Yu[2], Deborah Myers[3] and David A. Cullen[2]; [1]National Renewable Energy Laboratory, United States; [2]Oak Ridge National Laboratory, United States; [3]Argonne National Laboratory, United States

Hydrogen has unique advantages as an energy carrier, with a high energy density and abilities for long term storage and conversion between electricity and chemical bonds. Although hydrogen currently has a significant role in transportation and agriculture, its use in energy consumption overall has been limited, particularly in the case of electrochemical water splitting. With decreasing electricity prices, electrolysis cost reductions can be achieved and allow for an opportunity for greater use.(1) While load-following renewable power sources can reduce feedstock cost, further cost reductions can be achieved by reducing the platinum group metal (PGM) content.(2) Efforts are needed to understand and mitigate electrolyzer degradation, particularly when accounting for lower PGM loadings and intermittent operation.

In this presentation, studies related to anode catalyst durability will be discussed and include the impact of individual stressors, observed degradation mechanisms, and the development of catalyst-specific accelerated stress tests. First, whether through simulated load-following profiles or accelerated cycling, significant performance losses were found as a result of cycling between open circuit and operating potentials.(3) Losses were further aggravated by using a thinner anode catalyst layer or reducing loading, an increase in cycling frequency, and an increase in cell operating voltage. Performance losses primarily appeared through kinetics and were accompanied by anode catalyst dissolution, migration, catalyst layer changes, and interfacial tearing. Second, how components are integrated into membrane electrode assemblies had a significant impact on catalyst layer properties and electrolyzer durability.(4, 5) Properties were modified by varying ink and spray variables during the deposition of the anode catalyst layer and several trends were found with regards to how catalyst-ionomer integration and catalyst layer uniformity affected performance non-idealities and how losses grew during extended operation.

Finally, membrane thickness and ohmic losses were deconvoluted from catalyst layer durability experiments, allowing for a transition from potential-driven parametric observations to current-driven stress tests for advanced materials and coating processes.(5, 6) Through the screening of available catalysts, increased performance losses were found with materials that incorporated less stable elements or contained sub-stoichiometric oxides, particularly when accounting for PGM thrifting and intermittent or start-stop operation. Perspectives on anode catalyst development thrusts and future needs will be also discussed. Specifically, increasing utilization beyond the catalyst layer/membrane interface is needed to better understand the role of catalyst advancements in mitigating electrolyzer performance losses during operation.

Going Beyond the Average Value—Depth-Specific Ion Conduction and Stiffness Behavior Across Ionomer Thin Films and Bulk Membranes Shudipto K. Dishari; University of Nebraska–Lincoln, United States

To improve the performance of electrochemical devices (like fuel cells, electrolyzers, batteries), it is critical to deeply understand very thin ionomeric materials. Ionomers in thin films experience multiple interfaces to which they interact very differently. It is thus of high interest to see how a specific property changes across the thickness of a sub-micron thick ionomer film, and how far the interfacial effects propagate deep down inside it. Techniques, like neutron reflectometry and X-ray computed tomography can offer information about mass or density distribution of water and ionomer across ionomer films. However, ion conduction and mechanical properties, the two most critical performance parameters of ionomers, are still reported as an average value for an entire sample. Understanding the need, we have developed an innovative, simple, and every day-usable strategy using fluorescence confocal microscopy to explore depth-specific ion conduction and stiffness behavior within ionomer bulk membranes and thin films. Ionomer samples were stained with suitable functional dyes first, and then placed under a confocal microscope. A number of xy-plane images were taken and z-stacked to obtain the distribution of relevant properties across the material. The technique revealed a unique distribution of ion conduction and stiffness environment across a

range of fluorocarbon and hydrocarbon-based ionomer thin films from substrate to air interfaces and identified the critical parameters governing such distributed behavior.

Laser-Generated Iridium Nanoparticles Deposited on Nanoscaled Boron-Doped Silicon as Cost-Effecient Electrocatalyst for PEM Water Electrolysis Sven Reichenberger[1], Jasmin Beverungen[1], Norbert Kazamer[2], Martin Underberg[3], Florian J. Wirkert[2], Jeffrey Roth[4], Ulrich Rost[4], Michael Brodmann[2], Stephan Barcikowski[1] and Tim Huelser[3]; [1]University of Duisburg-Essen, Germany; [2]Westphalian University of Applied Sciences, Germany; [3]IUTA e.V., Germany; [4]Propuls GmbH, Germany

One of the most promising ways of meeting the high demand for clean and renewable energy is the synthesis of green hydrogen via electrocatalytic water splitting. Nevertheless, green hydrogen production is currently challenged in industry-scale deployment mainly due to high material and stack costs. The present research aims to address this topic by minimizing the amount of iridium by optimization of the electrode design. Here, an Ir-decorated boron-doped Si nanoparticulate electrocatalyst is being developed and integrated into a scalable proton exchange membrane water electrolyzer by coating it to a porous titanium transport layer in an argon atmosphere.
The B-doped silicon powder was synthesized by thermal decomposition of the gaseous precursors SiH_4 and B_2H_6, while the B/Si - ratio was chosen to be 4%. Laser-generated Ir nanoparticles were subsequently deposited onto the Si@B support in an aqueous suspension.
A homogeneous catalyst distribution on the substrate was noticed by SEM, while TEM analysis reveals a high degree of crystallinity within the particles. Furthermore, it was found that electrostatically-stabilized iridium nanoparticles (~8 nm), gained from surfactant-free laser synthesis with gram-scale productivities and quantitatively were successfully adsorbed to conductive boron-doped silicon nanoparticles (100 – 300 nm) from kg-scale gas-phase synthesis under sufficiently optimized pH condition.
The activity of an $Ir_{10wt\%}$@Si(B) catalyst for oxygen evolution reaction as well as the prepared anode layer on the Ti-substrate ($Ir_{10wt\%}$@Si(B) +Ti-Layer) showed comparable activity in the range from 0.4 V to 1.3 V which was competitive with the activity of a pure Ir-black catalyst indicating a high Ir-accessibility and catalyst layer conductivity of the anode layer.
For validation of the catalyst's activity, a PEM electrolyzer test stack based on hydraulic compression of single cells will be developed. The stack will be suitable for simultaneous operation of 5 single test cells with 25 cm^2 active area each. The test system will be automated for an unattended long-term operation, during which conditions like temperature and pressure can be controlled and monitored.

11:30 AM EN14.18.06
Electrochemical and Structural Behavior of Nickel Polysulfides for Anion Exchange Membrane Water Splitting Lu Xia[1,2], Meital Shviro[1] and Werner Lehnert[1,2]; [1]Forschungszentrum Jülich, Germany; [2]RWTH Aachen University, Germany

Anion exchange membrane (AEM) water electrolyzers, with economically feasible and resource-rich transition metal (TMs)-based catalysts, are promising for large-scale hydrogen production. However, compared to noble-metal catalysts, the low activity and stability of these TMs catalysts are one of the main challenges.[1] Recently, TMs chalcogenides, like sulfides/polysulfide, have been widely used as catalysts for oxygen evolution reaction (OER) and exhibit remarkably high activity due to higher conductivity and more exposed active sites than TMs oxides.[3-4] However, the electrochemical behavior, microstructural and phase composition changes of these chalcogenides in the OER processes need further investigation.
In this work, a scalable electrochemical method was used to activate an S-rich Nickel polysulfide nanocube microstructure prepared by a one-step hydrothermal method to obtain a Nickel-rich polysulfide/(oxy)hydroxide heterostructure. The activated Ni polysulfides show higher activity (370 mV@50 mA cm^{-2}) than that of Ni/NiO (>460 mV) and $Ni(OH)_2$ (>470 mV), and stability (> 60 h) for the oxygen evolution reaction compared to commercial Ni/NiO and synthesized Ni(oxy)hydroxides. Moreover, the results of single-cell tests show that cells based on Ni polysulfides (1450 mA cm^{-2}) have 650 mA cm^{-2} higher current density than cells based on Ni/NiO (800 mA cm^{-2}) in polarization performance at 2.0 V, and nearly no degradation after 80 h@1000 mA cm^{-2}. This work provides a strategy for better utilization of TMs-based polysulfides by in-situ electrochemical approach, and their actual stability under high current density.

Is Proton Conducting Solid Oxide Electrolysis Cell (p-SOEC) Ready for Scalable Electrochemical Hydrogen Production? A Overview of Research Advancement of p-SOEC at Idaho National Laboratory Dong Ding; Idaho National Laboratory, United States

The proton-conducting solid oxide electrolysis cells (p-SOEC) is an emerging and attractive technology for hydrogen production via water electrolysis at intermediate temperatures (400-600ºC). Compared to its counterpart, oxygen-ion conducting SOEC (o-SOEC) that normally operated at >750ºC, reduced operating temperatures can significantly improve the cell/stack durability, minimize stack sealing problems, enable the use of less expensive materials (e.g., ferritic stainless steels for interconnect), and improve response to rapid start-up and repeat thermal cycling needs. Furthermore, p-SOEC can overcome the problems that the o-SOEC encounter, including the mixture of hydrogen and steam, severe delamination of electrodes at high current densities, and partial oxidation of the Ni-based electrode. While these remarkable merits exist, there are still tremendous research efforts needed to address challenges related to electrolyte and electrode materials in p-SOEC. They include poor sinterability, unproven chemical stability and electronic leakage of electrolyte, as well as limited availability of oxygen electrode materials. It raises concerns about whether the technology could move forward for scale up and commercialization. At Idaho National Laboratory, the extensive effort is placed on these topics by both independent research and close collaboration with the universities and industry. Significant advancement is achieved by integrating the materials and microstructure R&D into cell fabrication and manufacturing, implying a

prosperous future of p-SOEC.

1:30 PM EN14.19.02
Development of Triple-Conducting $PrNi_xCo_{1-x}O_{3-\delta}$ Electrode for Proton-Conducting Solid Oxide Electrolysis Cells Hanping Ding, Wei Tang, Wenjuan Bian, Clarita Regalado Vera, Wanhua Wang and Dong Ding; Idaho National Laboratory, United States

High-temperature electrolysis by proton-conducting solid oxide electrolysis cells (p-SOECs) is a highly efficient technology to produce hydrogen at intermediate temperatures (400~600ºC). The robust and stable performance is very critical to evaluate the technical feasibility of this ceramic electrolyzer in the realistic operation, particularly high steam condition. The praseodymium cobaltite-based perovskite $PrNi_xCo_{1-x}O_{3-\delta}$ (PNC) has been discovered to show triple conduction behavior which is utilized as steam electrode for water splitting reaction. The excellent initial performance and nature of high chemical stability make this electrode with great potential to be a benchmarking material for p-SOECs. To systematically evaluate the electrode properties on more aspects, a series of composition optimization study have been carried out to understand structure-property relationship, chemical/performance stability in high steam condition, and interfacial stability. In addition, the origin of the triple conduction has also been investigated to give more guidance on tuning conductivity and material composition.

1:45 PM EN14.19.04
Computational Defect and Thermodynamic Modeling of Redox Behavior of Complex Oxides for Solar Thermochemical Hydrogen (STCH) Production Anuj Goyal[1], Michael Sanders[2], Ryan O'Hayre[2] and Stephan Lany[1]; [1]National Renewable Energy Laboratory, United States; [2]Colorado School of Mines, United States

The two-step metal oxide water-splitting cycle is one of theost viable approach for Solar Thermochemical Hydrogen (STCH) production. Challenges exists in finding suitable oxides that can satisfy thermodynamics of the STCH redox cycle under viable range of temperatures and partial pressures. Recently, novel quaternary oxides $Sr_{1-x}Ce_xMnO_3$ (SCM) and $Ce_xSr_{2-x}MnO_4$ (CSM) (where x from 0.05 to 0.25) are demonstrated to exhibit promising STCH performance. however, a defect model establishing how changing Ce/Sr composition can be used to tune the STCH redox behavior of SCM/CSM systems is still missing. In this study, we investigate the atomic, electronic and defect structure of these strongly correlated oxides using first principles supercell calculations employing different levels of theory (DFT+*U*, SCAN+*U*, Hybrid-DFT). We find that O vacancy formation energy is highly sensitive to the choice of level of theory, and strongly depend on the fraction of Mn^{4+}/Mn^{3+} in the system, ratio of which changes with Ce concentration (x) as well as with the extent of reduction or oxygen off-stoichiometry. Here, we present a defect model that incorporatea dependence of Ce/Sr composition and oxygen off-stoichiometry on the O vacancy formation energy, followed by the thermodynamic modeling to quantitatively predict the redox behavior of these complex quaternary oxides. This study help develop new general approaches for modeling defects in complex oxides beyond the dilute limit and at high temperatures, which is still a critical scientific challenge for the entire computational community.

2:00 PM EN14.19.05
Liquid Metal Alloys for Hybrid Thermo-Electro-Chemical Water Splitting Cycles Andrea Ambrosini, Laura A. Achola, Matthew Witman, Margaret E. Gordon and Anthony McDaniel; Sandia National Laboratories, United States

As the world pursues the goal of lowering carbon emissions to meet the challenges of global climate change, the utilization of hydrogen in transportation, energy storage, and commodity chemical production is becoming increasingly widespread . Water-splitting using renewable energy sources such as electricity from PV or wind, or heat from concentrating solar, is a green method of hydrogen production. However, widespread adoption of these renewable, carbon-free technologies is hindered by materials challenges, low efficiencies, and high costs.

In this talk, a novel route to hydrogen production via a hybrid thermo- electro-chemical route utilizing a liquid metal solution (LMS) as the water splitting medium will be introduced. In the first step of this process, steam is thermochemically reduced by the LMS producing hydrogen and a metal oxide (Eq. 1), while in the second step, the metal oxide is electrochemically reduced back to metal and oxygen is evolved (Eq. 2):

$MM' (l) + H_2O (g) \rightarrow M (l) + M'O_x (s) + H_2 (g)$ (Eq. 1)
$M'O_x (l) + M' (l) + e^- \rightarrow MM' (l) + O_2 (g)$ (Eq. 2)

In this reaction, MM' is an alloy consisting of two metals, one that is inert to steam (M) and remains as solution and one which is redox-active (M') and is oxidized during the water-splitting process. The reaction can be driven using heat and electricity from concentrating solar or nuclear power. Alternatively, the electrical input may be provided by wind or PV. The LMS process has the potential to produce hydrogen via water splitting at temperatures much lower than current CSP-driven thermochemical processes and at applied potentials lower than conventional high-temperature electrolysis.

A number of possible binary LMS compositions were identified using machine learning. Several candidates were downselected and tested for hydrogen production in a custom-built flow reactor. The metal alloys were characterized pre- and post-reaction to analyze changes microstructure, grain size, and metal oxide particle growth. The results of these analyses will be presented.

2:15 PM EN14.19.06
Redox Defect Thermochemistry of $FeAl_2O_4$ Hercynite in Water-Splitting from First Principles Methods Samantha Millican[1], Jacob M. Clary[1], Charles B. Musgrave[1] and Stephan Lany[2]; [1]University of Colorado Boulder, United States; [2]National Renewable Energy Laboratory, United States

Solar thermochemical hydrogen (STCH) production is a promising route to produce fuels from sunlight via high-temperature water splitting. However, efficient and technologically viable implementations of this process only allow a narrow window of thermodynamic boundary conditions that can be used to cycle the system, thus limiting the design space for suitable metal oxide redox mediators. An oxygen defect redox mechanism can contribute a favorable reduction entropy to expand this window, and computational evaluation of materials with high oxygen defect entropies could play a pivotal role in guiding the discovery and design of suitable oxides. This study employs first-principles calculations to investigate the redox mediating defect mechanism of the STCH candidate material, hercynite ($FeAl_2O_4$). We compare the results from density functional theory (DFT) with beyond-DFT approaches, including hybrid functionals and the random phase approximation, which are among the most advanced methods currently feasible for supercell defect calculations. Using the predicted total energies, we perform thermodynamic modeling of $FeAl_2O_4$ reduction and oxidation via free energy minimization that incorporates ideal gas, configurational, and vibrational entropy contributions evaluated within the quasi-harmonic approximation. Special attention is devoted to understanding interactions among co-existing defects, such as the association of pairs and complexes of O vacancies and cation antisite defects, as well as the effect of mutually compensating defect charges. Our results corroborate the notion that the details of defect interactions can be decisive for the viability of hydrogen production within the desirable STCH process window.

2:30 PM EN14.19.07

Ca and Co-Doped LaMnO3 Perovskite for Two-Step Thermochemical Water Splitting Seyfettin Berk Sanli, Ihsan E. Yigiter, Fatih Piskin, Berke Piskin and Gulhan Cakmak; Mugla Sitki Kocman University, Turkey

Increasing interest in sustainable energy sources and climate change has encouraged research in the production of H2 from H2O. One of the significant methods being explored for the generation of H2 is the thermochemical splitting of H2O and by using oxide materials.
Perovskite oxides have been suggested as promising substances for solar thermochemical separation of H2O and have been widely studied recently. We have carried out a systematic experimental production study of doped Ca and Co-doped perovskites within the compositions of La1- CaxMn1-yCoyO3(Ca=0.2-0.8, Co=0.2-0.8).
In the study, LCMx perovskite oxides were synthesised by a solution-based method (Pechini, 19673). For this purpose, nitrated salts of the elements La, Ca, Mn and Co, suitable proportions for the prescribed composition, were used. Deionized water and citric acid in appropriate proportions were added to the structure. The solution was stirred by heating at 120 ° C with ethylene glycol addition. After gelation, the system was dried, and the obtained powders were ground.
Powders were calcined at three different temperatures. The phase analysis of the powders were performed by using X-ray diffraction (Rigaku SmartLab X) using monochromated Cu Ka radiation at 40 kV and 200 mA. The structures are refined using the Maud programme to identify their crystal structure. BET surface area was evaluated by N2 adsorption at 77 K in a constant volume adsorption apparatus (Quantachrome Autosorb 1C-MS).The Powders obtained were examined morphologically using SEM (JEOL JSM-7600F). The effect of the composition and applied temperatures on the surface area and particle size was investigated.
The studies started by determining the synthesis parameters for each LCMx oxide composition. For this purpose LCMC4664 composition was selected and synthesized under four different conditions (1. citric acid addition, 2.citric acid addition and ph ~8, 3. Citric acid and ethylene glycol addition, 4. Citric acid and ethylene glycol addition and ph ~8. All systems are calcined at 900 ° C-1300 °C. The X-ray diffraction results show that the main diffraction peaks are characteristic of the typical cubic perovskite structure. However, with the addition, the structure turns into an orthorhombic structure. The change in lattice parameters were also obtained with Rietveld refinement of the sample. the Bragg peaks of LCMC perovskites doped on both the A and B sites were noticeably shifted due to the distinct ionic radii of the introduced metal ions
LCMC4664 compositions synthesized with different parameters and also characterized by SEM, EDS and BET to compare their grain structure, morphology, chemical composition and surface area.Within all synthesis parameters TM: CA: EG 1: 1,5: 1,5 pH = 8,00 gives the lowest surface area. Among the synthesis conditions, the highest surface area is achieved was for synthesis condition for TM: Ca 1: 1.5 pH≤1.00 (0.66m2 / g).
The thermochemical H2O splitting performances of the samples were evaluated in a laboratory-scale reactor (and the O2 and H2 produced during the thermochemical process were monitored using a mass spectrometer (MS). We compared the thermochemical performances of the A-site doped and B site doped perovskites. The extents of oxygen vacancies generated by the prepared samples in high-temperature thermal reduction processes were investigated by measuring O2 production, which in turn will determine the maximum solar fuel production.
In the second step, H2O splitting tests were conducted and H2 production was immediately detected after the aspiration of H2O vapour into the system. The thermochemical performance of LCMC systems are discussed with respect to their BET surface area, which is directly related to the solid-gas reaction during the thermochemical catalytic process.

Alkaline and Bipolar Membrane Electrolyzers Shannon W. Boettcher, Grace Lindquist and Haokun Chen; Univ of Oregon, United States

Commercialized membrane electrolyzers use acidic proton exchange membranes (PEMs). These systems offer high performance but require the use of expensive precious-metal catalysts such as IrO_2 and Pt that are nominally stable under the locally acidic conditions of the ionomer. Here I will discuss our efforts to study and develop alternative electrolysis platforms.

First, I will discuss alkaline exchange membrane (AEM) electrolyzers that, in principle, offer the performance of commercialized proton-exchange-membrane electrolyzers with the ability to use earth-abundant catalysts and inexpensive bipolar plate materials. I will present progress in building high-performance AEM electrolyzers and studying fundamental aspects of their operation and degradation. To date, our best systems operate at 1 A cm^{-2} in pure water feed at < 1.9 V at a moderate temperature of 69 °C. These devices, however, degrade rapidly (~ 1 mV/h) compared to PEM electrolyzers. I will discuss our work assessing chemical changes to the anode and cathode catalyst and ionomer that is correlated with this performance loss, as well as strategies to mitigate degradation modes.

Second, I will introduce the use of bipolar membranes (BPMs) in electrolysis-type devices. BPMs consist of an AEM and PEM laminated together. Under the appropriate bias, they conduct ionic current by dissociating water into protons and hydroxide at the AEM/CEM junction. Commercially, BPMs are used in electrodialysis, but generally are used at low current densities below 100 mA cm^{-2} to avoid large losses in driving water dissociation. I will present our fundamental studies on how to accelerate water dissociation in BPMs (*Science*, 2020) and how that has enabled BPMs operating at > 3 A cm^{-2} and with improved efficiency. BPMs limit crossover and enable operation of a cathode and anode in different pH conditions and are thus seeing substantial interest for CO_2 electrolysis, advanced electrodialysis systems, and water electrolysis; applications that I will highlight.

4:30 PM EN14.20.02
Covalent 0D–2D Heterostructuring of Co9S8–MoS2 for Enhanced Hydrogen Evolution in All pH Electrolytes Minkyung Kim[1], Mohsin A. Anjum[2], Min Choi[1], Sun Hee Choi[3], Noejung Park[1] and Jae Sung Lee[1]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]Pakistan Institute of Nuclear Science and Technology, Pakistan; [3]Pohang University of Science and Technology, Korea (the Republic of)

Ultrasmall Co9S8 nanoparticles are introduced on the basal plane of MoS2 to fabricate a covalent 0D–2D heterostructure that enhances the hydrogen evolution reaction (HER) activity of electrochemical water splitting. In the heterostructure, separate phases of Co9S8 and MoS2 are formed, but they are connected by Co–S–Mo type covalent bonds. The charge redistribution from Co to Mo occurring at the interface enhances the electron-doped

characteristics of MoS2 to generate electron-rich Mo atoms. Besides, reductive annealing during the synthesis forms S defects that activates adjacent Mo atoms for further enhanced HER activity as elucidated by the density functional theory (DFT) calculation. Eventually, the covalent Co9S8–MoS2 heterostructure shows amplified HER activity as well as stability in all pH electrolytes. The synergistic effect is pronounced when the heterostructure is coupled with a porous Ni foam (NF) support to form Co9S8–MoS2/NF that displays superior performance to those of the state-of-the-art non-noble metal electrocatalysts, and even outperforms a commercial Pt/C catalyst in a practically meaningful, high current density region in alkaline (>170 mA cm−2) and neutral (>60 mA cm−2) media. The high HER performance and stability of Co9S8–MoS2 heterostructure make it a promising pH universal alternative to expensive Pt-based electrocatalysts for practical water electrolyzer.

4:45 PM EN14.20.03
Nanoporous Gold Obtained by Dealloying AuFe2 Precursor—A Promising Low-Cost Electrocatalyst for Hydrogen Evolution Reaction Deepti Raj[1], Federico Scaglione[1], Gianluca Fiore[1], Federica Celegato[2] and Paola Rizzi[1]; [1]Università di Torino, Italy; [2]Istituto Nazionale di Ricerca Metrologica (INRIM), Italy

As an efficient and sustainable alternative to fossil fuels Hydrogen gas (H_2) has emerged to be of great importance for the future of energy generation and storage. However, H_2 production from the electrocatalytic hydrogen evolution reaction (HER) still remains a challenge. Although platinum and its alloys have been the benchmark electrocatalysts for HER, the scarcity, substandard stability and expensiveness limit their usage making it crucial to develop economical electrocatalysts with elevated activity and stability. In this quest, nanoporous metals, built of 3D scaffolds of bi-continuous ligament-pore structure, have shown growing inclination because of their large surface area to volume ratio and enhanced catalytic properties. This work focusses on Nanoporous Gold (NPG) as a promising candidate with its noble nature, high conductivity and large surface area. Instead of common precursors constituting various alloying metals and high Au concentration, a metastable supersaturated solid solution of $AuFe_2$ was selected – with cheap and abundant Fe and minimum possible Au concentration according to the parting limit. Long and homogeneous melt-spun ribbons were obtained by rapid solidification of the arc-melted precursor. The as-quenched ribbon was dealloyed chemically in 1 M HNO_3 and 1 M HCl at 70 °C for different durations. The structural and compositional investigation was accomplished using XRD, SEM and EDS techniques. The as-dealloyed samples possessed nanoporosity both on surface and cross-section with high Au content. One of these samples was tested as an electrocatalyst for HER in 0.5 M H_2SO_4. Low onset potential of -4 mV; low overpotential of -0.38 V at a current density of -5 mA/cm^2; small Tafel slope of 47 mV/dec; and high exchange current density of 0.12 mA/cm^2 have been obtained. Thus, the NPG sample demonstrates excellent electrocatalytic activity considering that an overall low-cost, fast and simple synthetic route combined with the cost-effective precursor were employed for the fabrication.

5:00 PM EN14.20.04
Selenium-Doped Copper Oxide Nanoarrays for Enhanced Oxygen Evolution Reaction (OER) Lamya Tabassum and Steven Suib; University of Connecticut, United States

Global energy demand is projected to increase by 50% by 2050. Existing fossil fuels can meet this energy demand only until the end of this century. Fossil fuels are also a major source of greenhouse gas emissions. Therefore, it is one of the biggest challenges to find a sustainable, clean, and efficient energy source. Ongoing research efforts have led to the invention of promising energy storage technologies like alkaline water splitting, metal-air batteries, and fuel cells.[1] The oxygen evolution reaction (OER) is the critical anodic reaction in the aforementioned devices. OER is a four-electron process with sluggish reaction kinetics, thus the overall efficiency of these systems is low. RuO_2 and IrO_2 catalysts are considered the benchmark for OER in both acidic and alkaline media.[2,3] However these noble metal-based catalysts are costly and suffer from disadvantages such as instability (oxidized to RuO_4 and IrO_3) under high anodic potential and dissolution into the electrolyte solution.[4,5] Transition metal-based catalysts are cheap and abundant. Fe, Co, Ni, Mo, and W transition metal-based catalysts have been well explored in the past decade for OER and show promising results.[6-7] However, copper oxide-based catalysts are less explored for OER due to their poor conductivity, inappropriate crystal structure, and narrow bandgap.[8] Doping is an effective strategy to improve the conductivity and thus the electrocatalytic activity of the material. For example, doping sulfur into Cu_2O has been reported to significantly lower the onset potential for OER.[9] In this work, we have doped Se into CuO nanoarrays for OER application. We have observed that upon doping Se into CuO nanoarray structures, the overpotential for OER can be lowered significantly. Comprehensive characterization and electrochemical performance of the Se doped CuO nanoarray for OER will be presented.

Key Material Parameter Estimation for High-Performance Polymer Electrolyte Electrochemical Cell Evaluated by Current-Voltage Temperature Dependence Daichi Matsui[1,2], Katsushi Fujii[2], Satoshi Wada[2] and Atsushi Ogura[1,3]; [1]Meiji University, Japan; [2]RIKEN Center of Advanced Photonics, Japan; [3]Meiji University MREL, Japan

High-performance water electrolysis is an important device for green hydrogen production. Polymer electrolyte electrochemical cell (PEEC) is considered a suitable device for renewable energy storage due to the toughness of the fluctuated energy sources.
We focused on PEEC as a device to convert electricity into hydrogen in this report. The evaluated PEEC has an electrode area of 12.5 cm^2 with IrO_2 as the cathode catalyst and Pt as the anode catalyst. The operating temperature of this device was varied from 30 to 70°C in order to evaluate the current-voltage characteristics. The results were compared with a chemical reaction-based device model [1,2].
The threshold voltage and the slope of the polarization curve of the current-voltage characteristics were changed with the operating temperature. The threshold voltage decreased and the slope of the polarization curve increased with increasing operating temperature. There were clarified that the activation energy of the electrochemical reaction mainly affects to change of the threshold voltage, and the resistance of the solid polymer membrane mainly affects the change of the slope of the polarization curve from the device model analysis. The other chemical parameters did not significantly affect the PEEC current-voltage temperature dependence. The results show that the reduction of activation energy of the electrochemical reaction and the suppression of

ohmic resistance of the solid polymer membrane were important parameters to improve the performance of PEEC.
The PEEC performances were evaluated quantitatively by the current-voltage temperature dependence using the device model. The results of these quantitative evaluations give guide the material designs for the high-performance PEEC.

High Stability PtAu Thin–Film Catalyst for Oxygen Reduction Reaction Xianxian Xie, Ivan Khalakhan, Mykhailo Vorokhta and Iva Matolínová; Charles University, Czechia

Oxygen reduction reaction is a key reaction for proton exchange membrane fuel cells (PEMFCs), which is the perspective of renewable energy for many practical applications. Platinum is the most efficient element for oxygen reduction reaction on the cathode side. However, Pt-based cathode catalysts are undergoing severe degradation due to the high potential changes. Therefore, we introduce a small amount of Au into Pt, form bimetallic PtAu alloy thin film catalyst by magnetron co-sputtering technique, resulting in a significant stability improvement in oxygen reduction reaction. Moreover, the PtAu alloy thin film catalysts show similar electrochemical activity with the identical Pt-loading, indicates its applicability for industrial PEMFCs. The stability of thin film catalysts is studied in half-cell rotating disk electrode (RDE). The morphology, structure and composition of thin film layer are characterized by scanning electron microscopy (SEM), X-ray diffraction (XRD), and X-ray photoelectron spectroscopy (XPS).

8:15 AM EN14.07.03
Characterization of Silicon Carbide Coatings for Hydrogen Permeation Barriers Michael Drory[1], Sean M. Lam[2], Dale Hitchcock[1], Timothy Krentz[1], Garrett Pataky[2] and Marian S. Kennedy[2]; [1]Savanah River National Laboratory, United States; [2]Clemson University, United States

Silicon carbide (SiC) thin films are of interest for hydrogen permeation barriers in fusion reactors. Stainless steels such as 316L are sought for nuclear applications (for example, fission reactor and tritium process components) because of wide availability and low cost, however they are susceptible to tritium uptake that may affect tritium accountancy and release to the cooling system and environment. We examine SiC coated 316L by magnetron sputtering, followed by deuterium permeation testing at elevated temperature and pressure. Permeation was measured in a concentration-driven gas-phase experimental setup. The Arrhenius permeation behavior was derived by varying temperature and pressure gradients in a stepwise fashion. As seen in other studies, more than an order of magnitude reduction in deuterium permeation is found for thin SiC coatings compared with uncoated 316L. The emphasis here is to characterize the SiC coating and 316L substrate interface to elucidate any effects of microstructure on permeation resistance.

New Compute Trajectories for Energy-Efficient Computer Victor V. Zhirnov; Semiconductor Research Corp, United States

Computing and, more generally, Information and Communication Technologies (ICT) is the social-economic growth engine of modern world. Rapid advances in computing have provided increased performance and enhanced features in each new generation of products in nearly every market segment, whether it be servers, PCs, communications, mobile, automotive, entertainment, among others.
The use of the information and communication technologies continues to grow without bounds dominated by the exponential creation of data that must be moved, stored, computed, communicated, secured and converted to end user information. Ever-rising energy demands for computing versus global energy production are creating new risk, therefore new computing paradigms need to be discovered that would result in dramatically improved energy efficiency of computing.
How to get 10^6 more semiconductor energy efficiency? Inventing the next hardware/software computing paradigm is a tall order, to be sure. However, it is achievable if the right questions are asked and right resources are put in place. These steps are outlined in the Decadal Plan for Semiconductors (https://www.src.org/about/decadal-plan/) which is currently being proposed to government and the ICT industry.

2:00 PM EN15.01.02
Downscaling Effects on Resistivity of Topological Semi-Metal MoP Nanowires Hyeuk Jin Han, James L. Hart and Judy Cha; Yale University, United States

The increasing resistance of Cu interconnects is a major challenge in the continued downscaling of integrated circuits beyond the 5-nm technology node. Topological semi-metals that exhibit high conductivity and mobility are promising material candidates for low-resistance interconnects to potentially replace current Cu interconnects. Particularly, nanoscale topological semi-metals might outperform their bulk counterparts as interconnects as the contributions of the topologically protected surface states to the overall transport signals will be enhanced at the nanoscale. Recently, molybdenum phosphide (MoP) was discovered as a triple-point topological semi-metal with excellent transport properties of bulk resistivity of 8.2 μΩ*cm and a high carrier density of 1.1×10^{23} cm^{-3} at room temperature (N. Kumar, et al., Nat Commun (2019) 10, 2475). Due to the topological protection predicted to suppress electron scattering at the surface, MoP may preserve its low resistivity values at the nanoscale, which may rival the line resistance of current Cu interconnects.
Here, we report the synthesis and transport properties of MoP nanowires, which were synthesized by reacting MoO_3 nanostructures with phosphorous precursors (H. J. Han et al., APL Materials (2020), 8(1), 011103). We observe that the initial diameter of the MoO_3 nanowires critically determines the crystalline quality of the converted MoP nanowires, from porous flakes to poly-crystalline nanowires, and finally to single-crystalline nanowires. This size-dependent crystallinity is attributed to the suppression of nucleation at the nanoscale. While the resistivity values of the polycrystalline MoP nanowires were measured to be higher than the reported resistivity of MoP bulk single crystals due to the presence of nanoscale grains, we observe that the resistivity values approach that of the bulk with decreasing diameter of MoP nanowires. Importantly, we demonstrate that the line resistance versus the total cross-sectional area of MoP nanowires is comparable to, or even better than, those of effective Cu and barrier-less Ru interconnects, suggesting MoP is an attractive solution to the current scaling challenge of Cu interconnects. In this talk, we will also discuss the role of topological surface states in the transport properties of MoP nanowires.

2:15 PM EN15.01.03
Microstructure and Electro-Optic Response of Thick Epitaxial $BaTiO_3$ Films Integrated on Silicon (001) by Molecular Beam Epitaxy Marc Reynaud[1], Wente Li[1], Agham Posadas[1], Alex Demkov[1], Zuoming Dong[1], Daniel Wasserman[1] and Albina Borisevich[2]; [1]The University of Texas, United States; [2]Oak Ridge National Laboratory, United States

Recent advances in epitaxial oxide deposition enabled fabrication of thick films of ferroelectric perovskite $BaTiO_3$ capable of providing a robust electro-optic (EO) response via the Pockels effect. This created a plethora of potential applications in silicon photonics ranging from optical interconnect to optical neuromorphic and quantum computing. However, the EO response being a tensor property, is very sensitive to crystal microstructure. And microstructure control is therefore key to building functional EO devices such as phase shifters and modulators. We report a microstructure analysis along with the deposition process of thick EO-active films integrated on Si(001) by molecular beam epitaxy, showing how the crystal orientation changes as a function of thickness. In addition to x-ray diffraction, we have performed cross-sectional high-angle annular dark-field scanning transmission electron microscopy (HAADF-STEM) imaging to analyze in detail the crystalline structure of the BTO films. Geometric phase analysis (GPA) was performed on the STEM images to extract information regarding the orientation of the BTO crystal as a function of layer position. Phase field simulations were used to help interpret the GPA. In addition to GPA, sliding fast Fourier transformations (FFTs) of the film were performed that showed similar results and good agreement with GPA. The electro-optic properties of the film have been measured in free space as well as using Si waveguides, deposited atop the film, and correlate well with the microstructural analysis and demonstrate the potential of Si-integrated $BaTiO_3$ for silicon photonics. The work at Austin is supported by the Air Force Office of Scientific Research under grant FA9550-18-1-0053.

2:30 PM EN15.01.04
Manufacturable Process for Thick Epitaxial $BaTiO_3$ Films Integrated on Silicon for Electro-Optic Modulators Agham Posadas[1], Hyoju Park[1], Marc Reynaud[1], Wei Cao[2], Goran Mashanovich[2], Jamie Warner[1] and Alex Demkov[1]; [1]The University of Texas at Austin, United States; [2]University of Southampton, United Kingdom

We report on a process for fabricating thick epitaxial $BaTiO_3$ films on silicon that is compatible with large scale production and capable of producing optical quality material of sufficient thickness for use in silicon photonics and neuromorphic computing elements. Thick $BaTiO_3$ films ranging from 120 nm to 1 mm were grown by off-axis rf magnetron sputtering on $SrTiO_3$-templated silicon-on-insulator substrates. The films microstructure was characterized in detail by x-ray diffraction and cross-section scanning transmission electron microscopy. The films are of high quality, rivaling those grown by molecular beam epitaxy in crystalline quality, but can be grown ten times faster while maintaining process repeatability. Extraction of lattice parameters from geometric phase analysis of atomic resolution scanning transmission electron microscopy images revealed how the in-plane and out-of-plane lattice spacings of sputtered $BaTiO_3$ changes as a function of layer position within a thick film. Our results indicate that, compared to molecular beam epitaxy, sputtered films retain their c-axis orientation for larger thicknesses. Electro-optic measurements using a transmission setup of a sputtered $BaTiO_3$ film grown using the optimized conditions yields an effective Pockels coefficient as large as 165 pm/V. A Si_3N_4 waveguide Mach-Zehnder modulator fabricated on such films exhibits phase shifting with an equivalent Pockels coefficient of 157 pm/V. These results demonstrate that the off-axis sputtering process is a manufacturable solution for making thick $BaTiO_3$ films that can be used for fabricating high efficiency and compact electro-optic modulators integrated on silicon.

2:45 PM EN15.01.05
Measuring Ionic Mobility in Oxide Thin Films by Dynamic *I-V* Analysis–Impact of Interfaces Dmitri Kalaev[1], Baoming Wang[1], Takashi Ando[2], John Rozen[2], Frances M. Ross[1] and Harry Tuller[1]; [1]Massachusetts Institute of Technology, United States; [2]IBM Thomas J. Watson Research Center, United States

Ionic transport in solids, e.g. nonstoichiometric oxides, is key to the design and control of non-volatile RAM devices considered for use in neuromorphic hardware. While significant progress has been achieved in the development of neuromorphic devices based on Resistive and ElectroChemical RAM, their performance is limited in part by knowledge of ionic transport phenomena that control conductance changes in filamentary regions and/or at oxide interfaces. We study ionic mobility in oxide materials, e.g. doped ceria, by applying our previously developed Dynamic *I-V* Analysis technique[1] capable of measuring oxygen vacancy mobility dependence on temperature, thermal history and oxygen non-stoichiometry. Here we show that interface resistance, that might arise either at the contact between the oxide under study and its electrodes or between grain boundaries created during pulsed laser deposition, varies significantly. While the interfacial contributions to overall device resistance is sometimes negligibly small, in many cases they become significantly larger than the bulk value. We show that the interface resistance has a direct impact on the effectiveness of the measurement of ionic transport in the oxides of interest. Electrical impedance spectroscopy supported with XRD and electron microscopy are applied to determine the interfacial resistance, and its origins, in oxide thin films, that impacts the oxygen defect transport and impedes characterization. We will present possible ways to mitigate the interfacial resistance, by tuning the PLD parameters and by carefully choosing the electrodes and the supporting substrates materials in the test devices. Finally, we will report near room temperature values for ionic mobility in crossbar devices with optimized ceria layers.

3:00 PM EN15.01.06
High Sensitivity SIMS Analysis of Oxygen Movement in Silicon Oxide ReRAM Devices—Materials Challenges for Energy Efficient Memristive Devices Horatio Cox[1], Mark Buckwell[1], Wing H. Ng[1], Daniel J. Mannion[1], Adnan Mehonic[1], Paul Shearing[1], Sarah Fearn[2] and Anthony Kenyon[1]; [1]University College London, United Kingdom; [2]Imperial College London, United Kingdom

Resistance modulation in oxide-based intrinsic ReRAM devices is a promising technology for energy efficient computing based on neural network multiply-accumulate (MAC) accelerators or neuromorphic engineering. Such modulation is driven by oxygen movement in metal-oxide-metal (MIM) stacks under electric fields. However, the sensitivity of existing analysis techniques at the nanometre scale is too limited to systematically examine complex interactions, oxygen exchange, formation of novel layers, and the role of ambient conditions. Given that the movement and storage of oxygen across the MIM stack to a large extent determines the energy efficiency of resistance modulation, the cycling endurance of devices and the stability of resistance states, it is critical to the development of novel energy efficient devices that such effects are characterised and understood. Here we report the measurement of oxygen movement in silicon oxide-based ReRAM devices using a novel Secondary Ion Mass Spectrometry (SIMS) normalisation technique that allows the measurement of ionic movement with unparalleled sensitivity

Our technique allows us for the first time to observe the movement of ^{16}O across electrically biased silicon oxide (SiO_x) ReRAM stacks, measuring bulk concentration changes in a continuous profile with unprecedented sensitivity. This reveals nanoscale details of the reversible field-driven exchange of oxygen across the ReRAM stack. We present modelling of the electric fields in ReRAM devices which, for the first time, uses real measurements of both interface roughness and electrode porosity. This supports our findings and helps to explain how and where oxygen from ambient moisture enters devices during operation.

Using Magnetic Domain Walls and Skyrmions for Cognitive Computing Jean Anne C. Incorvia[1], Matthew Marinella[2], Sam Liu[1], Can Cui[1], Priyamvada Jadaun[1], Christopher Bennett[2], Tianyao Xiao[2], Joseph Friedman[3], David Paydarfar[1], Thomas Leonard[1], Mahshid Alamdar[1], Suyogya Karki[1], Vivian Rogers[1] and Otitoaleke Akinola[1]; [1]University of Texas at Austin, United States; [2]Sandia National Laboratories, United States; [3]The University of Texas at Dallas, United States

Over the past decades, tremendous effort has gone into designing and building computers to accomplish tasks outside the reach of humans. But, despite the revolution in computing that has occurred, there are still tasks where humans easily outperform computers. The efficiency and adaptiveness of the mammalian brain enables many immersive tasks, such as language understanding, coherent processing of multiple senses to make a decision, object perception, and consciousness.

The field of cognitive computing is inspired by continually emerging understanding of advanced brain behavior that enables efficient and real-time learning, reaction, and cognition. To achieve true brain-like computing, we need to understand 1) the advanced cognitive features of the brain to accomplish tasks and 2) how to translate those features to nanoengineered materials and devices that are 3) compatible with circuits and systems to perform actual tasks.

In particular, there are rich dynamical behaviors in magnetic materials that are bio-mimetic and highly applicable to cognitive computing. Here, we will present our recent results on understanding and leveraging the materials properties of magnetic domain walls (DWs), skyrmions, and magnetic tunnel junctions (MTJs) for energy efficient cognitive computing.

We will show that DW motion in a magnetic track can be engineered to have highly linear position vs. time behavior as it is moved along the track via either spin transfer torque or spin orbit torque, acting as an artificial synapse. We show the DW-MTJ synapse can have the necessary characteristics for energy efficient backpropagation on-chip learning: linear weight updates, controllability, and symmetry. Therefore, it can tolerate the relatively lower change in total resistance compared to other nonvolatile device types. We will show the stochasticity of the DW position is helpful for high accuracy of MNIST and Fashion-MNIST image recognition [1].

We will then show a brain-inspired “edgy-relaxed” behavior seen in biological neurons can be implemented inherently in the DW-MTJ device when it acts as an artificial neuron. When a neuron is activated often (edgy), a depolarizing shift causes the cell to be at a lower threshold for generating additional action potentials. Conversely, a neuron that is not activated often (relaxed) requires a higher threshold. This is a biological behavior that has heretofore never been used in neural networks. As in the mammalian system, edgy-relaxed neuron function should be beneficial when performing repetitive tasks. We will show that the edgy-relaxed behavior in DW-MTJ neurons improves the classification accuracy of ordered datasets, and that the materials properties can be engineered such that the classification accuracy is not lost for completely random datasets [2]. The degree of edgy-relaxed behavior can be dynamically tuned, an exciting result for task-adaptable computation: based on the expected ordering of a dataset, the magnetic neuron behavior can then be adjusted to most efficiently complete the task.

While DW dynamics are one useful materials property for cognitive computing, magnetic skyrmions can offer additional dynamics including coupled and

multi-modal oscillatory behavior. We will show results on designing a coupled skyrmions neuron. By having multiple inputs that can change the resonant behavior of the skyrmion system, we show it can be dynamically modulated based on context and environment. We will show this can implement cognitive features including context awareness (processing different types of inputs differently), neuromodulation (simultaneously processing different information), feature binding (combining information to
construct a coherent perception), and bursting (neurons respond as a group to a coherent input) [3].

***Ab Initio* Investigations of Novel 2D Materials as Next-Generation Field-Effect Transistors** Mathieu Luisier[1], Cedric Klinkert[1], Aron Szabo[1], Christian Sieger[1], Davide Campi[2] and Nicola Marzari[2]; [1]ETH Zurich, Switzerland; [2]EPFL, Switzerland

Since the first experimental demonstration of a monolayer MoS_2 transistor in 2011, transition metal dichalcogenides (TMDs) have received a wide attention from the scientific community as potential replacement for Silicon FinFETs at the end of the semiconductor roadmap. As graphene, TMDs exhibit excellent electrostatic properties due to their 2-D nature, but contrary to it, they are characterized by large band gaps, while keeping decent phonon-limited mobilities up to 100's cm2/Vs. However, so far, no TMD-based transistor has been shown to outperform the Si technology. While this limitation can be partly attributed to technology challenges, e.g. high contact resistances, poor crystal quality, or absence of native oxide, the TMD bandstructure also explains this behavior: electrons/holes are not fast enough to allow for large ON-state currents.

A recent theoretical study based on density functional theory (DFT) predicted the existence of more than 1,800 2-D materials. Among them components with the same advantages as TMDs, but with better transport properties can be found. We selected 100 monolayers out of this database according to their band gap and effective masses, combined DFT and quantum transport to simulate their "I-V" characteristics in a single-gate configuration, and identified 13 candidates with both *n*- and *p*-type ON-state currents exceeding 3,000 μA/μm at a gate length of 15 nm. Such 2-D materials could reach the same performance level as Si FinFETs, if they can be exfoliated and patterned into transistors.

In this talk, the *ab initio* simulation approach that was developed to investigate devices made of 2-D materials will be briefly reviewed before presenting a summary of the performance of the 100 2-D transistors that were examined.

11:00 AM *EN15.02.02
Thin and Ultra-Thin Antiferroelectric Thin Films—From Fundamental Science to Applications Nazanin Bassiri-Gharb; Georgia Institute of Technology, United States

Discovered in the last century, antiferroelectric materials offer exceptional energy storage capacity with high efficiencies, giant electrocaloric effect and large electrostriction. Additionally, antiferroelectrics are impervious to stray electromagnetic fields, substantially fatigue resistant, not depoled by temperature or electric field, and often radiation hard. The wide range of functionalities, accompanied by the limited vulnerability to adverse environmental effects (radiation, temperature, stray electromagnetic fields) makes these material an exciting venue to design a new generation of micro- and nano-scale electronic devices. Applications range from micro/nano-actuators, to tunable dielectrics for next-generation filters, miniaturized solid state cooling, ultra-high power capacitors or negative capacitors, adaptive pyroelectric sensors, multi-state memory devices, nanoscale opto-magneto-electric couplers, and actively tunable metamaterials.
Among antiferroelectrics, zirconia-based materials have received special attention. The perovskite-structured $PbZrO_3$ occupies a prominent role as the first discovered antiferroelectric and an end member in the lead zirconate titanate solid solution (PZT, of eminent technological importance for many electromechanical sensor, actuator and acoustic transducer transducers). Ultra-thin films of fluorite-structured ZrO_2 have similarly received substantial attention over the last decade, as CMOS compatible antiferroelectrics with functional characteristics exhibited in films of thickness down to a few nanometers. In both material systems, experimental and theoretical studies have moved beyond the original Kittel theory of antiferroelectricity. Literature reports have indicated the presence of cycloid polarization vectors and incommensurate polarization modulations (in amplitude and direction) in chemically modified $PbZrO_3$. Similarly, the antiferroelectric characteristics of zirconia have been attributed to possible paraelectric to ferroelectric phase transitions, rather than field-induced realignment of antiparallel dipoles in adjacent unit cells.
Here, we discuss some of the recent advances in the science of antiferroelectric materials, as well as properties of thin and ultra-thin lead zirconate and zirconia thin films. Specifically, we will address the size reduction effect on the properties of these materials, particularly with respect to the stability of the ferroelectric phase and its origin.

11:30 AM EN15.02.03
New Materials for Three Dimensional Ferroelectric Microelectronics Susan E. Trolier-McKinstry; The Pennsylvania State University, United States

In the last decade, there have been major changes in the families of ferroelectric materials available for integration with CMOS electronics. These new materials, including $Hf_{1-x}Zr_xO_2$, $Al_{1-x}Sc_xN$, $Al_{1-x}B_xN$ and $Zn_{1-x}Mg_xO$, offer the possibility of new functionalities. Whereas the hafnia-based materials show excellent scalability, the wurtzite-structured compounds couple large polarizations (~ 100 microC/cm^2) with excellent temperature stability of the polarization. In addition, the deposition temperatures are quite low (<400°C), opening up the possibility of straightforward integration in the back-end-of-the-line, including the possibility of 3D scaling. This talk will discuss the possibility of exploiting the 3rd dimension in microelectronics, enabling 3D ***non-von Neumann*** *computer architectures exploiting ferroelectrics for local memory, logic in memory, digital/analog computation, and neuromorphic functionality*. This approach circumvents the end of Moore's law in 2D scaling, while simultaneously overcoming the "von Neumann bottleneck" in moving instructions and data between separate logic and memory circuits. The talk will cover the relevant materials, their deposition conditions, and what is known about the wake-up, fatigue, and retention processes.

Critical Role of Synthesis Temperature on Small Polaron Carrier Concentrations in Hematite—A First-Principles Study Mingpeng Chen[1], Tyler Smart[1,2], Yat Li[1] and Yuan Ping[1]; [1]University of California, Santa Cruz, United States; [2]Lawrence Livermore National Laboratory, United States

Achieving highly efficient energy conversion with transition metal oxides necessitates overcoming conductivity limitations due to the formation of small polarons. Detailed understanding of defects, dopants, and carriers can help to devise strategies for achieving higher carrier concentrations, therefore improving conduction and conversion efficiency. This work uses first-principles calculations to investigate carrier concentrations in prominent polaronic oxide, hematite, by resolving interactions between charged defects and carriers in order to reliably predict free carrier concentrations. This work addresses that both O vacancies and Fe interstitials can be primary donors in undoped hematite depending on the synthesis condition, although O vacancies possess a high ionization energy compared to kT. Furthermore, from calculations of a plethora of n-type dopants (group IV, group V,group XIV, and group XV elements), we identify dopants which are most successful at raising carrier concentrations in hematite such as Ti, Ge, Sb, and Nb. We reveal the critical role of synthesis temperature on tuning the carrier concentration of both intrinsic and doped hematite. Our theoretical analysis provides insights and general design principles for the engineering of more conductive polaronic oxides.

6:45 PM EN15.03.02
Effect of Device Geometry on Electrically-Stimulated Insulator-to-Metal Transition in Vanadium Dioxide Thin-Films Sumaiya Kabir, Shruti Nirantar, Mahta Monshipouri, Sumeet Walia, Sharath Sriram and Madhu Bhaskaran; RMIT University, Australia

Vanadium dioxide is a multifaceted phase change material that undergoes insulator-to-metal transition triggered by multiple stimuli, including temperature, light, and electricity. Among all the excitations, the electrically-driven insulator-to-metal transition is of particular advantage as it provides a higher degree of control over the scalability and fast-switching speed. However, there is limited understanding of parameters that control electrically-stimulated insulator-to-metal transition, especially device structure and channel width. In this work, we present a metal–insulator–metal structure to investigate three electrode arrangements: offset, no offset, and overlapping. We experimentally determine that the overlapping configuration of the device needs the least amount of voltage for switching among the three electrode arrangements, which is also supported by simulation results. In contrast, insulator-to-metal transition in vanadium dioxide is independent of the extent of overlap between top and bottom electrodes and channel width. These findings are integral to designing and controlling the functional domains of vanadium dioxide for energy-efficient, addressable, and scalable micro/nano-scale devices and sensor applications.

7:00 PM EN15.03.03
Differences in van der Waals Epitaxial Growth of Sb_2Te_3 Films by Sputtering and Pulsed Laser Deposition Jing Ning[1], Jose C. Martinez[1], Jamo Momand[2], Heng Zhang[2], Subodh Tiwari[3], Fuyuki Shimojo[4], Aiichiro Nakano[3], Rajiv Kalia[3], Priya Vashishta[3], Paulo Branicio[3], Bart J. Kooi[2] and Robert Simpson[1]; [1]Singapore University of Technology and Design, Singapore; [2]Zernike Institute for Advanced Materials, University of Groningen, Netherlands; [3]University of Southern California, United States; [4]Kumamoto University, Japan

High quality van der Waals chalcogenides are important for energy-efficient phase change data storage, thermoelectrics, and spintronics. Here, we combine the statistical design of experiments and density functional theory to illustrate how out-of-equilibrium epitaxial deposition methods can develop the crystal quality of Sb_2Te_3. We found the factors influencing the crystal quality were different for RF sputtering and Pulsed laser deposition (PLD) methods. A thin polycrystalline Sb_2Te_3 seed layer most significantly improves the crystal quality for PLD grown films. However, the temperature is more significant in sputtered films. This difference is very intriguing as both methods are out-of-thermal-equilibrium plasma-based methods. Time-dependent density functional theory molecular dynamics was performed to study the effect of excitation energy on the crystal quality. The PLD plasma is substantially higher in energy than the RF plasma, this increases the adatom diffusion length of deposited atoms as bonding states at the top of the valence band are depopulated. Thus, the electron excitation dominates the adatom diffusivity in PLD. On the contrary, the adatom diffusivity is determined by the thermal temperature in RF sputtering. These results provide a reasonable explanation for the wide-ranging observation of Sb_2Te_3 and superlattice crystal qualities in the literature. They also show how high-quality crystals of Sb_2Te_3, superlattices, and related materials, can be grown using different deposition methods.

Memory Integration into 3D Integrated Circuits H.S. Philip Wong and Wei-Chen Chen; Stanford University, United States

The integrated circuit (IC) was invented more than 60 years ago. We have witnessed how semiconductor technology has become vitally important to our everyday life, from servers, to PCs, and smartphones. Semiconductor technology plays a truly vital role for humanity, not only in terms of economic development, but also in the way we live, the way we work, and the way we enjoy life. Today, this vital role is manifested in the use of high-performance computing to find a cure for COVID-19, and the computing and communication technologies that enabled work from home, online teaching and learning, and online purchase and delivery of goods and services. Future electronic systems will continue to rely on, and increasingly benefit from, the advances in semiconductor technology as they have had for more than five decades.

Three dimensional integration is one of the major technology directions for integrated circuits. I will give an overview of the new materials and device

technologies that may need to be developed to realize monolithic 3D integration with multiple logic transistor and memory device layers. I will speculate on how they will be integrated into future electronic systems and what future technologies need to be invented to realize energy-efficient 3D ICs.

8:30 AM *EN15.04.02
Achieving High Performance Resistive Switching Using Ionic Thin Films Judith L. MacManus-Driscoll, Ming Xiao, Chao Yun, Mahmoud Eishenawy, Thomas Sun, Matthew Wells and Markus Hellenbrand; University of Cambridge, United Kingdom

Resistive switching (RS) materials, often called memristors, are promising candidates for next-generation non-volatile memory and neuromorphic computing applications. Positive attributes include simplicity, compatibility with conventional semiconductor processes, and the potential for 3D and scaling. For memory applications, achieving all optimized properties *together* of very long retention, fast switching time, endurance, uniformity, and scaling is challenging. In this talk, we revisit the challenge of achieving simultaneous performance optimization and show how tuning the transport properties in the ionic material is important to this end. We demonstrate pronounced resistive switching at low voltages (SET voltage of <1.2 V without high-voltage electroforming), strong endurance (no change in resistance states after >1E6 cycles), uniformity, stable switching, and fast switching speed.

9:00 AM *EN15.04.03
Ferroelectric Doped Hafnium Oxide—From Switching Kinetics to Neuromorphic Elements Uwe Schroeder[1,2]; [1]NaMLab gGmbH, Germany; [2]Technische Universität Dresden, Germany

Fluorite-structured ferroelectrics have outstanding potential for commercial applications due to their scalability, CMOS compatibility, and ease of fabrication. These advantages make ferroelectric HfO_2 very attractive for non-volatile memory solutions such as ferroelectric random-access memories (FRAM), ferroelectric field-effect transistors (FeFET), and ferroelectric tunnel junctions (FTJ). Significant efforts have been made for the physical understanding and technological exploitation of ferroelectric HfO_2. Due to the wide range of conditions under which ferroelectricity can occur in HfO_2 thin films, the scientific community has improved and optimized the ferroelectric properties using various approaches. As a result, progress in thin-film technology for ferroelectric devices is advancing rapidly.
Neuromorphic devices represent one of the most promising examples of overcoming today's computers' energy efficiency and processing speed limitations. While traditional neuromorphic circuits are based on CMOS transistors and capacitors, recently emerging nano-electronic devices appear to be promising candidates for building the fundamental neuromorphic elements: Neurons and Synapses. Unlike digital memories, this requires gradual switching to many different levels. Moreover, neuromorphic systems realized by spiking neural networks also make use of the timing between spikes. As a result, two basic functions are required: synaptic functions based on the time-dependent plasticity of spikes and neural functions that integrate input signals and generate spikes.
Before discussing the device function, a detailed characterization of the switching kinetics in doped HfO_2 films is necessary, which will be performed on ferroelectric capacitors and FeFET structures.
Different models of polarization switching are investigated and evaluated against the existing literature. Especially, nucleation-limited switching (NLS) and inhomogeneous field mechanism (IFM) data are compared with experiments for ferroelectric capacitor structures. We conclude that models are not necessarily mutually exclusive but rather provide a diverse perspective on the switching phenomenon based on thermodynamic, kinetic, statistical, microscopic, and/or macroscopic viewpoints. In the next step, a small number of grains within the gate stack of a nanoscale FeFET structure with the channel length of 30 nm are characterized, and a detailed analysis of the switching behavior of these individual grains is possible. Again, nucleation-limited switching is observed with a distribution of coercive fields for different individual grains. Multiple excitation pulses, each insufficient for polarization reversal, induce an accumulative effect that eventually leads to ferroelectric switching.
Using this knowledge, hafnium oxide-based FeFETs can be used to realize both artificial neurons and synapses for spiking neural networks. Accumulative switching can be exploited to mimic the integrate-and-fire activity of biological neurons, which, together with FeFET-based synapses, could enable the construction of basic computational blocks of brain-inspired neural networks.

9:30 AM EN15.04.04
Artificial Synapse Based on a Space Charge Modulated Double-Oxide Memcapacitor Pei-En Lin, Jia-He Yang, Cheng-Han Lu and Jen-Sue Chen; Department of Materials Science and Engineering, National Cheng Kung University, Taiwan

Memristor-based devices have been widely investigated to resemble biological synapses used in neuromorphic computation applications, such as big data processing, pattern recognition, and learning tasks. While the memristors have been widely reported, other types of memelements remain underexplored. Capacitive neural networks provide an alternative physical embodiment of neural networks and can lower the power consumption of the circuit because the signal is expressed as voltage rather than current. Therefore, memcapacitors should be the superior candidates for neuromorphic computation. In this work, we design a novel bilayer WO_x/ZrO_x stack which is well-performed in capacitive switching characteristics. Furthermore, the stack unveils a broad range of capacitance states when stimulating with voltage pulses of various amplitudes and frequencies.
The WO_x/ZrO_x stack is sandwiched between Ta (top electrode) and Pt (bottom electrode) to form a memcapacitor. In addition to the capacitive switching performance, the $Ta/WO_x/ZrO_x/Pt$ device also exhibits resistive switching characteristics under voltage sweeping operation. The memresistance and memcapacitance characteristics in the presented $Ta/WO_x/ZrO_x/Pt$ stack are ascribed to the carrier trapping-and-detrapping processes by the interaction of injected carriers and defects, which is associated with the space-charge limited conduction (SCLC) depending on the different biasing conditions. In order to confirm the connection between resistive-capacitive switching and SCLC mechanism, we controlled the thickness of WO_x with different sputtering time to observe the relationship between the current density and the thickness in WO_x. When the thickness of WO_x decreases, the current density and the capacitance increase in following with the formula of SCLC mechanism, indicating that the space charge is mainly confined in the WO_x layer and dominates the continuing resistance and capacitance variation.
Finally, the biological synapses have been successfully mimicked by emulating several synaptic functions, such as potentiation and depression, paired-pulse facilitation, short-/long-term memory, and learning-relearning behavior. This result can be integrated into the implementation of neuromorphic computing, which can provide a better guarantee for its large-scale application.

Devices for Efficient Analog In-Memory Neural Computing at the Edge Matthew Marinella, Sapan Agarwal, Christopher Bennett, Tianyao Xiao, Donald A. Robinson, Elliot J. Fuller and A. A. Talin; Sandia National Laboratories, United States

Deep learning has gained significant interest over the past decade due to unmatched pattern recognition capabilities. However, due to the high computational load, it has been challenging to use deep neural networks (DNNs) and deep convolutional neural nets (CNNs) in applications with significant size, weight, and power (SWaP) constraints. This is further complicated by challenging environments like temperature extremes and radiation encountered by embedded or edge computing systems, such as smart sensors and autonomous system controllers. In-memory computing (IMC) based on analog matrix operations has emerged as a promising hardware architecture with the potential to achieve a power-normalized performance of 100 TOPS/W (tera-operations per second per watt), which is more than 20 times that possible with today's best digital systems. However, analog IMC accelerators are not yet mainstream, due in part to the challenges involved with using nonvolatile memory devices in an analog capacity. Unlike digital computing, analog IMC closely links the final output of an algorithm to physical properties of the device and materials. Device properties such as noise, static and dynamic linearity, state drift, and even interconnect properties directly affect the neural network classification accuracy. Device research must now consider the system and algorithm in context, in order to ultimately execute neural algorithms with acceptable accuracy. With this challenge comes the opportunity to investigate both mature and emerging nonvolatile memory devices and materials for efficient, accurate inference (recognition) and training in analog IMC architectures. We have found that charge trapping semiconductor-oxide-nitride-oxide-semiconductor (SONOS) devices similar to those used in flash memory are well suited for accurate, energy-efficient CNN *inference* in edge systems. In fact, using SONOS, is possible to achieve inference accuracies on par with digital systems on state of the art deep CNNs such as resnet50 with more than an order of magnitude energy efficiency improvement. As a digital memory, SONOS is mature, but adapting this device technology for analog computing requires addressing new challenges to maintain accuracy and reliability in edge systems. Emerging devices including electrochemical memory (ECRAM) and magnetic domain walls offer exciting possibilities for both ultra-efficient training and inference at the edge, but these devices are less mature and have materials and device research challenges that need to be addressed before utilization in edge computing systems. This talk discusses recent progress and remaining challenges as we work to enable efficient analog in-memory neural computing at the edge.
SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525

11:00 AM *EN15.05.02
Exploiting Polarization for Energy Efficient Devices Chris G. Van de Walle; University of California, Santa Barbara, United States

Spontaneous polarization and ferroelectricity can be exploited to enhance the performance of electronic devices. Materials with spontaneous polarization can give rise to large bound charges at heterointerfaces. If the resulting two-dimensional carrier gas can be modulated, it can be used in devices such as high electron-mobility transistors. Fixed charges can be exploited in tunnel field-effect transistors or in tunnel junctions. Accurate prediction of spontaneous and piezoelectric polarization is therefore critical for understanding and designing heterostructures. We have developed a rigorous first-principles formalism for addressing polarization in wurtzite-structure semiconductors [1], and have applied the methodology to a number of other systems: (1) II-IV-nitride semiconductors, which can be integrated with III-nitrides for additional design flexibility [2]; (2) rocksalt-wurtzite interfaces, such as ScN/GaN, which exhibit a giant polarization discontinuity [3]; and (3) polar/nonpolar II-VI heterostructures that can also give rise to huge sheet carrier densities [4].
Polarization is also at the core of ferroelectric transistors. The recent finding that adding Sc to AlN not only enhances the piezoelectricity but gives rise to ferroelectricity has generated great interest for novel applications within the family of nitride semiconductors. The behavior of the alloy is surprising, given that the ground-state structure of ScN is rocksalt, which is centrosymmetric. However, when adding modest amounts of ScN to AlN, the alloys retain the wurtzite structure. One might expect the alloy properties to be interpolated between wurtzite AlN and a metastable wurtzite ScN phase. However, when ScN is constrained to a hexagonal unit cell, it is not stable in the wurtzite structure, but rather assumes a layered hexagonal structure. We have found that the enhanced piezoelectric polarization in ScAlN alloys actually arises because of the nonpolar nature of hexagonal ScN. The addition of Sc brings the alloy closer to the centrosymmetric structure, which constitutes the "saddle point" for switching of the polarization. I will present detailed first-principles results for polarization, piezoelectric coefficients, and switching barriers.

11:30 AM EN15.05.03
Imaging Oxygen Transport in Oxide-Based ReRAM Devices Baoming Wang[1], Kevin May[1], Teodor Todorov[2], Takashi Ando[2], Dmitri Kalaev[1], Harry Tuller[1], Bilge Yildiz[1], John Rozen[2] and Frances M. Ross[1]; [1]Massachusetts Institute of Technology, United States; [2]IBM T.J. Watson Research Center, United States

Resistive switching (RS) has been studied in detail over the last decade due to its importance for the fabrication of electronic devices. By combining fast switching, long retention, and high-density stacking, resistive switching random access memory (ReRAM) has the potential to meet the high demand for ultra-high-density and low-cost future data storage and logic circuits. While significant progress has been achieved in the development of devices based on ReRAM, performance, including inherent stochasticity, is limited by our knowledge of ionic transport phenomena that control conductance changes in filamentary regions and at oxide interfaces. To guide the design of ReRAM devices, we applied scanning transmission electron microscopy techniques to image oxygen transport in ReRAM devices based on oxides (HfO_{2-x}) during operation in situ, allowing us to correlate electrical characteristics and compositional/structural changes in the layers and interfaces in state-of-the-art ReRAM devices. We have achieved electrical switching behavior in various electron-transparent cross-section lamellar devices and find that electrical performance of the devices in situ, both forming and cycling, can be made to replicate the behavior of complete devices. We measured oxygen elemental redistribution during operation in situ and obtained evidence for the buildup of inhomogeneous fields within HfO_{2-x} layers during device operation. Our ongoing work involves locating oxygen vacancy filaments or oxide interface layers and atomic imaging of oxygen vacancy transport during in situ operation. We are combining advanced imaging techniques including energy filtered imaging, 4D-STEM and DPC (differential phase contrast), and correlating scanning electron microscopy (SEM) and transmission electron microscopy to achieve this goal. Correlation of different microscopy modes helps to locate and measure filaments within complete devices; 4D-STEM and DPC can be employed to map the electrical field change during switching thus characterizing the filament or interface; and EELS and integrated DPC are capable of imaging the oxygen atoms directly.

8:00 AM *EN15.06.01
Memory Device Options for Energy Efficient Synapses in Brain-Inspired Neuromorphic Systems Daniele Ielmini; Politecnico di Milano, Italy

The human brain can execute complicated tasks with a power consumption of about the same as an electric bulb. Neuromorphic computing aims at replicating the same connectivity and the same energy efficiency of the human brain by integrated circuits. In the neuromorphic hardware, synapses play a key role as they control the energy consumption, the computing functionality, the inter-neuron connectivity and the scalability of the circuit. While several memory technologies have been considered as artificial synapses, there is increasing evidence that synaptic materials must display a unique set of properties that cannot be met by conventional and emerging memory devices.
In this talk, I will present novel synaptic devices based on nanoscale memristive materials. First, I will discuss a volatile resistive switching memory (RRAM) with Ag top electrode, capable of tunable retention times for spatio-temporal sensing and computing. Second, I will present a random nanowire network, where nanowire synapses connect and disconnect under dynamic stimuli enabling cognitive behavior based on heterosynaptic plasticity and reservoir computing. Third, I will discuss artificial synapses consisting of 2D semiconductors, such as MoS2, displaying outstanding weight-update linearity and low current. Finally, the prospects of synaptic materials will be finally discussed in terms of functionality, cost, scalability, CMOS integration and energy efficiency.

8:30 AM *EN15.06.02
Energy Efficiency Neuromorphic Computing with Oscillatory Neural Networks Aida Todri-Sanial, Corentin Delacour, Stefania Carapezzi, Madeleine Abernot, Gabriele Boschetto and Thierry Gil; LIRMM, University of Montpellier, CNRS, France

Current classical computers are playing a critical role in advanced research such as in biology, climate analysis, economics, genomics, finance, etc. In many aspects, computing fuels the advances of our modern society. Yet, recent developments in artificial intelligence (AI) and machine learning will require even more powerful computing systems such as exascale computations per second due to an ever-increasing amount of data. But classical computing systems are hindered by the von-Neumann communication bottleneck, the physical separation between processor and memory. This offers the opportunity to explore a novel computing paradigm where the brain can serve as a computational model of how to deal with large amounts of (often fuzzy) information while being extremely dense, error-resilient and power efficient.

In this talk, a novel and alternative neuromorphic computing paradigm based on oscillating neural networks (ONN) will be presented. Energy efficient relaxation oscillators based on phase-change VO_2 material for oscillating neurons and tunable 2D TMD MoS_2 memristors for synapses are the building blocks of ONN architecture [1-3]. Inspired by neural oscillations or brain waves, in ONN, the information is encoded in the phase of coupled oscillators. The talk will cover aspects from materials, devices, circuits to ONN architecture design and hardware implementation and demonstration on AI tasks. This work is conducted in the framework of the EU H2020 NEURONN project, www.neuronn.eu.

9:00 AM *EN15.06.03
Two-Dimensional Materials for Neuromorphic Computing Tania Roy; University of Central Florida, United States

Two-dimensional materials (2D) have gained significant attention in neuromorphic applications due to their low power consumption, high endurance, high retention and high linearity in weight update. A synaptic device for neural computing needs to demonstrate high endurance with low cycle-to-cycle (C-C) variability for efficient training. However, low C-C variability in conductance weight update for a substantially high number of cycles has not been demonstrated yet. We report MoS_2 based synapses with Ti/Au electrodes that exhibit ultra-low variability in SET voltage with a low reset power of 2-10 nW for over 115 cycles. Additionally, these devices show almost no variability in conductance weight update for over 100 pulsed cycles for multiple (10) devices. These devices outperform conventional Si-based memristors, indicating the viability of 2D materials for reliable implementation of neural networks.
Optoelectronic synapses are devices that behave like photodetectors with analog memory. In neuromorphic computing, these devices have the potential to perform imaging and object identification using the same device. We first demonstrate that the strong photogeneration efficiency of methylammonium lead bromide perovskite quantum dots (PQDs) can be exploited by growing PQDs from the lattice of a single layer graphene by a defect-mediated process. The rationale for designing this hybrid superstructure stems from the ability of PQDs to absorb light and generate charge carriers. The charges generated are transferred to graphene, which transports the carriers across the active layer of the device. Through the implementation of this thin superstructure in a phototransistor geometry, we produce a photoresponsivity of 1.4×10^8 AW^{-1} at 430 nm and a specific detectivity (D^*) of 4.72×10^{15} Jones, which is by far the best responsivity and detectivity across similar devices reported to date. This is promising for the development of highly efficient optoelectronic materials for high-speed communications, sensing, ultra-sensitive cameras and high-resolution imaging and displays. The graphene-PQD superstructure behaves as an optoelectronic synapse with low energy consumption of 36.75 pJ/ spike that mimics crucial characteristics of its biological equivalent, with unique optical potentiation and electrical habituation function**.**
We also utilized the persistent photoconductivity of 2D MoS_2 layers to demonstrate an optoelectronic synapse. A CVD-grown monolayer MoS_2 FET exhibits substantial enhancement in drain current when illuminated with a laser of 450 nm wavelength as well as a negative shift in its threshold voltage due to the generation of photocarriers. The device undergoes optical potentiation and electrical depression. The device is “optically” potentiated by applying light pulses with ON/OFF interval of 5 s for each at 450 nm wavelength – measured at a constant drain bias of 1.0 V with V_G = -2 V. Also, it is “electrically” depressed by applying 50 electrical pulses with ON/OFF interval of 1 s and 9 s, respectively – measured at a drain bias of -100 mV with V_G = -2 V. These results confirm the active and simultaneous tunability of conductance essential for the electrical/optical training of optoelectronic synapse in neural network applications. The negative voltage pulses applied at the drain de-traps the holes from the SiO_2/MoS_2 interface, thus gradually depress the device to its initial low conductance state. By engineering the gate electrode, we observe synaptic behavior at infrared wavelengths.

Synaptic Functionalities in P(VDF-TrFE) Coupled Zinc-Tin Oxide Hybrid Ferroelectric Transistors for Neuromorphic Computing Ching-Kang Sheng, Kuan-Ting Chen, Yun-Huei Tseng and Jen-Sue Chen; National Cheng Kung University, Taiwan

In order to expedite data processing speed, numerous synaptic devices have been investigated for their potential implementation in neuromorphic hardware systems. In comparison with the two-terminal memristors, the concurrent learning process in three-terminal transistors can be easily designed and more advantageous because the crosstalk noise can be avoided without additional transistors (i.e. 1T1R) in the circuits. Among the synaptic transistors, the ferroelectric field effect transistors (FeFETs) have attracted much attention for their strong polarization, nonvolatile properties and lower power consumption.
Poly(vinylidenefluoride-trifluoroethylene) (P(VDF-TrFE)) is a commonly applied polymer ferroelectric material for its spontaneous polarization. It had been applied to transition metal dichalcogenide (TMD) transistors and served as synaptic devices. However, the synaptic characteristics of P(VDF-TrFE) incorporated amorphous oxide semiconductor FeFET has not been studied yet. In this work, we fabricate an organic/inorganic FeFET based on Zinc-Tin Oxide (ZTO) semiconductor channel and encapsulated by the P(VDF-TrFE) layer to investigate the charge transport characteristics modulated via the ferroelectric effects.
With P(VDE-TrFE) coated on the ZTO channel layer, a net upward dipole alignment in P(VDF-TrFE) attracts holes from the ZTO, which enables more electrons to accumulate in the effective channel. Therefore, the P(VDF-TrFE) encapsulated ZTO FET shows higher IDS than that without P(VDF-TrFE). Based on the band diagram analysis, the band bending of ZTO reflects the influence and reversal of dipole alignment, which is attributed to the accumulated electrons in the channel. In addition, the conductance, acted as weight, gets updated more easily and retains longer in the P(VDF-TrFE) coupled ZTO. Accordingly, the synaptic performance can be mimicked by stimulation on the gate terminal. We demonstrate paired-pulse facilitation (PPF), potentiation/depression cycle (P/D cycle) and spike timing dependent plasticity (STDP) of asymmetric Hebbian learning in this FeFET device. The transition from short-term memory to long-term memory is achieved via increasing the pulse number, amplitude, frequency, and duration time. The experimental results manifest that this ferroelectric coupled ZTO synaptic device has great potential for neuromorphic computing hardware systems owing to its successful emulation in functionality of the human brain.

Harnessing Anharmonicity and Electron Correlations for Energy Effecient Computing Panchapakesan Ganesh; Oak Ridge National Laboratory, United States

Metal oxide-based Resistive Random-Access Memory (RRAM) exhibits multiple resistance states, arising from the activation/deactivation of a conductive filament (CF) formed by oxygen vacancies inside a switching layer – due to an underlying metal-insulator transition (MIT). In a crossbar device architecture, you have a highly dense information-storage&computing system, that you want to be reliable, fast switching and utilizing low-power. This can enable emulating 'brain like' neuromorphic computing with co-located memory and compute. Similarly, ferroelectric materials – such as Hafnia – are promising candidates for synaptic weight elements in neural network hardware because of their nonvolatile multilevel memory effects. But conventional RRAM materials require high forming potentials and show high variability (device-to-device or cycle-to-cycle) and are plagued by less reliability as well as the voltage-time dilemma, similar to ferroelectric synapses. To address these challenges, we are working to answer the following open questions: what material characteristics we need when choosing a memristor material? What factors triggers a state-change (e.g. MIT, or ferroelectric-switching) in these materials? What determines the dynamics of the switching mechanism?

Using a combination of high-throughput phase-field and machine-learning methods [1] we discovered that harnessing electron-electron correlations in binary oxides can be advantageous for improved performance of RRAM devices. Using a combination of various correlated electronic structure methods, we further uncovered the underlying factors that control the MIT in non-stoichiometric correlated binary oxides – such as VO_2 [2,3]. We subsequently demonstrated how many of the correlated perovskite metals that undergo MIT are negative charge-transfer metals, with the magnitude of ligand-hole being the key to controlling MIT[4]. These works provides a fundamental understanding of the role of electron correlations in resistive switching materials. For ferroelectric-based synapses, we explored the recently discovered layered-thiophosphate family of materials [5]. We discovered [6] presence of strong anharmonic coupling in these materials between the ferroelectric polar-mode and a Raman active symmetric-mode, even down to the single-layer limit, that could allow optical or mechanical control of ferroelectric switching, potentially alleviating the voltage-time dilemma in conventional ferroelectrics.

Magnetic Antiskyrmions in Tetragonal Inverse Heusler Materials Rana Saha[1], Abhay Srivastava[1], Jagannath Jena[1], Ankit Sharma[1], Tianping Ma[1], Börge Göbel[1], Claudia Felser[2] and Stuart Parkin[1]; [1]Max Planck Institute of Microstructure Physics, Germany; [2]Max Planck Institute for Chemical Physics of Solids, Germany

One of the major topics in spintronics today is the study of steady-state and dynamical properties of non-collinear spin textures with various topologies[1]. One of the most important of these are skyrmions that are magnetic nano-objects with chiral magnetic boundaries, which are potential information carriers for future dense and energy-efficient racetrack memory devices[2]. Recently, a novel chiral spin texture, magnetic antiskyrmion that has distinct topological features from that of Bloch and Néel skyrmions, was discovered in tetragonal inverse Heusler compounds[3-4]. Antiskyrmions have boundaries that have a complex structure consisting of successive left-hand Bloch, left-hand Néel, right-hand Bloch, and right-hand Néel wall segments. This complex structure results from an anisotropic Dzyaloshinskii-Moriya exchange interaction set by the symmetry of the underlying lattice. This causes the magnetic structure of the antiskyrmion to be aligned with the crystal lattice that leads to enormous stability of antiskyrmions over a wide range of temperature, magnetic field, and thickness of the lamella in which they are formed. This magnetic texture is of great current interest both for its topological characteristics and potential spintronic applications. Therefore, it is of significant importance to understand the physical properties of these nanoscopic spin textures. In this presentation, I will describe some recent *in-situ* investigations on the nucleation, stability, and manipulation of antiskyrmions using Lorentz transmission electron microscopy (LTEM) and magnetic force microscopy (MFM). By employing these two techniques, we showed the thickness-independent intrinsic stability of antiskyrmions, robust tunability of the size of antiskyrmions, and stabilization of elliptical Bloch skyrmions in the antiskyrmions system due to long-range dipole-dipole interactions[5-7]. From these studies, we have developed a significant fundamental understanding of these fascinating chiral magnetic nano-objects, which are potential for spintronic applications.

Materials Discovery for Energy-Efficient Neuromorphic Computing—A Co-Design Approach Christian Mailhiot; Sandia National Laboratories, United States

The report of the *Basic Research Needs for Microelectronics* workshop (2018)[1] documents that “as Moore’s Law nears its end, a fundamental rethinking of the science behind the materials, devices, synthesis and fabrication technologies, architectures, and algorithms is needed to enable continued advances in computing, communication, and sensing technologies.” These advances must be conceived and developed collectively and concurrently, using an inter-disciplinary co-design framework, where each scientific discipline informs and engages the others, with multi-directional information flow, to achieve orders of magnitude improvements in system-level performance. This presentation will identify opportunities for transformative advances in microelectronics that uniquely result from a co-design approach. In addition, we will explore whether modern artificial-intelligence (AI) methods may accelerate co-design. Finally, the application of the co-design approach to analog computing via ion-tunable electronic materials will be presented[2]. This application builds on the emerging science of ion-tunable materials, complex networks of devices, and evolutionary algorithmic discovery to create a revolutionary neuromorphic computing platform with extreme energy efficiency, application-driven on-demand architectural flexibility, the ability to tolerate errors and self-repair against radiation damage, programmable complex dynamics, and dramatic algorithmic speedups[3].

Late News: Investigation of Ionic Programming Dynamics of Metal-Oxide Based Electrochemical Memory for Energy-Efficient Neuromorphic Computing Da Gil Ryu[1], Yanho Jeong[1], Hyunjoon Lee[1], Seong Ho Cho[1], Gawon Lee[1], Sangbum Kim[1], Seyoung Kim[2] and Yun Seog Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]Pohang University of Science and Technology, Korea (the Republic of)

Crossbar arrays of synaptic devices is a key platform for neuromorphic computing architectures. To achieve time and energy efficiency compared to the von Neumann architecture, it is essential to develop synaptic devices with optimal characteristics. Among various candidates, metal-oxide based electrochemical random-access memory (ECRAM) is considered as a promising analog synaptic device due to its excellent programming characteristics and CMOS-compatibility. However, the switching mechanisms of metal-oxide ECRAM is unclear, impeding improvements of the synaptic characteristics and device performance.

In this contribution, we elucidated the mechanism of operation of metal-oxide ECRAM devices. We fabricated devices with a planar structure with a channel of tungsten oxide and an electrolyte of hafnia. Tungsten oxide thin films with different conductivities were obtained by controlling the oxygen flow rate during reactive sputtering, and their off-stoichiometry x was obtained from XPS analysis. It was confirmed that oxygen acts as a dopant that x proportional to conductivity. Hafnia thin films with different ionic conductivity were deposited by controlling deposition temperature during ALD, and their ionic conductivity was confirmed by EIS measurement. The electrical characteristics of the device were analyzed through gate voltage sweep, transmission line measurement, voltage bias programming, and voltage pulse programming. In conclusion, we show that the metal-oxide ECRAM devices work through an electrochemical mechanism. We modeled that programming dynamics are determined from these two factors: field-driven migration occurs in the electrolyte, and diffusion of ions occurs within the channel, resulting in conductance change[1]. Furthermore, we devised a vertical three-dimensional metal-oxide ECRAM structure to achieve high-density integration as well as high energy-efficiency.

Low Power, Multistate, Fast Phase-Change Artificial Synapse Based on Transient-Amorphous-State-Mediated Plasticity Shao Xiang Go[1], Qiang Wang[1], Tae Hoon Lee[2], Stephen R. Elliott[2], Natasa Bajalovic[1] and Desmond K. Loke[1]; [1]Singapore University of Technology and Design, Singapore; [2]University of Cambridge, United Kingdom

The human brain is capable of parallel information processing while consuming low energy. Motivated by the efficiency of the brain, CMOS-based architectures are being developed for image classification and machine learning. However, the volatility, design complexity and high bias voltages for CMOS architectures complicate the path to achieve the interconnectivity, information density and energy efficiency of the brain. Here we describe a phase-change material (PCM) memory operating with a different phenomenon from existing PCMs. The PCM switches at low voltage and energy, display multiple distinct nonvolatile conductance states within a small voltage range, and achieves excellent distribution of conductance states when implemented in neural network simulations. Fast crystallization pulses were also achieved enabling the integration of neuromorphic functionality in high-density electronic systems. Thermal simulations reveal the transient-amorphous-state-assisted change in synaptic weight. Our findings pave a way towards power-efficient artificial intelligence (AI) operations that could mimic the functionalities of a human brain.

Near-Infrared Wavelength Quantum Emitters Peter Udvarhelyi[1], Song Li[1], Gergo Thiering[1], András Csóré[2], Viktor Ivády[1,3] and Adam Gali[1,2]; [1]Wigner Research Centre for Physics, Hungary; [2]Budapest University of Technology and Economics, Hungary; [3]Linköping University, Sweden

The quest of near-infrared (NIR) solid-state quantum emitters is one of main driving forces in the crossing of computational and experimental materials science and quantum optics (e.g., Ref. [1]). Solid-state quantum emitters in the wavelength region of 1.1-1.6 micrometers have a minimum absorption in living cells, thus would be ideal *in vivo* probes or biomarkers when they operate at room temperature. Furthermore, coherent emission from the single photon sources in the telecom bands at 1.3-1.6 micrometers could be directly applied for building metropolitan quantum networks through the existing infrastructure of optical fibers. Here we show the latest results about identification and characterization of NIR quantum emitters in diverse systems. We recently identified in a bioinert material, silicon carbide (SiC), room-temperature quantum emitters with high readout contrast associated with divacancy in stacking faults. Furthermore, we carried out in-depth analysis of the fine electronic structure of vanadium defect in SiC which is a promising telecom O-band quantum emitter. Here we mention that the scalability and deterministic creation of quantum emitters are still very challenging issues in SiC, and in general, in threedimensional materials. In twodimensional materials, techniques exist to generate atomic defects on demand. We proposed defects in hexagonal boron nitride (hBN) that can act as quantum bits that have been realized in experiments. However, deterministic creation of those defects is still

not in reach. Very recently, activation of single defect spin in tungsten disulfide (WS_2) has been demonstrated at atomistic precision [2] which is a single carbon atom substituting sulfur atom. We show that the carbon defect spin can be initialized, optically readout and coherently manipulated with NIR emission. This result constitutes a scalable quantum bit in a twodimensional material that can be activated at atomistic precision. This work was supported by the Ministry of Innovation and Technology and the National Research, Development and Innovation Office of Hungary (NKFIH) within the Quantum Information National Laboratory of Hungary, the National Quantum Technology Program (NKFIH Grant no. 2017-1.2.1-NKP-2017-00001). Designing Quantum Interfaces to Emitters at the Nanoscale Prineha Narang; Harvard University, United States

The potential impact of active quantum emitters (impurity-based color centers) on creating quantum information systems in the near-term is evident [1,2]. Yet, design and control of robust quantum interfaces to these impurity systems at the nanoscale has remained challenging. In this talk, I will present promising physical mechanisms and device architectures for coupling emitters to other qubit platforms *via* dipole-, phonon-, and magnon-mediated interactions. I will present our latest work on coupling magnons to emitters as a natural step towards magnon-mediated efficient manipulation of spin-qubit states with applications in sensing and quantum information science. I will start with a scheme that uses magnetic nanoparticles that sustain antenna-like magnon resonances as nanomagnonic cavities for microwave magnetic fields. Here, in recent work we have shown that nanomagnonic cavities can modify the local magnetic environment of spin emitters in the microwave domain, facilitate the magnetic drive of spin transitions, and allow for strong coupling of these emitters with single magnons[3]. Next, I will discuss how the magnetic fields of nanomagnonic cavities that change spatially on the length scales of single molecular or defect emitters, coupled with descriptions of spin emitters beyond the point-dipole approximation, enables selection rule-breaking of orbital-spin transitions[4]. Such nanomagnonic cavities could pave the way towards magnon-based quantum networks and magnon-mediated quantum gates. Taking this further, I will present some of our recent work in capturing non-Markovian dynamics in open quantum systems (OQSs) built on the ensemble of Lindblad's trajectories approach [5,6]. In the outlook, I will discuss new approaches from quantum chemistry for OQSs that could guide the controllable coupling of active quantum emitters and create robust quantum interfaces to the nanoscale.

Investigation of Stark Shift and Charge Noise on a Centrosymmetric Diamond Defect Lorenzo De Santis[1,2], Matthew Trusheim[1], Kevin Chen[1] and Dirk Englund[1]; [1]Massachusetts Institute of Technology, United States; [2]Delft University of Technology, Netherlands

Color centers in diamond are among the best performing optically accessible qubits in the solid state. Group IV-vacancy centers in particular can provide highly coherent and stable optical interfaces, a property which is attributed to their inversion symmetry. In this work we investigate the effect of an external electric field on the optical transition of a single tin-vacancy (SnV) center. Our study reveals a vanishingly small permanent electric dipole as well as a suppressed polarizability of the emitter, more than 4 orders of magnitude lower than for an NV center, demonstrating the inversion symmetry protection of a Group IV-vacancy defect in diamond from charge noise. Additionally, we show that by modulating the SnV electric-field-induced dipole we can use the emitter's linewidth as a nanoscale probe to quantify electric field noise at its location. To gain further insight on the effect of the electric field noise, we also probe the optical transition at different timescales. This allows to resolve the individual spectral jumps of the transition, and to measure the homogeneous linewidth of the emitter without spectral diffusion effects.

Defect Polaritons from First Principles Derek Wang[1], Susanne Yelin[1] and Johannes Flick[2]; [1]Harvard University, United States; [2]Flatiron Institute, United States

Precise control over the electronic and optical properties of defect centers in solid-state materials is necessary for their applications as quantum sensors, transducers, memories, and emitters. In this study, we demonstrate, from first principles, how to tune these properties via the formation of defect polaritons. Specifically, we investigate three defect types---CH, CB-CB, and CB-VN---in monolayer hexagonal boron nitride (hBN). The lowest-lying electronic excitation of these systems is coupled to an optical cavity where we explore the strong light-matter coupling regime. For all defect systems, we show that the polaritonic splitting that shifts the absorption energy of the lower polariton is much higher than can be expected from a Jaynes-Cummings interaction. In addition, we find that the absorption intensity of the lower polariton increases by several orders of magnitude, suggesting a possible route toward overcoming phonon-limited single-photon emission from defect centers. Finally, we find that initially localized electronic transition densities can become delocalized across the entire material under strong light-matter coupling. These findings are a result of an effective continuum of electronic transitions near the lowest-lying electronic transition for both pristine hBN and hBN with defect centers that dramatically enhances the strength of the light-matter interaction. We expect our findings to spur experimental investigations of strong light-matter coupling between defect centers and cavity photons for

applications in quantum technologies.

2:15 PM EQ01.02.03
Telecom Quantum Emitters in Atomically-Thin Molybdenum Ditelluride ($MoTe_2$) Huan Zhao, Michael Pettes, Yu Zheng and Han Htoon; Los Alamos National Laboratory, United States

Recently, as atomically-thin transition-metal dichalcogenides (TMDCs) have advanced to the forefront of quantum information science research, quantum emitters (QEs) have been demonstrated in these materials. However, QEs discovered to date in 2D materials have their operating wavelength confined to the visible spectral range and the technologically important near-infrared (NIR) regime still remains an unconquered territory. Bringing 2D TMDCs into the research of NIR quantum photonics is highly motivated by the potential of creating on-demand telecom-compatible quantum light sources and the possibility of coupling the unique valley pseudo-spin qubits to photons propagating in optical fibers.

Meeting this challenge head on, here we report the first deterministic creation of QEs capable of high purity single photon emission at wavelengths covering entire NIR emission band from 1080 nm to 1550 nm. We achieved this by coupling mono and multi-layer molybdenum ditelluride ($MoTe_2$) to strain inducing nano-pillar arrays. Our Hanbury Brown and Twiss experiment yielded near-complete photon antibunching ($g^2(0) < 0.1$), unambiguously proving the single-photon nature of the emitters. Polarization-resolved magneto-optical spectroscopies further revealed that while valley symmetry, which is essential for the valley pseudo spin based quantum information processing, is preserved in some QEs, the strain induced anisotropic exchange interaction mixed valley states in other QEs to display cross-linearly polarized doublets with ~1 meV splitting at zero magnetic field. The valley symmetry in these QEs is restored under 8T magnetic field. These findings together point to the exciting potential of accessing valley pseudo-spin through telecom single photons.

Overall our experiment extends the quantum optics research of 2D TMDCs into the technologically important telecom regime for the first time, and establishes layered $MoTe_2$ as a new platform for quantum communication and transduction research. In contrast to telecom quantum emitters of other material systems such as self-assembled quantum dots and single wall carbon nanotubes, our QEs offer unique opportunities in providing access to valley pseudo-spin degree of freedom and facile integration into quantum-photonic, electronic, and sensing platforms via the layer-by-layer-assembly approach.

2:30 PM EQ01.02.04
Circulating Current and Orbital Stray Fields from a Spin-Defect in Non-Centrosymmetric Two-Dimensional Systems Adonai R. Cruz[1] and Michael E. Flatté[2,1]; [1]Eindhoven University of Technology, Netherlands; [2]The University of Iowa, United States

Single spin states associated with point defects in solid-state systems are promising candidates for the realization of qubits and novel quantum spintronic devices with applications in communication, sensing, and information processing [1]. Isolated magnetic defects embedded in two-dimensional electron gases (2DEG) with spin-orbit coupling (SOC) can be electrically and optically addressed [2] and coherently manipulated.
We present a theory of circulating current induced by spin-defect in a two-dimensional electron gas (2DEG) with Bychkov-Rashba (α) and linear Dresselhaus (β) spin-orbit couplings [1,2]. We show that the spatial anisotropy dependency on the ratio of the strengths of the spin-orbit fields (α/β) offers a possibility to locally tune spin-orbit induced features of the defect such as the dissipationless circulating current associated with its ground state. The orbital contribution to the magnetization density is sensitive to the spin-orbit ratio, changing sign with respect to the spin magnetization and being null at α=β. The spatial structure of the stray field associated with the current is calculated for different 2D systems and provides a direct way to measure the host spin-orbit fields and the defect spin orientation through nanoscale magnetometry techniques such as NV-centers in diamonds [3].

Room Temperature Coherence of Silicon Vacancy Ensembles in Isotopically Purified 4H-SiC Ignas Lekavicius[1], Rachael Myers-Ward[1], Daniel J. Pennachio[1], Jenifer R. Hajzus[1], D K. Gaskill[1,2], Andrew Purdy[1], Andrew L. Yeats[1], Peter G. Brereton[3], Evan R. Glaser[1], Thomas L. Reinecke[1] and Samuel G. Carter[1]; [1]U.S. Naval Research Laboratory, United States; [2]University of Maryland, United States; [3]U.S. Naval Academy, United States

Due to the industrial maturity of the host crystal, defects in silicon carbide (SiC) have drawn considerable attention for quantum information and sensing applications. In particular, silicon vacancies in SiC have demonstrated impressive ground state spin properties such as optical spin initialization and readout. This has generated significant interest in room temperature sensing applications, which up until recently have been dominated by nitrogen vacancies in diamond. A key parameter in numerous sensing applications is the inhomogeneous dephasing time T_2^*, which thus far has been limited to a few 100ns in silicon vacancy ensembles. As the nuclear spin bath of the SiC is predicted to be the dominant source of dephasing, we perform isotopic purification of the host crystal leading to an order of magnitude improvement in T_2^*. Furthermore, the S=3/2 ground state quartet of the V_{Si} allows for a novel choice of basis with increased coherence due to a suppression of strain induced dephasing. A combination of these techniques leads to a nearly 2 order of magnitude improvement in the T_2^* of the defect ensemble even at high defect densities.

SESSION EQ01.03: Defects and Color Centers: Creation and Integration

Ultra-Fast Laser Fabrication of NV Centres in Diamond Andrew R. Kirkpatrick, Benjamin Griffiths, Guangzhao Chen, Patrick Salter, Martin Booth and Jason Smith; The University of Oxford, United Kingdom

The nitrogen-vacancy (NV) defect centre in diamond is a promising candidate in spin-photonic applications such as quantum computing and sensing. The centre's spin-dependant fluorescence transitions allow for a purely optical initialisation and readout of the electron spin states, providing a powerful interface to control a solid state qubit. However, the technological application of the NV centre requires its integration into optical and electronic components requiring a highly accurate and high yield fabrication method.

Ultra-fast laser fabrication has demonstrated the ability to produce coherent NV centres with high accuracy and yield. Vacancies are produced through an initial high energy 300fs seed pulse in a process which drives electrons into the conduction band using multi-photon ionisation. The electrons form a plasma which is able to redeposit its energy into the lattice. Following this initial seed the processed site can be exposed to a low energy ultra-fast pulse train which allows the vacancy to migrate through the lattice without causing additional damage. The formation of an NV centre can be monitored using a confocal fluorescence microscope to observe the centre’s 627-800 nm fluorescence window. Fluorescent traces taking during laser annealing is shown to be used to monitor the creation of NV centres, whilst providing some information on their singularity and orientation. Additionally, we explore the effects of laser pulse parameters, such as pulse energy and width, on these traces.

Within, we use present an experimental and theoretical study of the laser fabrication process. Density Functional Theory (DFT) is used to investigate the interactions between the NV centre and the carbon self-interstitial involved in laser writing and report on simulations which suggest that the intermittent fluorescence spiking is caused by the NV's emission being suppressed by interactions between the two defects. In particular, we investigate simulated strain and electronic interactions between the two defects and the effect of these interactions on the NV centre's band structure and the specific excitation pathway that leads to NV emission.

Electronic interactions between configurations of the NV centre and <100>-split interstitial were simulated by generating all symmetrically unique second and third near neighbour ensembles of the two defects. Some configurations of the <100>-split interstitial and the NV centre demonstrate hybridisation between the defects in these bands. Out of the 48 total configurations simulated, 8 lead to reconstruction and 15 resulted in hybridisation. In such cases hybridisation occurs between one of the degenerate π-orbitals of the <100>-split interstitial and the e-manifold of the NV centre in the ground state, which is involved in fluorescence. This electronic hybridisation may lead to the creation of non-radiative pathways for fluorescence, which would quench the NV emission since the decay through these pathways is typically much faster than the lifetime of the NV centre excited state. Additionally it is demonstrated through a simple Monte-Carlo simulation that the migration of interstitials, around an NV centre, that can suppress fluorescence can lead to similar photon traces to those that are experimentally observed.

Tunable and Transferable Diamond Membranes for Integrated Quantum Technologies Xinghan Guo[1], Nazar Delegan[1,2], Jonathan C. Karsch[1], Zixi Li[1], Tianle Liu[1], Robert Shreiner[1], Amy Butcher[1], David Awschalom[1,2,1], F. Joseph P. Heremans[1,2] and Alexander A. High[1,2]; [1]The University of Chicago, United States; [2]Argonne National Laboratory, United States

Color centers in diamond are widely explored as qubits in quantum networking and sensing due to their exceptional quantum coherence and straightforward optical interface. The further evolution of these quantum technologies will require the integration of diamond – i.e. the quantum state host – into complex device heterostructures, akin to the multi-material heterostructures widely utilized in CMOS technology. However, the material properties of diamond create fundamental difficulties for effective and efficient device integration. Despite recent progress developed to address this material challenge, a fully realized process to reproducibly generate and transfer single-crystal diamond thin films hosting coherent color centers remains outstanding. Here we demonstrate the robust and tunable synthesis of uniform diamond membranes with sufficient quality for advanced quantum technologies. These nanoscale-thick membranes are created based on the "smart cut" technique combined with isotopically (^{12}C) purified overgrowth. The membranes have tunable thicknesses (demonstrated 50 nm to 250 nm) and can be deterministically transferred to other substrates via a "dry transfer" technique involving polydimethylsiloxane/polycarbonate (PDMS/PC) stamps. Moreover, the finished membranes have bilaterally atomically flat surfaces ($Rq \leq 0.3$ nm) and bulk-diamond-like crystallinity. Furthermore, color centers are able to be synthesized via both implantation and incorporation during growth. Within 110 nm-thick membranes, individual germanium-vacancy (GeV^-) centers exhibit stable photoluminescence at 5.4 K, with average optical transition linewidths as low as 125 MHz. The room temperature spin coherence of individual nitrogen-vacancy (NV^-) centers shows Ramsey spin dephasing times (T_2^*) and Hahn-echo times (T_2) as long as 100 μs and 300 μs, respectively. This membrane platform provides a straightforward and deterministic method to integrate diamond into device heterostructures for next-generation quantum technologies and has the potential to supplant bulk diamond in many other quantum applications.

Ion Implantation and *In Situ* Optical Characterization for Deterministic Creation of Single Defects Vignesh Chandrasekaran[1], Michael Titze[2], Anthony R. Flores[2], Edward Bielejec[2] and Han Htoon[1]; [1]Los Alamos National Laboratory, United States; [2]Sandia National Laboratories, United States

Ideal quantum photonic chip requires single photon emitters, processors and detectors integrated into a single chip where the single photon sources must have higher degree of brightness, purity and indistinguishability [1]. This requires a precise location of emitting sources in pre-determined positions coupled to nano-photonic structures & nano-electronic devices. Defects in solid state host matrices are promising single photon sources considering their on-demand emission, scalability and room temperature operation [2]. Recently, silicon vacancy point defects in wide band gap material like SiC were demonstrated using focused ion beam (FIB) implantation [3,4]. However, the conversion yield of creating those single vacancy defects using FIB is less than 10%. In order to achieve fully deterministic creation of these single defects in SiC, we integrated our ion implantation system with an in-situ micro-photoluminescence setup sensitive enough for single defect optical characterization. By getting a feedback on the creation of defect in real time through checking the photoluminescence on the irradiated spot, while the sample is still inside the implantation chamber without annealing, we successfully fill an array of single defects following a loop of irradiation maintained at a lower dose level. Considering the nanometer spatial resolution and the versatile energy range of our FIB system, we believe that we can extend our capabilities to other lower dimensional materials and reproduce the precise defect creation onto nano-photonic structures & nano-electronic devices.

Late News: Surface Dynamics in p-InAs and n-GaAs Probed with Scanning Ultrafast Electron Microscopy Christopher Perez[1,2], Scott Ellis[2,2], J Michael[2], David Chandler[2], A. A. Talin[2] and Suhas Kumar[2]; [1]Stanford University, United States; [2]Sandia National Laboratories, United States

Understanding the spatio-temporal carrier dynamics in semiconductors, especially III-V materials, is critical for improving electronic and optical devices. Here, we develop a new technique, scanning ultrafast electron microscopy (SUEM), that resolves transient carrier densities and surface-sensitive potentials with 15 ps temporal and 100 nm spatial resolution. SUEM is used to quantify the surface defect density and the recombination of surface trap states in III-V semiconductors, n-GaAs and p-InAs: two parameters which often limit electro-optical device performance. The high temporal resolution probing of transient carrier densities reveals photosaturation at high laser fluences (0.2 and 8 μJ/cm^2, for p-InAs and n-GaAs, respectively) due to surface band flattening. Surprisingly, our SUEM signal is more sensitive to the local surface potential and the potential in the vacuum at short distances above the surface as opposed to the conduction band electron density itself. Our novel interpretation of SUEM contrast mechanisms opens doors for the carrier dynamics involved in the practical design of defect-driven microelectronic devices.

SESSION EQ01.04: Quantum Dots and Molecular Systems

1:30 PM *EQ01.04.01
Photogenerated Molecular Quartet States as Defect Center Surrogates Michael R. Wasielewski; Northwestern University, United States

Photogenerated molecular spin systems hold great promise for applications in quantum information science because they can be prepared in well-defined spin states at modest temperatures, often exhibit long coherence times, and their properties can be tuned by chemical synthesis. We will discuss molecular spin systems composed of organic chromophores such as porphyrins and perylenediimides (PDIs) covalently linked to stable organic radicals. Following photoexcitation of the chromophore, femtosecond optical spectroscopy shows that the exchange interaction between the electrons on the chromophore and the unpaired electron spin of the radical results in quartet state formation in >10^{11} s^{-1}. The linkers between the chromophores and the radicals are used to control the spin-spin exchange interaction between the chromophore and the stable radical. Time-resolved pulsed electron paramagnetic resonance experiments show that the resulting quartet state is strongly spin-polarized, having spin lattice relaxation times > 100 μs and relatively long coherence times of ~2-4 μs at temperatures as high as 80 K. Using microwave pulses to manipulate the quartet spin sublevel populations is accompanied by chromophore optical changes. These systems function in a manner analogous to defect centers in solids, such as NV centers, because they can be optically pumped to a highly spin-polarized state, manipulated using microwave pulses, and read out by monitoring optical changes making them viable for quantum information studies.

2:00 PM *EQ01.04.02
Incorporation of Pnictogen Atoms into Dysprosium Single-Molecule Magnets Fu-Sheng Guo[1], Mian He[1], Richard Layfield[1], Sean R. Giblin[2], Akseli Mansikkamäki[3] and Ming-Liang Tong[4]; [1]University of Sussex, United Kingdom; [2]University of Cardiff, United Kingdom; [3]University of Oulu, Finland; [4]Sun-Yat Sen University, China

Single-molecule magnets are compounds of transition metals or lanthanides that display slow relaxation of magnetization in the absence of a static magnetic field. SMMs may also show magnetic hysteresis and, hence, magnetic bistability, which has led to proposals that SMMs could be used in magnetic information storage. Significantly, the properties of SMM originate from within individual molecules with dimension of less than 1 nm rather than from cooperative interactions across much larger magnetic domains.

The problem with SMMs is that their magnetic bistability is typically only observed with liquid helium cooling. Recently, we reported the first SMM to function above the boiling point of liquid nitrogen. Molecules of this SMM consist of a single dysprosium atom sandwiched between two organic (i.e. cyclopentadienyl) rings, a structural arrangement that creates excellent conditions for addressing the electronic structure of the lanthanide.

In this presentation, new results describing the impact of incorporating phosphorus and arsenic atoms into the cyclopentadienyl rings on the SMM properties will be described.

2:30 PM EQ01.04.03
Near Atomistic Mesoscale Tomography of PbSe Quantum Dot Superlattices Xiaolei Chu[1], Alex Abelson[2], Caroline Qian[2], Davis Unruh[1], Chase Hansen[1], Matthew Law[2] and Adam J. Moule[1]; [1]University of California, Davis, United States; [2]University of California, Irvine, United States

Three-dimensional epitaxially fused quantum dots superlattices are theoretically predicted to exhibit band-like charge transport behavior while still retaining tunable semiconductor properties, making them promising candidates for future energy materials. Realization of the predicted emergent electronic properties has remained due in part to defective interdot epitaxial connections. These defects include edge dislocation, screw dislocations and stacking fault that contribute to the tilting and rotational misalignment between the atomic lattices of neighboring connected dots. Existing imaging techniques such as Scanning Transmission Electron Microscopy allow for direct observation of local attachment in atomic scale and characterizing two-vector-based local atomic orientations with the help of scanning diffraction techniques like the 4D-STEM. However, it is still not fully understood enough on how a collective of these geometric frustration in the atomic scale will affect the structural regularity of the local or even long-range superlattice structure variations, hence, preventing our access to defect-free superlattice attachment, especially for a three-dimensional film. Here, we present the combination of using full-tilt HAADF Electron Tomography with Geometric phase analysis in 3D to characterize and understand structural features spanning two orders (0.1 ~ 10 nm)

of magnitude in spatial length scale throughout a multi-layer superlattice film. We apply 3D windowed diffraction calculations based on the tomogram to extract phase information of desired lattice planes, with which allow us to obtain in 3D the local atomic lattice orientations, vectorial displacement field, local strain tensor field and dislocation lines that propagate in-between particles. With this vast amount of information of atomic structural details, quantitative analysis can be conducted on thousands of quantum dot pairs to understand the relation between atomic dislocations and QD orientational misalignment as well as how these geometric frustrations are reflected in strain field. The insights we gained from this particular QD SL material promises a step toward minimizing structural fault in the oriental attachment and hence further approaching the goal of charge delocalization. We also believe that the analytical method we present here provides a novel way of comprehensively understanding structural variations with multi-dimensional quantifications, which we expect, to become increasing important in the rise of complex materials.

SESSION EQ01.05: Poster Session: Quantum Dots and Molecular Systems
Wednesday Afternoon, December 1, 2021
8:00 PM - 10:00 PM

EQ01.05.01
Novel Methods in Data Analysis of Tomographic Reconstructions Applied to PbSe Quantum Dot Materials Ethan M. Field[1], Xiaolei Chu[1], Caroline Qian[2], Alex Abelson[2], Matthew Law[2] and Adam J. Moule[1]; [1]University of California, Davis, United States; [2]University of California, Irvine, United States

Colloidal quantum dot (CQD) superlattices with semiconductor properties promise many exciting properties for organic opto-electronic devices including the delocalization of electronic bands with tunable properties. The scaling up of these devices would allow low-cost high-throughput methods to make organic photovoltaics and other opto-electronic devices but this is only possible through higher quality processing methods that achieve these delocalized band structures. Current characterization methods like transmission electron microscopy (TEM) and grazing-incident small angle x-ray scattering (GISAXS) do not probe the exact the structure of the superlattice in three dimensions. We have applied novel data analysis techniques to tomographic reconstruction data from STEM images to determine the center of mass of each quantum dot, the number of necks each of the PbSe quantum dots has to its nearest neighbors, the thickness of the necking, the in-plane and out-of-plane misorientation angles, and local strain measurements in the CQD superlattice. This presentation will highlight data used and its applications in improving the superlattice structure to achieve next-generation opto-electronic properties.

Single Rare-Earth Ions in Solid–State Hosts—A Platform for Quantum Networks Andrei Faraon, Andrei Ruskuc and Chun Ju Wu; California Institute of Technology, United States

Optically addressable spins in solids are an area of intense research interest in quantum information science with applications in quantum networks, computing and sensing. Due to recent advances in nanophotonic cavity design and fabrication, detection and control of single rare-earth ions via their highly coherent 4f-4f optical transitions have recently been demonstrated. We focus on the 171 isotope of Yb doped into a YVO4 crystal due to low electric and magnetic field noise sensitivity facilitated by no 1st-order DC stark shift combined with optical and spin clock transitions. In this talk I will introduce this platform by characterizing the optical and spin transitions. Subsequently, we leverage the high-fidelity control and long coherence times to explore the interaction of single ^{171}Yb ions with a small local ensemble of vanadium lattice spins. We propose using collective modes of this ensemble as a secondary quantum register, a key resource for building quantum repeaters.

Room-Temperature Optically Detected Magnetic Resonance of Single Defects in Hexagonal Boron Nitride Hannah Stern[1], John Jarman[1], Qiushi Gu[1], Simone Eizagirre Barker[1], Noah Mendelson[2], Dipankar Chugh[3], Sam Schott[1], H. Hoe Tan[3], Henning Sirringhaus[1], Igor Aharonovich[2] and Mete Atature[1]; [1]University of Cambridge, United Kingdom; [2]University of Technology Sydney, Australia; [3]The Australian National University, Australia

Optically addressable spins in materials are important platforms for quantum technologies, such as repeaters and sensors [1]. Identification of such systems

in two-dimensional (2d) layered materials offers advantages over their bulk counterparts, as their reduced dimensionality enables more feasible on-chip integration into devices.

Hexagonal boron nitride (hBN) is a two-dimensional van der Waals crystal that was recently shown to host a plethora of defects that display photoluminescence (PL) spectra ranging from 580 nm to 800 nm. Here, we show that previously identified [2] carbon-related single defects in 2d hexagonal boron nitride (hBN) show ODMR at room temperature [3].

We show that single-defect ODMR contrast is up to 100x stronger than that of hBN ensembles and displays a magnetic-field dependence with positive or negative sign per defect. By measuring hundreds of defects we can identify a yield of spin active defects of ~5%. Further, the ODMR lineshape comprises a doublet resonance, indicating a S=1 state with low but finite zero-field splitting. Our results offer a promising route towards realising a room-temperature spin-photon quantum interface in hexagonal boron nitride.

11:45 AM EQ01.06.04
A New Paradigm for Quantum Optical Networks—Highly Uniform Single Photon Source Arrays Jiefei Zhang[1], Qi Huang[1], Swarnabha Chattaraj[1], Lucas Jordao[1], Siyuan Lu[2] and Anupam Madhukar[1]; [1]University of Southern California, United States; [2]IBM T.J. Watson Research Center, United States

The realization of integrated quantum optical circuits (QOCs) to enable single and high dimensional entangled photons for quantum communication, robust quantum teleportation and quantum sensing with quantum limited resolution has been a long-sought goal in the field of quantum information processing (QIP). All these applications explore the effect of quantum interference and entanglement between different on-demand single photon sources (SPSs) in a scalable architecture. The lack of a starting ordered array of SPSs so far has stood as a major obstacle to realizing compact quantum information technologies.

In this talk I will present our proposition and continued work on demonstration of such a starting platform of SPS arrays based on a unique class of spatially-ordered arrays of surface-curvature driven mesa-top single quantum dots (MTSQDs) [1-3]. These AlGaAs/InGaAs MTSQDs exhibit spectral uniformity as low as 1.8nm across 5×8 arrays including clusters of 6 as-grown QDs having emission energy within 250μeV (within on-chip electrical tuning range) and single photon purity > 99.5%. For the usage of this unique class of ordered spectrally uniform MTSQD SPSs to create interconnection between different SPSs for quantum circuits or networks via monolithic or hybrid integration, we also demonstrate planarization of the MTSQDs without compromising their spectral uniformity and single photon emission characteristics [3]. The highly pure single photons from such planarized MTSQD are also indistinguishable with as-measured indistinguishability of 0.5±0.12 at 18.5k (without Purcell effect), limited by the spectral diffusion and phonon induced dephasing at this elevated based temperature of 18.5K of our cryostat at hand. Potential unity indistinguishability can be reached at low temperatures ~4K. Such planarized MTSQDs can have single photon emission from 700-1300nm using our AlGaAs/InGaAs material system that can be further extended to 1550nm using Phosphorus based material system to cover the full range of wavelength needed for quantum communication, teleportation, and sensing in space.

Such planarized ordered array of highly spectrally uniform SPSs generating highly pure and indistinguishable photons offers the long-sought platform for on-chip deterministic integration with light manipulating structure using either hybrid, conventional 2D PhC or dielectric metastructures [4,5] to realize QOCs generating needed multiphoton entangled states for the aforementioned applications. Work on integration of MTSQD with light manipulating units and study of photon interference/entanglement is undergoing.

The work is supported by the US Army Research Office (W911NF1910025) and the Air Force Office of Scientific Research (FA9550-17-1-0353).

Late News: Toward Scalable Telecom Single-Photon Emitters for Quantum Photonics Alex Kaloyeros, Natasha Tabassum and Spyros Gallis; SUNY Polytechnic Institute, CNSE, United States

Single-photon emitters (SPEs) associated with point-defects and ions in semiconductors are currently considered a significant resource for the solid-state implementation of quantum repeaters and fiber-based long-distance quantum networks, and interconnecting quantum computers. Specifically, non-classical single-photon light sources emitting in the near-infrared region of the electromagnetic spectrum around 1.5 μm, falling in the lowest loss wavelength range of fiber optics networks, are critical chip-scale building components for the development of fiber-based quantum networks. The realization of scalable on-chip quantum devices, such as single-photon sources and quantum memories, requires novel nanostructured materials that must be compatible and can be integrated with existing electronic circuits, waveguide architectures, and current chip-scale and silicon process technology. We present nanophotonic structures composed of arrays of silicon carbide (SiC) nanowires (NWs) based on a novel and fab-compatible nanofabrication process. Furthermore, these NW-based structures enable the positioning of erbium (Er^{3+}) ions with an accuracy of 10 nm, an improvement on the current state-of-the-art ion implantation processes, and are pivotal in engineering the Er^{3+}-induced 1.54 μm emission. An approximately 22-fold increase of the room-temperature Er^{3+} PL emission is observed in these optical nanostructures compared to their thin-film analog at saturation, while using 20 times lower pumping power. These nanostructures demonstrate broadband and efficient excitation characteristics for Er^{3+}, with an absorption cross-section (~2×10^{-18} cm^2) two-order larger than typical benchmark values for direct absorption in rare-earth-doped quantum materials. Additionally, we have explored the modeling foundations for plasmonic cavity engineering of the Er^{3+} emission to significantly enhance its spontaneous emission rate. Finally, we benchmark and optimize our state-of-the-art near-infrared single-photon detector system to study single-photon behavior from these Er:SiC NW telecom nanophotonic structures.

12:15 PM EQ01.06.06
Indistinguishable Single Photons from a Tin-Vacancy Center in Diamond Johannes Goerlitz[1], Robert Morsch[1], Dennis Herrmann[1], Philipp Fuchs[1],

Benjamin Kambs[1], Pierre-Olivier Colard[2], Matthew Markham[2] and Christoph Becher[1]; [1]Saarland University, Germany; [2]Element Six Global Innovation Centre, United Kingdom

For various applications in the field of quantum information processing stationary qubits are required, providing long-lived spin coherence and suitable level schemes for coherent control and optical read out. In addition, transferring the spin information to indistinguishable single photons is necessary e.g. to distribute entanglement in quantum networks. Similarly, quantum computing with linear optics (LOQC) inherently relies on bright light-matter interfaces that provide single indistinguishable photons.
Color centers in diamond, more specifically the group-IV-vacancy centers, have emerged as promising candidates among solid state qubits. They exhibit favorable features such as individually addressable spins with long coherence times and bright emission of single, close to transform limited photons. While for silicon-vacancy centers (SiV) long spin coherence times are only achieved at milliKelvin temperatures, recent experiments have shown that the negatively charged tin-vacancy center (SnV) [1] overcomes this drawback. Its large ground state orbital splitting results in the suppression of phonon induced dephasing processes of the spin states, allowing long spin coherence times at significantly higher temperatures (>1K) [2]. Among its good spectral qualities such as bright single photon emission and transform limited linewidths [3,4] the indistinguishability of the emitted single photons remains a missing cornerstone to be demonstrated.
By means of Hong-Ou-Mandel interferometry we here investigate the indistinguishability of single photons consecutively emitted by an off-resonantly excited single SnV-center. We find high Hong-Ou-Mandel visibilities, being a direct measure for high indistinguishability of the single photons. We compare the experimental results with the predictions of a theoretical model [5] and extract the magnitude of spectral diffusion potentially affecting single photon indistinguishability in the present system. Furthermore we estimate the timescale of spectral diffusion by repeating the experiment with various delays between emissions of the interfering photons.

Emergence of Entanglement Between Single Photon Emitters by Dielectric Mie Resonant Metastructure-Based Optical Circuits Swarnabha Chattaraj[1], Jiefei Zhang[1], Siyuan Lu[2] and Anupam Madhukar[1]; [1]University of Southern California, United States; [2]IBM Thomas J. Watson Research Center, United States

On-chip quantum optical circuits (QOCs) comprising ordered single photon sources (SPSs) coupled to network of light manipulating elements (LMEs) that allow manipulation of the emitted photons in a single or few photon regime to enable on-chip photon interference and photon mediated emitter-emitter entanglement is a major goal for scalable quantum information processing (QIP). The path to realization of such QOCs is recently enabled by the new class of spectrally uniform on-chip integrable mesa top single quantum dot (MTSQD) [1-3] single photon sources that provide a platform for indistinguishable photon emission with >99% purity from ordered and spectrally uniform QDs that are also integrable in the monolithic or hybrid integration techniques for codesign with LMEs to interconnect different SPSs. The LMEs must provide the needed light manipulating functions of (1) enhancement of emission rate of the emitters, (2) enhanced emission directionality (3) on-chip propagation, (4) splitting and (5) recombining of single photons to enable efficient extraction of photon, photon interference and photon mediated emitter-emitter coupling in a horizontal architecture for quantum entanglement.
The conventional approach to implementation of such LMEs has been photonic crystal and ridge waveguides-based cavities and waveguides that demand mode-matching between components and hinders scalable implementation of all the above functions. In contrast, we have recently introduced [4,5] the approach of Mie resonance of subwavelength scale dielectric building blocks (DBBs) that exploits a single collective mode of the entire circuit to provide all the five above mentioned functions- thus eliminating mode mismatch between the components. We have demonstrated via finite element method-based simulations of the EM fields [4] that such Mie resonance based DBB metastructures can provide simultaneously a Purcell enhancement ~5-10, emission directionality resulting in 50% photon coupling to the Mie mode, and at the same time propagation, splitting and combining using the same collective magnetic dipole mode of the DBB array- thus enabling realization of quantum optical circuits without any impedance mismatch.
Importantly, the Mie mode of such MTSQD-DBB quantum optical circuits allow coupling between distant emitters- spontaneously resulting in emitter-emitter entanglement over large on-chip distance, critical for applications in quantum metrology, sensing and computation. We present theoretical work to understand the emergence of emitter-emitter entanglement of a system of two MTSQDs coupled via the collective magnetic dipole mode of a DBB based back-to-back nanoantenna waveguide unit [4]. We show a ~1.7 times faster decay rate of the coupled emitter system compared to single emitter- a signature of super radiance. Owing to the lossless propagating nature of the Mie mode, the super-radiant state can be formed over large ~10-100 μm on-chip distances. The emergence of such super radiant states has been explored by employing Von-Neumann Lindblad approach to account for the coherent and incoherent processes involved in the general Hilbert space involving multiple excitons and photons. Further, using the same approach, emergence of a positive degree of entanglement between the distant emitters is shown starting from a purely product state. Spontaneous creation of entanglement between distant on-chip emitters in such MTSQD-DBB integrated optical circuits provides a way to realize architectures for quantum metrology and computation. Further work on optical studies on such DBB based light manipulating structure is ongoing.

Optical Vortex Manipulation for Topological Quantum Computation Chengyun Hua, Gábor Halász, Eugene Dumitrescu, Matthew Brahlek and Benjamin Lawrie; Oak Ridge National Laboratory, United States

Topological quantum computation based on Majorana bound states may enable new paths to fault-tolerant quantum computing. Several recent experiments have suggested that the vortex cores of topological superconductors, such as iron-based superconductors, may host Majorana bound states at zero energy. \textcolor{red}{However, quantum computation with these zero-energy vortex bound states requires a precise and fast manipulation of individual vortices which is difficult to do in a scalable manner. To address this issue, we propose a control scheme based on local heating via, for example, scanning optical microscopy to braid vortex-bound Majorana zero modes in a two-dimensional topological superconductor. First, we derive the conditions required for transporting a single vortex between two defects in the superconducting material by trapping it with a hot spot generated by local optical heating. Equipped with critical conditions for the vortex motion, we then establish the ideal material properties for vortex braiding and describe how transition errors resulting from finite speed and/or temperature can be minimized. Our work paves the way toward optical or microscopic control of zero-energy vortex bound states in two-dimensional topological superconductors. *This work has been conducted by UT-Battelle, LLC, under contract DE-AC05-00OR22725 with the US Department of Energy (DOE). Coherence Properties of Quantum Emitters in hBN Mehran Kianinia, Simon J. White, Milos Toth and Igor Aharonovich; University of Technology Sydney, Australia

Solid state quantum light sources are emerging as promising candidates for many applications in quantum technologies [1-3]. Among these sources, optically active point defects in hexagonal boron nitride (hBN) are attracting considerable attention due to their extreme brightness, and high Debye Waller factor which means the majority of the photons are emitted into the zero phonon line (ZPL) . While final defect assignments are still under debate , a number of recent experiments and theoretical papers hint at carbon related defects adjacent to a vacancy site in the hBN lattice [4,5]. In addition, numerous recent studies have shown that several defects in hBN exhibit spin dependent optical transitions, and exhibit optically detected magnetic resonance (ODMR), which is vital for their employment as solid state qubits and quantum sensors at the nano-scale [6,7].
For practical quantum photonic applications, where photon interference and generations of indistinguishable photons are required , it is important to characterize the coherent properties of the emitted photons. Specifically, studies of dephasing mechanisms, coherence and line broadening effects underpin the applicability of quantum emitters for photon interference experiments. Previous studies of hBN quantum emitters have revealed the emissions in hBN are broadly affected by spectral diffusion. Preliminary resonant excitation experiments showed that observation of Fourier Transform limited lines is possible, but rather rare, as compared to other solid state emitters, such as diamond [28,29]. Some of the challenges stemmed from the fact that the level structure of the emitters is still poorly understood, and environmental effects in layered materials are strongly sample-dependent.
In this presentation, we will report on spectroscopy of hBN defects at cryogenic temperature to study dephasing mechanism of quantum emitters in details. Importantly, our work focuses predominantly on coherent excitation (i.e. the excitation laser is on-resonance with the hBN emission). First we characterize the significant dephasing and spectral broadening mechanisms in an hBN single photon emitter under resonant excitation. We find that the resonant linewidth, even at cryogenic temperature, is dominated by phonon broadening and results in linewidths of ~ 1 GHz. We also see that degenerate electronic states and strain do not play a significant role in phonon dephasing. We further showed that spectral diffusion can be minimized by employing excitation powers well below saturation. Overall, the brightness of the emitters exemplify that emission rate in excess of 200 MHz with bandwidth of less than 1 GHz [8]. Next we employed a weak non-resonant laser at a wavelength between 500 nm and 532 nm, in addition to the resonant laser that drives the system coherently to stabilise the optical transition of single defects in hBN. The secondary laser acts as an additional excitation pathway and re-initializes the system into its bright state. The two laser repumping scheme enables the observation of brighter resonant fluorescence [9]. We provide an in-depth analysis of the photodynamics of the system, and discuss its applicability for an improved coherence. Our results provide an important analysis and required modification for future experiments on two photon interference with quantum emitters in hBN.

Electrical Manipulation of Quantum Light Sources in 2D Hexagonal Boron Nitride Jieun Lee; Seoul National University, Korea (the Republic of)

Single photon emitters are fundamental resources of quantum optics and quantum information technologies. Recently, the emergence of single photon emission in atomically thin materials such as hexagonal boron nitride (h-BN) has triggered tremendous interests in 2D material based single photon sources. For full exploitation of 2D single photon emitters for quantum technologies, however, the ability to control each atomic defect individually is critical. In this talk, we introduce methods to generate and manipulate single photon sources in 2D h-BN crystals using local crystalline geometries and electrical controls. First, we show the role of strain for the creation and orientation of the single photon emitters in h-BN. Second, we demonstrate that the photon energy of single photon sources in h-BN can be controlled using an electric field by fabricating 2D van der Waals heterostructures composed of h-BN and graphene layers. A diverse trail of Stark shifts is observed, providing information on crystallographic ground states of defect structures. Lastly, we will discuss the electrical switching of the quantum emitters enabled by the Fermi level tuning of graphene electrodes.

First-Principles Predictions of Out-of-Plane Group IV and V Dimers as High-Symmetry High-Spin Defects in Hexagonal Boron Nitride Jooyong Bhang[1], He Ma[2,2], Donggyu Yim[1], Giulia Galli[2,2,3] and Hosung Seo[1]; [1]Ajou University, Korea (the Republic of); [2]The University of Chicago, United States; [3]Argonne National Laboratory, United States

Hexagonal boron nitride (h-BN) has been recently found to host a variety of quantum point defects, which are promising candidates as single-photon sources for solid-state quantum nanophotonics applications. Most recently, optically addressable spin qubits in h-BN have been the focus of intensive

research due to their unique potential in quantum computing, communication, and sensing. However, the number of high-symmetry high-spin defects that are desirable for developing innovative spin qubits in h-BN is highly limited. Here, we combine density functional theory (DFT) and quantum embedding theories (QET) to show that out-of-plane X_NY_i dimer defects (X, Y=C, N, P, Si) form a new class of stable C_{3v} spin-triplet defects in h-BN. We find that the dimer defects have a robust $^3A_2$ ground state and ^3E excited state, both of which are isolated from the h-BN bulk states. We show that ^1E and ^1A shelving states exist and they are positioned between the ^3E and $^3A_2$ states for all the dimer defects considered in this study. To support future experimental identification of the X_NY_i dimer defects, we provide an extensive characterization of the defects in terms of their spin and optical properties. We predict that the zero-phonon line of the spin-triplet X_NY_i defects lies between the infrared (~1.0 eV) and the visible (~1.8 eV) range. We compute the zero-field splitting of the dimers' spin to range from 1.79 GHz ($Si_NP_i^0$) to 29.5 GHz ($C_NN_i^0$). Our results broaden the palette of high-spin defect candidates that would be useful for the development of spin-based quantum technologies in two-dimensional hexagonal boron nitride.

Determinisitc Creation of Optically Active Defects in Hexagonal Boron Nitride Aleksandra Radenovic; Ecole Polytechnique Federale Lausanne, Switzerland

One of the *grand challenges* in imaging defects in 2D materials is a lack of spatial structures to resolve, which complicates the interpretation of the resolution in our system. In addition, there is still very little control over the type of defects. One approach taken in diffraction-limited PL imaging exploited the strain imposed by nanopillar arrays that were spaced at least 6 microns apart. To be able to characterize better the existing SMLM setup, we will use variable spacing arrays. Currently, to induce defects, we still treat pristine exfoliated material with Oxygen, Nitrogen or Hydrogen plasma typically, obtaining defects at a random location. To address the main challenge of engineering defects deterministically at various densities, Focus ion beam (FIB), naimley electrically discharged, Xe^+ of several kV that will be focused on the sample, allowing the creation of the defects in a predefined location. Given the spatial limitations linked to the substrate charging and instrument drift, achieving sub 100 nm spacing of the defects stil presents a challenge.

11:00 AM *EQ01.08.02
Novel Quantum Nanostructures of Diamond Related Materials by Nanosecond Laser Annealing Jagdish Narayan; North Carolina State University, United States

We present laser synthesis and processing of novel quantum nanostructures of diamond related materials. With our recent breakthrough in nonequilibrium laser processing, we have shown than amorphous carbon layers can be converted into phase-pure graphene, diamond or Q-carbon (new allotrope of carbon) by increasing the undercooling before melt quenching. Carbon layers can be converted into graphene, graphene oxide or reduced graphene oxide. Parallel results are obtained for the conversion of amorphous BN into phase-pure h-BN, c-BN or Q-BN. We will focus here on nanodiamonds, epitaxial thin films, and nanoneedles, which can be grown epitaxially by domain matching epitaxy. Through epitaxial growth, nanodiamonds are grown with a controlled orientation, such as <111> on <0001> sapphire. These nanodiamonds and nanoneedles can be doped with single NV or SiV centers, in addition to higher concentrations in macrodiamonds and thin films. Pure (undoped) Q-carbon is ferromagnetic, and it becomes superconducting upon doping with boron with record BCS transition temperature of over 57K so far. We discuss the properties and applications of these graphene, diamond and Q-carbon related nanostructures with a wafer-scale integration in nanosensing, quantum computing and quantum communication.

11:30 AM *EQ01.08.03
Engineering and Device Integration of Optically Addressable Spin Defects Nazar Delegan[1,2], Xinghan Guo[2], Sean Sullivan[1,2], Jonathan C. Karsch[2], Martin Holt[1], Stephan Hruszkewycz[1], Alexander A. High[2], David Awschalom[2] and F. Joseph P. Heremans[1,2]; [1]Argonne National Laboratory, United States; [2]The University of Chicago, United States

Optically addressable point-defects in wide band-gap semiconductors are a versatile platform for quantum information science (QIS). Such qubits are intrinsically sensitive to their local crystalline, charge, and nuclear environments. These variations directly affect the coherence, charge stability, and the optical transition frequency of the defects, limiting their use as scalable platforms for nanoscale sensing and quantum communication. Interestingly, with recent advances in host growth, nanofabrication, and defect synthesis, these environments can be engineered via control of crystal structure, isotopic purity, and host dimensionality. Herein, we will present work on the optimization of these defect systems via isotopically controlled synthesis and localization of various defect systems in silicon carbine and diamond. An emphasis will be placed on exploring how advanced, synchrotron-based characterization techniques provide a direct means to better understand the local crystal environment surrounding the defects and offers a pathway for improving the defect-based quantum technologies. Finally, recent advances in synthesising low-dimensionality (nano-scale particles and membranes) defect hosts for deterministic integration with other classical or quantum systems will be presented.

Late News: Tuning Color Centers at a Twisted Interface of Hexagonal Boron Nitride Cong Su[1,1,2], Fang Zhang[1], Salman Kahn[1], Brian Shevitski[1], Jingwei Jiang[1], Chunhui Dai[2], Alex Ungar[1], Ji-Hoon Park[3], Kenji Watanabe[4], Takashi Taniguchi[4], Jing Kong[3], Zikang Tang[5], Wenqing Zhang[6], Feng Wang[1], Michael Crommie[1], Steven Louie[1], Shaul Aloni[2] and Alex Zettl[1]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Massachusetts Institute of Technology, United States; [4]National Institute for Materials Science, Japan; [5]University of Macau, China; [6]Southern University of Science and Technology, China

Color center is a promising platform for quantum technologies, but their application is hindered by the typically random defect distribution and complex mesoscopic environment. Employing cathodoluminescence, we here demonstrate that an ultraviolet-emitting single photon emitter can be readily activated and controlled on-demand at the twisted interface of two hexagonal boron nitride flakes. The brightness of the color center can be enhanced by two orders of magnitude by altering the twist angle. Additionally, a brightness modulation of nearly 100% of this color center is achieved by an external voltage. Our *ab-initio GW* and *GW*-BSE calculations suggest that the emission is correlated to nitrogen vacancies and that a twist-induced moiré potential facilitates

electron-hole recombination. This mechanism is further exploited to draw nanoscale color center patterns using electron beams.

12:15 PM EQ01.08.05
Towards a Two-Dimensional Single Spin-Photon Interface at Room Temperature Simone Eizagirre Barker[1], Hannah Stern[1], John Jarman[1], Qiushi Gu[1], Noah Mendelson[2], Dipankar Chugh[3], H. Hoe Tan[3], Igor Aharonovich[2] and Mete Atature[1]; [1]University of Cambridge, United Kingdom; [2]University of Technology Sydney, Australia; [3]Australia National University, Australia

Colour centres in two-dimensional hexagonal boron nitride (hBN) have emerged as a promising platform for quantum photonic applications, as they emit single photons at room temperature and can be readily integrated into nanoscale devices thanks to their reduced dimensionality. Recently, we showed the first demonstration of optically-detected magnetic resonance (ODMR) from single spin defects in a van der Waals material at room temperature,[1] with ODMR contrasts of up to 30%, demonstrating the potential of hBN for applications in quantum information and quantum networks. Interestingly, single defects with similar spectral properties can show negative, positive or no ODMR contrast, indicating rich photo- and spin dynamics in the material. Integration of these colour centres into devices such as cavities to enhance emission or improve collection efficiencies will lead to a stronger platform to investigate and exploit their fundamental physics, and to evaluate their potential as solid-state qubits or nanoscale quantum sensors. In this contribution, we present our latest results towards integrating these individually optically addressable spin defects into tunable devices to enable a room-temperature single spin-photon interface in a two-dimensional material.

1:00 PM *EQ01.09.01
Scalable Semiconductor Quantum Systems Jelena Vuckovic; Stanford University, United States

At the core of most quantum technologies is the development of homogeneous, long lived qubits with excellent optical interfaces, and the development of high efficiency and robust optical interconnects for such qubits. To overcome inhomogeneities in semiconductor spin qubits and in their connections, we have been relying on fast photonics inverse design and on optimization (Floquet engineering) of the qubits themselves. We illustrate this approach to scalable semiconductor quantum systems with our results on quantum photonics based on diamond and silicon carbide.

1:30 PM *EQ01.09.02
Focused Ion Beam Implantation for the Fabrication of Single Defect Centers in Wide Bandgap Substrates Using *In Situ* Counting and Photoluminescence Edward Bielejec; Sandia National Laboratories, United States

We will present an overview of Sandia's focused ion beam (FIB) implantation capability as it pertains to the fabrication of single defect center-based devices via direct write nanofabrication in a wide range of devices and substrates. Sandia's Ion Beam Laboratory (IBL) has seven main accelerators including three high energy (250 keV to ~50 MeV) FIB systems with micron-scale resolution and three low energy (2 keV to 200 keV) FIB systems with nanometer scale resolution. In this talk we will highlight both the A&D nanoImplanter and the Raith Velion. These are both multi-species kV energy level FIB systems with a minimum spot size of <10 nm with both mass resolution using an ExB filter and single ion implantation using fast blanking. The combination of high spatial resolution, variable energy and the ability to implant a wide range of elements from the periodic table makes these versatile machines for a range of topics from device modification including the deterministic seeding of TaOx memristor devices, detector testing using high resolution ion beam induced charge collection (IBIC) to probe the structure of defect cascades, device fabrication including deterministic single donor devices for quantum computing research, to the formation of individual defect centers in wide bandgap substrates including diamond, SiC, hBN, etc…. Here we concentrate on FIB implantation to create defect centers in diamond making use of in-situ counting to reduce the error associated with the Poisson distribute and in SiC using a newly developed in-situ photoluminescence (PL) setup to create near deterministic array formation.

Using in-situ diamond detectors combined with FIB implantation we have demonstrated the fabrication of SiV arrays with a factor of two reduction in the error for single defect center formation as compared to standard timed implantation. This allows us to develop an improved understanding of the defect center activation under high temperature annealing. In the same accelerator we have demonstrated in-situ PL that allows for the near deterministic formation of Vsi arrays in SiC via an implant, measure PL and repeat process.

This work was performed, in part, at the Center for Integrated Nanotechnologies, an Office of Science User Facility operated for the U.S. Department of Energy (DOE) Office of Science. Sandia National Laboratories is a multi-mission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC., a wholly owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA-0003525.

***In Situ* Ion Counting for Deterministic Placement of Single Photon Emitters** Michael Titze, Heejun Byeon, Jacob D. Henshaw, Anthony R. Flores, Tom Harris, Andrew Mounce and Edward Bielejec; Sandia National Laboratories, United States

Single photon emitters (SPE) in wide bandgap semiconductors play a crucial role quantum sensing, computing, and communication. For utilization of SPEs for these quantum applications, it is crucial to locally place a precise number of ions in the host semiconductor for the highest possible yield of devices. Various techniques have been proposed for the deterministic creation of SPEs, including vacancy generation through pulsed laser, electron irradiation, and localized annealing by laser heating. However, none of these techniques can introduce non-naturally occurring impurity-type emitters, which are especially suitable for deterministic SPE creation, enabling near background free SPEs. Vacancy-centers in diamond have attracted great interest for the use in quantum information science.
The silicon vacancy center (SiV) in diamond is an ideal candidate for the use as a SPE in quantum communication because of its potential for high photon emission rate, small phonon sideband emission, large Debye-Waller factor, and microwave-controllable electronic spin. Creation of SiV through a

combination of ion implantation and high-temperature annealing is routinely realized, but to enable fabrication of large-scale devices a high confidence in the number of created SiV , implying control over the number of implanted Si ions, is required. Typical ion implantation experiments rely on measurement of the beam current and timing the ion beam implantation to obtain implantation of a specific number of ions. Since the number of ions implanted by an ion beam is determined by Poisson statistics, the uncertainty on the number of ions is large when only a few ions are required.
In this presentation, we present an in-situ ion counting experiment which can reduce the uncertainty in the number of implanted Si ions, which is especially important for small total number of implanted ions. We show that for implantation of 30 ions, required to generate on average a single SiV, the uncertainty on the number of ions per implantation is reduced to $1/4^{th}$ the uncertainty in a timed implantation. We determine the number of SiV per implantation spot through using Hanburry Brown Twiss interferometry and find that the yield is approximately 3% for both timed and counted implantation techniques, demonstrating our ability to count implanted Si ions. The activation rate of 3% for implanted Si ion to SiV conversion prevents us from fully realizing the potential for counting implants, as the yield is dominated by the Poisson statistics of activation. However, in future work, implementing our counted implant technique combined with defects with high activation rates, will bring us closer to truly deterministic SPE placement.
Sandia National Laboratories is a multi-mission laboratory managed and operated by the National Technology and Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International, Inc., for the DOE's National Nuclear Security Administration under Contract No. DE-NA0003525. 2:15 PM EQ01.09.04
Synthesis and Characterization of Quantum Optical Materials at Gigapascal Pressures Peter Pauzauskie and Chaman Gupta; University of Washington, United States

Developing novel methods for the synthesis, processing, and characterization of quantum optical materials for quantum sensing and communication applications remains an outstanding challenge. This talk will present recent results in designing and creating quantum defects in insulators and wide-gap diamond semiconductors using extreme (GPa) pressures and temperature (>1800K) within a diamond anvil cell (DAC). Molecular dopants including tetraethyl orthosilicate (TEOS) and hexamethylenetetramine (HMT) can be chemically doped within amorphous carbon aerogels to create the negatively charged silicon split-vacancy (SiV) as well as both neutral and negatively-charged nitrogen-vacancy (NV) point defects. Pressure-dependent optical spectroscopy of the SiV center correlates well with computational predictions based on *ab initio* / DFT quantum cluster calculations. Recently the use of lithium fluoride (LiF) as a pressure transmitting medium has enabled the recovery of novel quantum optical materials for *ex -situ* characterization at cryogenic temperatures via time-correlated single photon counting. High-pressure has also been used to tune the crystal field energies of lanthanide point defects within insulating ceramic materials that have recently demonstrated the first experimental measurements of solid-state laser refrigeration at GPa pressures.

2:30 PM EQ01.09.05
Late News: Scanning Ultrafast Electron Microscopy Reveals Photovoltage Dynamics at a Deeply Buried p-Si/SiO2 Interface Scott Ellis[1], Norm Bartelt[1], Francois Leonard[1], Kimberlee Collins[1], Elliot J. Fuller[1], David R. Hughart[1], Diana Garland[1], Matthew Marinella[1], Christopher Perez[2,1], Suhas Kumar[1], J Michael[1], David Chandler[1], Bolin Liao[3] and A. A. Talin[1]; [1]Sandia National Laboratories, United States; [2]Stanford University, United States; [3]University of California, Santa Barbara, United States

The understanding and design of carrier dynamics and their interactions with defects at a buried insulator/semiconductor interface is essential for achieving optimum performance in modern electronics. We report on the use of scanning ultrafast electron microscopy (SUEM) as a non-contact and non-destructive technique to remotely probe the sub-nanosecond dynamics of excited carriers at a silicon surface buried below a 1 μm thermal silicon oxide. Our measurements illustrate a novel SUEM contrast mechanism, whereby optical modulation of the space-charge field in the semiconductor modulates the electric field in the thick oxide, thus affecting its secondary electron yield. By analyzing the SUEM contrast temporally, spatially and as a function of laser fluence we demonstrate the diffusion mediated capture of excited carriers by interfacial traps.

SESSION EQ01.10: Defects and Color Centers V

EQ01-Virtual

8:00 AM *EQ01.10.01
Spin Defects in hBN as Promising Temperature, Pressure and Magnetic Field Sensors Vladimir Dyakonov; University of Wuerzburg, Germany

Van der Waals materials have emerged over the last decade as the new playground for quantum photonics devices. Among them, hexagonal boron nitride (hBN) is an interesting candidate, mainly because of its crystallographic compatibility with many different 2D materials, but also because of its ability to host optically active spin defects. We have recently reported [1] the optically detected magnetic resonance (ODMR) of spin-triplet negatively charged boron vacancies (V_B^-) in hBN and determined their spin-Hamiltonian parameters. Furthermore, we demonstrated the coherent control of V_B^- at room temperature and determined the relevant spin-relaxation times. In this respect, sensors based on such color centers embedded in an intercalated hBN layer may be particularly attractive, since the distance between the sensor and the object to be sensed can be quite small. The influence of external stimuli (magnetic field, temperature and pressure) on this spin defect will be also discussed.[2]

8:30 AM *EQ01.10.02
Dipolar Interactions Between Quantum Emitters in van der Waals Heterostructures Ajit Srivastava; Emory University, United States

Atomically thin transitional metal dichalcogenides (TMDs), have recently come to the forefront of research in materials physics. This is largely due to the ease with which they can be combined into artificially engineered heterostructures that exhibit emergent electronic and optical properties. Optical excitations in semiconducting TMDs, viz., excitons, can be localized in potential wells resulting in quantum emitters. Unlike their monolayer counterparts, excitons in heterobilayers, such as $MoSe_2/WSe_2$, feature a permanent electric dipole which can be used to tune their emission energy electrically. Moreover, the few-body interaction between dipolar quantum emitters can be exploited for quantum nonlinearity. Furthermore, many-exciton dipolar interactions result in effective magnetic fields of ~ 6 Tesla. Thus, dipolar quantum emitters are a promising platform to study quantum optical phenomena

and to realize strongly interacting phases of optical excitations in 2D materials.

9:00 AM *EQ01.10.03
Thermodynamics of Carbon Defects in Hexagonal Boron Nitride Audrius Alkauskas[1,2]; [1]Center for Physical Sciences and Technology (FTMC), Lithuania; [2]Kaunas University of Technology, Lithuania

Single-photon emitters (SPEs) in hexagonal boron nitride, emitting in the 1.6-2.1 eV spectral region, have attracted a lot of experimental and theoretical activity since their discovery [1]. Many defects have been proposed to explain the observed emission. However, the jury is still out regarding the chemical origin of these emitters. Despite intense theoretical investigations, no single defect seems to describe the experiments in a consistent manner. In a recent work [2], it was confirmed that the presence of carbon increases the concentration of SPEs. However, it remains unclear whether carbon participates in the structure of the SPEs directly or helps create SPEs indirectly.

In this work I discuss a first-principles computational study of the thermodynamics of carbon defects in hexagonal boron nitride (hBN). The defects considered are carbon monomers, dimers, trimers and larger carbon clusters, as well as complexes of carbon with vacancies, antisites, and substitutional oxygen. Our calculations show that monomers (C_B, C_N), dimers, trimers, as well as C_N-O_N pairs are the most prevalent species under most of growth conditions. In comparison to these defects, complexes of carbon with vacancies and antisites occur at much smaller concentrations ($< 10^{14}$ cm^{-3}). Taking into accound the emission wavelength of these defects, our results show that carbon trimers are the only carbon-related defects that can likely explain the results of Ref. [2]. This finding is in agreement with recent calculations that showed that optical lineshapes of trimer defects are in very good agreement with experimental spectra [3], affirming the potential role of carbon trimers in single-photon emission in hexagonal boron nitride.

The work has been performed with M. Maciaszek and L. Razinkovas.

Chemically Enhanced NV Centers in CVD Diamond for Quantum Technologies Sayali Vispute; Blue Wave Semiconductors, Inc., United States

Quantum technologies are attracting attention worldwide due to their projected benefits over existing technologies. Modern devices such as computers, communication devices, and sensors could benefit from quantum technologies because quantum devices will have the ability to collect data at a precise accuracy and a record-breaking speed. One of the quantum technologies is the NV center in CVD diamond. In this technology, NV centers, or nitrogen vacancy centers, occur when two carbon atoms are removed from a diamond and replaced with a single nitrogen atom that has a vacancy next to it. When a sufficiently high energy photon (a green light (532nm)) is directed on diamond with an NV center, the diamond re-emits a red light (665nm), and the strength of the re-emitted red light depends on the spin of the NV center. The spin of the NV center can be altered by exciting a microwave at a specific frequency, resulting in the strength of the red light emitted by the diamond to change. The ability to measure the change of strength of the light re-emitted by NV centers is often used in supercomputers, radars, and other quantum technologies. NV centers can also be used for a single photon emitter. Most importantly, NV centers can be formed in lab grown CVD diamonds by generating a plasma in a Microwave Chemical Vapor Deposition (microwave CVD). Hydrogen, nitrogen, and methane gases can be flowed into the microwave CVD and nitrogen can be introduced into the growing diamond structures to create the NV centers. Using this method, we have grown CVD diamond films with varying concentrations of NV centers. The effect of various process parameters such as deposition power, gas ratios, substrate temperatures, and growth pressure have been studied on NV center formation, density, quality, and in-situ doping of nitrogen. Quantum structures have been characterized using Raman spectroscopy, X-ray diffraction, and scanning electron microscopy. In-situ laser reflectivity was also implemented to investigate growth characteristics of CVD diamond layers. In this paper, we will discuss the dependence of process conditions and characterization of NV centers and highlight potential applications and sensor development.

SESSION Tutorial EQ02: Heterostructures of Various Dimensional Materials—From Epitaxy to Device Applications
Session Chairs: Jeehwan Kim and Xiuling Li
Monday Morning, November 29, 2021
Hynes, Level 2, Room 200

8:30 AM
Remote Epitaxy—Growth of 3D Materials on 2D Materials Jeehwan Kim; Massachusetts Institute of Technology, United States

The instructor will discuss about new epitaxy lift-off technique so called remote epitaxy that can produce freestanding semiconductor membranes. Discussion will include 1) Remote epitaxy mechanism 2) High yield peeling mechanism 3) Reusability of the substrates 4) Economic aspect of remote epitaxy 5) Heterointergration of 3D materials with 2D materials for advanced heterostructuring.

10:00 AM BREAK

10:30 AM
van der Waals Epitaxy—Epitaxial Growth of 2D and 3D Materials Xinqaing Wang; Peking University, China

The instructor will provide the overview regarding the epitaxial growth of Nitride-based semiconductor materials by MOVPE including GaN and h-BN, and design device structures for opto-electronic devices. In addition, Instructor will cover the fabrication of nanostructures and materials characterization. The epitaxial growth of 3D and 2D materials and characterization of them is the basis of fabrication of heterointegration system for various device applications.

12:00 PM BREAK

1:30 PM
Heterostructures Built on Three-Dimensional (3D) Semiconductor Zhenqiang (Jack) Ma; University of Wisconsin–Madison, United States

Heterostructures built on three-dimensional (3D) semiconductor materials are rooted from the theory conceived by Nobel Laureate Hebert Kroemer in 1957. Since then, the four classes, namely, GaAs-, InP-, Si/Ge-, and III-nitrides-based heterostructures, have revolutionized the electronics and optoelectronics that set the foundation of today's communications, lighting, sensing, infotainment, etc. These heterostructures were universally formed by epitaxy techniques uniquely governed and enabled by the stringent requirements of lattice matching. Limited by this requirement, realizing heterostructures between lattice-mismatched semiconductors has been a decades-long obstacle, although the materials space to explore and the number of heterostructures that can be made are vast compared to its lattice-matched counterparts. In this tutorial, lattice-mismatched heterostructures, i.e., heterogeneous heterostructures, or arbitrary heterostructures, formed via semiconductor grafting based on a quantum tunneling gluing approach are described. The tutorial will include the history of attempts on forming lattice-mismatched heterostructures, physical principles of bypassing the lattice constraints, fabrication methods and scalability, and a set of application examples that are selected from about 18 pairs of heterostructures formed between Si, Ge, GeSn, GaAs, InGaAs, AlGaAs, GaN, AlGaN, SiC, GaN, Diamond, β-Ga2O3, and CsPbBr3.

2:30 PM
van der Waals Heterostructures Deep M. Jariwala[1] and Xiangfeng Duan[2]; [1]University of Pennsylvania, United States; [2]University of California, Los Angeles, United States

The isolation of a growing number of two-dimensional (2D) van der Waals (vdW) materials has inspired worldwide efforts to integrate distinct 2D materials into vdW heterostructures. Over the past decade a tremendous amount of research activity has occurred in assembling disparate 2D materials into "all-2D" van der Waals heterostructures and thereby making outstanding progress on fundamental studies at 2D/2D interfaces. However, practical applications of 2D and other low-dimensional materials will require a broader integration strategy. Namely integration of 2D materials with other self-passivated, quantum-confined or molecular materials will be necessary. In this regard significant progress has been achieved in recent years, which involve successful integration of 2D materials with organic small molecules, quantum-dots, nanocrystals, semiconducting polymers, inorganic nanowires as well as carbon-nanotubes. These studies have produced interesting results both in terms of basic science as well as device applications including in photodetectors, logic, memory and light emitting devices. In addition, 2D van der Waals layers have also provided a rich and interesting avenue in terms of hetero-integration with three-dimensional (3D) and bulk materials including 3D semiconductors, piezoelectrics, ferroelectrics and magnets. The 2D/3D combinations are particularly favorable and attractive in terms of vertical integration on Silicon CMOS and enabling "More than Moore" approaches including memory, electronic-photonic integration etc. for semiconductor chips. In this tutorial, I will provide an overview of the progress on the above described heterostructures and their devices focusing on the unique advantages and capabilities that each materials combination provides. I will end with a broad and forward-looking perspective on future investigation and development opportunities in mixed-dimensional heterostructures and their applications for the research community.

3:30 PM BREAK

4:00 PM
Van der Waals Integration beyond 2D Materials: Probing and Pushing the Limit of Emerging Electronic Materials Xiangfeng Duan; University of California, Los Angeles, United States

The heterogeneous integration of dissimilar materials is a long pursuit of material science community and has defined the material foundation for modern electronics and optoelectronics. The typical material integration approaches usually involve strong chemical bonds and aggressive synthetic conditions and are often limited to materials with strict structure match and processing compatibility. Alternatively, *van der Waals* integration, in which freestanding building blocks are physically assembled together through weak *van der Waals* interactions, offers a bond-free material integration strategy without lattice and processing limitations. In this tutorial, I will discuss the fundamental forces involved in *van der Waals* integration and generalize this approach for

flexible integration of highly disparate materials to produce artificial heterostructures with minimum interfacial disorder and to enable high-performing devices.
I will start with a brief introduction of some early background on using this approach for damage-free dielectric integration to enable high speed transistors from atomically thin graphene and 2D semiconductors, and then focus my most of my discussion on our recent efforts in exploring this approach for low-energy metal integration to enable high performance contacts for delicate materials. In particular, I will highlight our recent advancement in exploiting the *van der Waals* integration approach for seamless integration of conventional metal thin film electrodes with the 2D semiconductors to create nearly ideal metal-semiconductor junctions essentially free of interface states and Fermi level pinning, for the first time the experimental achieving Schottky-Mott limit that has been difficult to achieve in Schottky diodes, and realizing the 2D diode approaching the intrinsic exciton physics limit. Next, we further extends this approach for damage-free integration of metal contacts on delicate halide perovskite thin films, realizing high performance *van der Waals* contacts with an atomically clean contacting interface and greatly reduced contact resistance, for the first time allowing systematic electrical transport studies of halide perovskites down to cryogenic temperatures and establishing technical foundation towards unraveling the complex transport behavior and exploring new physics in this unique class of “soft-lattice” materials.
These advancements highlight the unique merit of the bond-free *van der Waals* integration approach in creating pinning-free heterostructure interfaces. I will conclude with a brief perspective on these strategies for creating diverse artificial heterostructures as a versatile material platform with electronic structure by design to unlock new physical limits and enable a new generation of devices with unprecedented performance or unique functions, as illustrated in our recent effort including a new class of high-order *vdW* superlattices integrating highly distinct atomic crystals and molecular layers, solution processable vdW thin electronics, hybrid vertical transistors and low voltage memoristors, programmable devices from 2D/superionic solid vdW heterostructures sensitive pressure sensors and electronic skins, highly reliable molecular tunneling transistors.

SESSION EQ02.01: Epitaxy of Mixed Dimensional Structures I
Session Chairs: Jeehwan Kim and Kyusang Lee
Tuesday Morning, November 30, 2021
Hynes, Level 2, Room 200

10:30 AM *EQ02.01.01
Defect-Seeded Lateral Epitaxy and Exfoliation on Graphene-Terminated Surfaces Jason K. Kawasaki; University of Wisconsin, United States

We exploit defects in a 2D barrier layer to drive the seeded lateral epitaxy of atomically smooth, exfoliatable, single-crystalline membranes [1]. This growth mode offers many of the advantages of the recently discovered remote epitaxy, including novel strain relaxation pathways and the ability to exfoliate free-standing membranes [2], plus additional advantages of (1) tolerance for imperfect graphene/substrate interfaces and (2) the ability to engineer the growth by patterning the 2D graphene layer. We show that GaSb films grow on graphene-terminated GaSb (001) via a seeded lateral epitaxy mechanism, in which pinhole defects in the graphene serve as selective nucleation sites, followed by lateral epitaxy and coalescence into a continuous film. Importantly, the small size of the pinholes permits exfoliation of a continuous, free-standing GaSb membrane. By combining molecular beam epitaxy with in-situ electron diffraction and photoemission, plus ex-situ atomic force microscopy and Raman spectroscopy, we track the graphene defect generation and GaSb growth evolution a few monolayers at a time. Our discovery provides a highly tunable method to engineer single-crystalline 3D materials on precisely tuned 2D barriers.

11:00 AM EQ02.01.02
Wafer-Scale Remote Epitaxy of III-V Semiconductors and Applications Hyunseok Kim, Kuangye Lu, Sangho Lee, Ki Seok Kim, Sanghoon Bae and Jeehwan Kim; Massachusetts Institute of Technology, United States

In conventional epitaxy of single-crystalline semiconductor materials, it is challenging to separate the grown layer with the substrate due to the strong bonding at the interface. Remote epitaxy is a recently discovered method to grow single-crystalline thin films on graphene, wherein the grown film can be exfoliated at the graphene interface to form freestanding membranes.
Here, we present our recent development on remote epitaxy of III-V semiconductors. We show that directly growing 2D materials on III-V substrates as a remote epitaxy template is an ideal pathway that can eliminate transfer process-related defects and can realize wafer-scale process of remote epitaxy and substrate reuse. We present the strategies to grow 2D materials on the surface of III-V materials, which is much more challenging than thermally robust substrates such as SiO2/Si or sapphire. The nucleation of III-V on 2D material-coated III-V platforms via remote interaction is investigated both experimentally and theoretically. Lastly, we show advanced remote epitaxial platforms and optoelectronic applications enabled by remote epitaxy, and the capability to recycle the III-V substrates for repeated remote epitaxy and production of freestanding III-V thin films.

11:15 AM EQ02.01.03
Remote Epitaxy of InP on Amorphous 2D Materials for Low-Cost High-Performance Photonics Kuangye Lu[1], Hyunseok Kim[1], Sangho Lee[1], Ki Seok Kim[1], Sanghoon Bae[2] and Jeehwan Kim[1]; [1]Massachusetts Institute of Technology, United States; [2]Washington University in St. Louis, United States

Indium phosphide (InP) is a III-V semiconductor that offers outstanding photonic properties that outperforms silicon, but the cost of InP wafers is extremely expensive. Although reusing original wafers can effectively minimize the cost of wafers, current techniques for wafer recycling of InP add significant costs in fabrication, nullifying the cost savings by reusing the wafers. Besides, unlike other III-V materials such as gallium arsenide (GaAs), commonly used epitaxial lift-off method for wafer recycling is not well studied for InP due to lack of latticed matched sacrificial layers, which makes reusing InP wafers more difficult. Remote epitaxy is a newly discovered method that enables single-crystal growth of III-V semiconductor thin films and easy exfoliation of the grown film, thus promising for a new cost-effective pathway of reusing InP wafers. However, previous methods of transferring 2D materials onto InP wafers, which use polymethyl methacrylate (PMMA) or metal stressor layers to transfer 2D materials grown on foreign substrates like copper or silicon carbide, introduce defects and damages on the 2D layer and/or substrates during the transfer process. Remote epitaxial films grown on the damaged 2D layer/substrate suffer from lower crystal quality and imperfect exfoliation, which undermines wafer reusability and device performance.

Here we report the MBE growth of amorphous boron nitride (a-BN) on InP wafers at low temperature that enabled improved quality of remote epitaxial films and their perfect exfoliation. We show fully covered a-BN on InP substrates despite phosphides' low decomposition temperatures. The surface of a-BN coated InP substrate remains smooth with a RMS roughness of around 3Å. We also demonstrate 100% coverage of single-crystalline InP thin films

grown on a-BN, with the film's quality significantly improved compared to the case of transferred 2D materials. In addition, roughness of the substrate's surface remains the same after exfoliation of grown InP film, and the growth and exfoliation were successfully repeated multiple times, proving the feasibility for InP wafer recycling. Through this low temperature MBE growth approach and remote epitaxy, we successfully demonstrate large-scale flexible thin film exfoliation and recycling of InP substrates, which will lead to new opportunities in InP thin film-based photonics and novel heterostructures with significantly reduced cost.

11:30 AM EQ02.01.04
Spontaneous Incommensurate van der Waals Heteroepitaxy Hesham El-Sherif[1,2], Stephen Jovanovic[1], John Preston[1] and Nabil Bassim[1]; [1]McMaster University, Canada; [2]Harvard University (Starting Fall 2021), United States

High-quality single-crystalline thin films are a significant factor for achieving substantial electrical and optical properties of various dimensional materials. Heterogeneous integration of these films may be achieved by in-situ fabrication or lift-off technologies from compliant substrates with remote and van der Waals epitaxy growth of semiconductors.[1] However, the quality of transferred semiconductor films depends on the quality and real-size of manually transferred two-dimensional (2D) materials, limiting the size of direct large-area single-crystal films.

In this presentation, a one-step growth method will be introduced to fabricate thin films that are incommensurate to their substrate through a s*pontaneous van der Waals-like epitaxy*.[2] In this low-temperate growth, a buffer layer of chalcogenide is spontaneously attached to the interface with a weak chemical interaction between a surface-reconstructed substrate and a 3D film. An epitaxial relationship between the substrate and film is maintained across this interfacial layer. Moreover, no mismatch dislocations are observed at the interface, which allows high-quality single-crystal thin film growth. This unique interface complexion allows for the lift-off of films, such as CdTe and InSb, without first transferring a 2D material onto their growth substrate for remoting epitaxy.

The presentation will focus on the fundamental interface understanding of cadmium telluride (CdTe) on a sapphire, fabricated via pulsed laser deposition at approximately 300 °C.[2, 3] A monolayer of chalcogenide (tellurium) at the interface is examined by various spectroscopic scanning transmission electron microscopy (STEM) techniques, including low-loss and core loss electron energy-loss spectroscopy (EELS) to reveal both the bonding and chemical composition at the interface. The CdTe film is investigated at the bulk-scale using 3D x-ray diffraction measurements and the atomic-scale using STEM imaging of the interfacial and CdTe film regions. The strain at the CdTe-sapphire interface is examined using both geometric phase analysis (GPA) and the STEM-moiré analysis. Microscopic investigations provide evidence that strain-free CdTe films grow with high quality on the Tellurium-terminated sapphire surface. The relatively low growth temperature maintains the top-most sapphire layer to the single aluminum reconstruction, as confirmed by core-loss EELS. Tellurium is more kinetically favorable to nucleate above oxygen sites in sapphire than Cadmium at these growth and interface conditions. This is followed by the CdTe film with its first tellurium layer oriented toward the pseudomorphic tellurium layer on the sapphire forming van der Waal-like bonds. This interface complexion allows for a unique incommensurate van der Waals heteroepitaxy growth.

Finally, the presentation will show the realization of a monolayer *Tellurene*, a 2D form of tellurium with a 3-atom thick, if more tellurium is deposited at the film/substrate interface. The growth progress of this interface complexion could lead to the fabrication of various dimensional (3D/2D/3D) high-quality heterostructures via one-step growth using a pulsed laser deposition system.

11:45 AM EQ02.01.05
Integration of MoS_2 Monolayers onto III-V Nanowires into 1D/2D Heterostructures Akshay Balgarkashi[1], Valerio Piazza[1], Jakub Jasinski[2], Riccardo Frisenda[3], Michael Baranowski[2], Alessandro Surrente[2], Andres Castellanos-Gomez[3], Paulina Plochocka[4] and Anna Fontcuberta i Morral[1,1]; [1]École Polytechnique Fédérale de Lausanne, Switzerland; [2]Wroclaw University of Science and Technology, Poland; [3]Instituto de Ciencia de Materiales de Madrid, Spain; [4]CNRS-UGA-UPS-INSA, France

Transition metal dichalcogenides (TMDs) are 2D semiconductors characterized by unique features such as layer-dependent direct/indirect band gap transition, high spin-orbit coupling and strain modulation [1]. Depending on the number of layers, their band gap can vary within the visible/near-infrared range making TMDs suitable for a wide variety of optoelectronic applications [2]. In particular, the possibility to induce the local emission of photons by applying strain is highly beneficial for the design of quantum emitters [3]. In this context, the combination with 1D nanostructures offers an elegant solution as the dimensionality mismatch between ultrathin TMDs and nanowires results in a localized strain [4]. For these reasons, the integration of MoS_2 with compound semiconductor nanowires in the form of a heterostruture is expected to widen the functionalities of the ensemble. Selective area epitaxy (SAE) can be used to grow ordered arrays of III-V nanowires. Due to the small footprint, nanowires with very low defect density can be grown on a large number of substrates [5]. Additionally, III-V nanowires can act as natural waveguides increasing the directionality of the photon emission [6].
In this work, we report on the fabrication of heterostructures formed by exfoliated mono- and bi-layers MoS_2 and GaAs nanowires (NWs) and preliminary optical characterization of the ensemble. Self-catalysed vertical GaAs NWs were grown by SAE on Si (111) substrate, with a diameter of 150nm and height of 400nm. The exfoliated flakes were transferred on the NWs using an all-dry viscoelastic stamping method. Atomic force microscopy (AFM) was used to get feedback on the integration. AFM analysis indicates that the monolayer is stable on top of the NWs in most of locations, although a non-zero possibility of piercing events exists. Raman analysis evidenced a small shift of the in-plane (E_{2g}) mode at low temperature. Photoluminescence (PL) spectra on bare MoS_2 showed the existence of A exciton and trion peaks as well as a large band peaked around 1.7 eV, attributed to sulfur vacancies [7]. PL analysis on MoS_2/GaAs NWs highlights an enhanced intensity of the same peaks. PL micromapping was used to visualize the increase in emission intensity within the array. The defect peak centered around 1.7 eV shows a non-uniform intensity enhancement whereas the direct bandgap emission from MoS_2 is uniformly enhanced across the nanowire array.

SESSION EQ02.02: Epitaxy of Mixed Dimensional Structures II
Session Chairs: Xiuling Li and Rachael Myers-Ward
Tuesday Afternoon, November 30, 2021
Hynes, Level 2, Room 200

1:30 PM *EQ02.02.01
SiC Stackable Electronics Using Remote Epitaxy Rachael Myers-Ward[1], Daniel J. Pennachio[1], Jeehwan Kim[2], Kuan Qiao[2], Yeongin Kim[2], Matthew T. Dejarld[1], Shojan P. Pavunny[1], Jenifer R. Hajzus[1] and D K. Gaskill[1]; [1]Naval Research Laboratory, United States; [2]Massachusetts Institute of Technology, United States

Remote epitaxy (RE) is a novel growth process performed on graphene covered substrates where adatom registry is guided by the partially-screened electrostatic fields from the underlying substrate rather than interactions with the graphene lattice. The graphene acts as a spacer, allowing the ease of epitaxial layer removal and transfer to desired substrates. This RE technique has the possibility of impacting many research areas including SiC and GaN SMART power, integration of opto- and electronic devices, HEMT performance, flexible electronics and quantum sciences.

In this work, we focus on the RE of SiC, which is directly grown on epitaxial graphene (EG) on SiC(0001) using a chemical vapor deposition (CVD) reactor. The graphene is grown via the Si sublimation of SiC. Both on-axis (6H-SiC) and off-axis (4H-SiC cut 4° off-axis towards the [11-20]) substrates were investigated where the ability to maintain this graphene at elevated growth temperatures in a SiC CVD environment is crucial for the success of remote epitaxy. Following epitaxial graphene growth, SiC growth was performed and the growth parameters were modified to reduce SiC polytype conversion and other extended defects. Films were characterized using scanning electron microscopy, transmission electron microscopy and electron backscattering detection. To evaluate the ability to grow SiC remote epitaxially, a Ni metal stressor technique was used to exfoliate the layers and demonstrate exfoliation yields up to 50 – 70 %.

This work was supported by the U.S. Office of Naval Research.

2:00 PM DISCUSSION TIME

2:30 PM EQ02.02.03
Nanopatterned Graphene Based Universal Epitaxy Platform for Single-Crystalline Membrane Transfer Sangho Lee[1], Yanming Zhang[2], Hyunseok Kim[1], Sanghoon Bae[1], Kuangye Lu[1], Jiho Shin[1], Ki Seok Kim[1], Yunfeng Shi[2] and Jeehwan Kim[1]; [1]Massachusetts Institute of Technology, United States; [2]Rensselaer Polytechnic Institute, United States

Remote epitaxy – an emerging growth method of single-crystalline membranes copied from underlying substrates through atomically thin graphene interlayer – has greatly expanded the material spectrum by efficiently producing costly thin films or heterogeneously integrating unique nanosystems. It was recently demonstrated that slippery graphene promotes a strain relaxation of epitaxial film on its surface, which also allows the heteroepitaxy of lattice-mismatched systems with reduced defect density. Despite such benefits, remote epitaxy has its fundamental limitations in non-polar materials because the ionicity of materials strongly governs a distant atomic interaction between the substrate and epitaxial layer. Thermally or chemically weak materials that are incompatible with graphene transfer or growth on them also restrict their remote epitaxy. Here, we introduce periodic openings in graphene to induce a lateral overgrowth of thin films, where an opening acts as a favorable nucleation site allowing the epitaxy to occur regardless of polarity and process compatibility of materials. Nanostructured graphene interlayer enables a facile exfoliation of epitaxial films from substrate as well as a spontaneous relaxation of misfit strain during heteroepitaxy depending on its structural parameters such as period and size of openings. Engineered graphene is, thus, expected to provide a universal epitaxy platform that can accommodate the growth, release, and transfer of a wider variety of high-quality membranes.

2:45 PM EQ02.02.04
Remote Epitaxy of GaN Membranes Towards Commercialization Kyusang Lee[1,2]; [1]University of Virginia, United States; [2]Future Semiconductor Business, United States

GaN has been widely used for various applications including power electronics, RF devices and optoelectronic applications. Recently, remote epitaxy technology has been introduced, a substrate below 2D materials also plays a role to intervene in the epitaxial growth process, leaving room to realize a novel epitaxial growth process. Potential fluctuation—the difference between potential energy maxima and minima along the surface of the substrate—is influenced by this remote interaction; the fluctuation is predominant over the vdW force, due to the atomic thickness of 2D materials. The remote interactions can be controlled by modulation of polarities of 2D materials and epitaxy materials. Polar-material-based heterostructure, such as GaAs, InP, GaP, and GaN with their substrate sandwiching 2D materials, enables the semiconductor film to be exfoliated from the underlying substrates through the 2D materials. This process is expected to open a novel avenue for the field of non-silicon electronics and photonics, where the ability to re-use graphene-coated substrates allows savings on the high cost of non-silicon substrates.

3:00 PM EQ02.02.05
Ultrathin 2D/3D Heterostructures Kate Reidy, Joachim D. Thomsen, Baoming Wang, Aubrey Penn and Frances M. Ross; Massachusetts Institute of Technology, United States

One of the frontiers of mixed dimensional heterostructure design lies in the ability to grow thin epitaxial films of conventional three-dimensional (3D) metals or semiconductors on two-dimensional (2D) materials. The structure and alignment at this 2D/3D interface affects properties, such as electron transport, contact resistance, and photo-current, of devices that utilize 2D materials.[1] Moreover, integration of 2D/3D heterostructures can result in unique (opto-)electronic, magnetic, thermal, or mechanical properties of the combined heterostructure not present in individual components.[2,3]

Here, we report the direct epitaxial growth of ultrathin titanium/gold (Ti/Au) heterostructures on suspended 2D materials. The Ti/Au system is important due to Ti's continued use as an adhesion layer across a variety of applications in micro- and nano- electronics. Moreover, ultrathin (<1nm) Ti/Au layers exhibit improved thermal stability, plasmonic response, and superconducting transition temperature compared to thicker (>2nm) layers. We perform epitaxial metal growth on suspended 2D materials substrates in ultra-high vacuum (UHV) and monitor the structure evolution during annealing using *in-situ* transmission electron microscopy (TEM). We find that ultrathin (<1nm) epitaxial Ti nanoislands can be grown on graphene at high temperatures. The

island geometry exhibits a large dependence on the layer number of the 2D material, and on thin 2D layers the Ti is extremely thin and compliant to the substrate. Subsequent Au deposition without breaking vacuum shows 100% selectivity on these ultra-thin Ti layers, and the Au completely wets the surface instead of forming conventional Volmer-Weber islands. In contrast, the Au forms islands when the Ti layer is exposed to oxygen at 10^{-6} Torr before Au deposition. Moreover, we observe greatly improved thermal stability against dewetting of the Ti/Au layer up to 1000ºC. Electron energy loss spectroscopy (EELS) evidence that the thin Au capping layer prevents the Ti from oxidation. We discuss the potential of these Ti layers as a general strategy for creating ultrathin bottom-up 2D/3D heterostructures through epitaxially anchoring other metallic or semiconducting layers on 2D materials, and consider routes towards post-oxidation of the layers to form thin oxide/2D interfaces. This opens up a new set of possibilities for the heterointegration of 2D materials and thin epitaxial 3D films, adding to the toolbox of multidimensional heterostructure growth and design.

Selective Area Growth of III-V Semiconductor Heterostructure Quantum Devices with *In Situ* Shadow-Wall Assisted Superconductor Patterning Aranya Goswami[1], Hao Wu[2], Connor P. Dempsey[1], Po Zhang[2], Sergey Frolov[2] and Chris Palmstrom[1]; [1]University of California, Santa Barbara, United States; [2]University of Pittsburgh, United States

Semiconductor-superconductor hybrid structures offer an attractive platform to explore interesting low temperature transport phenomenon. In particular, one dimensional semiconducting nanowires with spin orbit coupling proximitized by a s-wave superconductor has been proposed to host Majorana Fermions, relevant for topological quantum computing. Selective area growth offers a scalable route to growing and fabricating complex networks of such semiconductor superconductor nanostructures. However selective area grown in-plane semiconductor nanowires often suffer from a high density of defects due to lattice and symmetry mismatch between the nanowire material and the substrate. This leads to poor electrical characteristics such as low electron mobility and low coherence lengths. Heterostructures can potentially solve this problem by incorporating buffer layers to reduce lattice mismatch and using capping layers to reduce surface scattering. Further, a clean interface between the superconductor and the semiconductor is crucial for inducing a hard proximitized superconducting gap in the nanowire. Since post-growth superconductor etching can often introduce defects in the semiconducting nanowire, an in-situ selective superconductor deposition can prove to be extremely useful in this respect.
In this talk, we discuss selective area growth of III-V nanowires on InP(001) substrates using chemical beam epitaxy. Specifically, we grow InP/InGaAs/InP quantum wells in in-plane nanowire geometry with lattice matched ($In_{0.53}Ga_{0.47}As$) and strained ($In_{0.75}Ga_{0.25}As$) channels that are 20nm thick. Cross-sectional scanning transmission electron microscope (STEM) imaging of the grown nanowires shows abrupt defect-free interfaces. In addition, we show growth of InAs nanowires with graded InGaAs buffers. Effects of InGaAs buffer on growth morphology are studied using high resolution cross-sectional STEM analysis. To grow superconductor islands on the in-plane nanowires, we fabricate high aspect ratio SiO_2 shadow walls positioned within 200nm of the nanowires. Together with angled low-temperature deposition, this enables in-situ growth of superconductor islands on the in-plane nanowires at predetermined positions, while maintaining the pristineness of the interface - as confirmed by the proximity induced superconductivity in the nanowire. Superconductor-normal-superconductor junctions with sub 100nm normal junction lengths are achieved with tin as the superconductor on InAs nanowires. By incorporating different shapes of shadow walls, positioned close to the nanowire trench, we show that various semiconductor-superconductor hybrid geometries can be directly grown without breaking vacuum. Finally, we discuss magneto-transport measurements on these hybrid nanostructures.

Mixed Dimensional Heterostructures Enabled by Freestanding 3D Materials and 2D Materials Sanghoon Bae; Washington University in Saint Louis, United States

Next-generation electronics will expect new functionalities such as high performance, low power consumption, lightweight, flexibility, conformality, and self-power. In this regard, demand for new heterostructures has been getting high. In this talk, I will discuss how we can produce freestanding 3D materials and 2D materials that are stepping stones to realize new heterostructures. As they are a new form of heterostructures, new architectures for functional devices and physical phenomenon can be realized. For freestanding 3D materials, we have studied single crystalline growth on graphene-coated substrates. As graphene has lattice transparency, single-crystalline materials were successfully grown. Because the interface between grown single crystals and graphene-coated substrates has substantially small binding energy, the grown single-crystalline materials can be exfoliated to produce freestanding 3D materials. For freestanding 2D materials, we have conceived a unique idea that selectively separates monolayer 2D materials from multilayers, named layer-resolved splitting, thereby multiple monolayer 2D materials are harvested from multilayer 2D materials. With such approaches, 2D and 3D mixed dimensional heterostructures have been developed for new physical coupling phenomena and new device architectures.

Mixed-Dimensional 1D/2D van der Waals Heterojunction Diodes and Transistors in the Atomic Limit Jakub P. Jadwiszczak[1], Jeffrey D. Sherman[1], David Lynall[1], Boyan Penkov[1], Erik Young[1], Alice Castan[2], Marija Drndic[2] and Kenneth Shepard[1]; [1]Columbia University, United States; [2]University of Pennsylvania, United States

Mixed-dimensional heterojunctions (MDHJs) are an emerging class of nanoscale devices whose electrical and optical properties reflect the nature of their

constituent materials. The prospect of mixed-dimensional van der Waals transistor architectures (1D/2D or 2D/3D) may offer substantial advantages in both the ease of fabrication and performance of the realized devices. For example, bulk *p–n* junctions usually need diffusion or implant-anneal sequences to achieve the necessary doping profiles, while these steps may be bypassed entirely by using synthetic van der Waals MDHJs.

In this work, we demonstrate ultra-downscaled MDHJ diodes and transistors based on the van der Waals heterojunction formed between monolayer *n*–type MoS_2 and an individual *p*–type single-walled semiconducting carbon nanotube (SWCNT). We fabricate these heterojunctions using a non-deterministic wet transfer process where chemical vapor deposition (CVD)-grown monolayer MoS_2 flakes are deposited directly on top of individual CVD-grown semiconducting SWCNTs. We demonstrate that the rectification ratio of the formed individual MDHJs can be tuned by several orders of magnitude by back-gating through the SiO_2 substrate, while the transfer characteristics of the individual junctions demonstrate anti-ambipolar behavior previously observed in ensemble CNT/MoS_2 junctions.

Moreover, we utilize the MDHJ diode to fabricate atomic-scale *p*-type junction field-effect transistors, where the voltage applied to the MoS_2 gate can modulate the conductance through the underlying SWCNT transistor channel. Our experimental results match well with technology computer-aided-design (TCAD) device modelling, where the transistor functionality is found to be dominated by band-to-band tunneling (BTBT) across the heterojunction forming the JFET gate region. In addition, we find that in extreme bias limits, the high breakdown voltages inherent to this mixed-dimensional van der Waals interface can push the device into unusual operating regions, where the polarity of the transistor drive current can be controlled by the gate voltage magnitude.

EQ02.04.01
Heterogeneous Integration of 2D MoS_2 on Silicon Nanoparticle in a Core-Shell Architecture for Photonic Applications Yea-Shine Lee[1], Tatsuki Hinamoto[2], Sina Abedini Dereshgi[1], Matthew Cheng[1], Jennifer DiStefano[1,1], M. Arslan Shehzad[1,1], Roberto dos Reis[1,1], Hiroshi Sugimoto[2], Koray Aydin[1], Minoru Fujii[2] and Vinayak Dravid[1,1,1]; [1]Northwestern University, United States; [2]Kobe University, Japan

The high exciton binding energy and mechanical flexibility of transition metal dichalcogenides (TMDs) make them attractive for next-generation photonics. However, because of their atomically thin nature, there is a challenge in obtaining sufficient absorption and emission of the incoming electromagnetic (EM) field. Plasmonic core-shell structures of TMD-encapsulated nanoparticles have demonstrated significantly improved light-matter interactions, highlighting this architecture for applications in nanophotonic and optoelectronic devices. Recently, a high index silicon dielectric nanoparticle in the core-shell architecture has been theoretically predicted to further reduce losses and enhance resonance of the near-EM fields. The resonance coupling of the magnetic dipole mode of the silicon core and exciton transitions in the TMD may thereby enable longer exciton lifetimes, yielding enhanced energy transfer and absorption/emission of the field. However, to date, this architecture has not been experimentally demonstrated.

Here, we experimentally realize this proof-of-concept of advanced Si@MoS_2 heterogeneous architecture, encapsulated via chemical vapor deposition. The size of the silicon nanoparticles, which have diameter 175±25 nm, is comparable to the wavelength of the EM field, putting this hybrid system in the Mie scattering regime. Structural and chemical analyses confirm the presence of Mo and S in the shell and Si in the core. In the core-shell architecture, we observe an enhanced photonic response relative to the bare Si nanoparticles and planar MoS_2. This distinct behavior can be explained by a displacement current loop circulating inside the dielectric Si core which leaks out to the shell and enhances the near-EM field. Here, the Si core acts as an antenna to effectively excite the TMD shell emitter. Moreover, there are two major factors that control the degree of coupling response: the core diameter and shell thickness. Tuning the size of the core has enabled us to optimize the optical resonance. Dark-field single-particle optical scattering measurements confirm the energy coupling between the core and the shell measured through Rabi splitting of the magnetic dipole resonance mode of the nanoparticle. We believe Si@MoS_2 is a technological-relevant material system and can assist to understand novel optical responses and the principles underlying these phenomena.

This work is primarily supported by the National Science Foundation (NSF) under Grant No. DMR-1929356. We made use of the EPIC and KECK II facility of Northwestern University's NUANCE Center, which has received support from the SHyNE Resource (NSF ECCS-2025633), the IIN, and Northwestern's MRSEC program (NSF DMR-1720139).

EQ02.04.02
Tradeoffs Between Translational and Orientational Order in 2D Superlattices of Polygonal Nanocrystals with Differing Edge Count Justin Ondry[1,2], Layne B. Frechette[1], Phillip L. Geissler[1] and A. Paul Alivisatos[1,2,3]; [1]University of California, Berkeley, United States; [2]Kavli Energy NanoScience Institute, United States; [3]Lawrence Berkeley National Laboratory, United States

The goal of this work is to identify factors which modulate transitional and orientational order in 2D self-assembled superlattices using polygon shaped nanocrystal building blocks. Using a combination of transmission electron microscopy, electron diffraction, and hard particle Monte Carlo simulations, we quantify the translational and orientational order in 2D superlattices of hexagonal prism shaped CdSe/CdS nanocrystals and cube shaped $CsPbBr_3$ nanocrystals. Superlattices derived from cube shaped nanocrystals display less translational order compared to hexagonal prism shaped nanocrystals both experimentally and in simulations. To first order, this effect can be understood based on geometric considerations inherent to the combined rotational and translational symmetries of different polygonal shapes and their superlattice geometries. Cubes form a simple cubic lattice in which entire rows of nanocrystals can slide past each-other with little energy penalty whereas hexagons interlock in a hexagonal tiling, leading to a structure which is robust to nanocrystal translations. Nanocrystal shape also modulates the degree of orientational order, and in this case, cube assemblies display a narrower orientation distribution than hexagonal prism assemblies. An intuitive explanation for this arises when the influence of organic ligands surrounding the polygonal inorganic core is considered. A hexagonal prism displays a more ``spherical" interaction potential compared to cubes explaining the observation to first order. The results presented here outline an intuitive framework for identifying nanocrystal superlattice structures which favor translationally versus orientationally ordered self-assembled superlattices.

EQ02.04.04
Cathodoluminescence Mapping of hBN on III-V Nanomembranes Claire Blaga, Akshay Balgarkashi, Valerio Piazza, Nicolas Tappy, Jin Jiang, Mitali

Banerjee and Anna Fontcuberta i Morral; EPFL, Switzerland

Hexagonal boron nitride (hBN) is a Van der Waals material with a 2D atomic structure similar to graphene, whose unique optical properties have raised significant interest; its wide direct band gap and robust excitons enable intense emission in the deep UV region. Additionally, the crystallographic defects in hBN form states within the band gap which can be engineered for efficient, high-brightness, quantum emission in the UV to IR range, even at room temperature [1,2]. Although extensively studied, the origin of the complex emission spectrum of hBN is still debated and mostly unknown. In this context, cathodoluminescence (CL) mapping is a powerful tool. By resolving the optical emission down to the nanoscale upon electron beam exposure, CL allows to access the optoelectronic phenomena occurring in specific locations. However, when dealing with ultrathin materials, high electron beam energies are not efficient probes as only a small fraction of the electron energy is transferred to hBN [3]. On the other hand, the use of low beam energies negatively impacts the spatial resolution.
This work explores the use of CL mapping with beam energies from below 1keV to 10keV to investigate the optoelectronic properties of hBN integrated onto different substrates. Thin flakes (3-50 nm) of hBN are exfoliated via the standard tape method and transferred on sapphire and horizontal GaAs nanomembranes (NMs) using an all-dry viscoelastic stamping method. Samples with different flake thicknesses were also fabricated to explore thickness dependent properties. Depositing the flakes onto sapphire or nanostructures allows to take advantage of the underlying substrate to increase the light emission, thus enabling the access to the optical fingerprint of the material.
GaAs NMs are grown on (111)B GaAs substrates by selective area epitaxy. These NMs present a slab morphology, whose dimensions can be tuned by modifying the growth parameters. In this study, nanostructure arrays with different heights, widths and pitches were explored. The NMs' morphology and aspect ratio are expected to dictate the strain induced on the hBN crystals as well as the contact area between membrane and hBN. Spectrally integrated CL maps evidenced that the presence of the membranes underneath the flake has an impact on the emission intensity in the whole photon energy range investigated. In particular, the emission bands at 320nm and 400nm, attributed to C/O impurities and N vacancies respectively, appear brighter in areas where there is a nanomembrane below the flake when compared to what is observed in the off-nanomembrane position. This effect is more pronounced with thicker flakes, where the light emission is more intense. Another notable variable is the topology imposed on the flake during its deposition onto the substrate. The flake can be conformal to the structures or suspended on top of them, mainly depending on the NM morphology. The results highlight how a suspended flake exhibits a stronger emission between membranes and lower emission on top of the membrane as compared to a flake conforming to the substrate. Monte Carlo simulations suggest that the topology has an impact on the interaction with backscattered electrons and therefore on the emission intensity.

Ultrafast Synthesis of High Entropy Oxide Nanoparticles by Flame Spray Pyrolysis Abhijit H. Phakatkar, Tolou Shokuhfar and Reza Shahbazian-Yassar; University of Illinois at Chicago, United States

The synthesis of high entropy oxide (HEO) nanoparticles (NPs) possesses many challenges in terms of process complexity and cost, scalability, producing nanoparticle morphology, and rapid synthesis. Herein, we report the synthesis of novel single-phase solid solution $(Mn, Fe, Ni, Cu, Zn)_3(O)_4$ quinary HEO NPs produced by flame spray pyrolysis (FSP) route. The aberration-corrected scanning transmission electron microscopy (STEM) technique is utilized to investigate the spinel crystal structure of synthesized HEO NPs and energy dispersive X-ray spectroscopy analysis confirmed the high entropy configuration of five metal elements in their oxide form within a single HEO nanoparticle. STEM analysis shows the synthesized HEO NPs are single phase solid solution spinel-structured with the lattice constant of 8.39 Å. Selected area electron diffraction, X-ray diffraction and Raman spectroscopy analysis results are in accordance with STEM results providing the key attributes of spinel crystal structure of HEO NPs. XRD results also indicate the presence of lattice distortions in the synthesized HEO NPs. Raman spectroscopy modes A_{1g}, F_{2g} and A_{1g}* corresponding to divalent metal cation – oxygen (M^{2+}- O) stretching vibrations indicates the evidence of spinel crystal structure fingerprints. X-ray photoelectron spectroscopy results provide the insightful understanding of chemical oxidation states of individual elements and their possible cation occupancy sites in the spinel-structured HEO NPs.

3D Discrete Dislocation Mechanics in Heterogeneous Materials and Structures—Theoretical Solutions and Advanced Finite Element Simulations Using Adaptative Remeshing Aurélien J. Vattré and Vincent Chiaruttini; ONERA, France

The remarkable versatility of the finite element method is used to model the three-dimensional discrete dislocation dynamics in heterogenous materials and structures. The present approach is based on the finite element strategy using advanced and flexible adaptative remeshing strategies for fine mesh resolution of complex curved dislocation loops. The numerical framework is capable of computing the stress fields and the driving forces acting on arbitrarily-shaped dislocations with a high degree of accuracy and with significant precision, as compared to novel theoretical elastic solutions for dislocation loops in the context of anisotropic hetero-elasticity theory.
The first part of the presentation continues beyond the theoretical contributions in the research area by treated dislocation loops in hetereostructures formed by elastically anisotropic crystals using the Stroh formalism combining with biperiodic Fourier-transform and dual variable and position techniques. The non-singular stress fields and driving forces are also used to investigate the comparison with the numerical finite element analysis of complex dislocation configurations. The fundamental Peach-Koehler force that governs the motion of the discrete dislocation loops is therefore captured by the numerical driving force calculation based on dissipative energy considerations. Because the numerical results show excellent agreement with analytical solutions in terms of non-singular stresses and forces, the finite element approach with adaptative remeshing techniques is used to explore more sophisticated microstructural situations, thus offering more realistic boundary-value description of dislocation loops in heterogenous materials and structures.

Thermionic and Thermoelectric Transport in Mixed Phase and Mixed Dimensional Samples Mona Zebarjadi, Md. Golam Rosul and Tianhui Zhu; University of Virginia, United States

Solid-state thermionic structures made out of 3-5 layers of van der Waals heterostructures sandwiched between metallic electrodes have shown promising thermal to electrical energy conversion efficiencies theoretically. Here, I discuss our detailed theoretical studying of these structures using first-principles calculations combined with Green's function method. We study the effect of the number of layers, the energy barrier, and the asymmetry of the contacts on the performance of transition metal dichalcogenide (TMD)-based thermionic converters. We show that the key is to make low-energy, low-resistance metallic contacts and we identify copper as the optimum metal to make ohmic low-resistance contact to MoSe2. Experimental demonstration of these structures involves a simple but mixed dimensional structure. I will next discuss the thermoelectric transport in mixed-phase 1T-2H MBE grown NbSe2 samples and will discuss the thermal, electrical and thermoelectric transport properties of these mixed phased samples.

11:00 AM EQ02.05.02
Localization and Modulation of Excitonic Emission in MoS_2 with Mixed-Dimensional Ferroelectric Heterostructures Joonseok Kim and Lincoln Lauhon; Northwestern University, United States

Semiconducting two-dimensional (2D) materials possess intriguing optoelectronic properties deriving from a strong light-matter interaction and large exciton binding energies, which create opportunities for novel room-temperature optoelectronics such as excitonic computing with optical interconnects. It is therefore of great interest to engineer and modulate excitonic behaviors. The most widely used approaches to modulate excitons in semiconducting 2D materials are tuning the dielectric environment,[1] applying strain,[2] and applying external fields.[3] Here we describe a platform to modulate exciton emission in monolayer MoS_2 by integrating dielectric Coulomb engineering, local strain, and ferroelectric doping. Mixed-dimensional heterostructures consisting of monolayer MoS_2, P(VDF-TrFE) copolymer, and hBN were fabricated by transferring 1L-MoS_2 flakes on sub-μm P(VDF-TrFE) islands on hBN substrates. Raman and photoluminescence (PL) maps were correlated with atomic force microscopy topography to determine how local strain, dielectric contrast, and ferroelectric doping for the MoS_2 layer induced by P(VDF-TrFE) islands influence exciton emission.
Notable differences in Raman and PL spectra were observed between MoS_2 on flat hBN, thinner islands, and thicker islands. The Raman E mode is redshifted on thicker islands, consistent with tensile strain generated by the topography. In addition, the PL A exciton intensity is enhanced, which could be associated with a strain-induced funneling effect that would reduce the band gap. However, the MoS_2-A exciton emission energy is increased on P(VDF-TrFE) islands, which likely arises from the decrease in exciton binding energy due to the strong dielectric screening of the P(VDF-TrFE) ($\varepsilon_r \approx 10$). Effects of dielectric environment and local strain on excitonic dynamics were further examined by analyzing the A and B exciton intensity ratio; a high A-to-B intensity ratio is a sign of low nonradiative recombination and is desirable for excitonic device applications. Regions of increased A/B ratio (up to 2x) correlate well with the P(VDF-TrFE) island locations. Moreover, the B intensity showed a negative correlation with height, suggesting that enhanced substrate screening combined with higher strain from the morphology enhances the intravalley scattering from the B exciton state to the A exciton state. The A and B exciton energy difference map demonstrates that, in contact with P(VDF-TrFE), the spin-orbit coupling-induced valence band splitting is reduced, which could lead to an increased intravalley scattering rate. Finally, the ferroelectric P(VDF-TrFE) islands were poled by applying a bias to the Si substrate with respect to conductive AFM tip. The MoS_2 A-to-B intensity ratio increases by a factor of two on negatively poled islands, whereas positive poling does not substantially change the intensity ratio. The correlation of Raman, PL, and topography maps revealed that the substrate dielectric screening, local strain, and ferroelectric doping provide a means to localized and modulate excitonic emission in monolayer MoS_2.

11:15 AM EQ02.05.03
Combining Colloidal Synthesis and Assembly with Epitaxial Growth to Fuse Colloidal Nanocrystals into Tunable 0D-2D Quantum Dot-in-Matrix Superlattices Justin Ondry[1,2], John Philbin[1], Michael Lostica[1], Eran Rabani[1] and A. Paul Alivisatos[1,2,3]; [1]University of California, Berkeley, United States; [2]Kavli Energy NanoScience Institute, United States; [3]Lawrence Berkeley National Laboratory, United States

In this talk we will discuss a new approach for preparing 0D-2D quantum dot-in-matrix heterostructures. We combine colloidal nanocrystal synthesis, self-assembly, and solution phase epitaxial growth techniques to develop a general approach for preparing single dot thick atomically attached quantum dot (QD) superlattices. These materials exhibit high quality translational and crystallographic orientational order along with state-of-the-art uniformity in the attachment thickness. Colloidal synthesis of well-faceted hexagonal prism shaped core/shell QDs, followed by liquid subphase self-assembly and immobilization of superlattices on a substrate creates a highly ordered structure for subsequent attachment. Importantly the nanocrystals are arranged such that they share a mutual crystallographic alignment. To attach the nanocrystals, we use a solution phase method to epitaxially grow additional semiconductor material in the voids between the particles resulting in a QD-in-matrix structure. The photoluminescence emission of the QD-in-matrix structure retains characteristic 0D electronic confinement. Finally, annealing of the resulting structures removes inhomogeneities in the QD-QD inorganic bridges, which atomistic electronic structure calculations demonstrate would otherwise lead to Anderson-type localization. The piece-wise nature of this methodology allows one to independently tune the size and material of the QD core, shell, QD-QD distance, and the matrix material. These four parameters can be tuned to control many properties depending on the specific applications (*e.g.* degree of quantum confinement, quantum coupling, band alignments, *etc*.). Further we can transform the QD superlattice to additional materials as demonstrated herein with a CdSe/CdS to HgSe/HgS conversion.

11:30 AM EQ02.05.04
Magnetic Properties of PrVO3 Thin Films Wilfrid Prellier; CRISMAT Laboratory, France

Transition metal oxides often having a perovskite structure form a wide and technologically important class of compounds. In these systems, ferroelectric, ferromagnetic, ferroelastic, or even orbital and charge orderings can develop and eventually coexist. These orderings can be tuned by external electric, magnetic, or stress field, and the cross-couplings between them enable important multifunctional properties, such as piezoelectricity, magneto-electricity, or magneto-elasticity. Here, will present the effect of thickness on PrVO3 thin films where a "dead layer" is found, and I will particularly focus on the change on the structural and magnetic properties with different substrates.

Financial support from ANR and Region Normandie (INCOX project) are acknowledged.

11:45 AM EQ02.05.05
Creating 2D Metal-Based Heterostructures—The Story of Epitaxial Graphene Nanoparticles Timothy Bowen, Alexander Vera, Maxwell Wetherington, Shalini Kumari and Joshua A. Robinson; The Pennsylvania State University, United States

It is possible to synthesize two-dimensional (2D), atomically thin metals using confinement heteroepitaxy (CHet), in which plasma treated epitaxial graphene (EG) is intercalated by a metal precursor such as Ga or In at near-atmospheric conditions. The resultant quasi-freestanding epitaxial graphene (QFEG)/2D metal heterostructure ideally provides a high-quality graphene substrate, enabling the scalable synthesis of vertical heterostructures with additional 2D materials, such as MoS_2, which are expected to exhibit extraordinary optical and sensing properties. However, this is limited by the surface

quality of the QFEG which directly impacts the adlayer nucleation, grain size, and performance.

We demonstrate that the traditional route of CHet leads to particulates on the surface following metal intercalation that can heavily impact the ability to create heterostructures with TMDs or TI adlayers. Through the growth of monolayer EG with small regions of buffer layer (BL), we show that intercalation occurs through the BL regions while maintaining high surface quality QFEG with pristine 2D metal underneath. Through use of atomic force microscopy (AFM), Raman, and x-ray photospectroscopy (XPS), we demonstrate that the 2D metal forms over the entire surface, leaving behind an atomically smooth graphene surface for subsequent growth of high quality 2D materials on these heterostructures.

SESSION EQ02.06: Physics and Devices of Mixed Dimensional Heterostructures III
Session Chairs: Jiwoong Park and Jian Shi
Wednesday Afternoon, December 1, 2021
Hynes, Level 2, Room 200

1:30 PM *EQ02.06.01
New 2D with Atomically Thin Crystals Jiwoong Park; University of Chicago, United States

Two dimensional (2D) electron transport has been one of the most important topics in science and technology for decades. It was originally studied in 3D semiconductors and then continued in 2D van der Waals (vdW) crystals. In this talk, I will start with the large-scale processes for generating 2D crystalline semiconductor films and superlattices that could be used to fabricate atomically thin integrated circuits. Then we will discuss more recent directions, where we use these 2D materials to realize non-electronic 2D transport phenomena, for example, observed from phonons, photons, and mass. These new approaches could empower the development of 2D phononics, 2D photonics, and 2D mechanics.

2:00 PM EQ02.06.03
Nanoscale TERS Characterization of the Junction Boundary in MoS_2-WS_2 Heteromonolayer Crystals Sourav Garg[1], Andrey Krayev[2], J. Pierce Fix[3], Connor Flanery[3], Audrey Sulkanen[4], Minyuan Wang[4], Gang-Yu Liu[4], Nicholas Borys[3] and Patrick Kung[1]; [1]The University of Alabama, United States; [2]Horiba Scientific, United States; [3]Montana State University, United States; [4]University of California, Davis, United States

We report the nanoscale characterization of the heterojunction in MoS_2-WS_2 hetero-monolayers by means of Tip Enhanced Raman Scattering (TERS). We demonstrate that a red-shifted PL in WS_2 adjacent to the MoS_2 core, observed in as-grown samples on sapphire substrates with confocal Raman/PL microscopy, is associated with a heterojunction boundary that shows significant alloying and a varying width from about 25 nm (pixel size limited) to few hundreds of nanometers even within the same crystal. In TERS spectra collected with resonant 638 nm excitation, we observed significant increase in the intensity of the 200 cm^{-1} and 215 cm^{-1} peaks over the heterojunction boundary as well as a shift of the 433 cm^{-1} peak in the WS_2 shell to 444 cm^{-1}. TERS signal of the same area collected with 785 nm laser showed no significant peaks in the 140-240 cm^{-1} range, while the 444 cm^{-1} peak was preserved, being slightly shifted to 442 cm^{-1}. The spectral position of this latter Raman peak as well as the presence of the resonant peaks in 140-240 cm^{-1} range proved to be related to the degree of alloying in $Mo_xW_{(1-x)}S_2$ compounds. Based on the specifics of the gap-mode TERS response, we discuss the in-plane vs. out-of-plane nature of the composition-specific Raman peaks. TERS imaging proved to be a valuable characterization technique enabling cross-correlation of the nanoscale structural composition of 2D heterostructures with useful observables like the surface potential, topography and other physical properties probed by scanning probe microscopy.

2:15 PM EQ02.06.04
High-Responsivity and Fast Response MoS_2/Ge van der Waals Heterojunction Broadband Phototransistor Youngseo Park[1], Aujin Hwang[1], Yeongseok Shim[1], Geonwook Yoo[2] and Junseok Heo[1]; [1]Ajou University, Korea (the Republic of); [2]Soongsil University, Korea (the Republic of)

Broadband photodetection and imaging have been of significant interest because different information is obtained depending on the wavelength. Especially, short-wave infrared (SWIR) has definite advantages such as a high visibility in adverse weathers and at night. Moreover, compared to mid- or far-wave infrared for thermal imaging, SWIR allows a lower dark current at room temperature due to a larger photon energy. On the other hand, visible light (VIS) provides color information, which can utilize identifying of traffic lights. Therefore, demand for broadband photodetection ranging from VIS to SWIR is increasing in many further applications, including autonomous vehicles. For broadband detection, photodetector of various structures has been proposed such as photodiode and field-effect phototransistor. Photodiode such as MoS_2/BP heterojunction shows high photoresponse without photocurrent gain, whereas field-effect phototransistor such as Si QDs/graphene FET shows high responsivity with slow photoresponse speed due to trapping photogenerated carriers.
In this paper, we have proposed and investigated n-MoS_2/p-Ge/n-Ge van der Waals heterojunction phototransistor for broadband photodetection with photocurrent gain and fast photoresponse speed. Transition metal dichalcogenides (TMDs) can easily form van der Waals heterojunction (vdWH) despite lattice mismatch. To achieve broadband detection, heterostructure was composed of large-bandgap MoS_2 and small-bandgap Ge. Moreover, n-MoS_2/p-Ge/n-Ge phototransistor forms high potential barrier in the conduction band of heterojunction, which blocks the transport of the electrons from n-MoS_2 to n-Ge. With illumination, photogenrated holes are accumulated in p-Ge, which lower potential barrier in the conduction band and thus a large number of electrons pass through the heterojunction. Hence, this device exhibits high photocurrent in spite of weak illumination.
Photoresponse characteristics of fabricated MoS_2/Ge vdWH phototransistor were measured with floating base. In I_C-V_{CE} curves under VIS (466 nm) and SWIR (1550 nm) illuminations of 10 mW/cm^2, broadband photodetection was clearly observed, caused by VIS detection in large-bandgap MoS_2 and SWIR detection of small-bandgap Ge. From measured results, responsivity (R), external quantum efficiency (EQE), and detectivity (D^*) were calculated.
As V_{CE} increases, R and EQE linearly increase regardless of the wavelength because higher V_{CE} lower potential barrier in heterojunction. Under VIS (SWIR) illumination, R and EQE are the maximum measured values of ~7.4 (~4.7) A/W and ~1969 (~376) % at V_{CE} = 4 V, respectively. MoS_2/Ge vdWH phototransistor shows high photocurrent gain regardless of wavelength because photogenerated holes are accumulated in base and then potential barrier is lowered. Despite higher R with increasing V_{CE}, D^* is constant with value of ~4×10^7 (~2×10^7) Jones at 466 (1550) nm illumination due to high noise caused by the high dark current.
Transient characteristics were measured under VIS and SWIR laser modulations with frequency of 20 Hz. From these results, rise times (t_{rise}) and fall times (t_{fall}) were extracted and shown fast response speed with 202.3 (88.1) μs and 214.9 (232.8) μs of t_{rise} (t_{fall}), respectively. This results show that the fabricated device has a fast enough photoresponse speed to be used as VIS/SWIR broadband image sensor.
Demand of VIS/SWIR broadband image sensors is increasing, which require photocurrent gain and fast photoresponse speed. In this work, we propose and fabricate n-MoS_2/p-Ge/n-Ge vdWH phototransistor. The proposed device absorbs VIS in MoS_2 with large bandgap and SWIR in Ge with small bandgap, enabling broadband photodetection. Moreover, vdWH phototransistor not only have photocurrent gain, but also have fast photoresponse speed at the same

time. We will confirm the possibility with the broadband image sensor with additional imaging measurements later.

SESSION EQ02.07: Large-Scale 2D Materials and Ultra-Thin 3D Membranes I

Robotic Four-Dimensional Pixel Assembly of van der Waals Solids Andrew Ye[1], Andrew Mannix[2], Suk Hyun Sung[3], Ariana Ray[4], Fauzia Mujid[1], Chibeom Park[1], Myungjae Lee[1], Jong-Hoon Kang[1], David A. Muller[4], Robert Hovden[3] and Jiwoong Park[1]; [1]University of Chicago, United States; [2]Stanford University, United States; [3]University of Michigan–Ann Arbor, United States; [4]Cornell University, United States

Van der Waals (vdW) solids can be engineered with atomically-precise vertical composition through the assembly of layered 2D materials (2DMs). To date, most structures that have been constructed to study their interesting phenomena have been produced using an artisanal method of assembling micromechanically-exfoliated flakes. However, further engineering and application of vdW solids requires a scalable and rapid production method to precisely design and control composition and structure over all three spatial dimensions (*x*, *y*, *z*) and interlayer rotation (θ). Here, we demonstrate such an approach, *Robotic 4D Pixel Assembly*, for rapidly manufacturing designer vdW solids with unprecedented speed, area, patternability, and angle control. We utilize the robotic assembly of prepatterned pixels made from atomically-thin 2DM components. Wafer-scale 2DM films are grown, patterned through a clean, contact-free process, and assembled together with engineered adhesive stamps actuated by a high vacuum robot. Our technique led to the fabrication of vdW solids of up to 80 individual layers, consisting of 100 μm^2 to 1 mm^2 areas with pre-designed patterned shapes, laterally/vertically programmed composition, and controlled interlayer angle. This enables us to create efficient optical spectroscopy assays of vdW solids, where we can study the layer dependent evolution of optical properties. Furthermore, our approach allows for the fabrication of twisted *N*-layer assemblies, where we observe atomic reconstruction of twisted 4-layer WS_2 at unexpectedly high interlayer twist angles of $\geq 4°$. Our vdW solids manufacturing enables rapid construction of atomically-resolved quantum materials and will help realize the full potential of vdW heterostructures as a platform for novel physics and advanced electronic technologies.

4:15 PM EQ02.07.02
Facile Chemical Route for Freestanding Complex Oxides—From the Preparation of $Sr_3Al_2O_6$ Sacrificial Layer to the Final Oxide Properties Pol Sallés Perramon[1], Ivan Caño[1], Roger Guzman[2], Wu Zhou[2], Florencio Sánchez[1] and Mariona Coll[1]; [1]ICMAB-CSIC, Spain; [2]University of Chinese Academy of Sciences, China

Complex oxides are of great interest for their rich variety of chemical and physical properties including magnetism, ferroelectricity, multiferroicity, catalytic behavior and superconductivity. Up to date, the preparation of crystalline complex oxide thin films has been mainly limited on substrates that can stand high temperature thermal treatments and on single crystal substrates when epitaxial growth is pursued.
These requirements dramatically limit their applicability excluding the possibility to prepare many artificial multilayered architectures to investigate emergent phenomena that arise in thin films and at their interfaces, as well as fabrication of flexible devices.
In the last few years, it has been proved successful the use of water-soluble $Sr_3Al_2O_6$ (SAO) as sacrificial layer to detach perovskite complex oxides from the growing substrate and freely manipulate them. In these cases, *in-situ* and high vacuum physical deposition techniques such as Pulsed Layer Deposition (PLD) and Molecular Beam Epitaxy (MBE) have been used.

Herein, our goal is to achieve this SAO sacrificial layer for freestanding complex oxides through the use of cost-effective chemical deposition techniques with atomic precision such as Chemical Solution Deposition (CSD) and Atomic Layer Deposition (ALD).
First, we have developed a solution-based procedure to prepare high quality textured SAO films. The relation between precursor chemistry, thermal decomposition and epitaxial growth has been thoroughly investigated by means of X-Ray Diffraction, Atomic Force Microscopy and Transmission Electron Microscopy, between others. [1]
Then, we have investigated the viability of SAO to transfer a wide variety of oxide membranes ranging from binary oxides to ternary oxides (ferrites, manganites). These oxides have been deposited on SAO by different deposition techniques (CSD, ALD and PLD), and the effect of these deposition techniques on the oxide membrane quality has been compared. The influence of air exposure on SAO degradation to subsequently transfer epitaxy has been carefully studied by means of Reflection High-Energy Electron Diffraction (RHEED) and identified an effective approach to overcome it. Finally, we studied the transfer of oxide membranes to several flexible and rigid supports (PET, PDMS, silicon wafer, …). As a case example, we have studied the fabrication of $CoFe_2O_4$ membranes. The changes in epitaxy and magnetic properties throughout the transfer process are monitored by means of XRD and SQUID magnetometry obtaining crystalline and magnetic $CoFe_2O_4$ membranes. [2]
In short, this work introduces a chemical-based route to prepare freestanding complex oxides tackling the challenges related to this procedure. These results prove that chemical deposition could become an alternative to high vacuum physical deposition techniques, providing simplicity and cost saving to the process, and therefore making the freestanding complex oxides a step closer to large-scale production.

4:30 PM EQ02.07.03
Diffusion-Driven Mechanical Exfoliation of Rare-Earth Iron Garnet Nanosheets Karthik Srinivasan, Andrew Schwarz, Jason C. Myers, Nicholas C. Seaton and Bethanie J. Stadler; University of Minnesota, United States

Rare-earth iron garnet thin films have advanced the development of on-chip non-reciprocal photonic and prototype spintronic devices due to their large Faraday rotations and spin diffusion lengths, respectively. However, non-epitaxial garnets deposited using pulsed laser deposition (PLD) or sputtering require an annealing temperature of 800°C or greater, and epitaxial garnet films are limited to lattice-matched substrates that are not foundry compatible. Here, a modified rapid thermal annealing process enabled mechanical exfoliation of high-gyrotropy cerium-doped terbium iron garnet ($Ce_{0.25}Tb_{2.75}Fe_{4.75}O_{12}$) from a silicon substrate without the need for an intermediary graphene layer, such as used in remote-epitaxy. Exfoliation is enabled by vacancy diffusion that followed a Nabarro-Herring model where strain was varied using different thicknesses for the garnet films. An increase in the tension between the film and the substrate resulted in a diffusion of vacancies away from the substrate. The diffusivities calculated by fitting the model to the strain rate-stress data identify iron and terbium as the rate-determining lattice diffusants. Furthermore, cross-section energy dispersive X-ray

spectroscopy shows an accumulation of cations to form an amorphous Fe-Tb-Si-O interlayer at the substrate, leaving behind vacancies that create an exfoliation plane ~30nm into the film. This distance is comparable to the cation diffusion length, verifying the model. Magnetic and optical measurements from the exfoliated nanosheets reveal a saturation magnetization of 18 emu cc^{-1} and a Faraday rotation of -2900°cm^{-1} at 1550 nm, both of which are comparable to bulk values. Exfoliation through controlled creep-diffusion will open non-traditional pathways for incorporating garnets with other crystalline wafer platforms and protect devices from the high-temperature processes often used in crystallizing garnet films.

4:45 PM EQ02.07.05
Epitaxial Crystallization of Amorphous Complex Oxides in Complex Geometries Rui Liu[1], Peng Zuo[1], Samuel Marks[1], Peiyu Quan[1], Donald Savage[1], Hua Zhou[2], Susan Babcock[1] and Paul Evans[1]; [1]University of Wisconsin–Madison, United States; [2]Argonne National Laboratory, United States

Crystallization from an amorphous precursor via solid phase epitaxy (SPE) enables a wide range of opportunities in the formation of oxide materials in new geometries. The use of low deposition temperatures to form the amorphous precursor reduces diffusion and phase separation during deposition and thus allows the formation of chemically and structurally uniform starting materials. Kinetic phenomena arising during crystallization of oxide materials in the form of 3D nanostructures via SPE pose challenging synthesis and characterization problems. A key challenge is to achieve nanoscale control of epitaxial crystallization. Selecting the locations of the initial step of crystallization and simultaneously maintaining a low rate of nucleation away from epitaxial interfaces are particularly important. In order to probe the propagation of the crystallization transformation, the location of crystallization sites in a study of $SrTiO_3$ (STO) SPE were set by forming micron-scale Si_3N_4 (SN) features on $SrTiO_3$ 001 single-crystal substrates using optical lithography. Amorphous STO was deposited on the patterned substrates at room temperature using radio-frequency sputtering and crystallized by heating to temperatures at which crystallization occurred from seeds while the rate of homogeneous nucleation remained low. A further challenge is to understand the microscopic mechanism that leads to crystallization at amorphous/crystal interface in nanoscale complex geometries. An *in situ* synchrotron hard x-ray nanodiffraction instrument at the Advanced Photon Source enabled this process to be studied using nanobeam diffraction and reflectivity probes during amorphous deposition and epitaxial crystallization. The results indicated that amorphous STO selectively crystallized on STO seed and laterally crystallized over the SN patterns before encountering separately nucleated crystals. Three-dimensional SPE of STO provides opportunities to create a wide range of other perovskite oxides in nanoscale geometries. The results will be discussed in terms of the competition between crystal/amorphous interface motion and homogeneous nucleation, the stress-induced from the density difference between the amorphous and the crystalline films, and the consequences of small deviations from the desired STO stoichiometry.

5:00 PM EQ02.07.06
Strain-Induced Lateral Heterostructures in Patterned Semiconductor Nanomembranes Mapped by X-Ray Nano-Diffraction Imaging Abdullah Gok[1], Xiaowei Wang[1], Shelley Scott[2], Abhishek Bhat[2], Hanfei Yan[3], Ajith Pattammattel[3], Evgeny Nazaretski[3], Yong S. Chu[3], Zicong Huang[4], Richard M. Osgood Jr.[4], Max G. Lagally[2] and Roberto Paiella[1]; [1]Boston University, United States; [2]University of Wisconsin–Madison, United States; [3]Brookhaven National Laboratory, United States; [4]Columbia University, United States

Semiconductor heterostructures have been used extensively in the development of electronic and optoelectronic devices such as transistors, lasers, LEDs, and photodetectors. Traditionally, these composite materials are synthesized by heteroepitaxy, where films of different compositions are grown on top of one another through various atomic deposition techniques. This approach is well established in micro and optoelectronics, where it provides a powerful tool to shape the energy band profile in order to promote and enhance desired device functionalities.
Here we report a new method, based on strain engineering, for the controlled introduction of variations in bandgap energy with lateral position in thin films. External stress is applied on a semiconductor nanomembrane stacked with an array of dielectric pillars, in order to create a non-uniform strain distribution commensurate with the sample thickness variations (with the largest strain accumulating in the thinnest regions between the pillars and vice versa). In typical group-IV and III-V semiconductors, in-plane biaxial tensile strain has the effect of decreasing the fundamental energy bandgap, while at the same time lifting the degeneracy of the heavy-hole and light-hole valence-band maxima. The end result is therefore a controlled bandgap modulation – i.e., the formation of a sample that effectively behaves like a lateral (in-plane) heterostructure, but consisting of a single semiconductor material with uniform chemical composition.
Specifically, we employ 90-nm-thick Ge nanomembranes coated with a square-periodic array of cylindrical amorphous-Si pillars having micron-scale lateral dimensions and 300-nm height. The nanomembranes are transferred and bonded on a flexible film of polyimide, which is then mounted on a gas pressure cell that allows introducing biaxial tensile strain in the Ge crystal in a highly controllable fashion. The resulting strain profiles are mapped using Bragg diffraction with a hard x-ray probe featuring nanoscale spatial resolution. A clear lateral strain modulation is observed in the measurements, with the strain going through a well-defined minimum at the location of each amorphous-Si pillar. The strain difference between coated and uncoated nanomembrane regions is also found to increase with increasing gas pressure, in agreement with finite-element simulations. The measured strain maps are finally used to compute the Ge-nanomembrane energy band lineup, showing the formation of pronounced energy barriers in both conduction and valence bands.
Compared with traditional heterostructures grown by epitaxial techniques, these strain-engineered samples are not limited in the choice of compatible materials by any restriction imposed by lattice-matching requirements. Furthermore, their energy band lineups can be patterned in nearly arbitrary shapes using nanolithography to control the thickness profile, and can be tuned actively by varying the applied stress. As a result, these structures are attractive for a wide range of device applications (including lasers, LEDs, solar cells, and thermoelectrics) that require complex heterostructure lineups with multiple bandgap energies.

SESSION EQ02.08: Nanostructures of Low Dimensional Materials I

Nanofabrication Through Molding Enables a Versatile Toolbox Naijia Liu and Jan Schroers; Yale University, United States

The fast development of nanotechnologies in the past decades desires various nanomaterials that span wide ranges of sizes, geometry, materials choice, crystal structures, and elemental distributions. However, the availability of these nanomaterials is usually leashed by the ability of specific nanofabrication methods in at least one of these aspects.

First applied for polymers and BMGs, nanomolding refers to a top-down fabrication method by which a formable or moldable material is shaped using a

mold of nanoscale dimensions. Recently, thermomechanical nanomolding (TMNM) has been developed for general crystalline materials, indicating potentially a very versatile method for large scale nanofabrication.

In this work, with carefully designed scaling experiments, we revealed the principle behind TMNM to be a diffusional atomic transport that happens at the very interface between material and mold. By controlling processing temperature and length scale, we are able to tune TMNM between this interface-diffusion principle and a dislocation-slip dominated regime. Such a transiting mechanism results in a highly versatile toolbox, enabling fully controlled nanofabrication over sizes, geometry, materials choice, and crystal structures. Specifically, the element dependence of diffusivity allows controlled growth down to single elements/components of the feedstock, indicating controllable elemental distributions. And by utilizing TMNM, we have successfully demonstrated the fabrication of heterostructure nanowires with fully controlled elemental layer sequences.

We will discuss the transiting mechanism behind TMNM and the versatile toolbox by utilizing this mechanism including controlled fabrication of heterostructures. The possibility of forming new phases through kinetical control of elements in TMNM will also be discussed.

10:45 AM EQ02.08.02
Perpendicularly Standing Two-Dimensional Fused Aromatic Network Structure Seok-Jin Kim[1,1], Tea-Hoon Kim[2], Ishfaq Ahmad[3], Hyuk-Jun Noh[3], Sun-Min Jung[3], Yoon-Kwang Im[3], Javeed Mahmood[3], Youn-Sang Bae[2] and Jong-Beom Baek[3]; [1]King Abdullah University of Science and Technology, Saudi Arabia; [2]Yonsei University, Korea (the Republic of); [3]Ulsan National Institute of Science and Technology, Korea (the Republic of)

Two-dimensional (2D) fused aromatic networks (FANs) have a planar structure, in which flat building blocks are horizontally connected to form optimized, layered π-π stacking. Three-dimensional (3D) FAN structures, in which building blocks are divergently linked in the space, provide the maximum accessible internal surface area with permanent porosity. As sorbent materials, the confined layered stacking pattern of FANs restricts segmental motion, and the available surface area is partially blocked by adjacent layers, resulting in weak uptake capacity and kinetics. To understand the relationship between structure and performance, here, a new type of pyrazine-linked FAN structure, with vertically standing building blocks connected along the 2D direction, was designed and synthesized to minimize layer-to-layer interactions and to maximize segmental freedom. In comparison studies with flat 2D and porous 3D FANs, the vertically standing FAN (V2D-Pz) displayed intermediate performance for gas storage and separation. For example, the results for the adsorption and separation of CH_4/N_2 fell in between those of the flat 2D and porous 3D FANs. However, the standing V2D-Pz had a more structurally accessible adsorption area and higher segmental freedom, and it exhibited the highest iodine uptake capacity (~4.2 g g^{-1}) and capture rate (1.51 mmol g^{-1} h^{-1}).

11:00 AM EQ02.08.03
Bulk Grain-Boundary Materials from Nanocrystals Yasutaka Nagaoka and Ou Chen; Brown University, United States

Grain-boundary engineering is essential to unleash the potential of materials. While a number of methods have been used to tune up grain-boundary conditions such as hammering, plasma-assisted sintering, deposition, etc, it still remains challenging to achieve precise grain boundary engineering at the nanoscale because these methods rely almost exclusively on top-down approaches. Meanwhile, recent theoretical studies have made a striking advance in the understanding of structure-properties relationships over nanoscale grain-boundary conditions and novel materials' design strategies, thus, a methodology to make a tailored grain-boundary condition in real experiments is wanted for experimental demonstration. Herein, we introduce a new grain-boundary engineering method, "the nanocrystal coining method". With this method, various grain-boundary factors such as grain-boundary shape and size are readily tuned at least one-nanometer precision. The produced materials possess a centimeter-scale size and freestanding nature, which is ideal for many applications. Other advantages include a wide range of available components and no restriction of substrates. In this presentation, we will discuss the nanocrystal coining method in the greater details
The nanocrystal coining method uses chemically synthesized colloidal metal nanocrystals as the starting materials. We treated the nanocrystals using a surface treatment, thorough washing and drying process, and a pressure process with a piston-cylinder pressure die. The resulting materials (which we call ''nanocrystal coins'') showed several strikingly improved properties owing to the nanoscale grain-boundary condition and the high material density. The nanocrystal coins successfully emerged metallic properties in the appearance and conductivity while the crystal domains of the original nanocrystal building blocks remained unchanged. In addition, nanoindentation measurements confirmed the superior mechanical hardness of the nanocrystal coins due to the Hall-Petch effect. Taking further advantage of this method, we created the first example of a single-component bulk metallic glass from amorphous palladium nanoparticles. The MD simulation supported the mechanisms of the nanocrystal coining method including preservation of grain-boundary condition, low-pressure sintering, and densification under pressure. Our methods will help researchers to finely iterate structure-properties relationships whose functionality crucially depends on the crystal-domain configuration, such as superhard materials, thermoelectric generators, and functional electrodes.

11:15 AM EQ02.08.04
Generation of 3D-Heterostructures by Mechanochemical Disassembly and Re-ordering of Metal Chalcogenides Viktor Balema[1], Ihor Z. Hlova[1], Prashant Singh[1], Oleksandr Dolotko[1,2], Serhiy Z. Malynych[3], Scott L. Carnahan[4], Arjun K. Pathak[5], Duane D. Johnson[1], Aaron J. Rossini[1,4] and Roman V. Gamernyk[6]; [1]Ames Laboratory of US DOE, United States; [2]Karlsruher Institut für Technologie, Germany; [3]Hetman Petro Sahaidachnyi National Army Academy, Ukraine; [4]Iowa State University of Science and Technology, United States; [5]SUNY, Buffalo State, NY, United States; [6]Ivan Franko National University of Lviv, Ukraine

Three-dimensional (3D) heterostructures with incommensurate arrangements of well-defined building blocks are created using an unconventional synthetic approach comprising of mechanically facilitated disassembly and reordering of layered transition-metal dichalcogenides, MX_2 [1,2], and non-layered rare-earth metal monochalcogenides, REX [2], where M = Ta or Nb, RE = Sm or La, and X = S or Se. The discovered solid-state processes are driven by mechanochemical transformations directed by quantum interaction between chemically and structurally dissimilar solids toward atomic-scale ordering.

Remarkably, in the case of a pair of layered MoS_2 and HfS_2 compounds[1], the experimentally observed 3D-heterostructuring is energetically favorable over the formation of homogeneous multi-principle element dichalcogenides that had been observed in related dichalcogenide systems including MoS_2, WS_2 , and TaS_2 materials [3].

Density-functional theory calculations reveal critical details about charge transfer between structural elements of the explored heterostructures and validate experimental results. High-temperature annealing improves crystallinity of 3D-heterostructures without altering their internal atomic arrangements, which resembles respective behaviors of molecular solids and polymers.

Powder X-ray diffraction, scanning transmission electron microscopy, ^{77}Se solid-state nuclear magnetic resonance, optical spectroscopy and electronic transport measurements unambiguously confirm the course of mechanochemical reactions and the identities of the created materials. The resulting 3D-heterostructures show broad range of electron transport behaviors varying from metallic conductivity to indirect band gap semiconductivity.

Results of this joint experimental and theoretical study open new avenues for generating unexplored metal-dichalcogenide heteroassemblies with incommensurate structures and tunable physical properties.

Color Tuning of Electrochromic TiO_2 Nanofibrous Layers with Embedded Metal and Metal Oxide Nanoparticle for Smart Colored Windows Cavit Eyovge, Arturo Susarrey Arce and Han Gardeniers; University of Twente, Netherlands

Co-axial electrospinning was applied for the structuring of non-woven webs of TiO_2 nanofibers loaded with Ag, Au, and CuO nanoparticles (NPs). The composite layers were tested in an electrochromic half-cell assembly. A clear correlation between NP composition and electrochromic effect in the nanofibrous composite is observed: TiO_2 loaded with Ag reveals a black/brown color, Au shows a dark blue color, and CuO a dark green color. For electrochromic applications, the Au/TiO_2 layer is the most promising choice, with a remarkable color modulation time of 6 s, transmittance modulation of 40%, coloration efficiency of 20 cm^2/C and an areal capacitance of 300 F/cm^2, and cyclic stability of over 1000 cycles. Electrochemical impedance spectra of the best performing sample, Au/TiO_2 fibers, was also analysed to understand the effects of additive NPs within the fibrous network. In this study, we offer an unexplored path for the rational design of TiO_2-based nanofibrous layers with unprecedented color switching and optical efficiency gained by the fibrous layer. We foresee co-axial electrospinning as an alternative nanofabrication technique applied in smart colored windows.

11:45 AM EQ02.08.06
Two-Dimensional Xene Heterostructures on Ag(111) by Molecular Beam Epitaxy Daya Sagar Dhungana[1], Carlo Grazianetti[1], Christian Martella[1], Simona Achilli[2], Guido Fratesi[2] and Alessandro Molle[1]; [1]CNR-IMM Agrate Brianza Unit, Italy; [2]Università degli Studi di Milano, Italy

The past decade witnessed several developments on 2D graphene analogs, also known as Xenes, and several milestones have been achieved on material synthesis and their application prototypes[1]. If the synthesis of new Xenes and their application prototypes are widely studied, piling up one Xene layer over another Xene layer to realize a Xene heterostructure to the date remains a challenging issue owing to interlayer mismatch, intermixing, etc.. Indeed, even if two different Xenes can be grown on the same substrate, composing heterostructure and superlattice geometry has remained quite puzzling. Making Xene heterostructure in this framework therefore will provide substantial technological throughputs for various applications, for instance nanoelectronics, optoelectronics, plasmonic and energy.

In this work, we first introduce the Xene heterostructure[2] concept and present two heterostructures based on two well-established configurations: silicene-on-Ag(111)[3] and stanene-on-Ag(111)[4]. We will further demonstrate Xene superlattices taking advantage of underneath Xene layer as a suitable template for another reciprocal Xene layer. Furthermore, the insights into co-deposition techniques where our results show it is possible to achieve both the heterostructure sequence by engineering the growth kinetics will be discussed in detail with various *in situ* and *ex situ* probes. Moving beyond monolayer silicene-stanene configuration, we will also present layer-by-layer growth of multilayer 4x4 Silicene on the same reciprocal stanene-on-Ag(111) template. In the end, Density Functional Theory calculations were carried out taking experimental data as starting input models in order to have deeper insights into structural stability and electronic structure.

The work is performed within the ERC-COG 2017 Grant No. 772261 "XFab".

Nanorafts—Clay Nanosheets Decorated with Magnetic Nanoparticles Paulo H. Michels Brito[1], Barbara Pacakova[1], Leander Michels[1], Ville Liljestrom[1], Sergio Toma[2], Daniel Wagner[3], Kenneth Knudsen[4], Koiti Araki[2], Josef Breu[3] and Jon O. Fossum[1]; [1]Norwegian University of Science and Technology, Norway; [2]University of São Paulo, Brazil; [3]Universität Bayreuth, Germany; [4]Institute for Energy Technology – IFE, Norway

Emerging field of 2D materials shifts nowadays towards preparation of metamaterials, combining efficiently functionality of 2D layers themselves with additional components such as nanocrystals, forming together multifunctional 2D material with complex properties[2]. It has been shown that combination of 2D sheets with nanoparticles does not bring together just individual properties of both components[3], but also affect behaviour of 2D sheets themselves[4]. Functionalized 2D nanosheets can serve as basic bulding blocks for fabrication of larger structures targeting metamaterial with desired properties, for example via self-assembly, hence implementation of additional functionality directly into the 2D nanosheets is of high importance.
We present here an efficient approach of decorating 2D nanosheets in liquid phase with magnetic nanoparticles, based on functionalized iron oxide nanoparticles and high-aspect ratio sheets of insulating transparent synthetic clay, sodium fluorohectorite. Efficiency of the process is confirmed by several complementary characterization methods, including TGA, X-ray diffraction (SAXS/WAXS), spectroscopy (FTIR, UV-VIS). Particle layout on nanosheets is determined by microscopy techniques (SEM and AFM). Options of tuning particle density on nanosheets and particle geometrical arrangement in a view of possible applications will be discussed.

Monolithic integration of MoS_2 with III-V Compound Semiconductors for Micro-LED Display Applications Jong-Hyun Ahn; Yonsei University, Korea (the Republic of)

Heterogeneous integration of transition-metal chalcogenides on III-V compound semiconductors provides development opportunities for a variety of new optoelectronic devices. In this talk, we present a novel method for heterogeneous integration of MoS_2 on III-V compound semiconductors. A thin film of MoS_2 was directly synthesized on a GaN-based epitaxial wafer through the MOCVD technique and fabricated as the TFT array. Subsequently, the MoS_2 TFT was monolithically integrated with micro-LED devices to produce an active matrix micro-LED display. This strategy represents a promising route to attain heterogeneous integration, which is essential for high-performance optoelectronic systems that can incorporate the established semiconductor technology and emerging 2D materials.

2:15 PM EQ02.09.02
Hydrogen Doping as a Method to Create Novel 2D-3D Metal-Oxide Heterostructures and Gradient Electronic Phases Qi Wang, Zhen Zhang and Shriram Ramanathan; Purdue University, United States

Perovskite nickelates undergo room temperature colossal electronic phase transitions which could modulate the electronic conductivity up to 8-10 orders of magnitude by hydrogen doping. This creates an unprecedented opportunity to fabricate 2D localization of electronic phases by atomic scale displacement of hydrogen in the lattice. One way to accomplish this is by locally storing hydrogen in metal gates such as palladium (Pd) that can be injected into the near surface perovskite lattice by an external electric field. Here we developed an asymmetric two-terminal device fabricated using $SmNiO_3$ (SNO) thin film which forms multiple heterostructures within each device. The two-terminal device, with one electrode comprising Pd and the other electrode gold (Au), enables a gradient in hydrogen doping which allows to create arbitrary electronic phases. We will describe the band structure physics of such novel electronic heterostructures that can form 2D electron puddles which can subsequently be distributed spatially by electric fields. The current-voltage characteristics show remarkable transitions in mechanisms depending on the local distribution of hydrogen proximal to the electrodes. We will discuss the response of such 2D-3D heterostructures to electric stimuli and the use in emerging neuromorphic computing architectures.

Late News: Bias-Modulated UV and NIR Colour Discrimination Using MoS2/ZnO (2D/3D) Heterostructure Based Photodetector Device Kishan L. Kumawat, Pius Augustine, Deependra Kumar Singh, K K Nanda and Krupanidhi S B; Indian institute of Science Bengaluru, India

Despite significant progress in the spectral discrimination properties of photodetectors (PDs), most of the conventional technologies use optical filters which results in expensive circuitry as well as high incident energy loss. 2D/3D integration of an MoS_2/ZnO heterostructure-based PD has been demonstrated which exhibits a bias-dependent switchable spectral response, in a manner different from the traditional PDs. Low band gap MoS_2 thin film has been vertically stacked on top of a high band gap ZnO film that allows selective charge transport from each layer by modulating the applied bias, resulting in a fine discrimination between ultraviolet (UV) and near infrared (NIR) light. Under lower applied bias, a dominant photoresponse in the UV region by the ZnO film is observed, whereas an enhanced response in the NIR region is obtained at higher bias which is attributed to the generation of charge carriers in the MoS_2 film. The device predominantly exhibits UV photoresponse at 1.0 V with respnsivity of 4.56 AW^{-1} (400 nm) and that in the NIR region at 8.0 V with responsivity of 6.04 x 10^3 AW^{-1} (900 nm). The excellent figures of merit of the device attest the high quality of the device. Thus, this approach paves a way for fabricating optical filter-free, low cost and energy-efficient imaging systems.

Heterostructures from 2D Materials and Phase Transition VO_2 Jian Shi; Rensselaer Polytechnic Institute, United States

Heterostructures based on 2D materials have been found to harbor a plethora of intriguing physical phenomena whose presence is largely due to the availability of a vast 2D materials space and a plenty of degrees of freedom (e.g. twist angle, lattice mismatch) in structural design. Introducing 2D/3D heterostructures would further expand the design space for discovering new physics and developing novel devices. In this talk, I will present the design and development of heterostructures based on 2D materials and a 3D phase transition oxide. The relevant heterostructures in this talk include MoS_2/VO_2 and hBN/VO_2. In these heterostructures, the phase transition oxide imposes controllable mechanical and electronic boundary conditions to the 2D materials allowing the discovery of flexo-photovoltaic effect in MoS_2 and reconfigurable transport behavior in hBN/VO_2. Further, the weak 2D-3D interface coupling has been harnessed to control the phase transition dynamics of VO_2. The demonstration of functional behaviors at 2D/3D interface suggests the promises of using 2D/3D heterostructures for designing new electronic and optoelectronic devices.

Remote Epitaxy of Micrometer-Sized Semiconductors for Fabricating Flexible and Transferable Optoelectronic Devices Young Joon Hong; Sejong University, Korea (the Republic of)

Solid-state electronics are currently under development toward the technological paradigm shift from miniaturization to deformable form factor.[1] However, typical semiconductors, including Si, III-V, metal-oxides, etc., are not intrinsically soft because of mechanical properties of bulk crystalline with brittleness and rigidity. An innovative way to fabricate flexible electronics is to make the device overlayer away from the rigid substrate and to assemble the devices on the other soft substrate in a form of spatially separate chip arrays. However, to separate the overlayer from the mother substrate, high energy irradiation (e.g., laser lift-off) and the use of corrosive etchants should have been unavoidable before emergence of non-covalent epitaxy (i.e., van der

Waals and remote epitaxy).[2] The remote epitaxy is to grow epitaxial overlayer remotely from wafer across a gap made of two-dimensional (2d) atomic layer.[3] The technique has no restriction to obtain in use of poly-domain graphene for growing single crystalline overlayer, which is distinct from the van der Waals epitaxy whose overlayer follows the surface crystal structure of 2d layer. In this talk, we focus to present and discuss how the remote epitaxy of micro- or nano-sized epitaxial architectures is applied to fabricate deformable and transferable devices. First, the epitaxy regime (i.e., covalent, remote, and van der Waals epitaxy) is discussed in terms of attracting force from wafer and graphene and role of graphene. We introduce the random nucleation-based remote epitaxy of ZnO and GaN micrometer-sized rod, which the spatially isolated geometry can be devised to fabricate the flexible light-emitting diodes (LEDs).[4] We also present the white LEDs fabricated by the remote epitaxy of GaN *p*–*n* junction microrods.[5] To increase the versatility of the remote epitaxy, it is necessary to control the position and size of rod structures. Thus, the methods of site-selective remote epitaxy are presented.[6, 7] The density-functional theory simulation and atomic-resolution transmission electron microscopic analysis results are also accompanied to discuss the mechanism of remote epitaxy.

Remote Epitaxy and Heterostructing Complex-Oxide Membranes Hyunseong Kum[1], Chang-Beom Eom[2] and Jeehwan Kim[3]; [1]Yonsei University, Korea (the Republic of); [2]University of Wisconsin–Madison, United States; [3]Massachusetts Institute of Technology, United States

Complex-oxide materials exhibit a plethora of physical properties desirable for next-generation electronics, photonics, and quantum devices. These properties may be present in bulk form or at a heterointerface, and may be created or enhanced by application of strain. However, to date, only epitaxial methods have been used to create various heterostructures with varying strain states. Unfortunately, epitaxial methods have strict limitations, requiring closely lattice mismatched and similar crystalline structure, which prevent unrestricted manipulation, integration, and utilization of these materials. Thus, the design space for heteroepitaxial systems are severely limited. Additionally, the range of strain that can be imparted by epitaxy is fixed by pseudomorphic conditions. Finally, epitaxial growth conditions, which typically occurs at high temperatures, preclude integration of materials that are less stable in such environments. This has been a consistent bottleneck preventing universal integration of dissimilar materials to date.

To alleviate these restrictions, we present methods to produce freestanding complex-oxide membranes allowing artificial creation of complex-oxide heterostructures with vastly different crystalline structure, lattice, and orientation, such as perovskite, spinel, and garnet films. The first lift-off method, remote epitaxy, allows epitaxial seeding of the substrate through monolayers of graphene, which can then be easily exfoliated due to the van der Waals nature of graphene. However, some complex-oxide materials, such as piezoelectric PMN-PT, are grown by sputtering, which damages the graphene due to the harsh plasma ambient. For these materials, we found that by choosing a substrate with a specific lattice misfit, the epitaxial layer can be precisely separated from the substrate using a high stress Ni layer.

We also demonstrate artificial heterostructures by stacking exfoliated complex-oxide membranes manually, observing the mechanical and physical interaction between the stacked membranes. We hope such demonstration of artificial 3D-3D and 2D-3D heterostructures will allow to significantly expand the possible permutations of materials and allow experimental realization of structures not possible by epitaxial means alone.

9:00 AM *EQ02.10.03
Atomic Structure of Nitride/Graphene/Sapphire Interface and Mechanism of Remote Epitaxy Peng Gao[1], Zhiqiang Liu[2], Tongbo Wei[2] and Zhongfan Liu[1]; [1]Peking University, China; [2]Institute of Semiconductors, Chinese Academy of Sciences, China

Wide-bandgap semiconductors, especially group-III nitrides (III-Ns), have excellent performance to be applied into optoelectronic and electronic devices in full-color range. In industry, as the most used epitaxial substrate, sapphire however, has large thermal and crystal mismatch with these nitrides and induces large compressive strains and density of dislocations, seriously troubling the device performance.
Recently, with the assistance of two-dimensional (2D) materials, such as graphene, remote epitaxy (or called quasi-van der Waals epitaxy) has given new choice to semiconductor films epitaxy. The weak van der Waals force in the nitride/graphene/sapphire sandwich structure alleviates the lattice and thermal mismatch, tunes nucleation behavior, reduces growth time, and/or achieves damage-free transfer for high-power and flexible devices. But still, owing to the lack of atomic resolution characterizations, the role of graphene acts in this process is still not clear. Meanwhile, the 2D materials transfer process which formal study mostly focused on can hardly be used into industry. Herein, we share some study about the atomic structure of nitride/graphene/sapphire interface and the mechanism of remote epitaxy, in which the graphene/sapphire substrates are 10*2-inch batch synthesized by chemical vaper deposition (CVD) method, offering opportunity for the usage in industry.
Firstly, we study the surface of the graphene covered sapphire. Instead of van der Waals interaction, the grown graphene is C-O-Al bonded with sapphire unexpectedly [1]. Compared with transferred sample, the grown graphene is stronger pasted on sapphire with larger lateral force, and the structure relaxation behavior of sapphire near the surface is suppressed compared with that of the bare surface.
Upon the graphene/sapphire substrate, we grow GaN film with metal organic CVD (MOCVD) method. After this process, the sapphire surface transforms into a high Al-O ending surface, significantly different from the case before MOCVD. We also find that the whole nitride film achieves low compressive strain as well as low density of dislocations. Based on the high-quality nitride films, we further fabricate high In composition InGaN alloy. The strain relaxed nitride film creates suitable environment for up to 32% In element doping. The as-fabricated light emitting device (LED) shows a 563 nm electroluminescence emission, corresponding to yellow light.

***In Situ* X-Ray Studies of Growth of $SrTiO_3$ (001) on Graphene by Molecular Beam Epitaxy** Xi Yan, Hui Cao, Yan LI, Hawoong Hong, Hua Zhou and Dillon D. Fong; Argonne National Laboratory, United States

Remote epitaxy is novel synthesis technique that allows the fabrication of ultrathin, flexible, and highly unique heterostructures that cannot be created by other methods. The technique was recently applied to construct freestanding, complex oxide membranes [1]. By inserting graphene between the film and substrate during thin film growth, the van der Waals interactions between graphene and other materials are strong enough to enable epitaxial growth but weak enough to allow the rapid release the thin film. The technique may eventually be exploited to create novel, single crystal heterostructures, as each film can be “stacked” atop another, regardless of degradation due to misfit strain or incompatibilities due to high temperature reactions. However, details

regarding how remote epitaxy actually occurs remains unknown as this requires an *in situ* investigation of the remote epitaxy process. Here we conduct *in situ* synchrotron X-ray measurements during growth by molecular beam epitaxy (MBE) to observe epitaxial synthesis through graphene layers. COBRA (COherent Bragg Rod Analysis) is used to reconstruct the electron density profiles of the epitaxial system after the growth of each monolayer. Subtle changes of the graphene layers during heating and in different oxygen pressures were captured, providing crucial details in understanding the remote epitaxy technique.

SESSION EQ02.11: Epitaxy of Mixed Dimensional Structures IV
Session Chairs: Young Joon Hong and Suresh Sundaram
Monday Morning, December 6, 2021
EQ02-Virtual

10:30 AM *EQ02.11.01
Wafer-Scale van der Waals Epitaxy of III-Nitride Devices on h-BN—An Overview of 2D/3D Epitaxy, Device Fabrication, Mechanical Release-Transfer Methods and Device Performances Abdallah Ougazzaden[1,2], Suresh Sundaram[1], Phuong Vuong[2], Soufiane Karrakchou[1], Adama Mballo[2], Rajat Gujrati[1], Ashutosh Srivastava[1], Gilles Patriarche[3], Paul Voss[1] and Jean-Paul Salvestrini[1,2]; [1]Georgia Institute of Technology-Lorraine, France; [2]CNRS, IRL 2958 Georgia Tech, France; [3]CNRS, Centre de Nanosciences et de Nanotechnologies, France

Van der Waals (vdW) epitaxy of 3D device structures on 2D layers is particularly interesting for III-nitrides and has attracted intensive investigation. Dislocations and defects seen in typical nitride 3D epitaxy could be avoided when grown on a 2D layer, because strain due to large lattice and thermal mismatches relaxes elastically during 3D growth. The technique is also very convenient for heterogenous integration. With simple sticky holders (tapes, PDMS, metallic films…), the III-N heterostructures can be mechanically detached over a large area from its substrates and the membrane transferred to arbitrary carriers, at minimum of time and low cost. Hexagonal boron nitride (hBN) is an excellent choice of 2-D material. It exhibits good stability at high temperature, excellent compatibility with III-nitride growth conditions and growth systems (MOCVD, MBE, CVD…) and can be grown on different types of substrates, with sapphire our substrate of choice.
We have demonstrated a range of devices using 2D/3D vdW epitaxy: LEDs, solar cells, sensors and HEMTs. In this talk we overview our results in epitaxy and materials characterization, device fabrication, mechanical lift-off and transfer, and pre- and post-transfer device characterization. Different mechanical liftoff and transfer approaches will be compared in term of material quality, crack generation and flexibility. Going beyond wafer-scale epitaxy, we will also present selective area vdW epitaxy and self-lift off and transfer techniques that can further simplify and lower the cost of heterogenous integration because of innovative epitaxy and process fabrication that use commercial systems.

11:00 AM *EQ02.11.02
One-Dimensional van der Waals Materials Alexander A. Balandin; University of California, Riverside, United States

The unique electrical and thermal properties of graphene stimulated the search for other two-dimensional (2d) atomic crystals with unusual properties. A number of 2D materials belong to the family of transition metal chalcogenides that contains weak van der Waals bonding between structural units. Until recently, most research utilized dichalcogenides such as MoS2, TaS2 and others, distinguished by 2D layers. Another class of transition metal chalcogenides – the trichalcogenides – has quasi-1D crystalline structures. In this presentation, I review our results, which show that the mechanical and chemical exfoliation approaches developed for 2D materials can be extended to a relevant class of quasi-1D van der Waals materials such as TaSe3, ZrTe3 and others. Electrical measurements established that the bundles of quasi-1D atomic chains have a breakdown current density approaching 100 MA/cm2 [1, 2]. The atomic chain single crystal nature of TaSe3 results in low surface roughness and the absence of grain boundaries. These features potentially can enable the downscaling of these wires to lateral dimensions in the few-nm range. The polymer composites with low loadings of quasi-1D TaSe3 fillers reveal excellent electromagnetic interference shielding in the X-band GHz and extremely high frequency sub-THz frequency ranges, while remaining DC electrically insulating [3, 4]. The unique electromagnetic shielding characteristics of these films are attributed to effective coupling of the electromagnetic waves to the high-aspect-ratio electrically conductive TaSe3 atomic-thread bundles even when the filler concentration is below the electrical percolation threshold. These novel films are promising for high-frequency communication technologies, which require electromagnetic shielding films that are flexible, lightweight, corrosion resistant, inexpensive, and electrically insulating.

This work was supported, in part, by the NSF DMREF program via a project DMR-1921958 Collaborative Research: Data Driven Discovery of Synthesis Pathways and Distinguishing Electronic Phenomena of 1D van der Waals Bonded Solids. 11:30 AM EQ02.11.03
MOVPE Epitaxy of Group III Nitrides via Few-Layer Graphene on GaN/Sapphire Templates Kazimieras Badokas[1], Arunas Kadys[1], Dominykas Augulis[1], Juras Mickevicius[1], Ilja Ignatjev[2], Martynas Skapas[2], Giedrius Juska[1] and Tadas Malinauskas[1]; [1]Vilnius University, Lithuania; [2]Center for Physical Sciences and Technology, Lithuania

Integration of group III nitrides and two-dimensional buffer layers, such as graphene, has been considered as a new material system for the next-generation optoelectronic devices. However, the growth of high-quality semiconductor membranes on the slippery van der Waals surface remains challenging. Harsh metalorganic vapor phase epitaxy (MOVPE) environment and graphene transfer technique have a great impact on the successful realization of remote epitaxy.

In this work, one-step and multi-step MOVPE growth approaches were realized to fabricate GaN layers on GaN/sapphire templates covered with graphene. While the one-step approach led to the disappearance of graphene Raman fingerprints, the multi-step growth protocol resulted in the successful formation of GaN films on GaN/sapphire templates. The quality of grown layers was investigated using atomic force microscopy, X-Ray diffraction and

photoluminescence techniques. Transmission electron microscopy analysis revealed a clean GaN/graphene/GaN interface.

The seeding effect of the substrate was previously shown to take place for up to two layers of graphene. The use of bilayer graphene could be favorable as it provides an aperture-free interlayer. To investigate the effect of the number of graphene layers and their transfer technique, seeds of GaN and InN were formed. Single transfer of bilayer graphene proved to be better suited for the realization of remote epitaxy rather than double transfer of monolayer.

11:45 AM EQ02.11.04
Metallic-Dielectric Multilayers as Substrates of van der Waals Epitaxy Xuejing Wang[1], Yeonhoo Kim[1], J. K. Baldwin[1], Andrew C. Jones[1], Jeeyoon Jeong[2] and Jinkyoung Yoo[1]; [1]Los Alamos National Laboratory, United States; [2]Kangwon National University, Korea (the Republic of)

Van der Waals (vdW) epitaxy has been studied as a promising materials preparation method which can overcome materials compatibility. Atomically thin two-dimensional (2D) materials serve as substrates of other low-dimensional and three-dimensional (3D) materials growth to provide surface dangling bonds-free surface, a prerequisite of vdW epitaxy. However, direct utilization of a 2D material as a substrate brings the issue of poor nucleation efficiency due to small number of nucleation sites where dangling bonds used to be. The nucleation efficiency issue has been resolved by dipole engineering method, which was developed by the presenter's team. The dipole engineering technique is based on increase in surface energy of a 2D material by transfer of the 2D material on a bulk or a thin film on which polarization is formed along the out-of-plane direction. To induce the required out-of-plane dipole moment, applying electrical bias or transfer of a 2D material onto a ferroelectric material has been utilized. However, the demonstrated techniques of dipole engineering have not been suitable for recycling the substrates due to changes of the substrates' characteristics under vdW epitaxy conditions. In the presentation, we will discuss a robust and recyclable dipole engineering based on refractory metallic-dielectric multilayers in which inherent out-of-plane dipole moments are formed. We transferred monolayer graphene onto the multilayer substrate. Then, crystalline germanium growth via chemical vapor deposition was successfully demonstrated.

12:00 PM EQ02.11.05
Remote Epitaxy of III-V Materials Using Hydride Vapor Phase Epitaxy Dennice M. Roberts[1], Elisabeth McClure[1], Hyunseok Kim[2], Kevin Schulte[1], Aaron Ptak[1], Jeehwan Kim[2] and John Simon[1]; [1]National Renewable Energy Laboratory, United States; [2]Massachusetts Institute of Technology, United States

The promise of remote epitaxy, in which epitaxial registry of a film can be maintained through two-dimensional layers, has emerged from an advanced understanding of the interactions between two dimensional materials and bulk semiconductors.[1] A promising application of this technology is to facilitate substrate reuse in epitaxial III-V systems, which could significantly reduce material cost and improve commercial viability of this high-efficiency photovoltaic technology. In this process the weak van der Waal bonds between the 2D layer and the III-V substrate make separation of epitaxially-grown layers simple and leaves a smooth substrate that can be reused for cost reduction.

Here we present a study of growth of GaAs on AlGaAs through a low dimensional carbon interlayer via hydride vapor phase epitaxy (HVPE). We Investigate the effect of various GaAs nucleation conditions such as V/III ratio, temperature and growth rate on film roughness, crystallinity, and degree of epitaxial alignment. We demonstrate growth of single crystal GaAs layer on top of the low dimensional carbon that follow the crystal orientation of the substrate. Surface roughness measured via AFM found that lower V/III ratios result in smoother III-V films grown on the low dimensional carbon, with a lowest RMS of ~60 nm obtained at a V/III ratio of 5. Growth temperatures are optimized at 650 °C, as temperatures below 550 °C show non-crystalline growth and higher temperature samples display very rough surfaces.

Additionally, we investigate HVPE growth on various forms of low-dimensional carbon including transferred graphene, CVD-grown graphene, and MOCVD-growth amorphous carbon and find the latter to be most well suited for III-V growth as this method results in cleaner interface and potential for direct, large-area coverage. We also identify techniques to mitigate surface degradation in carbon layers as a function of both exposure time and growth environment by analyzing surface changes via x-ray reflectivity. We show growth of heteroepitaxial III-V solar cells on carbon interlayers and preliminary cell results, which are currently limited to 4% efficiency under one sun.

[1] Y. Kim, S. Cruz, K. Lee, B. Alawode, C. Choi, Y. Song, J. Johnsen *et al.* Remote epitaxy through graphene enables two-dimensional material-based layer transfer. *Nature* **544** 340-343 (2017).

12:15 PM EQ02.11.06
Toward Large Terraces Underneath Monolayer Graphene Grown by 4H-SiC (0001) Sublimation Haitham Hrich[1], Matthieu Moret[1], Olivier Briot[1], Matthieu Paillet[1], Jean-Manuel Decams[2], Sylvie Contreras[1] and Périne Landois[1]; [1]Laboratoire Charles Coulomb, UMR 5221, France; [2]Annealsys, France

Our group has recently optimized a reproducible and controlled growth process of a monolayer graphene on silicon carbide (SiC, (0001)) at low Argon (Ar) pressure (10mbar). We highlight that such process is compatible with electronic applications hence no transfer is needed. The graphene samples obtained using this process have a mobility up to 2000 cm2V-1 s -1, at room temperature, which corresponds to the state of the art on similar substrates. One way to enhance the graphene's mobility is to reduce SiC steps density. These steps with different surface energies have different step velocities and therefore the steps are preferable to be bunched together aiming to minimize the total surface energy during the thermal treatment. This step bunching often occurs during epitaxial growth of graphene on SiC. The height and width of the steps depend on various factors, such as, polytype of SiC, miscut angle and growth conditions. First of all, the miscut angles in our SiC substrates have been measured using a combined optical alignment and X-ray diffraction method. This method, which is unusual for SiC substrates, allowed us to reveal cut-off angles inferior to 0.07° for our SiC wafers. This result led us to not take into account the effect of the miscut angle in our process and mainley foccus on the growth parameters. In this study, we have investigated both the etching of 4H-SiC (0001) by H2 (dihydrogen) and the occurrence of GSB (giant step bunching) in Ar-H2 mix gases system at low pressure. The steps width after our classical process, under Ar environment, is typically lower than 2 µm. The first results showed that the surface of the SiC samples annealed under Ar-H2 environment has a homogeneous distribution of well-aligned steps with terraces width up to 20 µm. A clear effect of H2 on steps formation is evidenced. However, the samples obtained had no graphene on top. Adding an isotherm of 900 s at 1500°C, and stopping the H2 right after, led to the growth of graphene on large steps, with an average steps width of 11 µm. Both optical microscopy and atomic force microscope were used to characterize the surface morphology and steps width. The presence of graphene was investigated using Raman maps. The number of graphene layers were estimated using the ratio of the integrated intensity of the G band of graphene on the integrated intensity of the G band of a highly oriented pyrolytic graphite (HOPG) used as reference ($A_{G\text{-}Gr}/A_{G\text{-}HOPG}$). Raman maps demonstrate that our samples are mostly covered with 1LG (up to 70% of the surface).

SESSION EQ02.12: Physics and Devices of Mixed Dimensional Heterostructures IV
Session Chairs: Sanghoon Bae and Jinkyoung Yoo
Monday Afternoon, December 6, 2021
EQ02-Virtual

1:00 PM EQ02.12.01
Interfacial Properties of a $NbSe_2$/ZnO Heterostructure to Form Ohmic Contact Yeonhoo Kim[1], Roxanne Tutchton[1], Ren Liu[2], Sergiy Krylyuk[3], Jianxin Zhu[1], Albert Davydov[3], Young Joon Hong[4] and Jinkyoung Yoo[1]; [1]Los Alamos National Laboratory, United States; [2]University of California, San Diego, United States; [3]National Institute of Standards and Technology, United States; [4]Sejong University, Korea (the Republic of)

Metal/semiconductor interfaces are essential to build devices for fabrication of electrical contacts. However, Schottky-Mott physics, a fundamental principle governing metal/semiconductor interfaces, is not applicable to metal/semiconductor interface in devices due to Fermi level pinning, affected by processings. Two-dimensional (2D) materials as contacts for semiconductor devices have attracted great attention due to minimizing Fermi level pinning. Schottky–Mott physics has widely employed to design 2D material-based electrodes and to elucidate the contact behavior. Nevertheless, the interface between 2D and three-dimensional (3D) semiconducting materials cannot be fully understood by Schottky-Mott physics. Charge transfer and interlayer coupling have been reported in various 2D/3D heterostructure. The phenomena also affect metal/semiconductor interface. In the presentation, we performed an integrated study of theoretical prediction and experimental observation of the electrical properties of the heterostructure composed of metallic $NbSe_2$ and semiconducting ZnO. The density function theory (DFT) calculations predicted that charge transfer between ZnO and $NbSe_2$ lowers barrier height at the heterojunction and conductive surface states of ZnO provides conduction channel in the ZnO/$NbSe_2$ heterostructures. Crystalline ZnO/$NbSe_2$ heterostructures were prepared by hydrothermal method. The surface characteristics of NbSe2 were investigated by X-ray photoelectron spectroscopy. Electrical characterizations of the ZnO/$NbSe_2$ heterostructures showed Ohmic-like behavior as predicted by the DFTcalculations, opposed to the prediction based on Schottky–Mott model.

1:15 PM EQ02.12.03
Composition and Strain Dependence of Phase Separation and Sn Surface Segregation in Ge/$Ge_{1-x}Sn_x$ Co-Axial Heterostructures Michael Braun[1], John Lentz[1], Ishaa Bishnoi[1], Andrew C. Meng[2] and Paul McIntyre[1]; [1]Stanford University, United States; [2]University of Pennsylvania, United States

There has been significant interest in germanium-tin (GeSn) as a promising silicon-compatible group IV direct bandgap material for electronics and photonics. However, the maximum tin solubility in bulk GeSn solid solutions is only ~1 at% tin compared to the >10 at% tin compositions required for a direct bandgap material.[1] The metastability of high tin content GeSn limits the thermal processing window for film deposition and post-growth annealing of epitaxial layers.[2, 3] Previous reports on annealing results of strained germanium-tin epitaxial layers have shown undesirable surface segregation of tin. We report X-ray photoelectron spectroscopy results from *in-situ* and *ex-situ* annealing of core/shell Ge/$Ge_{1-x}Sn_x$ nanowire assemblies. Previously, we have shown the elastic compliance of small diameter Ge core nanowires in the core/shell structure produce largely strain-free $Ge_{1-x}Sn_x$ epilayers.[4] Utilizing the variable strain control of this geometry, we investigate the annealing characteristics of the GeSn surface and native oxide for tin contents in the range of 2 at% - 12 at% in both air-exposed and oxide-free nanowires. For oxidized samples, we show the presence of a tin-rich oxide that exhibits a composition dependent temperature for thermal decomposition via *in-situ* annealing. By varying the shell thickness, we control the compressive strain in the shell enabling examination of phase separation behavior of the oxide-free, as-grown GeSn surface via *ex-situ* rapid thermal annealing and air-free transfer. Additionally, we have examined the annealing effects on bulk tin distribution and local surface structure via photoluminescence, X-ray diffraction, and high resolution transmission electron microscopy.

1:30 PM EQ02.12.04
Hetero-Structures of Perovskite and 2D Materials Gokul M. A and Atikur Rahman; IISER Pune, India

Perovskite materials and 2D materials are 2 promising materials for future optoelectronic applications. Perovskite materials are having great optoelectronic properties such as high PL quantum yield, great absorption coefficient, easy synthesis at relatively low temperatures, tunable bandgap, high carrier mobilities to name a few. These properties make them shine in device applications like photovoltaics and LEDs. 2D materials on the other hand offer an arsenal of materials with interesting optoelectronic properties. Their bandgap range from metallic to insulator. With emerging properties in the monolayer regime, which sets them apart from their bulk counterparts, they offer a rich field of study.
Here in this work, we focus on synthesizing these materials and making heterostructures out of these two classes of materials. We then explore their optoelectronic properties.

Late News: Enhanced Photodetector with Low Dark Current Based on 2D n-MoS2 Functionalized by p-MnO Quantum Dots Yusin Pak, Somak Mitra, Bin Xin and Iman S. Roqan; King Abdullah University of Science and Technology, Saudi Arabia

Incorporating a heterojunction architecture into photodetectors can significantly improve the photodetection characteristics. To construct a heterojunction with the nanostructured compound semiconductor materials (CSMs), a two-dimensional (2D) platform material for stably transferring photogenerated signals into circuitry is essential. In this work, p-type manganese oxide quantum dots (MnO QDs) with zero-dimension (0D) are synthesized through femtosecond laser ablation in liquid (FLAL). An exfoliated 2D molybdenum disulfide (2D-MoS_2) is used for the counterpart platform of the heterojunction. The ablated MnO QDs with a mean diameter of 4.9 nm were uniformly spray-coated onto the 2D-MoS_2. The p-n junction device based on p-MnO QDs functionalized 2D n-MoS_2 shows a reduced dark current and an increased photocurrent compared to that of pristine 2D-MoS_2 devices due to the p-n heterojunction effect. This report will greatly contribute to developing low-cost and high-performance optoelectronic devices based on heterojunctions between other TMDCs and nanostructured CSMs.

Selective Synthesis of Tunable TMD-COF Heterostructures Lucas K. Beagle[1,2], Ly D. Tran[1,2], Luke A. Baldwin[1] and Nicholas Glavin[1]; [1]Air Force Research Laboratory, United States; [2]UES, Inc., United States

Chemical and biological sensing using 2-D nanomaterials has been an area of intense investigation including inorganic materials that exhibit high sensitivity, however it has been limited as a field due to the lack of selectivity among analytes. While 2D inorganic materials, such as transition metal dichalcogenides (TMD), can readily decipher between donor/acceptor groups, strategies to incorporate selectivity in these devices is often challenging. Organic 2D materials known as covalent organic frameworks (COF) are large porous and repeated organic frameworks which have been shown to act as selectivity agents due to functionalization and porosity. This research focuses on the association of COFs with 2-D nanomaterials using top-down microwave-assisted activation of TMDs and deposition of COF nanoparticles. Several known TMD and COF species have been examined to understand the fundamental surface interactions between 2-D nanomaterials and few layer COFs, while Kinetics and mechanistic studies were used to determine the manner of association of the inorganic and organic substrates. Photoluminescence studies demonstrate a microwave power dependent electronic coupling of the inorganic and organic materials for a fully tunable interaction.

2:15 PM EQ02.06.02
Terahertz Dynamics of Correlated Quasiparticles in Moiré Superlattices Chenyi Xia[1], Jun Xiao[1], Fang Liu[1], Leo Yu[1], Christian Heide[1], Yuki Kobayashi[1], Burak Guzelturk[2], Eric Ma[1], Tony F. Heinz[1], Xiaoyang Zhu[3] and Aaron Lindenberg[1]; [1]Stanford University, United States; [2]Argonne National Laboratory, United States; [3]Columbia University, United States

Emerging twisted heterostructures based on 2D layered materials have opened a unique platform to explore exotic correlation physics and engineer Coulomb interactions in the atomically thin limit. The tunable Moiré potentials, arising from interlayer couplings, result in the emergence of various novel orderings such as Mott insulating phases, unconventional superconductivity, and Moiré excitonic phases. In particular, transition metal dichalcogenide heterostructures allow for optically-excited electrons and holes to reside in different monolayers and for trapping in the tens-of-meV Moiré potential, which is quite favorable for developing valleytronics, exciton condensation, and programmable quantum emitter arrays. Further progress along this direction requires a precise understanding of the formation of these Moiré excitons, and how such formation can be engineered by Moiré potentials and electron correlations.
Here we use ultrafast terahertz emission spectroscopy to probe interlayer charge transfer and other quasiparticle dynamics in several types of Moiré superlattices based on the transition metal dichalcogenides. With ultrafast visible and near-infrared laser pumping of these distinct Moiré superlattices, we observed nontrivial variations in the THz emission dynamics and spectroscopy as a function of twist angle. Experiments indicate such changes are closely associated with varying Moiré patterns and momentum mismatch conditions. Our findings advance our microscopic understanding of the formation, dissociation and manipulation of excitonic correlations in twisted heterostructures.

SESSION EQ02.13: Poster Session II
Session Chairs: Hyunseong Kum and Feng Miao
Monday Afternoon, December 6, 2021

9:00 PM EQ02.13.01
Synthesis of Epitaxial Pentasodium Trioxoundecafluoro-Trititanate with Plate-Like Morphology on Fluorine-Doped Tin Oxide Coated Glass Substrates Crispin M. Mbulanga[1], Rudolph Erasmus[2], Olivier Jaco[1], Christian Chinedu Ahia[3], Edson Meyer[3] and Johannes R. Botha[1]; [1]Nelson Mandela University, South Africa; [2]University of the Witwatersrand, Johannesburg, South Africa; [3]University of Fort Hare, South Africa

A route for synthesis of epitaxial pentasodium trioxoundecafluoro-trititanate ($Na_5(Ti_3O_3F_{11})$) with plate-like morphology on fluorine-doped tin oxide coated glass substrates (FTO- glass) through the hydrothermal bath method is described and discussed, followed by the presentation of a systematic study of the physical properties of the samples. The samples are textured with a small amount of micron sized crystals existing among predominantly plate like structures of $Na_5(Ti_3O_3F_{11})$. These structures are attached to the F:SnO_2 (FTO) layer due to their nucleation and growth on the substrate surface during the hydrothermal process. The preferred orientation of the crystal planes of $Na_5(Ti_3O_3F_{11})$ plates are with the (331), (222) and (440) parallel to the substrate. Additionally, an epitaxial relationship between the fluorine doped SnO_2 layer and plate-like ($Na_5(Ti_3O_3F_{11})$) exists: an alignment of planes along (111). Last of all, a set of unidentified vibrational Raman modes recorded from $Na_5(Ti_3O_3F_{11})$ plates grown on fluorine-doped tin oxide is presented. It is found that in the temperature ranging from 27 to -193 ^oC, $Na_5(Ti_3O_3F_{11})$ vibrational Raman modes peak at: 118.1 cm^{-1}, 150.9 cm^{-1}, 191.0 cm^{-1}, 237.4 cm^{-1}, 439.5 cm^{-1}, 527.1 cm^{-1}, 642.8 cm^{-1}, 687.9 cm^{-1}, 742.6 cm^{-1} and 943.5 cm^{-1}. Raman shifts at 527.1 cm^{-1}, 687.9 cm^{-1}, 439.5 cm^{-1}, and 943.5 cm^{-1} are assigned to A_g, B_{1g}, B_{2g}, and B_{3g} modes, respectively.

9:05 PM EQ02.13.02
Factors Affecting the Magnetic Properties and Reversal Process of Magnetic Nanowires Yicong Chen and Bethanie J. Stadler; University of Minnesota Twin Cities, United States

Magnetic nanowires (MNWs) are increasingly important for applications in memory, biolabels, and nanowarming of cryopreserved organs. Object Oriented Micromagnetic Framework (OOMMF) was used to visualize moments inside MNWs. The magnetic properties of MNWs, such as coercivity, remanence, and reversal mechanism were investigated as a function of nanowire shape. Experimental measurements of magnetic nanowires (MNW) often reveal features that are difficult to explain due to statistical shearing of features and interaction fields in large arrays. Measurements of individual nanowires can be used to remove interaction field effects, and other measurements such as first-order reversal curves (FORC) and the projection method often attempt to statistically separate bulk effects. For nickel MNWs with fixed length of 3 μm, the coercivity and the remanence are negatively correlated to the diameter of the wire. This is in consistent with the theory that expresses the coercivity field of the infinite long cylinder as: $h_{ci}=1.08D_0^2/D^2$, $D_0=2A^{0.5}/M_s$, where h_{ci} is the reduced coercivity field of the cylinder with high aspect ratio, D_0 is the fundamental unit length defined by the exchange constant A and saturation magnetization M_s of the material (Ni in this case) used to make MNWs.
When the diameter is increased to 200 nm, in addition to a continued reduction in coercivity and remanence, a ‘wasp waist’ appeared in the hysteresis loop. The reversal can be divided into three different parts showing three types of magnetic moment behaviors in the MNW. In the first part, since there is a large area for curling in 200nm-diameter nanowires, the magnetic moments at the tips of the MNW fall from pointing along z-axis to aligning in the xy-plane and in the form of vortex. Next, when the external field is further reduced, the outer shell of moments turns from in-plane to the negative z-axis. Finally, the axial core of the MNW switches to the negative z-axis and the wire is fully saturated in the negative z-direction. Interestingly, at H_c (M = 0), the two vortex walls converged in the center of the MNW, and a three-dimensional vortex(hedgehog) was observed.

Next, with all other parameters unchanged, flat-tipped cylinders were replaced with ellipsoids so that the tips of wire had infinitesimally small areas where vortex was no longer supported. With this shape, the coercivity of the nanowires significantly increased to Hc = 180, 160, 50, 11 mT from 140, 90, 30, 5 mT for the MNWs with 30, 50, 100, 200nm diameters, respectively. This increase in coercivity occurs because the field to nucleate a vortex at the tips is lower than to nucleate vortex in the center of the wire which is the case for ellipsoidal MNWs. For these ellipses, increasingly negative applied fields cause the vortex to expand to include the coherent curling of the whole nanowire.
In conclusion, the coercivity of the nanowire depends on the geometry of the wire in two ways. First, with the length of the wire fixed, the coercivity is reduced by increasing the diameter of the wire. Second, when the tip of the wire is engineered so that the nanowires are ellipsoidal rather than cylindrical, the coercivity is increased and the moment switching begins at the center of the wire instead of the end.

9:10 PM EQ02.13.03
Freestanding Relaxor Ferroelectric BCZT Membranes via Epitaxial Lift-Off Huandong Chen, Yang Liu, Mythili Surendran, Harish Kumarasubramanian and Jayakanth Ravichandran; University of Southern California, United States

$(Ba_{0.85}Ca_{0.15})$ $(Zr_{0.1}Ti_{0.9})$ O_3 (referred as BCZT), a solid solution of $BaTiO_3$, is a novel lead-free ferroelectric relaxor that possesses a high dielectric constant, large piezoelectric coefficient as well strong electro-optic coupling. High quality BCZT thin films have been successfully synthesized by various techniques, including the epitaxial growth using pulsed laser deposition (PLD) recently by our group. However, the requirement of lattice matching to substrates and the extremely high material growth temperature (up to 800°C) are extensively limiting the practical applications in Si-based electronics integrations, as well as the emerging flexible or stretchable devices that usually use polymer as supporting substrates. Here, we report the synthesis and transfer of freestanding defect-free ferroelectric BCZT membranes via epitaxial lift off from growth substrates using LSMO as sacrificial layer. Ferroelectric and piezoelectric properties of transferred film are comparable to the as-grown epitaxial BCZT film. Furthermore, 10×10 SRO/BCZT/SRO capacitor array were fabricated using wet chemical etching method and further transferred onto alien substrate as a demonstration of potential device application. Our work paves the way of integrating single-crystalline relaxor ferroelectric oxides for on-chip electronic or energy storage applications.

9:15 PM EQ02.13.04
Quasi-2D Polyamides Reinforced with 1D Nanotubes and Nanofibers for Novel Desalination Membranes Rodolfo Cruz-Silva, Hiroyuki Matsuda, Aaron Morelos-Gomez, Juan-Luis Fajardo-Diaz, Kazunori Fujisawa, Hiroyuki Muramatsu, Kenji Takeuchi, Takuya Hayashi and Morinobu Endo; Shinshu University, Japan

Crosslinked polyamides are a diverse and important group of polymers with many applications in the membrane and desalination fields. These polymers are usually synthesized by interfacial polymerization and supported over a porous polymer support that provide mechanical stability. In the last years, considerable effort has been put to make thinner and stronger polyamide films that can have higher water permeability yet mechanical robustness. The combination of thin films with one-dimensional (1D) reinforcing structures is an effective path to combine the functionality of the film with the structural stability provided by the 1D material. Indeed, this type of structures are so efficient that have resulted from evolution in many living creatures, and can be seen, for example, in insect wings and plant leaves. However, taking this design to the nanoscale poses great challenges. Ultrathin polymer films, sometimes referred as quasi two-dimensional (2D) materials, often show processing problems such as dewetting, phase separation, and creeping, among others. Nevertheless, the study of these materials has recently gained momentum. Here, we used tempo-oxidized cellulose nanofibers (CNFs) and double walled carbon nanotubes (DWCNTs) to synthesize thin and ultrathin (<30 nm) crosslinked -piperazine and phenylendiamine based polyamides films by interfacial polymerization. Tempo-oxidized CNFs are high-modulus water-dispersible colloids. They are biodegradable and its synthesis is environmentally friendly. On the other hand, DWCNTs are a superhigh modulus material that might have interesting transport properties due to their hydrophobic hollow core. We carried out liquid-liquid interfacial polymerizations to prepare sheet like quasi 2D polymer sheets reinforced with CNF, DWCNT and their combination. The mechanism of the interfacial polymerization in presence of the nanomaterials was also studied by using different methodologies to add the monomers. We use several techniques such as quartz-crystal microbalance, transmission and scanning electron microscopy to study how hydrophobic and hydrophilic 1D materials can be efficiently incorporated into interfacially synthesized polymer films. The location of the 1D materials across the films was also studied by X-ray photoelectron spectroscopy. The chemical interactions responsible for wetting, interfacial adhesion, and phase separation between the monomers and the 1D materials were studied at the atomic level through classical molecular dynamics. Understanding the incorporation of 1D materials and quasi 2D polymer films and the behavior of the resulting nanocomposite films is important to design new ultrathin nanocomposite polymers that might have applications for the next generation of separation membranes.

9:20 PM EQ02.13.05
Effect of Crystal Structure and Niobium Doping on $TiO_2/SrTiO_3$ Heterostructured Nanorod Arrays Takaki Kimura, Kan Hachiya and Takashi Sagawa; Kyoto University, Japan

$TiO_2/SrTiO_3$ heterostructured nanorod arrays have been attracted much attention in photovoltaic and/or photoelectrochemical (PEC) applications such as dye-sensitized solar cells (DSSCs) and PEC cells due to its unique feature of oriented 1D structure and heterostructure. In this context, we designed anatase $TiO_2/SrTiO_3$ heterostructured nanorod arrays grown on transparent conductive fluorine-doped tin oxide (FTO) substrate and the comparison of the characteristic properties with those of typical rutile $TiO_2/SrTiO_3$ heterostructured nanorod arrays. Furthermore, novel niobium doped $TiO_2/SrTiO_3$ heterostructured nanorod arrays were also synthesized to investigate the compensation for the low conductivity of TiO_2 and $SrTiO_3$ themselves.
$TiO_2/SrTiO_3$ heterostructured nanorod arrays were synthesized by two-step hydrothermal reaction. Oriented 1D structure is formed by the growth of anatase or rutile TiO_2 nanorod arrays on FTO substrate directly during the first hydrothermal reaction, and $TiO_2/SrTiO_3$ heterostructure is constructed by a dissolution-precipitation process on TiO_2 nanorod arrays through the second hydrothermal reaction by changing the reaction conditions such as reaction temperature, reaction time, the initial concentration of the starting materials, and basicity of the reaction mixture. As the typical method, the obtained crystal structure of TiO_2 nanorod arrays is mainly rutile phase, which is the most stable phase among the natural phases of TiO_2. Formation of rutile phase of TiO_2 sometimes restricts the formation of $SrTiO_3$ due to the higher chemical stability of the rutile TiO_2. The morphologies and chemical components of $TiO_2/SrTiO_3$ heterostructured nanorod arrays were characterized by the measurements of X-ray diffraction (XRD), scanning electron microscopy (SEM), transmission electron microscopy (TEM), energy dispersive X-ray (EDX) spectroscopy, X-ray photoelectron spectroscopy (XPS), and ultraviolet-visible (UV-vis) spectroscopy. The amount of strontium captured in anatase TiO_2 lattice was larger than that of strontium captured in rutile TiO_2 lattice. The extent of the increment of the average diameter of the nanorod before and after the second hydrothermal reaction was also different between the two crystal phases of TiO_2. It is suggested that better dissolution of anatase TiO_2 resulted in the larger amount of participation of $SrTiO_3$ and increase of the nanorod diameter effectively.
Niobium doping to $TiO_2/SrTiO_3$ heterostructured nanorod arrays was conducted by the Sr^{2+} insertion into the Nb-doped TiO_2 nanorod arrays. The existence of niobium was confirmed by XPS and scanning transmission electron microscopy (STEM) measurements. We will report the further regulation and optimization for formation of Nb-doped $TiO_2/SrTiO_3$ heterostructured nanorod arrays by changing the preparation conditions and crystal structures of TiO_2 in terms of the improvement of the conductivity.

9:25 PM EQ02.13.06
Nonlinear Optical Properties of Doped SiGe/Si/SiO_2 Core/Shell Quantum Dot Under Applied Electric Field Mohamed Kria[1], Varsha Yadav[2], V. Prasad[2], Kamal Lakaal[1], J. El Hamdaoui[1], A. El Aouami[1], L. M. Pérez[3], El Mustapha Feddi[1] and Gen Long[4]; [1]Mohammed V University in Rabat, Morocco; [2]University of Delhi, India; [3]Universidad de Tarapacá, Chile; [4]Saint John's University, United States

This work reports a theoretical study of the nonlinear optical and electronic properties in oblate core/shell quantum dots SiGe in the presence of a donor impurity under electric and magnetic field. Our computations were carried out within the effective mass approximations. For the numerical solution of the resulting 3D partial differential equation (PDE) via finite element method. A detailed study of the donor binding energies as a function of the external electric and magnetic fields, the dipole matrix elements for impurity related inter-level optical transitions as a function of the electric and magnetic fields and impurity position, the absorption coefficient, second (SHG) and third harmonic generation (THG). Our results show that the electric and magnetic fields have significant influences on the ground binding energies and the absorption coefficient, second (SHG) and third harmonic generation (THG). The effect caused by electric and magnetic fields and on-center of shell donor impurities, ostensibly enrich the nonlinear and electronic properties of the system.

9:30 PM EQ02.13.07
Effect of Growth Temperature on Alignment of GaN Growth Islands on Graphene/r-Plane Sapphire Substrate Kazuki Niwa, Masami Nonogaki, Yukito Kato, Yasuhiro Fukunishi, Takahiro Maruyama and Shigeya Naritsuka; Meijo University, Japan

The state-of-the-art epitaxial growth technique of group III nitride semiconductors can offer a wide range of the applications, such as light emitting diodes, laser diodes, and high-frequency power devices. Devices usually fabricated on the polar c-plane GaN. Therefore, the optical devices fabricated on the plane show inferior performances from the Stark effect. On the other hand, a-plane GaN, which is non-polar plane, will have advantage on the production of superior optical devices. A-plane GaN is usually grown on an r-plane sapphire, although the density of threading-dislocations is still very high. Remoteepitaxy [1] is newly proposed growth method, where growth is performed on graphene-coated substrate. The technique is expected to mitigate the lattice mismatch and the thermal stress produced from the difference between the growth layer and the substrate. A high-quality a-plane GaN crystal is expected to be grown by the method. The grown layer can also be peeled off from the substrate and suitable to make flexible devices. In addition, the reuse of the substrate is possible, which may lead to the sustainable development goals. In this study, we attempt a hetero remoteepitaxy to grow a-plane GaN on graphene/r-plane sapphire. The effect of growth temperature on the crystal alignment of GaN is especially focused on to study.
Single-layer graphene was synthesized on an r-plane sapphire substrate using low-pressure CVD [2]. GaN layer was grown using a radio frequency molecular beam epitaxy directly on the graphene-covered sapphire substrate using hetero remoteepitaxy. The nitrogen flow rate, RF plasma power, Ga equivalent pressure, and growth time were fixed at 2.0 sccm, 450 W, 4.0×10^{-7} torr, and 10 min while the substrate temperature was changed between 630 and 700 °C. The shape of GaN growth islands was investigated using atomic force microscopy.
C-plane GaN islands with hexagonal shape were observed on the sample grown at 630 °C. On the other hand, c-plane GaN islands decreased with the growth temperature and disappeared on the sample grown at 675 °C, and a-plane GaN islands generated instead of them. The crystal orientation of the a-plane GaN islands was found to be aligned to a certain direction from their rectangular shapes. Surprisingly, two-dimensional nuclei of GaN also started to generate on the sample grown at 700 ° C. A thin GaN layer was also successfully grown whose thickness was as thin as 20nm in the condition. Namely, the hetero remoteepitaxy was succeeded above 675 °C because the crystal orientation of the rectangular a-plane islands aliened to a certain direction. On the other hand, the hexagonal c-plane islands didn't align at 630 °C. One of the possible reasons of the success is the change of the gap between graphene and the substrate. The gap may be shorten by the removal of some atoms, such as oxygen or hydrogen, from the surface of the sapphire during the thermal treatment. In conclusion, the growth temperature was found as a very important parameter for a-plane GaN remoteepitaxy, and even two-dimensional nucleation was successfully obtained at 700 °C.

WITHDRAWN 12/7/2021 EQ02.13.08 Late News: Structural and Electrical Properties of CNT/Cu Heterostructure—Future Electrical Wires Shivani Dhall[1] and S.k Tripathi[2]; [1]DAV College, Jalandhar, India; [2]Panjab University, India

The structural and electrical properties of carbon nanotubes (CNTs) and Copper (Cu) based nanostructure is presented keeping in mind their applications today and in the near future. CNTs are emerging as the most promising conducting wires in interconnection technology due to their higher electrical conductivity and extraordinary current-carrying capacity. Increased portability, versatility and ubiquity of electronics devices are a result of their progressive miniaturization, requiring current flow through narrow channels. Nowadays, devices operate close to the maximum current-carrying-capacity of conductors (such as copper and gold), leading to decreased lifetime and performance, creating demand for new conductors with higher ampacity. Therefore, researchers exploring electrical properties of CNTs/Cu composites by changing the concentrations of Cu content and vice versa. CNTs/Cu composites shows high conductivity and ampacity, making it uniquely suited for applications in microscale electronics and inverters.

9:40 PM EQ02.13.09
Effects of Graphene Layers in MoS_2/Graphene Heterostructure Ensemble Prepared by Dry Transfer Method for Optoelectronic Devices Sanju Gupta; University of Central Florida, United States

Two-dimensional layered materials that harvest or transduce light energy are of paramount interest. In this context, two-dimensional transition metal dichalcogenides such as molybdenum disulfide (MoS_2) are attractive for harnessing optoelectronics. In this work, we report the integration of MoS_2 with a strong electron accepting graphene yielding novel MoS_2 (1-2L)/graphene (1-2L) heterostructure ensemble by facile and efficient dry transfer method. We also found additional hetero-interfaces due to folded flakes such as MoS_2/MoS_2/graphene and MoS_2/MoS_2/Au hetero-interfaces. We characterized the heterointerfaces using correlated micro-Raman spectroscopy, photoluminescence (PL) spectroscopy, atomic force microscopy, Kelvin probe microscopy and conducting AFM, tip-enhanced Raman spectroscopy (TERS), and tip-enhanced photoluminescence (TEPL) techniques to gain insights into the structural quality, hetero-interfaces, and excitonic effects to elucidate the role of a number of graphene layers which are crucial in modulating the light emission. We studied the charge transfer in these vertical heterostructures unraveling the interlayer electronic coupling. We demonstrate strong evidence that the excitonic properties of MoS_2 are most effective for two layers of graphene layers underneath leading to a significant enhancement of the PL response as compared to MoS_2 supported on one-layer graphene and directly on the gold-coated substrate. We observed a marginal increase in work function with increasing MoS_2 layer as anticipated and for heterointerfaces which are indicative of electron injection. We measured C-AFM without light (dark) and with light in view of photoconducting properties of heterointerfaces and found a rectifying behavior with an apparent increase in current by almost twice for MoS_2/graphene heterostructures in contrast to MoS_2/Au which shows ohmic behavior. Our findings signify the importance of substrate engineering when constructing 2D multilayered architectures for harvesting or storing light energy. This work is financially supported in parts by NSF and NSF-MRI Grants.

Late News: Controlling Exciton Transport in 1D PbI2—2D MoSe2 van der Waals Heterostructure Naechul Shin; Inha University, Korea (the Republic of)

Van der Waals (vdW) heterostructures composed of two-dimensional (2D) semiconducting material stacks have garnered significant attention owing to their unique optoelectronic properties compared with their single constituent counterparts. Especially, heterostructure devices composed of 2D semiconductors of which the interfacial exciton transport is controllable hold great potential in photonic and optoelectronic applications. Here, we report vdW heterostructures made of PbI_2 and $MoSe_2$ and demonstrate that the local exciton distribution can be controlled by modulating the vdW interface between them. PbI_2 vdW layers are prepared in one-dimensional (1D) morphologies with discrete stacking orientations and transferred onto the 2D $MoSe_2$ layers grown via the chemical vapor deposition (CVD) method. Specifically, the vapor-liquid-solid (VLS) method was employed to grow 1D PbI_2 vdW nanostructures in two different layer stacking orientations (*i.e.*, [001] and [010]) and layer stackings (perpendicular vs. parallel to the wire axis). Upon the transfer onto $MoSe_2$, we confirm that the exciton transfer between the two materials is strongly dependent on the interlayer configurations (*i.e.*, layer-to-layer vs. edge-to-layer). Strong exciton binding energy of PbI_2 enables the transport of excitons along with the PbI_2 domain via waveguide effect and localized radiative recombination according to the interface with the $MoSe_2$ domain. Our results provide important insights into the engineering of vdW heterostructure interfaces and develop a new design rule of ultrathin optoelectronic devices.

From 3D to 2D—Understanding the Extraorinary Properties of "Traditional Materials" at the Atomic Limit Joshua A. Robinson; The Pennsylvania State University, United States

The last decade has seen an exponential growth in the science and technology of two-dimensional materials. Beyond graphene, there is a huge variety of layered materials that range in properties from insulating to superconducting that can be grown over large scales for a variety of electronic devices and quantum technologies, such as topological quantum computing, quantum sensing, and neuromorphic computing. Over the last few years, we have focused on understanding what happens to traditional bulk metals (Ga, In, Ag, Au, etc.) when they are reduced to to only a few atoms thick. In this talk, I will discuss recent breakthroughs in the realization of unique 2D forms of these traditional 3D metals. I will discuss a novel synthesis method, dubbed confinement heteroepitaxy (CHet), that utilizes graphene to enable the creation of atomically thin metals, enabling a new platform for creating artificial quantum lattices consisting of 2D and 3D materials, with atomically sharp interfaces and designed properties. By shrinking these traditional metals to atomically thin structures, we find that their properties are completely different than their bulk counterparts, lending themselves to unique quantum and optical applications not possible before.

Mixed-Dimensional van der Waals Heterostructures and Device Applications Berangere Hyot, Colin Paillet, Stéphane Cadot, Julien David-Vifflantzeff, Ligaud Clotilde and Lucie Le Van Jodin; CEA, France

Scientists around the globe are investigating how to integrate distinct 2D materials into van der Waals (vdW) heterostructures. Given that any passivated, dangling bond-free surface will interact with another via vdW forces, the vdW heterostructure concept can be extended to include the integration of 2D materials with non-2D materials. Such combinations of materials would yield vdW heterostructures showing a variety of structural and electronic properties that opening up new avenues for innovative device designs. This presentation will focus on three types of mixed-dimensional vdW heterostuctures. We successfully employed graphene/QDs (2D/0D) and graphene/MoS_2 (2D/2D) in their low dimensional heterostructures to form photodetector devices. Those devices showed novel functional behaviors, which are discussed based on electrical/optical characterizations and possible physical mechanisms. The third mixed-dimensional, 2D/3D, vdW heterostructure will be discussed on the basis on the growth study of (In)GaN on graphene for the preparation of relaxed templates for micro-display applications.

9:00 AM EQ02.14.03
Stability of Graphene Growth on Insulating Substrates in View of Absorption Energy Evaluated by Molecular Dynamics Satoru Kaneko[1,2,3], Takashi Tokumasu[4], Manabu Yasui[2], Masahito Kurouchi[2], Akifumi Matsuda[3], Mamoru Yoshimoto[3], Sumanta Sahoo[1], Kripasindhu Sardar[1], Jyh-Ming Ting[1] and Masahiro Yoshimura[1]; [1]National Cheng Kung University, Taiwan; [2]KISTEC, Japan; [3]Tokyo Institute of Technology, Japan; [4]Tohoku University, Japan

Graphene with “superclean” surface is prepared via selective etching in carbon dioxide (CO2) gas. Gentle etchant carbon dioxide selectively eliminate intrinsic contamination such as amorphous carbon during a post annealing process[1]. Is the etching process required as a post annealing?

We used CO2 as an atmospheric gas during carbon film deposition. Carbon films were prepared in carbon dioxide atmosphere by pulsed laser deposition (PLD) on insulating substrates; strontium titanate (SrTiO), sapphire(Al2O3) and silicon (Si) substrates. Target was a highly oriented pyrolytic graphite (HOPG), and slower Q-siwtched YAG was used for PLD system[2].

Graphene grew only on the STO substrate, and showed clean surface image observed by atomic force microscopy (AFM)[2]. CO2 is a colorless and stable

gas, but CO2 can be a gentle oxidant with reaction with carbon as,

CO2 + C -> 2CO.

As the same as “superclean” surface prepared via selective etching in CO2 atmosphere, assumed carbon cluster etched by CO2 and only graphitic materials reach the substrates. Stability of those cluster on the substrate surface was evaluated by absorption energy between the cluster and substrate surface.

In order to estimate an absorption energy of graphitic materials on insulating substrates, a carbon atom, six membered ring (6-ring), and 6 six membered rings (nano graphene) were placed on SrTiO, silicon and sapphire substrates, and the absorption energy was estimated by using the density functional theory (DFT) with a semi-core pseudopotential. The generalized gradient approximation (GGA) method was used to obtain the electron density. The energy difference for self-consistent field was set at 1.0x10-6 Ha. Crystal structure of each substrates was optimized with periodic condition, and supercell consisting of slab and vacuum layer was used to optimize the top layer of substrate. After optimal surface was prepared on each substrates, supercell with graphitic cluster and slab was optimized, and total energy was estimated on supercell combined cluster and substrate (Etot_combined).

Absorption energy was evaluated to be

Etot_sub + Etot_cluster - Etot_combined,

where Etot_sub and Etot_cluster) were total energy of subs and graphitic cluster, respectively.

The absorption energy of graphene on SrTiO(001) and Si(001) were estimated to be 570 and 550 kJ/mol, respectively. Although graphene grew on SrTiO substrate while DLC related materials on Si(001), there was not much difference in absorption energy between SrTiO and Si substrates. However form of six-ring on each substrates was remarkably different after optimal combined structure. After optimizing combined structure of six ring placed on Si(001), the six ring did not lie on silicon substrate but it stood up vertically on the substrate while a six ring flatly lied on SrTiO substrate. Actually on the silicon substrate, AFM image revealed the growth of nano balls on the surface while graphene grew with “layer by layer growth” on SrTiO substrate. Cluster generated from target HOPG can be etched and graphitic materials reached to the substrate. However film growth was affected by stability of the cluster placed on substrates because graphene grow from graphitic materials such as nano-graphene and six membered ring. Evaluation of variety of combination of carbon materials and substrates is in progress.

Tunable Vertical Schottky Barrier in Hexagonal Boron Nitride Inserted Monolayer Tellurene-Metal Interfaces Sanchali Mitra, Arnab Kabiraj and Santanu Mahapatra; Indian Institute of Science Bangalore, India

Vertically stacked 2D materials heterostructures show potential applications in next-generation nano-electronic devices due to atomic-scale thickness, ultrafast charge transfer, scaling flexibility and precise tuning of atomic band alignment. Tellurene, a recent addition to 2D materials family, has shown promising aspects in nano-devices due to its favorable properties like good ambient stability, high carrier mobility, excellent light absorption, and exceptional thermoelectric performance.[1,2] Atomistic understanding of the electronic properties of tellurene-metal interface is crucial to promote optimal device performance. Pristine monolayer (ML) β tellurene is semiconducting in nature and possesses an indirect bandgap of about 1.27 eV.[3] When monolayer tellurene is interfaced with metals, the bandgap of tellurene completely disappears and it becomes metallic from semiconducting.[4] This phenomena occurs for all metals that are commonly used as electrode materials, restricting the use of tellurene in vertical Schottky barrier devices. In a recent work, we have shown that inserting single layer of graphene between tellurene and metal can preserve the semiconducting nature of tellurene and hence useful to form Schottky barriers.[5]

In this work, utilizing density functional theory (DFT) we have evaluated the effect of inserting monolayer hBN between tellurene and metal. Using four metals (Au, Pd, Ru, Ti) we have shown that inserted hBN layer can also screen the metallization of tellurene and create vertical Schottky barrier. DFT calculations have been carried out using Vienna ab-initio simulation package (VASP) with Projector Augmented Wave (PAW) method and GGA-PBE exchange correlation functional. To create such heterostructures, first the tellurene-hBN interface is formed by aligning the supercells of the two and applying mean strain of 1.1% in both the surfaces. The tellurene-hBN structure is then interfaced with six layers of <111> cleaved surfaces of Au, Pd and <0001> cleaved surfaces of Ru, Ti. The applied strain on Au, Pd, Ru and Ti are 0.34, 3.45, 3.53 and 1.18% respectively. The surface area of the relaxed tellurene-hBN-metal heterostructures 22.6×8.6 $Å^2$, 8.5×23 $Å^2$, 25.7×4.5 $Å^2$ and 8.67×22.96 $Å^2$, respectively. From the projected band structure of tellurene, we found that the band structure of tellurene remains preserved in all the heterostructures, only the energy bands are shifted with respect to Fermi level creating vertical Schottky barriers between tellurene and hBN-metal interface. From Bader charge analysis we found that in Au and Pd-based heterostructures, the charge in tellurene layer is less than that of pristine tellurene, implying depletion of charge. As a result, the valence bands of tellurene shift towards the Femi level. In case of Ru and Ti, charge accumulation takes place in tellurene layer resulting in shifting of conduction bands towards the Fermi level. However, for Pd and Ti, the shifted bands touch the Fermi level, generating Ohmic contact. For Au, p-type Schottky barrier is formed with a height of about 0.2 eV, while for Ru the barrier is n-type with a height of 0.32 eV. In graphene inserted structures, only p-type Schottky barriers are formed for all these metals, the barrier heights change depending on the metal work-function. However, using hBN we can tune the barrier height as well as the type of contact only by changing the electrode materials. This study provides quantum-mechanical insights into the realization of high-performance vertical Schottky devices using monolayer tellurene based heterostructures.

Assembly of Close-Packed Ferroelectric Polymer Nanowires via Interface-Epitaxy with ReS_2 Kun Wang, Dawei Li, Shuo Sun, Zahra Ahmadi, Jeffrey Shield, Stephen Ducharme and Xia Hong; University of Nebraska - Lincoln, United States

Ferroelectric polymers such as poly(vinylidene-fluoride-trifluorethylene) (P(VDF-TrFE)) are promising material candidates for developing flexible wearable nanoelectronics and optoelectronics. For polarization-enabled device functionalities, large-scale fabrication of polymer thin films with high crystallinity and well-controlled polarization direction is highly desirable and remains a central challenge. The widely exploited Langmuir-Blodgett (LB), spin-coating, and electrospinning methods only yield polymorphous or polycrystalline films with compromised net polarization. In this work, we report a highly scalable approach for fabricating P(VDF-TrFE) thin films with high crystalline order and out-of-plane polarization via interface-epitaxy with 1T'-ReS_2 [1]. We deposited 1 - 9 monolayer P(VDF-TrFE) thin films on mechanically exfoliated ReS_2 flakes using the LB technique. Upon controlled thermal annealing, the as-grown LB films crystallize into close-packed (010)-oriented nanowire (P-NW) structure with radii of 10 or 25 nm. The P-NWs are well aligned along the direction perpendicular to the *b*-axis of the interfacial ReS_2 layer. High-resolution transmission electron microscopy studies show that the P-NWs are single crystalline in (001)-orientation and form an epitaxial van der Waals heterointerface with the underlying ReS_2. Piezo-response force microscopy studies confirm the uniform out-of-plane polarization direction of the P-NW films, and reveal nonvolatile polarization switching performance with coercive voltages as low as 0.1 V. Reversing the polarization of the P-NWs can induce a conductance switching ratio of $>10^8$ in a bilayer ReS_2 channel, which is among the highest values reported on P(VDF-TrFE)-gated 2D FETs. We also carried out in-situ atomic force microscopy to image the P-NW formation process. Our study points to an easily scalable approach for achieving wafer-size production of continuous P-NW films and high performance nonvolatile ReS_2 transistors. This work was primarily supported by DOE Award No. DE-SC0016153.

Inter-Valley and Inter-Electronic Transitions in MoS_2-WS_2 Heterostructures Sungjoon Kim[1], Rousan Debbarma[2] and Vikas Berry[1]; [1]University of Illinois at Chicago, United States; [2]Lund University, Sweden

Van der Waals heterostructures allow the integration of functionalities from different nanomaterials to achieve advanced, superimposed properties. Here, mixed MoS_2-WS_2 heterostructure grains were grown using atmospheric pressure chemical vapor deposition technique, and their optoelectronic properties were investigated. The field effect transistors fabricated from the heterostructure grains exhibited high photoresponsivity, which was influenced by the gating potential, as well as the measurement temperature. During the gating potential sweep from -5 V to +55 V, the light to dark source drain current ratio (I_{light}/I_{dark}) increased from 3 to 16 and from 2 to 7 at 60 K and 120 K, respectively. Such phenomena can be leveraged to realize novel optoelectronic and memory applications.

Freestanding Crystalline Oxide Membranes Harold Y. Hwang[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

The ability to create and manipulate materials in two-dimensional (2D) form has repeatedly had transformative impact on science and technology. In parallel with the exfoliation and stacking of intrinsically layered crystals, the atomic-scale thin film growth of complex materials has enabled the creation of artificial 2D heterostructures with novel functionality and emergent phenomena, as seen in perovskite oxides. We present a general method to create freestanding complex oxide membranes and heterostructures with millimeter-scale lateral dimensions and nanometer-scale thickness, using an epitaxial water-soluble buffer layer [1-3]. This facilitates many new opportunities we are beginning to explore, including the topological melting transition of 2D crystalline order [4], the application of extreme tensile strain and strain gradients [5-7], and integration with other materials families and synthesis techniques [8,9].

11:00 AM *EQ02.15.02
Molecular Beam Epitaxy and Dislocation Dynamics of Metamorphic InAsSb for Long-Wavelength Infrared Applications Stephanie Tomasulo[1], Chaffra A. Affouda[2], Jill A. Nolde[1], Mark E. Twigg[1], Michael K. Yakes[2] and Edward H. Aifer[1]; [1]U.S. Naval Research Laboratory, United States; [2]Formerly U.S. Naval Research Laboratory, United States

Long-wavelength infrared (IR) III-V based devices have long been of interest for potential applications such as chemical sensing and large format IR imaging. Within the III-V family, only the $InAs_{1-x}Sb_x$ bulk alloy in composition range $0.45 \leq x \leq 0.8$, offers the required bandgap energy (E_g) from 100 to 125 meV at an operating temperature of 80K and below [1]. Over this composition range however, the $InAs_{1-x}Sb_x$ lattice constant varies from 6.24 to 6.39 Å, where the lack of conventional substrates has restricted progress on the growth and study of this material system. To overcome this limitation, we employ a metamorphic step-graded $InAs_{1-x}Sb_x$ buffer on GaSb, enabling the study of low-E_g $InAs_{1-x}Sb_x$ as a function of growth conditions. Using this method, we investigated the effect of substrate temperature (T_{sub}) and group V to group III flux ratio (beam equivalent pressure, V/III) on Sb incorporation of the lowest-E_g cap layer [2]. We also used x-ray reciprocal space mapping (RSM) to examine the effect of growth conditions on strain and dislocation dynamics. Following these growth studies, we employed the metamorphic $InAs_{1-x}Sb_x$ in an InAs/InAsSb superlattice designed with a cutoff wavelength of 9 µm which leads to improved absorption compared with the lattice-matched counterpart.

We first grew several $InAs_{1-x}Sb_x$ step-graded structures in which the Sb/(As+Sb) flux ratio was varied from 0.05 to 0.50 in 0.05 increments, under various T_{sub} and V/III. Nomarski imaging revealed smoother surfaces under a V/III=10, the highest ratio we attempted. At this higher V/III, we observed

the cross-hatch morphology expected for metamorphic materials and found that the cross-hatch spacing changes, implying a change in dislocation dynamics, with T_{sub}. We also used photoluminescence (PL) to measure the Sb-content in the cap layer as well as compare intensities between samples. We found the highest Sb-incorporation to occur when T_{sub}=415 C and V/III=10, while the most intense samples used T_{sub}=415-430 C and V/III=10 [2].

We also identified the Sb composition in each layer using RSM along [110] with (004) and (115) reflections. This allowed comparison of Sb-content as a function of Sb/(As+Sb) for various T_{sub} and V/III. The results suggest that V/III has little effect on Sb incorporation, in direct conflict with our previous PL results [2]. To understand the discrepancy between PL and RSM, we measured (004) RSM of the same three samples with the x-ray beam incident along [1-10], revealing extremely different strain relaxation compared to the [110] case. Asymmetric strain relaxation has been observed in other III-V graded buffer systems and has been explained by different dislocation formation energies and glide velocities along each direction resulting from the core structure of the dislocation being terminated with either a group-III or a group-V element [3]. Transmission electron microscopy is ongoing to further understand the dislocation dynamics in these samples.

Ultimately, we used the lessons learned above to investigate the effect of substrate lattice-constant on strain-balanced InAs/InAsSb superlattices designed for 9 µm cutoff wavelength. Theoretically, by using a larger substrate lattice-constant the superlattice design results in larger electron-hole wavefunction overlap, ultimately increasing photon absorption. Our experimental results confirm this theory, even in the presence of increased threading dislocations.

Large Enhancement of Photoresponse Through Dielectric Engineering in Silicon-MoS_2 Heterostructure Vrinda Narayanan P and Atikur Rahman; IISER Pune, India

p-n junctions are at the heart of today's semiconductor industry and are the basic building blocks of numerous electronic and optoelectronic devices. Properties of conventional semiconductor p-n junctions are well defined by the type of materials and doping during fabrication and is difficult to tune them afterwards. Van der Waals materials have made it possible to realize atomic thickness p-n junctions. Due to the reduced screening in the out of plane direction, 2D materials and their heterostructures with other dimensional materials offer a unique platform with greatly tunable optoelectronic properties. In this study, we demonstrate how engineering the surrounding dielectric environment would help a p-n junction to improve the photoresponse to a great extent. A silicon-monolayer MoS_2 heterostructure was fabricated as a model system and the effects of surrounding dielectric environment on the electrical transport and photoresponse of the heterostructure was studied. We report nearly three order magnitude enhancement of photoresponse in the presence of higher dielectric environment. With increasing dielectric constant of the sorrounding environment, band gap reduces in two dimensional materials changing the band alignment of the heterostructure, photogenerated carriers become easily separable and scattering of charge carriers reduces due to the screening of long range coulomb impurities contributing towards the photoresponse enhancement. Our findings lay a general pathway of improving the efficiency of 2D materials based photodetectors through dielectric engineering.

High Quality Heteroepitaxial Diamond by Using Step-Flow Growth on Misorientated Sapphire Substrate Seong-Woo Kim[1], Ryota Takaya[2] and Makoto Kasu[2]; [1]Adamant Namiki Precision Jewel, Japan; [2]Saga University, Japan

Diamond semiconductors, owing to their wide bandgap of 5.47 eV and superior properties compared to SiC and GaN, can be used to develop high-power devices. However, the inch-scaled diamond wafer is essential. Recently, we have demonstrated high-quality one-inch heteroepitaxial diamond wafer (Kenzan Diamond®) with X-ray rocking curve (XRC) FWHM of 113.4 arcsec, 234.0 arcsec for (004) and (311) diffractions and threading dislocation density of $1.4x10^7$ cm^{-2} [1]. On the Kenzan Diamond, we have demonstrated field-effect transistors (FETs) with the highest available output power density of 345 MW/cm^2 [2]. So far, the Kenzan Diamonds were grown on Ir buffer layer/ just-oriented (11-20) sapphire substrate.
In this study, we performed diamond heteroepitaxial growth on Ir buffer layer/ misorientated (11-20) sapphire substrate. The heteroepitaxial diamond layer shows XRC FWHM of 98.35 for (004) and 175.3 arcsec for (311) diffractions. These values are the lowest and show the highest quality in heteroepitaxial diamonds. These results revealed that step-flow growth occurs on the misorientated surface and the misorientated layer structure releases the internal stress caused by the differences in coefficient of thermal expansion among diamond, Ir, and sapphire layers.

Intercalation-Induced Swelling Mechanisms of 2D-Organoclay Revealed by Molecular Dynamics Simulation Masaya Miyagawa, Fumiya Hirosawa, Hayato Higuchi and Hiromitsu Takaba; Kogakuin University, Japan

Since the first half of the 20th century, intercalation property of two-dimensional materials has been investigated energetically. Layered clay minerals such as montmorillonite are the well-known example, and intercalation of alkylammonium ion by exchange of the interlayer cation has been known to absorb hazardous molecules such as aromatic hydrocarbons. However, ideal functionalization has yet been achieved despite of abundance of the clay minerals. One of the biggest problems is difficulty in observation of the nanostructure of the interlayer space, whose height is merely around 1 nm. It is true that the gallery height is able to be measured by X-ray diffraction, but detail morphology of the intercalated molecules is not revealed easily by experiment. In this point of view, molecular dynamic (MD) simulation is a powerful tool to investigated the nanostructure of the organoclay and its intercalation property because the MD simulation directly visualized the nanostructure. Thus, in the present study, we performed the molecular dynamics simulation on montmorillonite modified by octadecyltrimethylammmonium ion (Mont-C_{18}) and the adsorption of anthracene (Ph_3) by using molecular dynamics simulation.

The gallery height of Mont-C_{18} obtained by the MD simulation is 11 Å, which is consistent with that reported experimentally. C_{18} ions are oriented horizontally and formed so-called pseudotrimolecular layer. The intercalation of Ph_3 induces vertical orientation of the C_{18} ions, which was revealed by atom distribution analyses, and the value of the gallery height is increased linearly along with the number of the intercalated Ph_3 molecule. Corresponding to the orientation change of the C_{18} ions, the Ph_3 molecules are oriented vertically against the Mont layer. By stepwise intercalation simulations, detail population changes of the Ph_3 molecules are revealed based on the molecular axis.
Atom distribution and orientation angle analyses reveals the detail swelling mechanisms of Mont-C_{18}: The intercalated anthracene molecules push out the C_{18} ions, resulting in the orientation changes from the horizontal to the vertical. The Ph_3 molecules are correspondingly localized on the Mont layer with its molecular axis vertical. The latter result is consistent with that suggested experimentally, where weak interaction of the H atoms of the Ph_3 molecule with the Mont layer may be significant. Thus, it is found that the interlayer of the Mont-C_{18} is highly inhomogeneous in the presence of the Ph_3 molecules even though the gallery height is only 11-21.6 Å, depending on the number of the intercalated Ph_3 molecules. In addition, the orientation of the Ph_3 molecules is parallel to each other as the number is increased. Because excimer emission is observed in this nanocomposite experimentally, it is strongly suggested that the localization of the Ph_3 molecules on the Mont layer is the key for the characteristic photophysical behavior.
We also concluded that the continuous increase in the gallery height originates from soft response of the C_{18} ions to the intercalation. In other words, the swelling of the interlayer is ascribed not to the volume of the Ph_3 molecules but to the orientation changes in the C_{18} ions. Summarizing the above results, it is concluded that Å-order inhomogeneity is introduced in interlayer by the intercalation of the Ph_3 molecules, which is significant to utilize the two-dimensional nanospace for ideal materials design.

8:30 AM EQ02.16.03
Al2O_{3-x}/IZO Heterostructure Transparent Resistive Switching Memory Jaemin Park, Daihong Huh, Soomin Son, Wonjoong Kim and Heon Lee; Korea University, Korea (the Republic of)

In this work, we fabricated the different number of IZO interlayer into Al_2O_{3-x} based transparent resistive switching memory on a transparent ITO deposited substrate at room temperature. Al_2O_3/IZO heterostructure transparent memory has sufficiently high transmittance in the visible region. Also, Al_2O_{3-x}/IZO heterostructure transparent memory has improvement results in lower electroforming voltages as the number of IZO interlayer was increased, as compared to ITO/pure Al_2O_{3-x}/IZO transparent memory. At this time, the transparent memory with 2-IZO interlayer showed a reduction in forming voltage of more than 37% compared to ITO/pure Al_2O_{3-x}/IZO memory. The fabricated transparent memory exhibit typical bipolar resistive switching behavior regardless of the number of IZO interlayer. Additionally, a flexible Al_2O_{3-x}/IZO heterostructure memory was fabricated using the same process on ITO coated PET. The fabricated flexible transparent memory also maintained resistive switching characteristics and stable switching properties during bending.

8:45 AM EQ02.16.04
Collective Modes of a Superconducting Heterostructure Jonathan Curtis, Nicholas Poniatowski, Prineha Narang and Amir Yacoby; Harvard University, United States

In this work we theoretically analyze the collective modes of a heterostructure built from materials with different pairing symmetries. In particular, we focus on the regime where the bulk superconductor has a higher transition temperature and conventional s-wave pairing, while the proximitized system has a lower-temperature transition into an unconventional pairing phase. We argue that, even when both pairing symmetries are topologically trivial, there ought to be signatures of the unconventional pairing in the collective mode spectrum of the joint heterostructure. We conclude by discussing relevant experimental probes and how they relate to the intrinsic pairing interactions in the materials.

9:00 AM EQ02.16.05
Modulation Doping in 2D Materials Yiping Wang and Kenneth Burch; Boston College, United States

2d materials offer great advantages as building blocks for the next generation of technological devices, due to their high-quality, versatility, and the ability to create heterostructures of countless combinations, each exhibiting unique properties. Despite great strides made in device fabrication over the past two decades, some aspects are still missing from the 2d material toolbox, for example being able to heavily charge dope 2d materials locally and cleanly. The ability to dope 2d materials uniformly and non-destructively is highly desirable for both exploring material properties and developing state-of-the-art nanoscale devices. In this work, we characterize the ability of the layered Mott insulator alpha-ruthenium(III) chloride (\arucl) to strongly hole dope graphene. We present that \arucl\ not only yields a large charge transfer in carbon-based heterostructures, but also that it does so cleanly and uniformly with quantifiable homogeneity. We also find that while the charge transfer is robust for any thickness of \arucl\ down to the monolayer limit, and can extend out of plane to multi-layer graphene and through insulating spacer layers.

9:15 AM EQ02.16.06
Looking at Structural Heterogeneity with Scanning Nano-Structure Electron Microscopy (SNEM) Yevgeny Rakita[1,2], James L. Hart[2], Partha Pratim Das[3], Stavros Nicolopoulos[3], Sina Shahrezaei[4], Suveen N. Mathaudhu[4], Mitra Taheri[2] and Simon J. Billinge[1,5]; [1]Columbia University, United States; [2]Johns Hopkins University, United States; [3]NanoMegas, Belgium; [4]University of California, Riverside, United States; [5]Brookhaven National Laboratory, United States

In recent years, Electron Diffraction, and especially the 4D-STEM [1] is growingly becoming a routine part of structural characterizations of materials at the nano-scale. Its un-matched spatial resolution (down to sub-nm) enables the exploration of local variations within a sample, which alternatively is averaged over the entire irradiated sampled area, when explored, for example, by x-rays. As often shown in electron-microscope, samples are often heterogeneous, and consequently their local properties, which then reflect on the average behavior of the material, composite, or device. Besides morphology and composition, the local structural order can vary, especially in evolving systems. In this study, we explore how far we can take electron diffraction when the interest is in the evolution of materials.
We challenge ourselves with mapping the local structure in a composite of crystalline Ni and amorphous Zr-Cu-Ni-Al Bulk Metallic Glass (BMG) was fused into a composite via hot-rolling [2]. Using a fast camera looking through a fluorescence screen on which diffraction patterns are observed, we use scanning precession electron diffraction to captured 4D-STEM data with 3 nm step size from a FIB-fabricated Ni/BMG/Ni laminate. Using an automated data reduction and analysis pipelines, including distortion correction, auto-masking, azimuthal-integration, Fourier-transformation, and least-square function fitting, to get electron Pair Distribution Function (ePDF) and a set of structurally-meaningful features, which we generalize as Quantities of Interest (QoI). Since we use both the 2D diffraction patterns and the 1D-ePDF's, we generalize the concept of mapping structurally-significant QoI's derived from a spatially-correlated diffraction pattern as scanning nano-structure electron microscopy (SNEM).
We use SNEM to generate QoI-based maps of, for example, the virtual-dark-field (VDF) from the 2D diffraction patterns, and the peak position, peak-width, and the goodness of fit to a structural model from the reduced ePDF's. We find clear variations in structural features across the Ni/BMG interface, as well as within the BGM itself, which indicate the presence of nano-crystalline inclusions with higher structural correlation length, and evidence for variations in the degree of clustering of alike atoms (e.g., Zr-Zr) in the BMG, which indicate a varying short-range chemical order. We could also follow

trends in compositional variations using the average interatomic bond-distance (as also verified with atomic fraction EELS maps) extract the distribution of atomic pairs, exposed the BMG/Ni inter-diffusion front, and estimate the effective local structure of the nano-crystalline inclusion within the BMG as an FCC structure.
Combining these results with atomic composition EELS maps, we learn that nano-crystalline inclusions within the BMG are located in Cu-deficient regions. We also learn that the formation of Ni/BMG composite via hot-rolling, which is often found to be challenging due to the excessive formation of nano-crystallites at the Ni/BMG interface has succeeded due to the metallic Ni being amorphized instead of [BMG--Ni] crystallites being formed. These results are an example of the richness SNEM can provide, and with the assistance of automated (and in the future - autonomated) pipelines, bring us closer to exposing (and potentially controlling) the history of heterogeneity in evolving systems.

Late News: SrVO3 as a Bottom Electrode for the Heterogeneous Integration of Ferroelectric BaTiO3 on SrTiO3 Asraful Haque, Sandeep Vura, Pavan Nukala, Shankar Kumar Selvaraja and Srinivasan Raghavan; Indian Institute of Science, India

$SrVO_3$ (SVO) is a conductive perovskite oxide with an electrical conductivity of 31μohm.cm and optical transparency (70 %) in the visible region [1]. Its lattice constant a = 3.8420 Å is conducive to integrating perovskite oxides on STO substrates for electro-optic applications. The growth window in pulsed laser deposition (PLD) (10^{-6}mbar and below) of SVO is relatively narrow to obtain the desired electrical and optical characteristics [2]. However, the integration of ferroelectric oxides like $BaTiO_3$ (BTO) requires a high deposition pressure of $5x10^{-3}$ mbar and above [3].
To epitaxially integrate BTO on STO via SVO layer, a dual pressure growth scheme is developed to obtain switchable out-of-plane polarized BTO film in tandem. Our XRD measurements and in-situ RHEED measurements confirm the epitaxial nature of the BTO on SVO/STO. The spotty RHEED pattern of the BTO surface indicates BTO grows on SVO via a Volmer-Weber growth mode. Both BTO and SVO films exhibit a sub-nanometer roughness. The SVO film resistivity (Vander-paw method) is 23.2μohm.cm, comparable to that of MBE-grown films. The BTO integrated via SVO/STO has a good crystal quality, as seen from symmetric ω-scan FWHM of 0.31°. The lattice parameters extracted from out-of-plane (*00l*) and in-plane (*h0l*) RSM scans confirm the out-of-plane orientation of the BTO film. The piezo force microscopy measurements show the switchable nature of polarization in the BTO film. A large tetragonality (c/a-1 %) of >2 % (vs. 1 % for a single crystal BTO) is observed in our BTO films and is dependent on deposition conditions. The underlying mechanism will be discussed in detail at the conference.

Aligned Carbon Nanotube Arrays-Based Transistors Operating in Terahertz Regime Donglai Zhong[1], Huiwen Shi[1,1], Li Ding[1], Jie Han[1], Zhiyong Zhang[1,2] and Lianmao Peng[1,1,2]; [1]Peking University, China; [2]Frontiers Science Center for Nano-optoelectronics, China

Advances in telecommunication technology has led to demand for faster operating frequencies and wider usable frequency ranges. The development of 5G and 6G communication technologies will, in particular, require devices capable of operating at frequencies beyond 90 GHz and up to 300 GHz. Currently, the two semiconductor technologies most used for RF devices are silicon complementary metal-oxide-semiconductor (CMOS) field-effect transistors (FETs) and transistors based on III-V compound semiconductors (primarily GaAs). Silicon transistors are capable of high levels of integration at low cost, but they suffer from poor linearity and noise performance at frequencies above 20 GHz. Devices based on III-V compounds can be used to build systems operating at frequencies beyond 20 GHz, but cannot be integrated directly with digital system in the same chip.
High-semiconducting-purity CNT arrays with suitable choice of array density and tube diameter should allow compatible fabrication of ultra-scaled digital CMOS FETs and high-performance RF transistors on the same substrate. Therefore, CNT FETs should make a better platform for SoC applications than silicon and III-V compound semiconductors-based technologies.
The performance of CNT transistors has been improved due to the developments in material preparation and device fabrication. FETs with the current gain cut-off frequency (f_T) and the power gain cut-off frequency (f_{MAX}) both over 100 GHz have been demonstrated, far behind theoretical predictions, because of lack of well-aligned semiconducting CNT arrays. Ideally, the CNT material for RF FETs is arrays with density ranged from 100 to 200 CNTs μm^{-1}, high semiconducting purity and as a high carrier mobility as possible. The most promising RF FETs have been built using arrays prepared through the floating evaporative self-assembly (FESA) method based on solution-derived CNTs, but their speeds are still limited by the relatively low density (<70 CNTs μm^{-1}) and low mobility (230 $cm^2V^{-1}s^{-1}$).
Here, we report aligned CNT arrays that offer high density (120 CNTs μm^{-1}), high semiconducting purity (at least 99.99%), carrier mobility (up to 1580 $cm^2 V^{-1} s^{-1}$) and a saturation velocity of up to 3.0×10^7 cm s^{-1}. We use a double-dispersion sorting and a binary liquid interface-confined self-assembly (BLIS) procedure, which allows for assembly of aligned arrays on both insulating or semiconducting substrates, such as silicon, glass and quartz. These processes for RF FETs are designed to be fully compatible with the fabrication digital CMOS CNT FETs, for SoC applications. FETs based on these CNT arrays exhibit high driving current, transconductance and f_T/f_{MAX} on both quartz and Si/SiO_2 substrates. In particular, FETs with a 50 nm gate length on Si/SiO_2 offer high d.c. performance with on-state current of 1.92 mA/μm and peak transconductance of 1.40 mS/μm at a bias of -0.9 V, and show high a.c. performance with f_T/f_{MAX} of 540 GHz and 306 GHz, respectively, and we show that f_T can be pushed beyond 1 THz when scaled to gate lengths of sub-28 nm. RF amplifiers made using 50 nm length FETs with multi-finger structure exhibit high power gain (23.2 dB) and inherent linearity (31.2 dBm OIP3) in frequencies of at least up to the K band (18 GHz).

Phase Dependence of Spin Pumping Effect for CoFeB/Sb_2Te_3 Bilayers Misako Morota, Yuta Saito and Noriyuki Uchida; National Institute of

Advanced Industrial Science and Technology, Japan

Sb_2Te_3 is well known as a phase-change and thermoelectric material and has recently attracted significant attention as a topological insulator (TI). TIs possess non-trivial electronic structures originating from the strong spin-orbit interaction, resulting in unusual properties, such as the presence of helical spin currents on the surface and formation of the Dirac cone. These properties are expected to enhance spin pumping. However, the effects of atomic ordering in TI films on spin relaxation have not yet been investigated. In this work, the spin-pumping effect in CoFeB/ Sb_2Te_3 bilayers was studied using ferromagnetic resonance (FMR) at 300 K for crystalline and amorphous Sb_2Te_3. FMR signal width enhancement was observed for the highly oriented crystalline Sb_2Te_3 film at thicknesses less than 7 nm compared with the amorphous counterpart. In contrast, the FMR signal widths of the amorphous sample and Pt reference were independent of the layer thickness. In particular, the enhancement of the linewidth was most remarkable at 4-nm thickness for the crystalline Sb_2Te_3 samples; this feature was not observed for amorphous Sb_2Te_3 samples. The significant increase in linewidth suggests more efficient spin injection from the ferromagnetic CoFeB layer into crystalline Sb_2Te_3 than into amorphous Sb_2Te_3. Furthermore, the stark contrast between the spin dynamics of the amorphous and crystalline Sb_2Te_3 films supports the idea that the topological phase protected by crystallographic symmetry plays a key role in spin pumping. Additionally, for the effective magnetization of Sb_2Te_3 samples, a change of the magnetic anisotropy direction depending on Sb_2Te_3 thickness was observed, implying the possibility of interactions between topological surface state in crystalline Sb_2Te_3 and ferromagnetic CoFeB films. These findings enhance understanding of the spin pumping effect between topological insulators and ferromagnetic materials and strongly suggest that it is possible to modulate the amount of injected spin by controlling the crystal structure, which provides a new perspective on spin conduction control using phase-change phenomena in conventional spintronics research. This could enable the realization of spintronic devices based on phase-change topological materials.[1]

Precipitation of Multilayer Graphene with Smooth and Large Domain on C-Plane Sapphire Using Crystallized Ni Catalyst Shigeya Naritsuka, Asato Nakashima, Tomoaki Murahashi, Tatsuya Kashio and Takahiro Maruyama; Meijo University, Japan

Graphene is one of the promising materials for realizing a wide range of applications from its unique electrical, mechanical, and chemical characteristics. We have studied a direct precipitation method of graphene to improve its productivity with avoiding the transfer process. The direct precipitation method is promising, although the characteristics of the precipitated graphene are still inferior to those of the CVD-grown graphene. To improve the quality, high temperature growth is attractive but the grain boundary of the catalyst brings another problem. It is because the carbon atoms easily diffuse through the boundaries of the catalyst even at low temperature, and severely deteriorates the precipitated graphene. Therefore, the crystallization of the catalyst without grains is an important issue in the study of graphene growth. The crystallization is beneficial to obtain a large graphene domain too because the superior crystallinity of the catalyst is good for aligning the orientation of the graphene islands and, subsequently, an ideal stitching of the graphene islands are expected. In this presentation, the crystallization of the Ni catalyst is firstly studied on the sapphire substrate. Then, the crystallized Ni catalyst is used to directly precipitate multilayer graphene.
A 100 nm-thick Ni (111) layer was grown on a c-plane sapphire by MBE. Then, 300 nm-thick Ni layer was deposited using electron-beam deposition. The samples were annealed at 1000ºC for 30min to crystallize it under hydrogen at atmospheric pressure. Then, the temperature was cooled down at a rate of 3ºC/min. After the formation of the Ni crystallized catalyst, the sample was coated by nanodiamond, and heated at 900ºC for 30min in a vacuum (10^{-4}–10^{-3} Pa) using an infrared lamp apparatus. Then, the temperature was cooled down at a rate of 3ºC/min. The catalyst was removed using a diluted $FeCl_3$ solution to directly observe the graphene on the substrate.
Almost whole surface of the sample was successfully crystallized by using the MBE layer as a seed, and a perfectly smooth and flat surface was obtained on it. It is useful to deposit an additional Ni amorphous layer on the MBE-grown layer because the amorphous layer is effective to suppress the dewetting of the Ni layer even at a high temperature.
An extremely flat surface with several growth islands was obtained on the precipitated multilayer graphene. The in-plane X-ray diffraction spectra shows an excellent crystallinity of the graphene from its quite narrow FWHM of 0.25º, which is the smallest FWHM yet reported for a graphene layer. The graphene [11] orientation was precisely aligned to the sapphire [1-100] axis. The Raman spectra indicates the precipitated graphene is multilayer. The Raman D/G mapping measurement with no associated increase also shows that their islands were smoothly connected without forming defects. In addition, no wrinkle was observed on the surface, which possibly came from the effective release of the contraction stress with gently slipping the layer with sandwiching both sides.

Wafer-Scale MoS_2/Graphene Heterostructures Synthesized by MOVPE and Their Application Anh Tuan Hoang[1], Ajit K. Katiyar[1], Heechang Shin[1], Neeraj Mishra[2,3], Stiven Forti[2,3], Camilla Coletti[2,3] and Jong-Hyun Ahn[1]; [1]School of Electrical & Electronic Engineering, Korea (the Republic of); [2]Istituto Italiano di Tecnologia, Italy; [3]Istituto Italiano di Tecnologia Piazza San Silvestro, Italy

Two-dimensional van der Waals heterostructures have attracted increasing interest, owing to the combined benefits of their constituents. These hybrid nanostructures can be realized via epitaxial growth, which offers the prospect of achieving ultraclean interfaces with strong electronic and optical coupling between layers. Here, the epitaxial growth of a continuous molybdenum disulfide (MoS_2) film on large-area graphene, which was directly grown on a sapphire substrate, is reported. Interestingly, the grain size of MoS_2 grown on graphene increases, whereas that of MoS_2 grown on SiO_2 decreases with an increasing amount of hydrogen in the chemical vapor deposition reactor. In addition, to achieve the same quality, MoS_2 grown on graphene requires a much lower growth temperature (400 °C) than that grown on SiO_2 (580 °C). The MoS_2/graphene heterostructure that was epitaxially grown on a transparent platform was investigated to explore its photosensing properties and was found to exhibit inverse photoresponse with highly uniform photoresponsivity in the photodetector pixels fabricated across a full wafer. The MoS_2/graphene heterostructure exhibited ultrahigh photoresponsivity (4.3×10^4 A W^{-1}) upon exposure to visible light of a wide range of wavelengths, confirming the growth of a high-quality MoS_2/graphene heterostructure with a clean interface.

Utilizing 2D Layer Transfer Technique to Fabricate Ultra-Thin Solid-State Battery Celesta S. Chang[1], Hyunseong Kum[1], Sangwook Han[2], Hanseul Choi[2], Daniele Vivona[1], Yang Shao-Horn[1], Yun Seog Lee[2] and Jeehwan Kim[1]; [1]Massachusetts Institute of Technology, United States; [2]Seoul National University, Korea (the Republic of)

Remote epitaxy, via so-called 2D material-based layer transfer (2DLT) has enabled a wide range of materials to be successfully grown as thin, free-standing layers that can be readily integrated into devices. Such method can be applied in the area of electrochemistry, where we can improve and overcome the limitations that liquid-based Li ion batteries have suffered over the past several decades. While liquid electrolytes have been mainstream owing to its high ionic conductivity and good wetting property with electrode surfaces, its fundamental limitations are set by low thermal, electrochemical stability, low energy density, and poor safety due to dendritic formation.

In particular, formation of Li dendrites penetrating through liquid electrolytes are identified as the main cause for explosions via thermal runaway, which also reduces the lifecycle of the battery. To solve this issue, solid-state batteries have been proposed as an alternative to conventional lithium batteries, which promise significantly reduced possibility of dendrite formations without sacrificing any other properties. However, high-performance thin single-crystalline solid-state electrolytes (SSE) have not yet been demonstrated since Li-containing ionic compound wafers are not commercially available in a single-crystalline form, as well as the difficulty to fabricate thin film SSE single-crystals, necessary for compact design of batteries with high volumetric energy and power density.

Here, we will demonstrate the use of graphene coated substrates for remote epitaxy of $LiLaTiO_3$ (LLTO) as the electrolyte for solid-state battery applications. We show comparable performance of our ultra-thin film battery to conventional lithium batteries and discuss overall improvements we are able to achieve.

11:30 AM EQ02.17.07
Viscoelastic Bandgaps in Multilayers of Inorganic-Organic Nanolayer Interfaces Rajan Khadka, Ganapati Ramanath and Pawel Keblinski; Rensselaer Polytechnic Institute, United States

Molecular nanolayers (MNLs) at inorganic interfaces are known to lead to unusual enhancements in interfacial fracture energy, thermal and electrical transport. Here, we demonstrate viscoelastic damping bandgaps in multilayered interfaces of MNL-bonded Au nanolayers. Molecular dynamics simulations of Au/octane dithiol/Au multilayers reveal high-damping-loss frequency bands in the $33 \leq \nu \leq 77$ GHz and $278 \leq \nu \leq 833$ GHz regions separated by a low-loss bandgap. The high-damping-losses are up to 31-fold higher than that in individual components in the bulk forms, and the low-losses range from ~ 40% to 120% of the bulk values. The viscoelastic bandgap scales with the Au-MNL interfacial bonding strength and density, and MNL coverage indicating that it is an interface effect. These findings suggest a variety of possibilities for accessing and tuning novel dynamic mechanical responses in nanocomposites, devices and systems with significant inorganic-organic interface fractions for applications.

11:45 AM EQ02.17.08
Quantum Transport in 3D Patterned SnTe Shuhang Pan, Stephen Albright, Frederick Walker and Charles Ahn; Yale University, United States

SnTe is one of the first materials in the class of topological crystalline insulators (TCIs) to be predicted and studied. In this work, we synthesize thin SnTe films (10 to 30 nm thick) patterned with a regular array of square holes on a $SrTiO_3$ substrate and compare quantum transport with that measured in unpatterned thin films. The weak localization/antilocalization (WL/WAL) in films is revealed by fitting the magnetoconductivity measurements with the Hikami-Larkin-Nagaoka (HLN) equation. The results show a mixture of WL and WAL in both films, indicating a partial electron spin-momentum locked state. The presence of square holes in the SnTe films suppresses conventional conduction at higher temperature, leading to a stronger WAL effect, and limits the coherence length to the hole size at low temperatures.

Anisotropic Interlayer Exciton in GeSe/SnS van der Waals Heterostructure Nikhilesh Maity; Indian Institute of Science, India

The observation of interlayer excitons (ILE), where the electron and hole are confined in different layers, in van der Waals (vdW) type II heterostructures has ignited a new interest in investigating the optical properties of these 2D semiconducting materials. Herein, using GW and Bethe–Salpeter equation simulations, we demonstrate the generation of linearly polarized, anisotropic intra- and interlayer excitonic bound states in the transition metal monochalcogenide (TMC) GeSe/SnS vdW heterostructure. The puckered structure of TMC results in the directional anisotropy in the band structure and in the excitonic bound state. Upon the application of compressive/tensile biaxial strain, a dramatic variation in excitonic energies, the indirect-to-direct semiconductor transition, and the red/blue shift of the optical absorption spectrum are observed. The variations in excitonic energies and optical band gap have been attributed to the change in effective dielectric constant and band dispersion upon the application of biaxial strain. The generation and control over the interlayer excitonic energies will find applications in optoelectronics and optical quantum computers and as a gain medium in lasers.

8:05 AM EQ02.09.03
MOVPE Growth of h-BN on Patterned Sapphire Substrates and Its Application on Selective Area Growth of GaN Based LEDs Structures Suresh Sundaram[1,2,1], Soufiane Karrakchou[1,2], Adama Mballo[2], Phuong Vuong[2], Yacine Halfaya[2], Gilles Patriarche[3], Tarik Moudakir[4], Paul L. Voss[1,2], Jean Paul Salvestrini[1,2,1] and Abdallah Ougazzaden[1,2]; [1]Georgia Institute of Technology-Lorraine, France; [2]CNRS, IRL 2958, GT- CNRS, France; [3]Universite Paris-Saclay, France; [4]Institut Lafayette, France

We report MOVPE growth of h-BN on sapphire substrates pre-patterned with SiO2 and SiN with the goal of investigating the possibility of new kinds of selective area growth. We see that after h-BN growth, the GaN-based device structures grow selectively on sapphire but not on SiO2 and SiN. This result is surprising because BN is not anticipated to exhibit strong selectivity on dielectric patterns.

To understand how this happens, 20 nm thick h-BN layers were grown separately on dielectric patterned sapphire substrates. On sapphire, the h-BN formed the typical semi-hexagonal wrinkles which is evidence of growth of high quality single crystalline 2D h-BN layers. On SiO_2, localized SIMS measurements confirmed the deposition of BN, so as expected there is not selective area growth of BN. Additional cross sectional TEM studies confirm that the h-BN on the sapphire substrates is highly oriented and layered whereas the BN on the dielectric patterns are nanocrystalline and randomly alligned. Given the lack of crystalline order on the surface of the SiO_2 and SiN regions, the presence of disordered BN there is not surprising.

We have performed several experiments growing functional GaN-based LED structures after h-BN growth during the same growth run, and the selective growth of the GaN-based structures on the h-BN/sapphire is reliable. TEM measurments show that homogeneous, single crystalline GaN based device structure growth occured only in regions where layered h-BN is deposited, and little to no GaN growth occurred on the randomly-oriented BN on SiO_2. SEM and cathodoluminescence studies confirm that the GaN regions are separated from each other by the dielectric patterns. We conclude from further structural and optical charcaterisations that the degree of order in BN deposits controls the selectivity of III-Nitride device structures. It seems that the

structure of the BN surface rather than its chemical composition determines whether or not GaN-based materials can grow. Compared to unpatterned areas, fewer GaN dislocations were found in patterned areas, and Spontaneous delamination of III-nitride device structures on h-BN, a problem with full wafer device structures on h-BN, was avoided. The results allow for localized device liftoff and transfer from h-BN since the devices are completely physically isolated from eachother. The possibility of pixel by pixel selective transfer opens up heterogeneous integration possibilities needed for realization of novel device architectures and device isolation and device passivation.

8:20 AM EQ02.03.02
Effect of Aluminum Diffusion into 2D hBN on the Mechanical Release of III–N Heterostructures Phuong Vuong[1], Suresh Sundaram[2], Adama Mballo[1], Gilles Patriarche[3], Soufiane Karrakchou[2], Tarik Moudakir[4], Simon Gautier[4], Paul Voss[2], Jean-Paul Salvestrini[2] and Abdallah Ougazzaden[2]; [1]CNRS, IRL 2958 Georgia Tech, France; [2]Georgia Institute of Technology, France; [3]CNRS, Centre de Nanosciences et de Nanotechnologies, France; [4]Institut Lafayette, France

Hexagonal boron nitride (h-BN) is a two dimensional wide-bandgap semiconductor, which can be used as a release layer for mechanical lift-off of as-grown III-nitride heterostructures and their processed devices such as LEDs and HEMTs. However, it has been challenging to control the strain in this layered material which results in spontaneous delamination during epitaxial growth or front-end processing of these devices, mainly for large surface areas. Here, we report a unique approach of controlling the adhesion of this layered material, which can result in either desired lift-off from layered h-BN or mechanically inseparable robust h-BN layers. We found that the growth conditions of an AlN buffer layer on top of h-BN plays an important role for controlling the adhesion of the subsequent device structure grown on h-BN. AlN layer grown above a certain temperature leads to the Al diffusion into h-BN, which enhances the surface and interface dangling bonds, and anchors the layered h-BN. The effect of the Al concentration into h-BN layers on the mechanical lift-off is verified by studying carefully BAlN alloys with different Al content. It has been observed that above a certain Al content, the layered BAlN sample cannot be lifted-off, supporting our investigation. In addition, we provide the flexible approach on the control of the lift-off process by variation of the thickness of h-BN. Furthermore, we illustrate the potential of this investigation by controlling the mechanical lift-off of two types of device structures (LED and HEMT). These results extend the control of the adhesion of 2D/3D materials, opening the route to large-scale fabrication of III-N devices grown on h-BN, and bringing them close to industrial applications.

1:00 PM *EQ03.07.01
Nanoscale Magnetic Resonance Enabled by Diamond Color Centers Fedor Jelezko; Ulm University, Germany

Single nitrogen-vacancy (NV) color centers in diamond currently have sufficient sensitivity for detecting single external nuclear spins and resolve their position within a few angstroms. The ability to bring the sensor close to biomolecules by implantation of single NV centers and attachment of proteins to the surface of diamond enabled the first proof of principle demonstration of label-free detection of the signal from a single protein. Single-molecule nuclear magnetic resonance experiments open the way towards unraveling dynamics and structure of single biomolecules. However, for that purpose, NV magnetometers must reach spectral resolutions comparable to that of conventional solution state NMR. New techniques for this purpose will be discussed. We will also show first experiments towards hyperpolarisation of extrneal nuclear spins using shallow NV centers..

1:30 PM *EQ03.07.02
Quantum Sensing with Optically Hyperpolarized Nuclei Ashok Ajoy; University of California, Berkeley, United States

We report on new experiments that demonstrate the potential of hyperpolarized nuclear spins to serve as sensitive magnetometers and sensors of their local environment. This methodology leverages two important features, (1) the ability of sensor nuclei to be hyperpolarized to >3% levels through optical pumping, and (2) their ability to be put into long-lived "Floquet prethermal" states that can be rendered highly sensitive to external magnetic fields. We demonstrate this with 13C nuclei in diamond that are optically hyperpolarized through interactions with lattice Nitrogen-Vacancy (NV) centers. We leverage the exquisite transverse spin lifetimes possible in 13C nuclei under RF driving, wherein we observe lifetimes in excess of T2'=90s at room temperature (see Fig. 1). These long-lived states constitute an extension of >60,000 over conventional FID decay times T2*~1.5ms in this system. Simultaneously, hyperpolarization and continuous spin readout enable significant gains in signal to noise, and forms the key basis for ultimately making these nuclei serve as quantum sensors. These experiments suggest interesting new opportunities for high-field spin sensors possible via hyperpolarized, low-gamma, nuclei.

2:00 PM *EQ03.07.03
Cryogenic Quantum Sensing and the Low Temperature Photo-Physics of Diamond NV Centers Patrick Maletinsky; University of Basel, Switzerland

Quantum two-level systems offer attractive opportunities for sensing and imaging at the nanoscale. Since its inception [1], this idea has advanced from proof of concept [2] to a mature quantum technology [3], with broad applications in condensed matter physics, materials science and engineering, and a demonstrated economic impact [4].

In this talk, I will present our activities in quantum sensing of mesoscopic, solid-state systems using scanning Nitrogen-Vacancy (NV) centre magnetometry in cryogenic environments. I will on one hand discuss engineering challenges we addressed in photonic engineering of all-diamond scanning probes for quantum sensing [5], and on the other hand highlight recent achievements in nanoscale imaging of two-dimensional, "van der Waals" magnetic systems [6][7].

In the second part of my talk, I will focus on recent studies we conducted in systematically addressing the photo-physics of individual NV centres under cryogenic conditions [8], with the goal to further advancing sensing performance of NV centres at cryogenic temperatures. We observed significant variations of optical spin readout and initialisation efficiencies with magnetic field, that we connect to excited state level anti-crossing in the NVs orbital excited state. The understanding and control of these features is key for NV magnetometry in that it enabled improvements of magnetic field sensitivities by up to an order of magnitude over established baseline values at cryogenic temperatures

I will conclude with an outlook on how these insights could be used to offer fundamentally new sensing modalities and how we will further push our single spin magnetometer developments into the range of extreme environmental conditions, such as high magnetic fields, or millikelvin temperatures.

Late News: Optical Hyperpolarization of 13C Nuclear Spins in Diamond at a Low Magnetic Field Kavtanyuk Vladimir[1], Jeong Hyun Shim[1], Sangwon Oh[1] and Keunhong Jeong[2]; [1]Korea Research Institute of Standards and Science, Korea (the Republic of); [2]Korea Military Academy, Korea (the Republic of)

Hyperpolarization of nuclear spins by Dynamic Nuclear Polarization (DNP) is significantly higher compare to the thermal polarization. As the result, many Nuclear Magnetic Resonance (NMR) and Magnetic Resonance Imaging (MRI) applications become possible. Optical DNP requires high-power laser irradiation for polarizing electron spins of negatively charged nitrogen vacancy (NV^-) centres and a microwave irradiation for inducing the polarization transfer to ^{13}C nuclear spins. The initial goal of our research is hyperpolarization of diamond powder and investigating ways to improve the polarization. However here we present our DNP measurements obtained on bulk diamonds at a low magnetic field of 18 mT. We have obtained triple DNP profile, ^{13}C polarization by multi-MW frequencies, dependences of ^{13}C polarization over different parameters and NV^- concentrations. This data will be helpful for maximizing the ^{13}C polarization in diamond powder.

Surface Modification of Diamond for Sensing and Imaging Applications Anke Krueger; Julius-Maximilians-Universität Würzburg, Germany

The surface of diamond plays a crucial role in the control of its electronic properties. Not only the electron affinity and thus the ability to emit electrons into the surrounding media depends on the actual surface termination, but also the interaction with components from the environment such as serum proteins etc. It is thus of great importance to develop methods for the functionalization of the surface in a highly controlled manner that include the termination itself but also the grafting of more complex units for dedicated purposes.
Here we report on different methods for the selective establishment of different oxygenated surface groups as well as an efficient fluorination using wetchemical methods. The influence on the materials properties will be discussed. Additionally, methods for the grafting of protein repelling moieties based on zwitterionic motifs are discussed as an essential tool for bioapplications. Besides, diamond nanoparticles functionalized with organic fluoroionophores for sensing applications will be presented.
This research has received funding from the European Commission's Horizon 2020 program under contract 665085 (DIACAT) and the Volkswagen Foundation under contract 88393.

Nitrogen Vacancy Magnetic Microscopy of Spin Textures in Magnetic Nanomaterials Adam Erickson, Wai Kiat Chin, Rupak Timalsina and Abdelghani Laraoui; University of Nebraska-Lincoln, United States

Magnetic microscopy based on nitrogen vacancy (NV) centers in diamond has become a multifunctional tool to study condensed matter phenomena at the nanoscale [1]. Unlike current magnetic imaging techniques, the NV microscopy platform works at a wide range of temperatures, frequencies, magnetic fields, and it does not perturb the target magnetic sample. We present recent results where NV microscopy is used in both far field and near field (scanning probe) geometries to map spin textures and magnetic excitation (spin-wave) modes in transition metal magnetic nanostructures. Understanding their static and dynamic spin textures can help in exploiting their useful properties such as high surface-to-volume ratio and tailorable surface chemistry for applications in biosensing, catalysis, spintronics, and ultra-high-density magnetic recording. At sizes below 10 nm, surface and edge effects play a major role in determining their magnetic moment and also effect significantly their spin-wave modes. Accurate measurements of spin textures of individual magnetic nanostructures would therefore shed light on their critical properties for tailored applications. Here we report ongoing experiments using NV magnetic microscopy to measure the static and dynamic magnetic properties of individual Co, FeCo (size range 4-15 nm), and CoFeB (size range 20-100 nm) nanostructures. Histograms of important parameters such as magnetization saturation, magnetic domain size, magnetic anisotropy, spin relaxation, and dynamic magnetic excitation modes are extracted and correlated with morphology data taken by atomic force microscopy, scanning electron microscopy, and transmission electron microscopy. We acknowledge support from NSF-DMR award #1809800 and NSF-EPSCoR RII Track-1: Emergent Quantum Materials and Technologies (EQUATE), Award OIA-2044049.

Current-Induced Switching of Thin–Film α-Fe_2O_3 Devices Imaged Using a Scanning Single-Spin Microscope Qiaochu Guo[1], Yang Cheng[2], Pengxiang Zhang[3], Isaiah Gray[1], Fengyuan Yang[2], Luqiao Liu[3], Katja Nowack[1] and Gregory Fuchs[1]; [1]Cornell University, United States; [2]The Ohio State University, United States; [3]Massachusetts Institute of Technology, United States

Antiferromagnetic (AF) materials are interesting for future generation memory and logic applications due to their sub-picosecond spin dynamics and potential for high density. α-Fe_2O_3 is an AF insulator with canted spin-order that leads to a weak magnetic moment oriented perpendicular to the Néel vector at room temperature. Recent studies have shown that the magnetic order of α-Fe_2O_3 can be manipulated using applied currents and read out using spin Hall magnetoresistance. The origin of current-induced switching is still under debate – with spin-orbit torque or thermomagnetoelastic effects due to Joule heating as the two leading mechanisms. To better understand the magnetism of α-Fe_2O_3 and how it is manipulated, here we report magnetic imaging of α-Fe_2O_3 thin film devices with a diamond nitrogen-vacancy (NV) center scanning microscope. We image at 110 nm above a 60 nm thick α-Fe_2O_3 thin film capped with 6 nm of Pt patterned into a Hall cross. The local magnetic texture switches after passing a current pulse through the Pt layer. The difference images between the magnetic field images before and after the current pulse show the switched regions and their switching directions. Our results show that the amount of switching depends on the current pulse duration and the current amplitude. Pulses shorter than 1 μs do not generate switching even with current density up to 8 x 10^{12} A/m^2. This indicates that spin-orbit torque may not be the most important mechanism for the current-induced switching. Meanwhile, we also observe switching outside the current path, where there is no spin-orbit torque. These results suggest that Joule heating from the current and/or heat-induced strain is sufficient to produce magnetic switching. The images also indicate that the current-induced switching can be reversed by an orthogonal current pulse. In addition, we perform autocorrelation analysis of the magnetic images to identify preferred directions of Néel order, which provides more information about the spin domains in thin-film α-Fe_2O_3. The high resolution, high sensitivity magnetic images obtained with scanning NV microscopy provides a means to further investigate the magnetization and switching dynamics of thin film AF insulators.

5:30 PM EQ03.08.05
Quantitative Imaging of Antiferromagnetic Spin Cycloidal Textures on Strain Engineered $BiFeO_3$ Thin Films with a Scanning Nitrogen-Vacancy Magnetometer Hai Zhong[1], Johanna Fischer[2], Angela Haykal[3], Aurore Finco[3], Alexander Stark[1], Felipe Favaro de Oliveira[1], Patrick Maletinsky[1], Mathieu Munsch[1], Stéphane Fusil[2], Vincent Jacques[3], Vincent Garcia[2] and Peter Rickhaus[1]; [1]Qnami AG, Switzerland; [2]Unité Mixte de Physique, CNRS, Thales, Université Paris Saclay, France; [3]Laboratoire Charles Coulomb, CNRS, Université de Montpellier, France

Antiferromagnetic thin films attract significant interest for future low-power spintronic devices [1]. Multiferroics, such as bismuth ferrite $BiFeO_3$, in which antiferromagnetism and ferroelectricity coexist at room temperature, appears as a unique platform for spintronic [2] and magnonic devices [3]. The nanoscale structure of its ferroelectric domains has been widely investigated with piezoresponse force microscopy (PFM), revealing unique domain structures and domain wall functionalities [4]. However, the nanoscale magnetic textures present in $BiFeO_3$ and their potential for spin-based technology remain concealed. In this report, we present two different antiferromagnetic spin textures in multiferroic $BiFeO_3$ thin films with different epitaxial strains, using a commercial non-invasive scanning Nitrogen-Vacancy (NV) magnetometer based on a single NV defect in diamond, with a calibrated NV flying height of ~60 nm and a proven DC field sensitivity of ~1 μT/√Hz. Two $BiFeO_3$ samples were grown on $DyScO_3$ (110) and $SmScO_3$ (110) substrates (later mentioned as BFO/DSO and BFO/SSO, respectively) using pulsed laser deposition. The striped ferroelectric domains in both samples are first observed by the in-plane PFM. The scanning NV magnetometry (SNVM) confirms the existence of the spin cycloid texture, with zig-zag wiggling angles of 90° and 127°, and propagation wavelength of λ_{DSO}=64 nm and λ_{SSO} =103 nm, respectively. At the local scale, the combination of PFM and SNVM allows to identify the relative orientation of the ferroelectric polarization and cycloid propagation directions on both sides of a domain wall. For the BFO/DSO sample, the 90-degree in-plane rotation of the ferroelectric polarization imprints the 90-degree in-plane rotation of the cycloidal propagation direction along k1=[-1 1 0], corresponding to the type-I cycloid. On the contrary, in the BFO/SSO sample, the propagation vectors are found to be along k1'=[-2 1 1] and k2'=[1 -2 1] directions in the neighbouring domains separated by the 71° domain wall. It is worth to mentioned that in the previous report [5], BFO/SSO, prepared in another growth chamber, showed G-type antiferromagnetic textures, compared to the observed type-II cycloid here. Our results here shed the light on future potential for reconfigurable nanoscale spin textures on multiferroic systems by strain engineering.

Nanoscale Free Radical Detection in Living Cells Using Diamond Magnetometry Linyan Nie[1], Anggrek C. Nusantara[1], Mayeul S. Chipaux[2] and Romana Schirhagl[1]; [1]Groningen University, Netherlands; [2]EPF Lausanne, Switzerland

Free radicals play a key role in many biological processes including cell communication, immune responses, metabolism or cell development. But they are also involved whenever something is wrong in a cell and are thus important in many diseases including cardiovascular diseases, cancer or bacterial and viral infection. Unfortunately, they are very reactive and short lived and thus difficult to detect for the state of the art. We have used diamond magnetometry to achieve this. We make use of nanodiamonds which we bring into cells. We then use of NV centers in diamonds to perform relaxometry measurements. These are sensitive to spin noise (in this case from radicals) and deliver signals that are equivalent to T1 in conventional MRI but from nanoscale voxels. Using this method, we are able to quantify free radical generation with nanoscale resolution in the nanomole range1. In our recent work we were able to detect free radical generation in single mitochondria (the energy factories of the cell) in isolated form as well as in their cellular environment2.

Magnetocardiography of Mammalian Animals Using Nitrogen-Vacancy Centers in Diamond Keigo Arai[1,2], Akihiro Kuwahata[3], Daisuke Nishitani[1], Ikuya Fujisaki[1], Ryoma Matsuki[1], Yuki Nishio[1], Zonghao Xin[4], Xinyu Cao[4], Yuji Hatano[1], Shinobu Onoda[5], Chikara Shinei[6], Masashi Miyakawa[6], Takashi Taniguchi[6], Masatoshi Yamazaki[7,4], Tokuyuki Teraji[6], Takeshi Ohshima[5], Mutsuko Hatano[1,5], Masaki Sekino[4] and Takayuki Iwasaki[1]; [1]Tokyo Institute of Technology, Japan; [2]JST PRESTO, Japan; [3]Tohoku University, Japan; [4]The University of Tokyo, Japan; [5]National Institutes for Quantum and Radiological Science and Technology, Japan; [6]National Institute for Materials Science, Japan; [7]Nagano Hospital, Japan

Magnetocardiography (MCG) is a contactless technique that remotely measures the stray magnetic fields produced by cardiac currents in the heart. The spatial resolution of MCG deteriorates significantly as the standoff distance between the target and the sensor increases. Commercialized MCG devices usually provide centimeter-scale spatial resolution. As an alternative approach, nitrogen-vacancy (NV) centres in diamond have gained interest as a magnetometor for biological experiments [1,2]. In this talk, I will present MCG of mammalian animals using an ensemble of NV centers [3]. A millimeter proximity from the sensor to heart surface enhances the cardiac magnetic field to greater than nanoteslas and allows the mapping of these signals with intra-cardiac resolution. I will also discuss the possiblity of further improvement in sensitivity and resolution as well as applying this technique to studying the origin and progression of myriad cardiac arrhythmias including flutter, fibrillation, and tachycardia.

NV-Based Hyperpolarization and High-Resolution Detection of Molecules on the Nanoscale Ilai Schwartz; NVision Imaging Technologies GmbH, Germany

Nitrogen vacancy (NV) centers in diamond have been used as ultrasensitive sensors for performing nuclear magnetic resonance (NMR) spectroscopy of molecules external to the diamond at nanometer to micrometer length scales. However, the spectral linewidth is typically limited to the kHz level on the nanoscale, both by the NV sensor coherence time and by rapid molecular diffusion of the nuclei through the detection volume.
In addition, NV centers offers promising opportunities for nanoscale hyperpolarization by combining dynamic nuclear polarization methods with optical hyperpolarization. We have previously shown that hyperpolarized signals could enable high spectral resolution on the nanoscale, not limited by molecular diffusion rates.

In this talk we will detail the schemes and challenges for nanoscale polarization using NV centers and show how these could be overcome. We will demonstrate the first unambiguous signal of NMR detection from NV-hyperpolarized external molecules and discuss the potential outlook and future applications.

Dynamic nuclear polarization (DNP), a technique to transfer spin polarization from electrons to nuclei, has been studied since its early discovery [1] and has opened the way for high sensitive nuclear magnetic resonance (NMR) spectroscopy and magnetic resonance imaging. In "conventional" DNP, which uses thermally-polarized unpaired electrons as the source of polarization, the DNP enhancement factor is limited to γ_e/γ_n, where $\gamma_{e(n)}$ are the gyromagnetic ratios of the electron (nuclear) spins. In DNP using the paramagnetic electrons in thermal equilibrium, experiments need to be performed at cryogenic temperature to increase the electron-spin polarization as much as possible. Conversely, the spins of optically created electrons in the triplet state can have much higher polarization than their thermal equilibrium value, DNP using the triplet state, referred to as triplet DNP, can lead to nuclear hyperpolarization beyond the limit of the conventional DNP using thermal electron polarization. Furthermore, experiments can be carried out at room temperature, by irradiating the sample with laser light. Recently, DNP of an ensemble of ^{13}C nuclear spins using negatively charged nitrogen-vacancy (NV^-) color centers in a bulk diamond single crystal has been demonstrated at room temperature and the ^{13}C polarization of 6 % has been achieved via the combination of the thermal mixing and the solid effect [2]. DNP using NV^- in powdered microdiamonds has been reported by Ajoy *et al.*, who took advantage of the reduced width of the anisotropic electron spin resonance powder pattern of the NV^- centers at the magnetic field of ca. 30 mT [3]. However, triplet DNP is much older and achieved a ^1H polarization of 34 % at room temperature and a magnetic field of 0.4 T using pentacene in *p*-terphenyl crystal [4]. Even though triplet DNP in both systems, NV^- centers and pentacene, relies on the transfer of spin polarization from optically hyperpolarized triplet electrons to nuclei , there are important differences. While the NV^- center has an electronic triplet ground state and is therefore paramagnetic, pentacene has an electronic singlet ground state, is diamagnetic, and only becomes paramagnetic through optical excitation into a triplet state. On the other hand, the zero-field splitting parameter *D* for pentacene is only half as large as in NV^- centers, which is an advantage when disordered powder is used as a sample.
In this work, we compare triplet-DNP of NV^- centers in diamond and pentacene doped in [carboxyl-^{13}C] benzoic acid (PBA) in polycrystalline samples at room temperature [5]. In the DNP experiments, the integrated solid effect (ISE) was used to transfer the polarization from electrons to nuclei. The ISE employs microwave irradiation and external magnetic-field sweep, so that the Hartmann–Hahn matching is implemented between the electron spins in the rotating frame and the nuclear spins in the laboratory frame. We study the behavior of the ^{13}C polarization buildup in terms of the polarization efficiency of the transfer from the electron to nuclei, exchange rate, and the ^{13}C spin diffusion. As a result, we obtained the ^{13}C polarization of 0.01 % in the microdiamonds, and of 0.12 % in PBA at room temperature in a magnetic field of 0.4 T by using the integrated solid effect and the obtained exchange rate was 0.87 % for microdiamonds and 3.5 % for PBA. The ^{13}C polarization enhancements for the diamond and the PBA were 300 and 3600 compared to the thermal NMR polarization. Besides the initial polarization transfer from the triplet electron to the nuclei, we also shed light on the process of nuclear spin-spin diffusion, which distributes the hyperpolarization within the sample.

Label-Free Phase Change Detection of Lipid Bilayers Using Nanoscale Diamond Magnetometry Hitoshi Ishiwata[1,2], Hiroshi C. Watanabe[1,3], Shinya Hanashima[4], Takayuki Iwasaki[2] and Mutsuko Hatano[2]; [1]PRESTO, Japan; [2]Tokyo Institute of Technology, Japan; [3]Quantum Computing Center, Keio University, Japan; [4]Osaka University, Japan

The cell membrane is a nanoscale 2D fluid crystalline assembly with sub-compartment domains that are critical for cellular functions, including transport of molecules, communications, and metabolic properties with its external medium [1]. These domains are distinguished by different phases of lipid membranes, and the fluidity of the lipid bilayer, described by the 2D translational diffusion of lipid molecules [2], determines the most fundamental property of lipids in different phases and therefore domains. Nanoscale NMR and correlation spectroscopy using a NV center has emerged as a quantum measurement platform that allows for label-free diffusion measurement with nuclear spin from a small detection volume of ~ $(6\ nm)^3$ [3].
In this study, we investigate nanoscale phase change detection of lipid bilayers utilizing ensemble-averaged nuclear spin detection from small volume ~ $(6\ nm)^3$, which is determined by the depth of the NV center. Analysis of nanoscale NMR signal confirms thickness of lipid bilayer to be 6.2 nm ± 3.4 nm with proton density of 65 proton/nm3 on top of diamond sample. The result of the correlation spectroscopy was compared with the 2D molecular diffusion model constructed by Monte Carlo simulation combined with results from molecular dynamics (MD) simulation. There is a change in diffusion constant from 1.5 ± 0.25 $nm^2/\mu sec$ to 3.0 ± 0.5 $nm^2/\mu sec$ when the temperature changes from 26.5 °C to 36.0 °C [4]. Our results demonstrate that label-free detection of changes in translational diffusion of lipid molecules is possible using nanoscale diamond magnetometry. Direct observation of changes in the diffusion constant paves the way for the label-free identification of domains that are formed in the cell membrane to understand the relationship between cell membrane dynamics and cell function [5].

Imaging of Weight Distribution Using a Hybrid System Based on Piezoactive Magnetic Material and Diamond Quantum Sensor Ryota Kitagawa[1], Shunsuke Nagata[1], Soki Urashita[1], Keigo Arai[1,2], Kosuke Mizuno[1], Hitoshi Ishiwata[1,2], Yota Takamura[1], Takayuki Iwasaki[1], Shigeki Nakagawa[1] and Mutsuko Hatano[1]; [1]Tokyo Institute of Technology, Japan; [2]Japan Science and Technology Agency, Japan

Imaging of weight introduces a new modality for the study of biological systems. Existing techniques either have high weight sensitivity but can measure only a single cell or offer a large field of view with limited weight sensitivity[1,2]. Thus, a key challenge in weight imaging is to provide a capability to measure various biological systems extending over multiple length scales from single cells to biological tissues. Such a high dynamic range in length scale can be realized by a hybrid sensor based on piezoactive magnetic material[3] and nitrogen-vacancy (NV) centers in diamond[4]. In the hybrid sensor, due

to the inverse magnetostrictive effect, weight is converted into the rotation of magnetization and domain wall motion in piezoactive magnetic material. This rotation and domain wall motion induce a change in the stray magnetic field, which can be detected by NV centers via optically-detected magnetic resonance (ODMR). For the realization of the hybrid sensor, accurate imaging of weight distribution is essential. Here, we demonstrate weight imaging using a hybrid system composed of piezoactive magnetic material and the NV center and calibrated weight.
We fabricated a hybrid sensor by gluing a piezoactive magnetic material of a $SmFe_2$ thin film, deposited on an ultra-thin glass substrate, and NV centers in a diamond film deposited on a type-Ib diamond (111) substrate. We applied weight onto the system in an area of 3.1 mm^2 by putting on a rivet with a total weight of 9 g. As a comparison, we performed the measurement without applying weight. Imaging of the magnetic field distribution was performed by continuous-wave ODMR while applying a bias magnetic field of ~2 mT to break the degeneracy of the NV center spin levels.
We observed a different response between the stressed and unstressed areas. The change of the magnetic field was more significant in the stressed area. On the other hand, the shape of the magnetic field distribution that is thought to originate from the magnetic domain did not change. These results imply that the rotation of the magnetization was dominant compared to domain wall motion. We can understand the weight response of $SmFe_2$ by a simple single domain model, including magnetization, intrinsic magnetic anisotropy, and strain-induced anisotropy. The observed magnetic field difference of about ±15 μT is comparable with the value estimated by the single domain model. We established essential techniques for constructing the hybrid system through imaging weight response of piezo active magnetic material by NV center.

The Case Against Entanglement Advantages in Quantum Sensing Liam Mcguinness; The Australian National University, Australia

In this talk I will outline reasoning as to why we should not expect entanglement to improve the performance of quantum sensors. I will consider the specific sensing example of estimating the frequency of an unknown field, and provide additional arguments for general sensing. The talk will also discuss published literature and why the experimental evidence is in agreement with this talk's central thesis.

11:00 AM EQ03.10.02
Remote Nuclear Magnetic Resonance Detected by Low-Frequency Quantum Sensing David Herbschleb[1], Izuru Ohki[1], Kohki Morita[1], Yoshiharu Yoshii[2], Hiromitsu Kato[3], Toshiharu Makino[3], Satoshi Yamasaki[4] and Norikazu Mizuochi[1]; [1]Kyoto University, Japan; [2]Sumida Corporation, Japan; [3]National Institute of Advanced Industrial Science and Technology (AIST), Japan; [4]Kanazawa University, Japan

Quantum sensing has a bright future for many applications given its potential for high sensitivity and resolution. Sensing with nitrogen-vacancy (NV) centres is a much explored option given its room-temperature operation, making it a feasible choice for biology applications. One example is measuring nuclear magnetic resonance (NMR) spectra of molecules. Given the potential for arbitrary resolution [1,2], Fourier-based algorithms have been implemented for measuring such NMR signals [3]. However, these are limited for use at high frequencies (over ~1 kHz) given the usage of dynamical decoupling sequences. On the other hand, low-frequency signals are important for chemical structure analysis [4] and for searching new particles beyond the standard model [5]. Here, we demonstrate a technique to measure low-frequency fields which sensitivity is frequency independent. Moreover, we apply it to measure low-frequency NMR signals with a remote NMR system, giving a line width for the free nuclear precession of water of 1.6 Hz.

11:15 AM EQ03.10.03
Detection of Nuclear Quadrupolar Resonance of a Nanoscale 2D Material by Optimized Nitrogen Vacancy Ensembles in Diamond Jacob D. Henshaw[1,2], Pauli Kehayias[1], Maziar Ziabari[2,3], Takashi Taniguchi[4], Kenji Watanabe[4], Erin Morissette[5], Jia Li[5], Edward Bielejec[1], Michael Lilly[1,2] and Andrew Mounce[1,2]; [1]Sandia National Laboratories, United States; [2]Center for Integrated Nanotechnologies, United States; [3]The University of New Mexico, United States; [4]National Institute for Materials Science, Japan; [5]Brown University, United States

Nuclear magnetic resonance (NMR) and nuclear quadrupole resonance (NQR) of bulk quantum materials has provided significant insight into magnetic phenomena such as quantum phase criticality, magnetism, and superconductivity. With the emergence of nanoscale 2-D materials with magnetic phenomena, traditional, inductively detected NMR is not sufficiently sensitive to detect the small nuclear density in these materials. The nitrogen-vacancy center in diamond (NV) has shown great promise in bringing the spectroscopic capabilities of NQR to the nanoscale and has been demonstrated utilizing single NV spins to detect 11B NQR in a monolayer of hBN[1]. Single NV spins provide 30nm resolution but can be unstable and maybe less sensitive to NMR than NV ensembles. However, NV NMR detection of 2D materials has yet to be demonstrated with NV ensembles. Furthermore, the optimal NV layer for NMR detection will require an optimized depth calibration which trades off sample-NV standoff (closer to the diamond surface) and higher activation/better spin properties (further from diamond surface).
In this work, we prepare a range of near-surface NV ensembles, determine their depths by 19F NMR, determine their NMR sensitivities, and use our most sensitive NV ensemble for detection of 11B NQR in hBN exfoliated onto the diamond surface. To prepare our near surface NV ensembles, we implant

approximately 100ppm nitrogen at energies from 1.5 to 7 keV and activate NVs by ultra-high vacuum annealing. By applying fomblin oil on the surface of these diamonds and detecting 19F NMR signal intensity, we find effective NV ensemble depths to be from 3 nm to 12 nm. The 19F NMR signal intensity also serves as an experimental determination of the nuclear spin sensitivity for our NV ensembles, and we find that our 3 keV (7.5 nm deep) NV ensemble is the most sensitive to 19F on the diamond surface. We then exfoliated 100nm thick flakes of hBN onto the surface of these diamonds and measure the NQR signal intensity of 11B by both CPMGXY8-N and correlation spectroscopy. The intensity of 11B NQR spectra are also found to be optimal for the 3keV NV implant, reenforcing the results of our 19F signal optimization. As a next step, with our optimized NV ensemble, we will measure the spatial dependence of the NQR frequency on our hBN flakes to determine the spatial variations of strain and electric fields.

High-Resolution NV-NMR Spectroscopy at the Micron-Scale Ronald Walsworth and Nithya Arunkumar; University of Maryland, United States

Nitrogen-vacancy (NV) quantum defects in diamond can detect nuclear magnetic resonance (NMR) signals with high-spectral resolution from micron-scale sample volumes. However, a key challenge for NV-NMR spectroscopy is detecting samples at millimolar molecular concentrations to enable analysis of complex micron-scale systems such as individual cells. Here we describe methods to increase NV-NMR concentration sensitivity by several orders of magnitude using hyperpolarization of target proton spins and a quantum memory readout. To date, these methods have allowed micron-scale NMR spectroscopy of small-molecule sample concentrations as low as 1 millimolar in picoliter volumes, with further sensitivity improvements expected.

SESSION Tutorial EQ04: Symmetry-Aware Neural Networks for the Material Sciences
Monday Morning, November 29, 2021
Hynes, Level 2, Room 205

8:30 AM
Euclidean Symmetry in Machine Learning for Materials Science Tess Smidt; Lawrence Berkeley National Laboratory, United States

Understanding symmetry's role in the physical sciences is critical for choosing an appropriate machine learning method. For example, coordinates used to describe positions of atoms in a material are traditionally a challenging data type to use for machine learning -- coordinates and coordinate systems are sensitive to the symmetries of 3D space: 3D rotations, translations, and inversion. One of the motivations for incorporating symmetry into machine learning models on 3D data is that it eliminates the need for data augmentation -- the 500-fold increase in brute-force training necessary for a model to learn 3D patterns in arbitrary orientations. Additionally, many features of physical systems are consequences of symmetry -- geometric tensor properties, point groups, and space groups, degeneracy, phase transitions, atomic orbitals, etc. By incorporating symmetry into a model by construction (rather than by training), these consequences arise naturally in the behavior of the model (even in untrained models). There are two general types of symmetry-aware models: invariant and equivariant. Invariant models get rid of coordinate systems by only dealing with quantities that are invariant to the choice of coordinate system (scalars), while equivariant models preserve how quantities predictably change under coordinate transformations. While invariant models are the most prevalent symmetry-aware models because they are mathematically simpler, equivariant models more faithfully represent the complexity of physical interactions. In this tutorial we will discuss how symmetry emerges when representing physical systems and strategies for accommodating these symmetries when building machine learning algorithms. As an example, we will give an overview of some of the properties of Euclidean neural networks, a general neural network framework that fully treats the equivariance of physical systems and naturally handles 3D geometry and operates on the scalar, vector, and tensor fields that characterize them. Later lectures will dive into how these and related methods are implemented and

applied to real-world materials challenges.

9:30 AM
Group Theory, Irreducible Representations, and Tensor Products and How to Use them in e3nn to Build Euclidean Neural Networks Mario Geiger; EPFL, Switzerland

In this tutorial we will introduce useful concepts group theory for creating symmetry invariant and equivariant algorithms for materials: representation of groups and the vector spaces they act on, including irreducible representations, and how to interact and combine group representations, e.g. tensor products.

We will connect this theory to practical examples in material science, for example we will give examples of tensor properties of materials and how to express them in terms of Cartesian tensors and irreducible representations.

Euclidean neural networks use these group theoretic principles to achieve global and local equivariance to 3D rotations, translations, and inversion at every layer. We will go through concrete coding examples for how to build these models using e3nn: a modular open-source PyTorch framework for Euclidean Neural Networks (https://e3nn.org). In e3nn, the group theoretic tools discussed above are implemented as practical PyTorch modules. We will cover the Irreps class and operations such as TensorProduct. We will also touch upon topics such as nonlinearities and how these differ from traditional neural networks. The e3nn package will continue to be used throughout the morning and afternoon tutorials to demonstrate core concepts in using invariant and equivariant algorithms for practical materials applications.

10:30 AM BREAK

11:00 AM
Analyzing geometry and structure of atomic configurations with equivariant and invariant functions Thomas J. Hardin[1] and Martin Uhrin[2]; [1]Sandia National Laboratories, United States; [2]EPFL, Switzerland

Some of the most challenging aspects of applying machine learning to atomic configurations have to do with interfacing atomic configurations (point clouds and species labels) with machine learning methods in a way that 1) respects geometric symmetry, 2) is flexible with respect to the number of atoms in a configuration, and 3) respects indistinguishability of atoms. e3nn handles each of these issues naturally, making it an ideal framework for machine learning on atomic configurations.
In this hands-on lecture we will use e3nn to 1) demonstrate how to project atomic environments onto basis function expansions (using the SphericalTensor and FourierTensor objects in e3nn), 2) use those expansions to calculate invariant representations of the atomic configurations, and 3) show how to use optimization techniques and the automatic differentiation capabilities of e3nn to recover geometry from these representations.

12:00 PM BREAK

1:30 PM
Molecular dynamics with NequIP Simon L. Batzner; Harvard University, United States

Machine-Learning Interatomic Potentials have over the past decade emerged as a powerful tool for increasing time- and length-scales of molecular dynamics simulations while retaining the high accuracy of the reference calculations they were trained on. Recently, the NequIP potential, an equivariant neural network-based interatomic potential has been demonstrated to obtain an unprecedented level of accuracy and sample efficiency, allowing ML Interatomic Potentials to be trained with up to 1000x fewer training data than competing methods.

In this tutorial, we will demonstrate how to train and subsequently deploy NequIP interatomic potentials in molecular dynamics simulations. We will outline best practices for data set selection and training of the NequIP model as well as how to successfully run efficient simulations. We will give an introduction to the NequIP software code and detail how to work with its interface to the LAMMPS molecular dynamics software suite, a highly efficient code for large-scale molecular dynamics simulations, enabling the efficient and accurate study of a diverse range of materials.

2:30 PM BREAK

3:00 PM
Predicting Electron Densities with e3nn Josh Rackers; Sandia National Laboratories, United States

One of the fundamental challenges of atomic-scale science for the 21st century is the ability to simulate large molecules with quantum mechanical accuracy. What makes this problem so challenging is the poor scaling of solving the equations of quantum mechanics on a classical computer. Even the most efficient quantum chemistry programs, such as Density Functional Theory (DFT), scale with the cube of the system size. This makes accurate simulations of large molecules with these methods fundamentally impossible.

One proposed method of breaking this “quantum scaling limit” is to use machine learning (ML) to learn quantum mechanics. In this tutorial, we will demonstrate how Euclidean Neural Networks in general, and e3nn in particular, are well-suited for this task. As an instructive example, we will show how to predict the electron density of clusters of water molecules and examine how that model can transfer to larger systems.

4:00 PM
Predicting Phonon Properties of Crystal Structures Zhantao Chen; Massachusetts Institute of Technology, United States

Phonon density of states (DoS) is a key determinant of many properties of crystalline solids. However, acquisition of phonon DoS is experimentally nontrivial due to limited inelastic scattering facility resources, and at the same time computationally expensive for complex materials, particularly disordered systems. These challenges further lead to a scarcity of phonon DoS data to perform data-driven studies.

e3nn enables efficient and direct prediction of phonon DoS using easily accessible input information about atomic structures, specifically atom types, masses, and positions. By directly incorporating crystallographic and 3D spatial symmetry constraints, e3nn can achieve good performance even when trained on a modest phonon DoS dataset of ~1000 examples. In this lecture, we will demonstrate how to predict phonon DoS from crystal structures using e3nn, as well as introduce the natural extension of predicting the DoS of alloy materials.

SESSION EQ04.01: Machine Learning for Spectroscopy
Session Chair: Mingda Li
Tuesday Morning, November 30, 2021
Hynes, Level 2, Room 205

10:30 AM *EQ04.01.02
Time-Resolved RIXS Technique and Applications in Nonequilibrium Quantum Materials Yao Wang; Clemson University, United States

Quantum material has become a new research frontier and is widely believed to be the cornerstone of the next technological revolution. To initiate revolutionary innovations, the precise control of the electronic properties in quantum materials is on demand. The ultrafast laser pump becomes a promising control approach due to the rich degrees of freedom and the extra time axis. However, it also places an urgent requirement for the ultrafast identification of the materials' property.

In this talk, I will briefly introduce the new ultrafast pump-probe technique, time-resolved resonant inelastic x-ray scattering, from a theoretical and computational perspective. Then I will use two typical classes of quantum materials, the topological material and correlated magnets, as examples to sketch the novel applications. As a nonlinear pump-probe technique, its intermediate state selectivity provides a clean characterization of topological edge states. Its sensitivity to multiple excitations and the broad momentum coverage gives a unique opportunity to Floquet-engineer spin excitations in correlated materials.

11:00 AM *EQ04.01.03
Using Complete, Symmetry Invariant Representations of Atomic Environments to Predict New Ionic Liquids from Experimental Data Martin Uhrin; EPFL, Switzerland

The ultimate goal of any atomistic design process, be it for materials or molecules, is to start with one or more target properties and predict atomic geometries that are statistically likely to possess these properties. In this talk, I will discuss how to construct complete, symmetry invariant descriptions of atomic environments that can be inverted to recover the original environment. Using this representation I will show that it is possible to build a model that can predict the conductivity of ionic liquids, an important potential electrolyte for future battery technologies. By training on a dataset of experimental results the model learns how to attribute contributions to the overall conductivity to fragments of the anion and cation. This allows us to virtually screen thousands of anion/cation combinations to pinpoint those with high conductivities. Furthermore, it opens the door to designing entirely new molecules by combining fragments to achieve properties that go beyond those that are possible using current ionic liquids.

11:30 AM *EQ04.01.04
Unravel the Frequency-dependent Phonon Transport with Scientific Machine Learning Zhantao Chen; Massachusetts Institute of Technology, United States

Phonon transport at the nanoscale intimately relates to various crucial applications in the modern society. However, our understandings about frequency-dependent transport mechanisms, especially across an interface, are scarce due to the fundamental gap between observables and computables. In this talk, we introduce a framework that combines the scientific machine learning and the Boltzmann transport equation (BTE) to unravel microscopic phonon transport information inside heterostructures from the ultrafast electron diffraction (UED). We show that the time- and momentum-resolved diffraction patterns can be reliably interpreted by our approach to reconstruct frequency-dependent properties such as transmission coefficients and relaxation times, as well as other general properties like material-air emissivities, from which real-time and real-space phonon dynamics can be further recovered. We validate our approach through several numerical scenarios and apply it to analyze experiment measurements of an Au/Si heterostructure. Our work opens a new avenue to reveal phonon transport mechanisms across interfaces at the nanoscale.

SESSION EQ04.02: Unsupervised Learning and Data Mining for Materials Discovery
Session Chair: Tess Smidt
Tuesday Afternoon, November 30, 2021
Hynes, Level 2, Room 205

1:30 PM *EQ04.02.01
Unsupervised Machine Learning and Band Topology Robert-Jan Slager; University of Cambridge, United Kingdom

The study of topological band structures is an active area of research in condensed matter physics and beyond. Here, we combine recent progress in this field with developments in machine learning, another rising topic of interest. Specifically, we introduce an unsupervised machine learning approach that searches for and retrieves paths of adiabatic deformations between Hamiltonians, thereby clustering them according to their topological properties. The algorithm is general, as it does not rely on a specific parametrization of the Hamiltonian and is readily applicable to any symmetry class. We demonstrate the approach using several different models in both one and two spatial dimensions and for different symmetry classes with and without crystalline symmetries. Accordingly, it is also shown how trivial and topological phases can be diagnosed upon comparing with a generally designated set of trivial atomic insulators.

2:00 PM *EQ04.02.02
Machine Learning Discovery of New Superhard Ternary and High-Entropy Borides Cheng-Chien Chen; University of Alabama at Birmingham, United States

Superhard materials exhibit a Vickers hardness $H > 40$ GPa, and they have extensive industrial and technological applications. Due to the huge search space of possible element combinations, it is challenging to explore new superhard ternary or quaternary materials. Here, I will first discuss machine

learning (ML) discovery of new superhard B-C-N and B-N-O compounds. The ML results are validated by evolutionary structure prediction and density functional theory (DFT). In particular, the proposed $BC_{10}N$ has a low formation energy and a high hardness $H \sim 86$ GPa only next to diamond. I will next discuss the calculations of entropy formation ability (EFA) using both DFT and ML approaches for 5-metal hexagonal high-entropy borides. The results indicate that EFA serves as a good descriptor for the synthesizability of high-entropy materials, some of which have superior mechanical properties promising for extreme-environment applications.

2:30 PM EQ04.02.03
Machine Learning the Relationship Between Debye and Superconducting Transition Temperatures Adam D. Smith[1], Sumner B. Harris[1,2], Renato P. Camata[1] and Cheng-Chien Chen[1]; [1]University of Alabama at Birmingham, United States; [2]Oak Ridge National Laboratory, United States

Recently a relationship between the Debye temperature and the superconducting transition temperature T_c of conventional superconductors has been proposed. The relationship indicates that the maximum T_c for phonon-mediated BCS superconductors is at most ~0.1×Debye temperature. In order to verify this bound and develop tools for predicting the Debye temperature we've trained machine learning models on over 10000 compounds with just chemical formula and crystal symmetry group as features. By examining over 9000 known superconducting compounds in the NIMS SuperCon database, our predictions show that conventional superconductors in the database follow the previously proposed bound of T_c versus Debye temperature. We will also use density-functional theory calculations to examine compounds very close and very far away from this bound, and discuss possible strategies of increasing T_c by manipulating the electron-phonon coupling in these systems.

SESSION EQ04.03: Emerging Tools of Machine Learning for Materials Science I

Wednesday Morning, December 8, 2021
EQ04-Virtual

8:00 AM *EQ04.03.01
Data Integration for Accelerated Materials Design via Preference Learning Koji Tsuda; The University of Tokyo, Japan

Machine learning applications in materials science are often hampered by shortage of experimental data. Integration with external datasets from past experiments is a viable way to solve the problem. But complex calibration is often necessary to use the data obtained under different conditions. In this paper, we present a novel calibration-free strategy to enhance the performance of Bayesian optimization with preference learning. The entire learning process is solely based on pairwise comparison of quantities (i.e., higher or lower) in the same dataset, and experimental design can be done without comparing quantities in different datasets. We demonstrate that Bayesian optimization is significantly enhanced via data integration for organic molecules and inorganic solid-state materials. Our method increases the chance that public datasets are reused and may encourage data sharing in various fields of physics.

8:30 AM EQ04.03.02
Automated Processing and Characterisation of EELS Spectral Images with Machine Learning Abel Brokkelkamp[1], Isabel Postmes[1], Jaco ter Hoeve[2,3], Sabrya van Heijst[1], Louis Maduro[1], Juan Rojo[2,3] and Sonia Conesa-Boj[1]; [1]TU Delft, Netherlands; [2]Vrije Universiteit Amsterdam, Netherlands; [3]Nikhef, Netherlands

Spectral images obtained with Electron Energy-Loss Spectroscopy (EELS) are two-dimensional sets of spectra where each pixel provide information on a localised region of the analysed sample. Each of these spectra contain a plethora of information related to the physical and electronic properties of the material. Exploiting this information requires reliable access to the low-loss region where the zero-loss peak (ZLP) overwhelms the inelastic scattering contributions of the specimen. Here we present a novel approach to process and analyse EEL spectral images in an automated manner based on machine learning. By clustering the constituent spectra into groups associated to sample regions with similar profiles using unsupervised learning, we can then subtract the ZLP in a model-independent manner using deep neural networks. The resulting processed spectral images can then be used to identify spatially-resolved local electronic properties such as the bandgap (and determine whether it is a direct or indirect bandgap) and the optical dielectric function across the sample. Furthermore, we correlate them to the thickness and other structural properties of the sample. In addition, our approach also allows us to identify interesting features in the low-loss region and determine how these features vary in the different regions of the sample. This strategy has been performed on both Tungsten Disulfide and Indium Selenide nanostructures obtaining results that are in agreement with the literature. Our novel method can be extended into higher-dimensional datasets in a straightforward manner and is implemented into a new release of the open source python package EELSfitter.

8:45 AM *EQ04.03.03
From Density Functional Theory to Machine Learning for Accurate Prediction of Materials Properties Silvana Botti; Friedrich Schiller University Jena, Germany

I will discuss different approaches to improve the accuracy of materials property predictions, combining density-functional theory calculations, different machine learning methods and experimental datasets.

I will present different examples of applications and discuss their performance for the determination of thermodynamic stability, geometry optimization and evaluation of the electronic band gap.

9:15 AM EQ04.03.04
Unsupervised Machine Learning for Spatio-Temporal Characterization of Ultrafast Electron Microscopy Datasets Arun Baskaran, Faran Zhou, Thomas Gage, Haihua Liu, Ilke Arslan, Haidan Wen and Maria K. Chan; Argonne National Laboratory, United States

Advancements in microscopy techniques have made materials investigations at nanometer-picosecond (nm-ps) spatio-temporal resolutions possible. This work details the use of a machine learning based approach to extract quantitative information, in terms of optical flow, pertaining to the motion of contrast bands as captured by an ultrafast electron microscope (UEM). UEM is an emerging technique that uses pulsed electron beams to image structural dynamics at nm-ps resolutions. This spatio-temporal characteristic of a UEM dataset is one of the main challenges encountered during its analysis. Classical image processing techniques for optical flow, such as functions that are part of the OpenCV library, are parametric and hence require manual supervision. In this

work, a U-net type convolutional neural network (CNN) is designed to take a pair of UEM images at different times as input and generate the optical flow at each pixel as output. A custom loss function is defined, consisting of a photometric loss term and a gradient loss term. The loss is regularized with the output from an adversarial model which is simultaneously trained to distinguish between image pairs with and without spatial displacement of objects. In order to overcome the lack of ground truth data for optical flow, the model is trained in an unsupervised manner. The performance of an OpenCV function for dense optical flow is chosen to be the baseline, and the optimal values for the parameters are selected through a grid search on candidate values. The model proposed in the current work outperforms the baseline method on the photometric loss metric. We detail the approach to study the effect of experiment variables, such as temperature, on the phonon dynamics of 2D semiconductor materials.

9:30 AM *EQ04.03.05
Progress Towards Leveraging Natural Language Processing for Collecting Experimental Data and Data Mining Anubhav Jain; Lawrence Berkeley National Laboratory, United States

Today, experimental data sets for various applications are almost exclusively curated manually because data is scattered throughout the research literature. In this talk, I will present progress towards using natural language processing (NLP) algorithms to automatically collect and organize data on a research topic. Such methods are particularly valuable in fields like quantum materials where simulation is difficult or time consuming, necessitating efficient use of experimental data where it is available. In particular, I will present our work on detecting named entities within research texts and connecting these entities into organized data sets. For example, we have collected data pertaining to how various materials are doped by applying NLP to a large corpus of published abstracts and full texts, and connected doping information with applications. Finally, I will discuss how such methods might be applied to a variety of quantum materials applications and how such methods may complement other sources of data such as theory and simulation.

Application of Machine Learning to Neutron Scattering from Magnets David A. Tennant[1] and Anjana Samarakoon[2]; [1]Oak Ridge National Laboratory, United States; [2]Argonne National Laboratory, United States

Inelastic and diffuse neutron scattering hold crucial information on the underlying physical states of materials and models that describe them. The difficulty of handling the large amounts of data and simulations involved as well as challenges of experiment planning and interpretation can be addressed using machine learning. We have been applying these approaches to topological flat band materials of importance as hosts to fractional quasiparticles with anyonic statistics as well as competing disordered phases. Complex behavior due to subtle competing interactions prove to be vital and machine learning provides an effective approach to handling the myriad of phases and behaviors involved. I show outcomes of our machine learning based experiments on quantum and classical spin liquids.

11:00 AM EQ04.04.02
Prediction of Localized Plasmon Resonances in Complex Nanoparticle Assemblies Using Autoencoder Networks Kevin Roccapriore[1], Maxim A. Ziatdinov[1], Shin-Hum Cho[2], Delia Milliron[3], Jordan Hachtel[1] and Sergei V. Kalinin[1]; [1]Oak Ridge National Laboratory, United States; [2]Samsung Semiconductor R&D, Korea (the Republic of); [3]The University of Texas at Austin, United States

Designing nanostructures with desired optical properties is critical to the field of nanophotonics. Traditionally, numerical methods and theoretical predictions are used to inform on design parameters of nanophotonic elements. On the other hand, having knowledge of the structure-property relationships of a given system provides another data-driven approach to design nanostructures. To pave the way towards stochastic design of nanoplasmonic structures, we establish the correlative relationship between local nanoparticle geometries and their plasmonic responses. By using an encoder-decoder neural networks within the framework of PyTorch, we demonstrate the predictions of spectra from local geometries in the *im2spec* network, as well as the predictions of local geometry from spectral inputs in the *spec2im* network [1].
By utilizing scanning electron transmission electron microscopy (STEM), we acquire an electron energy loss (EEL) spectrum image and its associated acquired high angle annular dark field (HAADF) image of a self-assembled monolayer of fluorine and tin doped indium oxide nanocrystal arrays [2]. While the particles mainly undergo self-assembly, many defects and irregularities are observed within and nearby the arrays – for example, missing particles, small clusters of particles, etc. With the knowledge that the plasmonic behavior at a position in space depends primarily on local geometry at that position, subimage-spectrum pairs are generated at each spatial pixel that are used to teach the network the correlative relationship between them. The network encodes the images (spectra) to a low-dimensional feature space consisting of a small number of latent variables, then decodes the latent variables back into spectra (images). The reduced descriptions contained in the so-called latent space can yield a surprising insight into the generative mechanisms of complicated plasmonic responses in nanoparticle arrays [3].
Equipped with the knowledge of correlative structure property relationships gained by the autoencoder networks, we predict the plasmonic response given an unseen nanoparticle geometry. Conversely, we predict nanoparticle geometry given a plasmonic spectrum. This method ultimately enhances the design capabilities for plasmonic systems, and may even permit a route to solving the inverse design challenge in nanophotonics.

Mapping Polarization from STEM and STM Images Ayana Ghosh[1], Christopher Nelson[1], Mark Oxley[1], Xiaohang Zhang[2], Maxim A. Ziatdinov[1], Ichiro

Takeuchi[2] and Sergei V. Kalinin[1]; [1]Oak Ridge National Laboratory, United States; [2]University of Maryland, United States

Scanning transmission electron microscopy (STEM) has become an important tool for studying atomic structures of complex materials with picometer precision and the associated order parameter fields. The latter includes polarization that is classically quantified by preprocessing images to remove noise and instrumental distortions, finding positions of all the observed atomic columns corresponding and calculating atomic displacements. This process is not only highly time consuming and laborious but also may lead to systematic errors in the polarization values.
In this work, we have proposed an alternate approach of utilizing deep convolution neural networks (DCNNs) for ***direct*** polarization mapping from STEM data. The DCNN is trained on the manually-labeled part of the image and is subsequently applied to other images. The training data is constructed using image patches (parts of original images cropped for a specific window size) generated with and without information about atomic positions. The patches are used as the (local) feature set and the corresponding polarization values become the target set. We show that this framework allows predicting polarization maps *without* atom-finding and compare the results with those obtained using the traditional approach.
We have demonstrated the workflow for STEM images with different Sm dopant concentrations in $BiFeO_3$, such that the explored feature space encompasses both ferroelectric and weakly-ferroelectric systems. We further intend to apply this technique to Scanning Tunneling Microscopy (STM/S) datasets of quantum materials to study other functionalities such as superconducting gap or the intensity of selected quasiparticle interference spots.

This effort (STEM) is based upon work supported by the U.S. Department of Energy (DOE), Office of Science, Basic Energy Sciences (BES), Materials Sciences and Engineering Division (S.V.K., C.T.N.) and was performed and partially supported (M.Z.) at Oak Ridge National Laboratory's Center for Nanophase Materials Sciences (CNMS), a U.S. DOE, Office of Science User Facility. This effort (ML) is based upon work supported by the U.S. DOE, Office of Science, Office of Basic Energy Sciences Data, Artificial Intelligence and Machine Learning at DOE Scientific User Facilities (A.G.). The work at the University of Maryland was supported in part by the National Institute of Standards and Technology Cooperative Agreement 70NANB17H301 and the Center for Spintronic Materials in Advanced Information Technologies (SMART) one of the centers in nCORE, a Semiconductor Research Corporation (SRC) program sponsored by NSF and NIST.

11:30 AM *EQ04.04.04
Detection of Topological Materials with Machine Learning Nikolas H. Claussen[1], Bogdan A. Bernevig[2] and Nicolas Regnault[2,3]; [1]University of California, Santa Barbara, United States; [2]Princeton University, United States; [3]Ecole Normal Superieure, France

Topological insulators and topological semimetals are solid-state systems which display unique macroscopic quantum effects due to the topology of their electronic wavefunction, such as protected edge or surface modes and quantized response functions, and have potential applications in quantum technology. Recently introduced theoretical methods have allowed for their large-scale discovery: databases compiled using ab initio calculations (density functional theory) now contain tens of thousands of topological materials. This makes the application of modern machine learning methods possible. Using gradient boosted trees, we show how to construct a machine learning model which can predict the topology of a given existent material with an accuracy of 90%. Such predictions are orders of magnitude faster and less expensive than actual ab initio calculations. We use machine learning models to probe how different material properties affect topological features. Notably, we observe that topology is mostly determined by the "coarse-grained" chemical composition and crystal symmetry and depends little on the particular positions of atoms in the crystal lattice. We identify the sources of our model's errors, discuss approaches to overcome them and create a simplified human-readable classification tree. In this talk, we will put a particular empahsis on methodological questions concerning machine learning as well as lessons learned and pitfalls encountered during the research process, in the hope that others looking to apply machine learning to material science may profit.

12:00 PM *EQ04.04.05
Forward and Inverse Design of Spectral Emissivity Using Machine Learning Models Mahmoud Elzouka, Charles Yang, Minok Park, Alok Singh, Adrian Albert, Vassilia Zorba, Ravi Prasher and Sean Lubner; Lawrence Berkeley National Lab, United States

A system's spectral emissivity determines how it will radiatively exchange energy with its environment and other interacting systems. This governs many natural phenomena and technologies such as optical sensors, energy harvesting and conversion, targeted drug delivery, sooty combustion, and global warming. Calculating radiative properties from known geometry and designs can be computationally expensive, and trying to invert the problem to come up with designs specific to desired radiative properties is even more challenging (typically one-to-many and nonlinear). In this talk, I will first discuss a machine-learning-based method for both the forward and inverse problem for dielectric and metallic particles. Our decision-tree-based model is able to provide explicit design rules for inverse problems. Furthermore, we can use the same trained model for both the forward and the inverse problem, which greatly simplifies the computation. Second, I will discuss our more recent work using generative models and latent space sampling to prescribe how to nanotexture a surface of a single material in order to produce a variety of desired optical properties through plasmon resonance and photon wave interference effects. These designs are experimentally realized by rapid laser machining of different substrates. Our methodologies show the promise of augmenting optical system optimizations by providing interpretable and actionable learned models for rapidly finding approximate solutions to the inverse design problem.

1:00 PM *EQ04.01.01
Real-Time Physics-Constrained Machine Learning in Multimodal Spectroscopy Joshua Agar; Lehigh University, United States

Machine learning (ML) has been all the rage in materials science in the past 5 years. While there have been promises of transformative acceleration of analysis capabilities, new insights, and even closed-loop control, it has yet to live up to the hype. The core challenge is that while ML models are fast to deploy they require arduous training of ensembles of models, hyperparameter tuning, and validation. In turn, ML ends up taking nearly the same or many times more person-hours as standard analysis protocols. While many ML efforts have focused on unraveling hidden insight in data, ML can also be a powerful tool to accelerate conventional analysis pipelines. There has been a boon in multimodal spectroscopy techniques that collect data with increasing volume, velocity, veracity, and variety. The use of these techniques has become limited not by their capability, but the time required to manage and process this data. Additionally, this imposes challenges to the experimentalist who cannot conduct even cursory on-the-fly analysis to guide subsequent experiments.

Here, we show how the confluence and codesign of physics-informed machine learning models and edge computing hardware can enable real-time streaming processing of band-excitation piezoresponse force switching spectroscopy without distributing computing. We acquire frequency-dependent cantilever resonance responses during ferroelectric switching at a frequency of 1 kHz. We use initial data to train a 1D-convolutional autoencoder model with a latent space that defines the amplitude, phase, quality factor, and resonance frequency. By constraining the decoder to be the empirical function of a simple harmonic oscillator, we can train the model fully unsupervised by minimizing the mean squared reconstruction loss. Training this model from scratch takes less than 5 minutes on 3M examples on a Graphical Processing Unit (GPU, Google Collab Free-Tier). Once trained, the model can fit the resonance curves; however, the necessary throughput of 1 kHz is only achievable through batching as GPU initialization takes ~1 ms. To avoid latencies associated with data movement, we deployed the model on a field-programmable gate array (FPGA). To do this, we pruned and quantized the model to fit the FPGA resources. Using a package hls4ml, we converted our model from TensorFlow to high-level synthesis (HLS). The HLS can then be compiled using vivadoHLS and was ultimately deployed on a Xilinx KU060 coprocessor in a Labview PXI chassis. By deploying this model on an FPGA, we could achieve streaming inference with latencies of <2 μs, orders of magnitude faster than is required.
Furthermore, because the fits are conducted more holistically, the fits are more robust to initialization and noise. We will also discuss how a similar methodology can be applied to fit piezoelectric hysteresis loops. The ability to conduct empirical fitting with sub-ms latency provides a pathway toward real-time control of dynamics processing in materials at beyond-human response times. We will provide additional insight into other characterization modalities, for example 4-dimensional transmission electron microscopy, where a similar methodologies can be applied.

SESSION Tutorial EQ05: Optical Metasurfaces—Materials, Designs, and Advanced Device Applications
Monday Morning, November 29, 2021
Hynes, Level 2, Room 210

8:30 AM
High Performance Metasurface Flat Optics—From Components to Systems Federico Capasso; Harvard University, United States

Metasurfaces are leading to the emergence of new optical components that circumvent the limitations of standard refractive and diffractive one by enabling dispersion engineering, which also leads to entirely new functionalities based on the local control of phase amplitude and polarization. Dispersion engineering has led to the demonstration of metalenses with correction of monochromatic aberrations and to achromatic metalenses and hybrid refractive/diffractive doublets across the visible spectrum. The planarity of flat optics will lead to the unification of semiconductor manufacturing and lens-making; recent industrial advances in this direction will be discussed. Polarization optics, polarimeters and polarization sensitive cameras without moving parts and conventional birefringent optics will be presented. Metasurfaces also offer fresh opportunities for structuring light as well as the dark. I will discuss spin to total orbital angular momentum (OAM) converters and OAM lasing, as well as flat devices that enable light's spin and OAM to evolve, simultaneously, from one state to another along the propagation direction. Finally, the demonstration of 2D phase and polarization singularities and the unique applications that they will open will be discussed.

10:00 AM BREAK

10:30 AM
Nonlinear Optical Metasurfaces—From Enhanced Light-Matter-Interaction to Functional Elements Thomas Zentgraf; Universität Paderborn, Germany

For efficient nonlinear processes, the engineering of the nonlinear optical properties of media becomes an important task. The most well-known technique for spatially engineering nonlinear optical properties is the quasi-phase matching scheme for second-order processes like second harmonic generation. However, the widely used technique of periodic polling of natural crystals only provides a binary state for the nonlinear material polarization, which is equivalent to a discrete phase change of π of the nonlinear polarization. The continuous tailoring of the phase of the nonlinear susceptibility would greatly enhance flexibility in the design and reduce parasitic effects. In this tutorial, we will discuss nonlinear metamaterials with a continuously controllable phase of the local effective nonlinear polarizability. We will focus on plasmonic metasurfaces with various designs for the meta-atom geometry together with

different polarization states of the light. In particular for circular polarization states, the controllable nonlinearity phase results from the phase accumulation due to the polarization change along the polarization path on the Poincare Sphere (the so-called Pancharatnam-Berry phase) and depends therefore only on the spatial geometry of the metasurface. By using a fixed orientation of the meta-atom, the nonlinear phase can be spatially arbitrarily tailored over the entire range from 0 to 2π. In contrast to the quasi-phase matching scheme, the continuous phase engineering of the effective nonlinear polarizability enables complete control of the propagation of harmonic generation signals, and therefore, it seamlessly combines the generation and manipulation of the harmonic waves for highly compact nonlinear nanophotonic devices. We will discuss the concepts of enhancing nonlinear processes with simultaneous phase engineering for the manipulation of second- and third-harmonic generation from metasurfaces and the restrictions with respect to symmetry and geometry of meta-atoms. Nonlinear metamaterials have fundamental significance in nonlinear optics and for tailored nonlinearities, as they provide a further degree of freedom in the design of nonlinear materials.

12:00 PM BREAK

1:30 PM
Electrically Tunable Metamaterials and Metasurfaces for Control of Absorption, Emission and Scattering Harry A. Atwater; California Institute of Technology, United States

Progress in understanding resonant subwavelength optical structures has fueled a worldwide explosion of interest in both fundamental processes and nanophotonic devices for imaging, sensing, solar energy conversion and thermal radiation control. For most nanophotonic materials, the optical properties are encoded and fixed permanently into the nanoscale structure at the time of fabrication. Achieving electronic tunability of the optical properties is an emerging opportunity to bring metamaterials and metasurfaces to life as dynamic objects composed of tunable nanoscale resonators and antennas. Gated field effect tuning of the carrier density in conducting oxides and two-dimensional materials enables the optical dispersion of individual structures to be altered from dielectric to plasmonic, yielding active nano-antenna arrays with electrically tunable absorption, radiative emission and scattering properties.

8:00 AM *EQ05.01.01
Van der Waals Active Metasurfaces and Heterostructures for Phase Modulation and Polarization Conversion Harry A. Atwater; California Institute of Technology, United States

A grand challenge for nanophotonics is the realization of tunable metasurfaces enabling active control of the key constitutive properties of light – amplitude, phase, wavevector and polarization. Active metasurfaces that enable dynamic modulation of reflection amplitude, phase and polarization have been recently explored using several active materials and modulation phenomena, including carrier index in plasmonic ENZ structures, reorientation of liquid crystal molecules, electrooptic effects in quantum well heterostructures and index change in phase change materials. The rapid advances in understanding of exciton resonances in layered van der Waals materials has now stimulated thinking about active metasurfaces that exploit excitonic modulation phenomena to enable ‘van der Waals active metasurfaces’. As one example, I will describe recent advances in electrically reconfigurable polarization conversion across the telecommunication wavelength range in van der Waals layered materials, integrated in a Fabry-Pérot cavity. The large electrical tunability of the excitonic birefringence in tri-layer black phosphorus enables spectrally broadband polarization conversion over nearly half the Poincaré sphere. We observe both linear to circular and cross-polarization conversion with voltage, demonstrating dynamic access to polarization diversity. As a second example, we discuss the observed large gate tunability of the complex refractive index in monolayer $MoSe_2$ by Fermi level modulation near the A and B excitonic resonances for temperatures between 4 K to 150 K. By tuning the charge density, we observe both temperature and carrier dependent epsilon-near-zero response in the permittivity and transition from metallic to dielectric near the A exciton energy, and directly observe active phase modulation in monolayer $MoSe_2$ gated heterostructures, whose voltage dependence is consistent with our complex index measurements. These results have broad implications for the use of monolayer transition metal dichalcogenides in active metasurfaces, and I also will give a general outlook for the wide range of possibilities for active van der Waals metasurfaces.

8:30 AM *EQ05.01.02
Directional Metasurface Light Emitters and Image Sensors Roberto Paiella; Boston University, United States

Plasmonic and dielectric metasurfaces have been widely investigated as a means to tailor the wavefronts of externally incident light for passive device applications. At the same time, their direct integration within active optoelectronic devices such as light emitters and photodetectors is far less established. In this work, we report the design and development of plasmonic metasurfaces that can promote directional light emission and angle-sensitive photodetection from a nearby active material. These results are significant for the continued miniaturization and large-scale integration of optoelectronic devices and related systems, and as a way to create new functionalities and enable novel applications. Specifically, the use of metasurface directional photodetectors for image sensing and processing will also be presented, including the demonstration of lensless compound-eye vision and optical spatial filtering for edge detection.

9:00 AM EQ05.01.03
Optomechanical Self-Stability of Freestanding Photonic Metasurfaces Avinash Kumar, Daniel Kindem and Ognjen Ilic; University of Minnesota, United States

Nanostructured photonic surfaces are a promising platform for shaping the radiation pressure of light for optical manipulation beyond the limits of conventional approaches. Here, we present a framework for self-stabilizing optical manipulation of freestanding metasurfaces in three dimensions [1]. Our framework reveals that the challenging problem of self-stabilization against translational and rotational perturbations in three dimensions can be transformed to a simpler scattering analysis of the metasurface unit cell in two dimensions. We derive universal analytical stiffness coefficients applicable to arbitrary three-dimensional radial metasurfaces and radial beam intensity profiles. These derivations are confirmed with ray tracing simulations, eigenvalue analysis of the Jacobian, and numerical solutions of the full nonlinear equations of motion.

The implications of this reduced problem dimensionality are twofold. First, the framework is universally applicable to arbitrary embedded element profiles and/or radial beam variations. Second, our formalism enables efficient design of optomechanical metasurfaces as well as light beam configurations. We present examples of non-conventional phase-gradient profiles and beam intensity variations with substantial (e.g., order-of-magnitude) improvement in longitudinal propulsion force while maintaining self-stability.

These results facilitate the discovery of macroscale photonic objects for stable manipulation in collimated, but otherwise unfocused light beams. This ability to manipulate macroscopic objects is in stark contrast with traditional methods of optical tweezing which rely on focused laser beams and external feedback. Such use of metasurfaces for mechanical stabilization could open up new perspectives for long-range manipulation of macroscopic objects, with potential for terrestrial and space applications.

9:15 AM EQ05.01.04
Ultrafast Broadband Dichroism by Transient Optical Symmetry Breaking in Plasmonic Metasurfaces Margherita Maiuri[1], Andrea Schirato[1,2], Andrea Toma[2], Remo Proietti Zaccaria[2], Paolo Laporta[1], Peter Nordlander[3], Giulio Cerullo[1], Alessandro Alabastri[3] and Giuseppe Della Valle[2]; [1]Politecnico di Milano, Italy; [2]Istituto Italiano di Tecnologia, Italy; [3]Rice University, United States

Ultrafast nanophotonics aims at the development of nanodevices for light modulation with unprecedented speed [1]. A promising approach exploits the optical nonlinearity of nanostructured materials to modulate their effective permittivity by exploiting intense ultrashort optical pulses [2]. In plasmonic nanostructures such pulses trigger a delayed third-order nonlinear response ruled by internal relaxation of the metallic nanosystems, thus allowing all-optical light modulation. Currently, challenge in ultrafast pulse manipulation remains the feasibility of all-optical modulation of light over a broad bandwidth, with a full recovery over sub-picosecond timescale. Among different kinds of all-optical functionalities, ultrafast polarization switching has recently attracted a huge interest for advanced applications in photonics and beyond [3,4].
Here we combine quantitative numerical model with polarization-resolved pump-probe spectroscopy to predict and observe that photoinduced spatio-temporal transients can break the symmetry of a plasmonic metasurface, even if composed of highly symmetric metaatoms. Symmetry breaking generates a broadband dichroic response with ultrafast recovery of the isotropic configuration well before the complete relaxation of the nanostructure [5].
The plasmonic metasurface used is made of symmetric gold nanocrosses, with polarization independent static transmittance with a broad dip around 800 nm, due to the degenerate longitudinal plasmonic resonances of the nanocross two arms. Such a degeneracy can be broken by the resonant absorption of a pump pulse with linear polarization along the direction of one of the arms. Photoabsorption creates a highly inhomogeneous near field. This asymmetric absorption pattern in each metaatom locally affects the electronic population of gold, inducing a non-uniform out of equilibrium hot-carriers distribution which anisotropically modifies the metal permittivity. The fingerprint of the ultrafast pump-induced symmetry breaking is a transient transmission anisotropy, which can be revealed in a polarization-resolved pump-probe experiment.
The quantitative numerical model describes the ultrafast spatial transients in terms of spatial and temporal variables linked by a set of three coupled equations, referred to as the Inhomogeneous Three-Temperature Model (I3TM). The I3TM extends the popular 3TM [6], by including the spatial dependence of these variables.
We employ finite-element method numerical analysis in the frequency domain to calculate the transmission spectrum of the metasurface for a linear polarization parallel and orthogonal to the pump, for a set of permittivity configurations obtained by sampling the gold permittivity distribution at different pump-probe delays. Such spatio-temporal electronic transients at the nanoscale translate into an anisotropic local permittivity distribution, and subsequent ultrafast dichroic optical response of the metasurface, dominated by non-thermal hot-electrons dynamics. This modulation is broadband and returns to the isotropic configuration within few hundreds of fs. Thus, the main contribution to this phenomenon arises from non-thermal carriers while thermalized carriers contribute less. This is remarkable given that the electronic temperature relaxation takes place on a much longer time scale, far beyond the symmetry breaking window.
Our results pave the way to all-optical control of light at TeraHz speed, focused on ultrafast polarization management.

Termination Dependent Optical Chirality in Gyroid Optical Metamaterials Bryan Cote, William Lenart, Chris Ellison and Vivian E. Ferry; University of Minnesota Twin Cities, United States

The ability to selectively interact with one circular polarization of light has wide ranging applications, including stereoscopic displays, document security, photonic circuits, biological detection, and others. Unfortunately, most molecular chiral materials only possess a weak circular dichroism (CD) response. Top-down fabricated pseudo-chiral metasurfaces have exhibited significantly stronger interactions with circularly polarized light (CPL), however it is often difficult and cost prohibitive to fabricate these lithographically patterned metasurfaces over large areas. In this presentation, we explore the effects of surface termination on the CD response of self-assembled, 3-D network-structure, optical metamaterials.
The gyroid is a triply periodic, minimal surface that contains screw axes in the [100], [110], and [111] directions and can be fabricated via block copolymer self-assembly. The single gyroid has been well described as a photonic crystal, where it has been shown to support both polarization dependent and complete photonic bandgaps. More recently, linear and circular dichroism have been detected in metal infilled gyroid optical metamaterials. In these structures both the bulk and surface structures affect the resulting optical properties; Dolan et al. recently showed that linear dichroism in a [110] oriented gyroid metamaterial arises from the anisotropic surface termination.
Here we use finite-element time-domain simulations to show that termination dependent resonances also play a dominant role in the CD response of [100], [110], and [111] oriented, silver infilled gyroid metamaterials. Films consisting of 4-unit cell thick gyroids with sharp interfaces and a unit cell size of 65 nm support CD resonances in the visible and near infrared on the order of 10 %, with large g-factors of 0.2. [100] oriented gyroids possess a termination dependent differential transmission of left- and right- CPL that repeats every quarter unit cell. Differential reflectance consists of strong, redshifted resonances that also occur every quarter unit cell, but alternate in handedness. These redshifted resonances arise from an antenna effect on the surface, where nearly touching nanostructures concentrate the incident electric fields by more than 100-fold. Varying the volume fraction of the silver infill results in different termination dependent CD responses, but the common theme of strong, redshifted resonances every quarter unit cell remains.
In the [110] direction, single gyroid metamaterials display both termination independent and termination dependent CD. The termination dependent resonance is observed in differential reflection and arises from a similar antenna effect. However, in contrast to the [100] direction, the surface terminated resonances of the two enantiomeric single gyroids are shifted by a quarter unit cell. Because of this, we find that [110] oriented double gyroids, which are

achiral in the bulk, can also exhibit either a strong positive or negative CD response depending on the termination exposed.
Lastly, while [111] oriented gyroid metamaterials cannot generate the antenna structures discussed above, they do support a variety of hexagonally packed, triangular metasurfaces that repeat every third of a unit cell. Depending on termination selected, [111] oriented gyroid metamaterials can either selectively resonate at the top or bottom surface or support metasurface resonances at both surfaces simultaneously.
In conclusion, chiral gyroid metamaterials support strong, termination dependent CD responses in each of the high-symmetry directions. This presentation will explore the mechanism of this termination dependent resonant response.

9:45 AM EQ05.01.06
Engineering Spectrally Narrowband Emission from Active, Coupled-Mode, Thermal Metasurfaces Arun Nagpal[1], Ming Zhou[2], Ognjen Ilic[3], Zongfu Yu[2] and Harry A. Atwater[1]; [1]California Institute of Technology, United States; [2]University of Wisconsin–Madison, United States; [3]University of Minnesota, United States

Optical metasurfaces that provide spectral and spatio-temporal control of thermal radiation, particularly that in the near-to-mid infrared temperature regime, have promising applications in chemical fingerprinting, infrared imaging, and in thermophotovoltaics. Here we demonstrate a narrowband thermal emitter platform that is tunable via the application of a gate voltage. The emitter consists of a 1D photonic crystal supporting a guided mode resonance that couples to a localized surface plasmon mode of a proximitized graphene ribbon array. We show a narrowband resonance at 7μm which can be tuned into high and low emissivity states. The on/off ratio between the high emissivity and low emissivity modes of operation is over 60, and the Q-factor of the resonant on-state is greater than 5000. We investigate the performance of the device under realistic material conditions, and excitation schemes. Furthermore, the resonant absorption characteristic is well-modeled by a coupled-modes theory. Using this theory, we predict the response of the emitter over a large range of geometric parameters, in both the near-field coupled and the far-field coupled regime.

Real-time Monitoring of Dissolved Carbon Monoxide in Non-Equilibrium State with Surface-Enhanced Raman Spectroscopy Junwon Min, Youngwook Lim, Taewook Kang and Dongchoul Kim; Sogang Univ, Korea (the Republic of)

The dissolved gas concentration in a reactor has significant importance in the chemical and biological processing industries as mass transfer from the injected gas to an aqueous solution must occur for the gas to be usable. As the solubility of the gas in the solution is low and there are no probes for measuring dissolved gas concentration, a volumetric mass transfer coefficient is selected as a criterion of design for bio-chemical reactors. However, it is difficult to accurately predict the non-equilibrium state dissolved gas distribution using only the volumetric mass transfer coefficient. In this study, we predict a local concentration of dissolved carbon monoxide based on surface enhanced Raman spectroscopy and a distribution of the concentration in the reactor in a real time using computational fluid dynamics and machine learning. Through these techiniques, biological C1 conversion reaction will be monitored in real-time without offline sampling.

Optical Properties of Electrically Interconnected Plasmonic Nanostructures with Sub-10 nm Nanogaps by Atomic Layer Deposition Brian Willis[1], Chengwu Zhang[1], John Grasso[1], Donal Sheets[1], Jason Tresback[2] and Jason Hancock[1]; [1]University of Connecticut, United States; [2]Harvard University, United States

Plasmonic nanostructures facilitate the interaction of light and matter with applications in photodetection, photocatalysis, biochemical sensing, photoelectrochemistry, and energy harvesting. In particular, the overlap of plasmon resonances with the solar spectrum makes them well suited for renewable energy technologies. A central concept in plasmonics is the strong electric field enhancement when plasmons are squeezed into nanogaps between adjacent particles. Field enhancement is directly related to physical processes including hot carrier generation. Electric fields can be enhanced by using high quality plasmonic materials such as Cu, Ag, and Au and engineering nanogaps with dimensions approaching 1 nm. Tuning plasmonic resonances to match lattice diffraction modes can further boost electric fields. Additional enhancements are possible by adding electric functions to plasmonic devices, but few studies have successfully integrated electrical interconnects with plasmonic nanostructures, and scalable fabrication of arrays with sub-10 nm nanogaps is challenging due to limits on conventional lithography. In this paper, we present a study of the optical properties of large arrays of interconnected plasmonic nanostructures with sub-10 nm nanogaps for strong field enhancements.

We use a nanofabrication approach based on selective area atomic layer deposition to modify lithographically defined nanostructures to create large arrays of plasmonic dimers with nanogaps 1-5 nm. Our plasmonic dimers are nanorod shaped with dipolar resonances tuned at 800 nm. Copper is deposited selectively on palladium coated gold nanorods and the optical resonances are monitored as nanogaps are narrowed to less than 5 nm. Palladium is used as a seed layer to promote copper growth, while gold provides high quality plasmonic resonances. Compared with pure gold, the addition of palladium increases the FWHM from 86 nm to 158 nm due to the inferior plasmonic properties of palladium. However, after copper growth to create Cu/Pd/Au layered nanorods, resonances improve and FWHM decreases to 141 nm. At early stages of deposition, plasmon resonances blue shift, which is unexpected.

Control experiments show that blue shifts are due to heat-induced rounding of features during the first cycles of growth. Single particle resolution AFM and high-resolution SEM data confirm feature rounding and reduced nanorod aspect ratios. Further deposition leads to red shifts due to narrowing of nanogaps between nanorods, as well reduction of FWHM from the improved plasmonic properties of Cu. Overall, resonance shifts are less than expected due to competing effects from deposition and heat induced shape changes.

Results for interconnected plasmonic devices are qualitatively similar to plasmonic dimers, but with more attenuation of the optical resonances. We investigate a dipole-line configuration where arrays of nanorods are interconnected and linear features are used as counter electrodes. Again, there are dominant blue shifts during the first few deposition cycles due to heat induced shape changes of the interconnected rods, but compared with control experiments, deposition adds more broadening. Continued deposition to reduce nanogaps to less than 10 nm causes expected red shifts and sharpening of the resonances, but compared to unconnected plasmonic dimers, the optical resonances are significantly broadened. Analysis of high-resolution SEM images shows that the electrical contacts contribute to reshaping of the dipole antennas more extensively than for unconnected devices. The reduced aspect ratios from reshaping leads to broader resonances. Strategies to improve the quality of resonances will be discussed. In this paper, we also discuss surface lattice resonances in the extended arrays, which can be used to reduce FWHM and increase local electric field intensity for hot carrier devices.

2:00 PM EQ05.03.04
Fabrication of Chain-Like Gold Nanoparticle Clusters and Their Application in Enhanced *In Vivo* Photoacoustic Microscopy Molecular Imaging of Eye Disease in Live Rabbits Wei Qian[1], Van Phuc Phuc[2], Alan McLean[2], Raoul Kopelman[2], Xueding Wang[2] and Yannis Paulus[2]; [1]IMRA America, Inc., United States; [2]University of Michigan–Ann Arbor, United States

Plasmonic metal nanoparticles have emerged as particularly attractive exogenous contrast agents for a wide variety of biomedical imaging techniques because their unique properties, including intense light absorption/scattering induced by the localized surface plasmon resonance (SPR), excellent biocompatibility, and lack of toxicity, hold great potential to improve these imaging techniques for detecting early-stage diseases with high sensitivity and specificity.

In this presentation, we first describe a facile and green method of fabricating chain-like gold nanoparticle (CGNP) clusters with narrow gap distances and a red-shifted longitudinal SPR that is tunable from 590 nm to 710 nm. These CGNP clusters are fabricated via self-assembly of gold NP monomers generated by a method of pulsed laser ablation (PLA) of the bulk target in deionized water. These PLA-generated gold NP monomers have unique capping agent-free surface and high purity, which allow precision surface engineering with different types of ligands in order to self-assemble them into highly linear nanochains [1,2].

In the second part of this presentation, the application of CGNP clusters as contrast agents for enhanced in-vivo photoacoustic microscopy (PAM) molecular imaging of eye diseases, named choroidal neovascularization, in live rabbits is explained. The synthesized CGNP clusters show excellent biocompatibility and photostability. These CGNP clusters are conjugated with linear arginine–glycine–aspartate (RGD) peptides (CGNP clusters- RGD) for molecular imaging. After intravenous injection of CGNP clusters-RGD, they bind to CNV in rabbit eyes, resulting in a selective PAM imaging of CNV only at 650 nm due to minimal tissue absorption at that wavelength. In addition, from the comparison of PAM signals before and after intravenous injection of CGNP clusters-RGD, it has been observed that CGNP clusters provide up to a 17-fold increase in PAM signal at 650 nm [3].

Plasmonic Metal Nanoparticles Supported on Oxide Aerogels for Decontamination of Toxic Organophosphorus Compounds Travis G. Novak[1], Wesley O. Gordon[2], Alex Balboa[2], Ashley M. Pennington[1], Debra R. Rolison[1] and Paul A. DeSario[1]; [1]U.S. Naval Research Laboratory, United States; [2]U.S. Army Combat Capabilities Development Command Chemical Biological Center, United States

Toxic organophosphorus pesticides and chemical warfare agents (CWAs) create health hazards for both civilian and military personnel, necessitating the design of materials that offer protection against the target molecules. Traditionally, activated carbon is used in this role, but high-surface area carbons typically only adsorb CWAs; the intact molecules persist on the material surface. Materials that adsorb and then degrade CWAs into nontoxic products are a desirable alternative as they negate the risk of re-exposure and lessen disposal burdens for spent materials. Oxide aerogels decorated with metal nanoparticles (NPs) provide ideal platforms to achieve this degradative sorption. Oxide aerogels provide a high surface area, mesoporous network that is stable under ambient conditions, while the addition of metal NPs offers additional chemical pathways and improved kinetics for CWA degradation. In this talk we compare the activity of metal NP–decorated oxide aerogels (Au/TiO_2, Cu/TiO_2, and Cu/CeO_2) for degradation of CWA simulants (DMMP), as well as live agents such as sarin, under a wide variety of environmental conditions. Generally, oxide aerogels adsorb these molecules intact under dark and dry conditions, but drive hydrolysis under humid and aerobic conditions and initiate photooxidative degradation upon excitation of the semiconducting bandgap with broadband light. Metal NP–decorated aerogels expand these capabilities by providing highly reactive basic OH sites at the interface between metal NP and networked oxide NPs to achieve rapid degradation under dark conditions. This arrangement further accelerates degradation under illumination by leveraging plasmonic absorption of visible light. Our results reveal oxide aerogel–supported metal NPs to be promising materials for decontamination of organophosphorus compounds under a wide variety of environmental conditions.

4:00 PM EQ05.04.01
ZnS:Mn-QD-Based Electroemissive Layer for Non-Toxic LED Applications Antonio Valerio Longo[1], Baptiste Notebaert[1], Alexandre Chevillot[1], Mériem Gaceur[2], Riccardo Messina[3], Alan Durnez[3], Téo Baptiste[3], Christophe Dupuis[3], Ali Madouri[3], Nicolas Battaglini[1] and Souad Ammar[1]; [1]Université de Paris, France; [2]ACTINOVA, France; [3]Université Paris-Saclay, France

Quantum dots (QD) form an emerging class of photo- and electroluminescent materials. Their narrow and tunable emission spectrum offers the benefits of a broad excitation-energy range with an environmentally stable, narrow emission. QD-based LED is a strongly active research field. In the typical device structure, the QD electroluminescent layer is stacked within hybrid heterostructures. Holes and electrons, injected from opposite sides through the application of a DC voltage, recombine radiatively in the QD layer, leading to light emission [1]. These devices suffer from a major drawback: the materials (their energy configuration and refraction index) of the stacked layers should be carefully chosen so as to optimize the energy-band diagram of the system for efficient electron-hole recombination in the photoactive layer [2] and minimize internal light reflection.
A further way exists to obtain emission of light from an electroluminescent QD layer, without any charge injection. It consists in sandwiching such a layer between two transparent dielectric layers and applying an alternate voltage. The presence of an electric field inside the photoactive region induces a relative shift between the energy levels of nanoparticles at different positions. This allows, above a threshold field, the creation of electron-hole pairs and their transport within the active layer. The recombination of an electron/hole pair on the same QD is at the origin of the observed light emission [3].
Previous QD-based devices present several limitations: the use of toxic Cd-based QD [3,4,5], the necessity of a complex multilayer structure [4,5] or the necessity of a combination of QD and bulk layers to obtain light emission [6].
We present a device overcoming all these limitations. Our device is based on an active layer of spin-cast non-toxic Mn-doped ZnS nanoparticles, sandwiched between two dielectric layers. By exploiting one-pot surfactant-free microwave-assisted polyol synthesis, we obtain high-crystalline nanoparticles, with enhanced phosphorescence emission due to Mn ions [7] at the solid state, which can be closely packed in the emitting layer, allowing an emission mechanism due to local charge creation and transport with only three layers. This new synthesis route paves the way to far less expensive paths for the active layer deposition such as spin coating or inkjet printing.
More specifically, our device is based on a glass substrate covered with a conductive and transparent thin layer of Indium Tin Oxide (ITO), followed by a dielectric layer deposited by Atomic Layer Deposition (ALD), a spin-cast ZnS:Mn nanoparticle film, and a second dielectric layer. Finally, metallic contacts are deposited by thermal evaporation.
Our device is characterized structurally by means of Scanning Electron Microscopy, showing an active layer with a very compact granular structure. We observe electroluminescence from the device only above a voltage threshold, coherently with previous observations. A direct comparison between electroluminescence and the photoluminescence spectra clearly shows that the observed luminescence corresponds to the emission coming from the transition taking place in Mn ions.
Monte Carlo simulations allow to show that the excitation mechanism cannot be linked to any impact triggering. Moreover, an effective-medium description of the active layer, along with a capacitance measurement on the device, allowed us to highlight a high packing of the QD inside the active layer. Moreover, the calculated potential fall per QD is compatible with an interpretation of light emission in terms of field-induced charge transfer and recombination.

Infrared Resonant Nano-Antennas for the Detection of Benzene Traces at ppb Levels Javier Nunez[1], Arjen Boersma[1], Julien Grand[2], Svetlana Mintova[2] and Beniamino Sciacca[2,3,4]; [1]TNO, Netherlands; [2]CNRS, France; [3]Aix-Marseille Université, France; [4]CINaM, France

The detection of volatile organic compounds (VOCs) at trace levels (ppb to ppm) is of extreme importance in the field of environmental monitoring for health related matters. The classical method for such measurements is gas chromatography, which is time consuming, expensive, and not portable. Spectroscopic techniques in the mid infrared (3–20 μm) are able to detect directly the unique fingerprints of molecular transitions, therefore offering a valid alternative in terms of versatility and selectivity. The target substance with an active IR vibration can be detected from the unique fingerprint of its vibrational transitions, without the need for an intermediate transducer, or any prior knowledge. However, light–matter interaction is extremely weak in the IR, due to the small absorption cross-section ($\propto a^3/\lambda$), with a being the molecule characteristic size. Long optical paths are needed to boost the signal to noise ratio for applications where detection at ppb levels is required. To keep a small footprint, it has been proposed to coat mid-IR waveguides or optical fibers with materials able to adsorb species of interest, thereby locally increasing the concentration. However, this approach often lacks sensitivity that is required in many applications. One example is the monitoring of benzene at ppb or sub ppb levels, that remains challenging even if a separate pre-concentration step is employed.
Surface-enhanced infrared absorption (SEIRA) has proven effective in detecting solid state monolayers via coupling resonant nano-antennas to vibrational transition of target molecules (Neubrech et al. Chem. Rev. 2017). However, for this to work, the target molecules have to be very close to the antenna surface, where the field enhancement is the highest. For low concentrated gases the probability of a molecule transiting within the strong field enhancement region can be very low, hampering the use of SEIRA for the detection of low concentrated volatile compounds.
In this talk we will present a hybrid system composed of a plasmonic nano-antenna array (gold nanorods) coupled with nanosized zeolite (Awala et al. Nat. Mat. 2015) coating for detection of volatile organic compounds in the near field of the resonators, enabling to extend the SEIRA toward the detection of gases at very low concentrations. We will show that the concerted action of the FAU zeolite coating and the resonant nano-antennas enables us to attain performance equivalent to a ≈120 m long optical path, and led to the detection record traces of benzene (25 ppb) within 10 min (Nunez et al. Adv. Func. Mat., 2021). To the best of our knowledge this sets a record for benzene detection using IR spectroscopy without external pre-concentration steps, and represent a great enhancement with respect to the low ppm range detection limit reported in the literature by using IR spectroscopy or IR tunable lasers. Then, we will show detailed characterisation of the system properties (SEM, EDX, optical), compare to numerical simulations (FDTD) and assess performance as a function of IR light polarisation. Finally, we will show that we can discriminate benzene from other VOCs such as toluene.
This approach may ultimately allow the fabrication of a compact system for rapid detection of pharmaceutical and biocompounds with high sensitivity and high selectivity.

Simulation and Fabrication of a Photonic Force Sensor Based on Silicon Nanopillars Elena Lopez-Aymerich[1,1], Daniel Navarro-Urrios[1,1], Mauricio Moreno[1,1], Sergi Hernández[1,1], Maria Dimaki[2], Florenci Serras[1], Winnie E. Svendsen[2] and Albert Romano-Rodriguez[1,1]; [1]Universitat de Barcelona, Spain; [2]Technical University of Denmark, Denmark

During de last decades photonic crystals (PC) have been widely studied. Most of these studies have been focused on the theoretical behaviour of these structures among almost all their configurations. Nevertheless, their experimental performance has been discussed but in a narrower number of configurations mostly focusing on the 1D and 2D structures based on a holed slab. In this work, we want to present both simulation and nanofabrication

results of 2D PC based on silicon nanopillars on silicon-on-insulator (SOI) substrates. The use of this reverse configuration has been scarcely studied and brought to a successful experimental performance. The addition of waveguides (WG) and cavities within the structure will allow light control through it. The potential application of these structures will be the development of a force sensor, which will measure horizontal forces. This system will operate in the Near Infrared (NIR) wavelength range.
The design of the structures has been carried out using the MEEP Python library what uses the Finite-Difference Time-Domain (FDTD) method to solve Maxwell's Equations over time and using eigenmode and eigenfrequencies solver. The determination of the best configurations has been done with a thorough study of the band diagrams of the structures both in 2D and 3D and their Transmission-Reflection spectra. Both strategies have shown good agreement between them and with literature. These simulations have shown the opening of a photonic bandgap (PBG) between 1.3 and 1.9µm for Transversal Magnetic (TM) polarised light. These results have been obtained for a triangular structure using pillars of 100nm radius and 500nm interpillar distance. The introduction of a WG shrinking de radii of one line of pillars has given rise to the introduction of a mode within the PBG raising from the bottom bands. Finally, the insertion of cavities within the WG has promoted the apparition of resonance peaks.
The nanofabrication of these structures has been carried out inside an advanced clean-room facility. A multi-step process has been studied and optimised for the successful fabrication of nanopillars with radii from 100nm down to 60nm. SOI substrates have been used to ensure the vertical confinement of light. The fabrication process uses an electron beam lithography (EBL) exposure, followed by a lift-off, and ending with an anisotropic dry etch of the silicon layer. The EBL process consists of the deposit of 180nm CSAR-P6200.09 photoresist, followed by a 20nm-thick layer of thermally-evaporated aluminium to ensure the correct discharge of the sample during the exposure. A JEOL JBX-9500FSZ e-beam writer, using a 100kV electron beam, is used for the exposure. The thermal aluminium layer is removed using TMAH, while the photoresist is developed using AR 600-546 developer. The lift-off process is carried out using Remover 1165 after the e-beam deposition of 20nm of aluminium. In this manner, the remaining photoresist will be removed leaving only the aluminium that was directly in contact with the substrate. This aluminium will work as a mask material during the etching step. The latest consists of a reactive ion etching (RIE) process which uses a combination of SF_6:C_4F_8 chemistries resulting in an anisotropic etch of the uncoated silicon and giving rise to the nanopillars.
Discussion about the similarities and differences between the simulated and the fabricated structures will be carried out and, if different, proposals of improvement in the nanofabrication process will be brought up.

4:45 PM EQ05.04.04
Scalable III-V Nanowire Networks for IR Photodetection Nicholas P. Morgan, Valerio Piazza, Didem Dede, Martin Friedl, Stéphane Nilsson, Lucas Güniat, Jean-Baptiste Leran and Anna Fontcuberta i Morral; Ecole Polytechnique Federale de Lausanne, Switzerland

InGaAs is an ideal material for photodetection at telecommunications wavelengths thanks to its direct bandgap, which is tunable by changing the relative In and Ga content. However, InGaAs devices typically require InP substrates, which are costly and difficult to process. Moreover, the In content of the InGaAs layer is limited by the requirement for lattice matching.[1] Nanowires (NWs) are a promising platform for heteroepitaxy of InAs and InGaAs on more common substrates like Si and GaAs thanks to their inherent strain relaxation. NWs also offer several performance advantages over bulk devices.[2] As an example, their thin, anisotropic geometry enables polarization-dependent absorption and fast carrier collection, making them suitable for multiplexed applications.[3] NWs also benefit from a significant reduction in the amount of scarce materials, such as In, required to make a device, and strain relaxation machanisms allow a greater degree of freedom over their chemical composition. NWs are most often grown vertically, perpendicular to the substrate, such as by the vapor-liquid-solid or vapor-solid techniques. However, vertical NWs are difficult to incorporate into devices, usually requiring transfer of a single NW to a secondary substrate, a process that is not scalable. A horizontal configuration is therefore preferred for many applications. Recently, horizontal networks of high-quality In(Ga)As NWs have been demonstrated by growing them on top of GaAs nanomembrane buffers using selective-area epitaxy on III-V substrates.[4,5]

In this work we investigate the growth of horizontal In(Ga)As NWs on two different crystal orientations of GaAs substrates by molecular beam epitaxy. For growth on (111)B substrates, we demonstrate InGaAs NWs positioned atop high aspect ratio GaAs nanomembranes and describe how such NWs might be used for advanced photodetector architectures. We also show that the In content of these NWs can be tuned by controlling growth conditions, but pure InAs NWs are not achievable.[6] Next, we demonstrate In(Ga)As NWs grown on (100) substrates. The NWs grow conformally on low-aspect-ratio GaAs nanomembranes, whose morphologies are dominated by either {111} or {110} facets, depending on their alignment on the substrate. We demonstrate the ability to control the In content of the InGaAs NWs with basic growth parameters and characterize the homogeneity of the alloy composition as a function of the NW geometry. We also show that pure InAs can be achieved with just a narrow intermixed region near the interface. Finally, we present preliminary electrical characterization from basic four-point photoconductive devices based on NWs grown under different conditions. The charge transport properties are largely determined by the crystal quality. Correspondingly, the presence of a surface passivation layer has a significant influence on the overall photoresponse. We compare NWs with and without a passivating shell and characterize the photoconductive response for both single NWs and ensembles in an array. Insights from these preliminary results will guide design choices for future photodetector devices based on these NWs.

Electron Beam Induced Current Measurements of Single Nanowire Solar Cells—Development of Nanowire Tandem Junction Photovoltaics Lukas Hrachowina, Enrique Barrigon and Magnus T. Borgström; Lund University, Sweden

Within one hour, the sun supplies our planet with energy sufficient for humanity's yearly energy consumption[1]. Nanowire solar cells are a sustainable complementary technology to silicon solar cells, as they have the potential to reach the efficiencies of world-record III-V solar cells while only using about 10 % of the material[2]. Although nanowire solar cells have demonstrated high efficiencies[3-6] and proven to have benefits compared to their bulk counterparts such as superior radiation tolerance[7] the next step in nanowire solar cell technology – a tandem-junction solar cell that combines different band gaps within the same nanowire – has been elusive up to now.
Here, we report on single nanowire tandem junction solar cells based on both InP/GaInP and InAsP/InP. These lattice mismatched combinations of materials are accessible because of elastic relaxation at the lateral free surface of nanowires[8]. The development of the nanowire tandem junction photovoltaics was supported by a setup that combines a nanoprobe system with electron beam induced current (EBIC) measurements and a light emitting diode (LED) inside a scanning electron microscope[9]. By the use of the nanoprobe system we show voltage addition of the two sub-cells. We are able to

study both sub-junctions independently with EBIC, by either using a light bias from the LED setup to saturate the bottom-junction, or by using a voltage bias to saturate the top-junction. We believe that this type of characterization will be helpful to further optimize the efficiency of nanowire tandem junction solar cells, and to develop nanowire multi junction solar cells using more materials similar to the six-junction solar cell which has the record efficiency of 47.1 %[10].

5:15 PM EQ05.04.06
Late News: CuFeS2—An Intermediate Band Semiconductor with Unique Optical Properties Yuan Yao, Anuj Bhargava and Richard Robinson; Cornell University, United States

Size-dependent changes in the electronic band structure is one of the key features of nanoparticles in the quantum confinement region. $CuFeS_2$ nanoparticles have a strong absorption feature in the visible region that has, controversially, been described as neither an excitonic transition nor a free carrier plasmon oscillation. Instead, the absorption feature in $CuFeS_2$ nanoparticles has been attributed to quasi-static optical resonances from inter-band transitions between the valence, intermediate, and conduction bands. Previous work has reported conflicting accounts of the existence of this absorption band, the size-dependent optical properties, and the cation oxidation states in this $CuFeS_2$.
In this work we answer these outstanding questions and determine the origin of the plasmonic behavior in $CuFeS_2$ by characterizing the nucleation and growth stages of the reaction through a series of *ex-situ* and *in-situ* probes (e.g., x-ray absorption spectroscopy (XAS) and x-ray emission spectroscopy (XES)), and by characterizing a size-series of nanoparticles through experiment and theoretical calculations and models. We found that $CuFeS_2$ nanoparticle growth is initiated by $Cu_{2-x}S$ seeds formation and then gradual Fe cation addition. Moreover, the growth of the quasi-static resonance feature during synthesis is driven by the band structure modification from Fe^{2+} incorporation into the nanocrystals. As opposed to the pure Cu^{1+}/Fe^{3+} predicted by DFT studies, a mixed oxidation state of Cu^{1+}/Cu^{2+} and Fe^{2+}/Fe^{3+} is observed, indicating that the chalcopyrite phase ($CuFeS_2$) encompasses a range of oxidation states depending on the synthesis conditions. Moreover, by examining a size-series of particles we find the quasi-static optical resonance redshifts while the absorption edge blueshifts as the particle size decreases. Through density functional theory (DFT) and tight binding modeling, we elucidate the size dependence of the band structure, especially focusing on the change in the intermediate band. Using a Lorentzian oscillator optical model to simulate the absorption spectrum with inputs from the DFT calculated band structure and band shifts from the tight-binding model, we find the size-dependent shifts of the optical resonance peak position in $CuFeS_2$ is due to a tri-band quantum confinement effect that results in both the valence band to intermediate band and intermediate band to conduction band bandgap expansion that accompanies a decrease in particle size. Moreover, the linear optical Lorentzian model predicts the optical resonance peak is tunable across the visible range by partially filling the intermediate band, lowering the conduction band, or expanding the intermediate band.
Overall, in this study, we provide fundamental understandings about the origin of the visible quasi-static resonance in $CuFeS_2$ nanoparticles, and elucidate the correlation between the absorption feature shift and the band structure. These results are relevant to other quantum-confined intermediate band systems, which have potential use in optical applications as well as photovoltaic devices.

Meta-Optics for Image Processing Jason G. Valentine; Vanderbilt University, United States

Image processing has become a critical technology in a variety of science and engineering disciplines. While most image processing is performed digitally, optical analog processing has the advantages of being low-power and high-speed though it requires a large volume. Meta-optics provide the advantage of thin form factor optics while also allowing complex transfer functions to be employed. In this talk, I will discuss the use of meta-optics for applications in image processing. Specifically, I will discuss meta-optic pre-filters including edge filters as well as filters for identifying higher level spatial features. These meta-optics are designed in conjunction with the digital system and I will discuss how co-design can make the hybrid optical / digital system more tolerant to deterministic and stochastic noise. These analog optical operations can be used to replace, or augment, digital processes for increasing speed while reducing power consumption.

Spatial Multiplexing Method for Multiwavelength Metalens Sangwon Baek, Jae Yong Park and Jong-Lam Lee; Pohang University of Science and Technology, Korea (the Republic of)

Bulk optics have been used for various optical instruments such as microscope or camera, but it has limitations in size and thickness because of accumulation of various lenses. Metalenses are an emerging field as one of the next-generation optical technology for miniaturization of optical system. Subwavelength thick nanostructures on metalens control the amplitude, phase, absorption, emission, and transmittance of incident light. Focal length can be control by adjusting phase shift from 0 to 2 according to the change of shape, size, and period of nanostructures. Many kinds of metalens such as GaN nanopillar, Si nanodisk, or TiO_2 nanofin have been studied recently, but chromatic aberration correction problem remains as the limitation in metalenses. Some researches such as group delay dispersion have been conducted to correct chromatic aberration, low focusing efficiency (~ 10 %) is unresolved limitation.
In this work, we suggested a new method to design achromatic metalens for 400, 600 and 800 nm wavelengths focusing. Spatial multiplexing method can correct chromatic aberration very simply. First, three metalenses are designed for each wavelengths. In the next step, meta-atoms of each metalenses are interleaved in one metalens. The coupling between three kinds of meta-atoms is small, therefore we can expect three wavelength focusing in one metalens. We used finite-difference time-domain (FDTD) simulation to investigate field distribution and focusing efficiency of each metalenses. By using this method, we demonstrated achromatic metalens with numerical aperture of 0.89, which focus light at 400, 600, and 800 nm to same focal spot. Focusing efficiency of achromatic metalens for 400, 600 and 800 nm are 38, 44 and 54 %, respectively. This design method can attend significant role to demonstrate desired achromatic metalens.

11:30 AM EQ05.06.03
A Layered Metallo-Dielectric Metasurface Inducing Stimulated Electron-Photon Interactions Matthias Liebtrau[1], Kelly W. Mauser[1], Marco van der Heijden[2], Pieter Kruit[2] and Albert Polman[1]; [1]AMOLF, Netherlands; [2]Delft University of Technology, Netherlands

Laser-driven optical near-fields mediate stimulated emission and absorption of photons by free electrons [1,2], providing unique control over the electron wave front in both space and time [3-5]. Besides a large field amplitude, efficient energy exchange in this process requires a match between the phase velocity of the optical field and the electron velocity – a condition that can be only fulfilled in the presence of matter [6,7]. Here, we explore how optical near fields can be tailored to efficiently manipulate slow non-relativistic electrons at the nanoscale. We design a thin-film metallo-dielectric metasurface perforated by a hexagonal array of circular holes, ensuring transparency to electrons while enabling diffractive coupling of resonant lattice modes to an external light field. The layer periodicity is optimized such that the normal component of the optical field inside the holes is dominated by a single Fourier component at a spatial frequency ω/v, determined by the electron velocity v and the optical pump frequency ω.

Experiments are performed in a scanning electron microscope (SEM) at a design electron energy of 5 keV. The metasurface is illuminated by a ns-pulsed near-infrared pump laser synchronized with sub-ns electron pulses that are generated by an ultrafast electrostatic beam blanker. To measure the energy distribution of electrons transmitted through the hole array, we use an electrostatic retarding field analyzer (RFA) with an energy resolution on the order of 0.1 eV. The employed Schottky field emission source provides an intrinsic electron energy spread as low as $\Delta E < 0.9$ eV, allowing us to fully resolve discrete electron energy-gain and -loss sidebands that are evenly spaced at multiple integers of the pump photon energy of 1.2 eV. The strength of the electron-near-field coupling can be quantified by the total width of the measured electron energy distribution, with its complex shape revealing the intriguing quantum nature of the electron-near-field interaction process. We show spatially resolved measurements of the electron-near-field interaction strength across the hole array and discuss how in-plane variations can be controlled to tailor the temporal and transverse phase profile of the incident electron beam.

Our work combines concepts of nanophotonics with a growing research field on coherent electron wave front shaping, while demonstrating SEM as a versatile and robust platform to study new quantum optical phenomena at the nanoscale. For the future, we plan to gain deeper insights into the wave/particle duality of free electrons by probing the emission of coherent cathodoluminescence and correlating it with the temporal shape and spatial phase profile of pre-defined electron quantum states.

Novel Silicon Bipodal Cylinders with Controlled Resonances and Their Use as Beam Steering Metasurfaces Samar Fawzy and Nageh K. Allam; American University in Cairo, Egypt

Metasurfaces have paved the way for high-performance wavefront shaping and beam steering applications. Phase-gradient metasurfaces (PGM) are of high importance owing to the powerful and relatively systematic tool they offer for manipulating electromagnetic wavefronts and achieving various functionalities. Herein, we numerically present a novel unit cell known as bipodal Cylinders (BPC), made of Silicon (Si) and placed on a Silicon dioxide (SiO_2) substrate to be compatible with CMOS fabrication techniques and to avoid field leakage into a high index substrate. Owing to its geometrical structure, the BPC structure provides a promising unit cell for electromagnetic wave manipulation. We show that BPC offers a way to shift the electric dipole mode to a frequency higher than that of the magnetic dipole mode. We investigate the effect of varying different geometrical parameters on the performance of such unit cell. Building on that, a metasurface is then presented that can achieve efficient electromagnetic beam steering with high transmission of 0.84 and steering angle of 15.2^o; with very good agreement with the theoretically predicted angle covering the whole phase range from 0 to 2.

12:00 PM EQ05.06.05
Late News: Strain-Tunable Fano Resonators Based on an Integration of Bragg Reflectors and Metasurfaces Sravya Nuguri[1], Ben Cerjan[2], Vince Einck[1], Daniel Shreiber[3], Naomi Halas[2], Mark Griep[3] and James Watkins[1]; [1]University of Massachusetts Amherst, United States; [2]Rice University, United

States; [3]U.S. Army Research Laboratory, United States

Fano resonance arises via interference between discrete and continuum bands. It undergoes a dramatic change in line shape shifts with any small perturbations in the system, thus proving its potential application in active tuning for display and sensors applications. Here, we explore and demonstrate the generation of Fano resonance from the coupling of symmetric or asymmetric-shaped Metasurfaces with Bragg reflectors. We have utilized a scalable route of soft-nanoimprinting lithography for the generation of Metasurfaces and incorporated layer-by-layer assembly of slide-ring-based materials to offer desirable elasticity and strain-tunable optical properties in the integrated device. Furthermore, we study the active tuning of the device by stretching the array in the x- and y-axis and the reflector in z-direction which allows for wide color tuning ability with narrow bandwidth in the colorimetric response. Our experimental findings agree well with simulations depicting high feature fidelity of Metasurfaces. By stretching the resulting device over 40% strain we demonstrate the mechano-chromic sensing abilities in a span of wavelengths.

SESSION EQ05.07: Lasing and Radiation Engineering I

1:30 PM *EQ05.07.01
Tunable, Multi-Wavelength Plasmonic Nanoscale Lasing Teri W. Odom; Northwestern University, United States

Nanoscale laser designs have seen major advances over the last decade, with breakthroughs in cavity architectures and gain materials. Plasmonic lasers based on nanoparticle lattices are of special interest because the cavity structure can be tuned at the unit-cell level, which then affects the type of near-field optical feedback contributing to lasing action. Moreover, depending on whether the gain materials are molecular or nanoparticulate in nature, new optical modes can contribute to the amplification process. This talk will describe different classes of plasmonic nanoparticle lasers that can produce reversible and switchable lasing. We will focus on both static and dynamic approaches to achieve tunable color and polarization at multiple, different wavelengths. Finally, we will discuss prospects for white-light lasing.

2:00 PM EQ05.07.02
Fluorescent Nanodiamond – Hyaluronate Conjugates for Molecular Imaging Hyehyeon Han and Sei Kwang Hahn; POSTECH, United States

Despite wide investigation on molecular imaging contrast agents, there are still strong unmet medical needs to enhance their signal-to background ratio, brightness, photostability, and biocompatibility with multimodal imaging capability. Here, we assessed the feasibility of fluorescent nanodiamonds (FNDs) as carbon based photostable and biocompatible materials for molecular imaging applications. Because FNDs have negatively charged nitrogen vacancy (NV) centers, they can emit bright red light. FNDs were conjugated to hyaluronate (HA) for the target-specific molecular imaging. HA is a biocompatible, biodegradable, and linear polysaccharide with abundant HA receptors in the liver, enabling the liver targeted molecular imaging. *In vitro* cell viability test revealed the biocompatibility of HA-FND conjugates and the competitive cellular uptake test confirmed their target-specific intracellular delivery to HepG2 cells with HA receptors. In addition, *in vivo* fluorescence lifetime (FLT) assessment revealed the imaging capability of FNDs and HA-FND conjugates. After that, we could confirm the statistically significant liver-targeted delivery of HA-FND conjugates by in vivo imaging system (IVIS) analysis and *ex vivo* biodistribution tests in various organs. The renal clearance test and histological analysis corroborated *in vivo* biocompatibility and safety of HA-FND conjugates. All these results demonstrated the feasibility of HA-FND conjugates for further molecular imaging applications.

2:15 PM EQ05.07.03
Light Emission by Thermalized Ensemble of Emitters Coupled to a Resonator Benjamin Vest, Aurelian Loirette--Pelous, Elise Bailly, Jean-Paul Hugonin and Jean-Jacques Greffet; Institut d'Optique Graduate School, France

Optical nanoantennas have become ubiquitous tools to enhance the spontaneous emission of atoms, molecules and quantum dots. In order to design practical sources with high power, it is necessary to move from a single emitter to an *ensemble of emitters*.

We can therefore use layers of emitters distributed on top of planar arrays of antennas of metallic or dielectric nanostructures to build light-emitting **metasurfaces**. They are designed to control the phase and amplitude of the electromagnetic modes in the plane. They can be engineered to emit light in specific directions and for specific wavelengths and polarization. However, metasurface designs rules that have been established over the years are still based on the understanding that optical antennas operate through the Purcell effect. Models based on this paradigm fail to fully explain spectral and spatial features observed in many experiments, such as the emergence of spatial coherence or spectral modifications of emitters.

In a first part, we start by discussing the differences between emission by a single emitter and emission by a thermalized assembly of quantum emitters to show that a statistical framework is required to understand their interactions with optical antennas. We then introduce a model of **light emission by thermalized ensembles of emitters**, based on fluctuational electrodynamics and the fluctuation-dissipation theorem **[1]**. A **generalized form of the Kirchhoff's law**, can be derived and extended to photoluminescence and electroluminescence. Light emission by the structure can be connected to the local absorptivity rate within the structure **[2]**.

In a second part, we use our modeling procedure in the context of two experimental and theoretical studies of light emitting systems. Firstly, we focus on the properties of light emitted by a patterned ensemble of quantum dots consisting in a lamellar grating on top of a slab. This system exhibits spatial and spectral features, such as bright, directional and polarized emission. Our model accurately reproduces and predicts all features of the system's photoluminescence. It also addresses modification of the optical properties of the resonator by the pumping process, allowing to explore regimes of intense pumping of the emitters.

Secondly we use our approach to explore the **origin of spatial coherence in light-emitting structures**. We consider a system consisting in layers of molecular dyes deposited on top of a silver metallic layer. We start by introducing a general coherence-absorption relation that connects the coherence of the fields at two positions in the system to the power absorbed by the system when illuminated by two sources **[3]**. This relation shows the degree of spatial coherence can be deduced from experimental measurements or numerical codes simulating absorption in the layers. We find that surface waves and delocalized modes play a major role in building the spatial coherence. Our model is a key asset in the design of directional light sources based on photoluminescence.

Our approach of light emitting systems involving ensembles of emitters provides simple and efficient design tools relying on the determination of absorptivity of the structure. It accounts for the interplay between the electromagnetic properties of the emitter (resonances, antenna effect…) and the matter excitations which are included in the model through the imaginary part of the permittivity of the material and the subsystem's temperature and chemical potential.

Dynamic Control of Epsilon–Near–Zero Resonance in Optical Fiber Jingyi Yang[1,2], Khant Minn[2], Aleksei Anopchenko[1,2] and Ho Wai (Howard) Lee[1,2]; [1]University of California, Irvine, United States; [2]Baylor University, United States

Optical fiber is a well-established waveguide that has been utilized in a variety of applications such as data communications, spectroscopy, imaging, remote sensing, surgeries, and seismic activity monitoring, *etc*. However, the optical properties of an optical fiber (for instance, mode intensity and propagation loss) are fixed after drawing fabrication due to the static property of the dielectric glasses. Therefore, integrating active materials and nanostructures into optical fibers is promising for enhancing processing and transmission capabilities and novel functionalities. Zero-index materials have been extensively studied recently due to their unique and extreme optical properties [1]. Ultrathin transparent conducting oxide (TCO) epsilon-near-zero (ENZ) layer with the real part of permittivity approaches zero can support ENZ mode with enhanced and highly confined optical field [2]. Furthermore, the ENZ properties of TCO can be dynamically tuned by nonlinear optical pulse excitation [3-4].
In this work, we demonstrated the excitation of hybrid ENZ mode in a side-polished optical fiber deposited with an ultrathin layer of aluminum-doped zinc oxide (AZO). The 40-nm-thick AZO layer on the side of the fiber, fabricated by the atomic layer deposition technique, has ENZ properties at a near-infrared wavelength of ~1550 nm. The confined ENZ mode in the AZO thin film is excited due to the evanescent field coupling between the fundamental mode of the fiber and the ENZ mode supported by the AZO layer. Transmission measurement shows a resonance at a wavelength of 1600 nm with resonant strength of 6 dB in an ~1cm long AZO-coated side-polished optical fiber, which agrees with full-wave electromagnetic simulation and phase-matching condition. We further demonstrated that the highly confined ENZ mode could be used for developing efficient tunable in-fiber devices such as ultrafast optical modulators and switches. Due to the giant nonlinearity at ENZ frequency, the mode propagating in the ENZ optical fiber can be dynamically manipulated by femtosecond laser excitation. Our preliminary results show that the modulation strength of ~9.6 dB/mm can be achieved by modulating the hybridized ENZ resonance under femtosecond laser pulse excitation with an intensity of 200 GW/cm^2. The dynamic control of hybridized ENZ-optical fiber mode offers a compact and efficient method of manipulating the ENZ property and functionality in the optical fiber, which can find potential applications for ultrafast optical switches, polarization controllers, and other active optical fiber devices.
This work was supported by the Air Force Office of Scientific Research (Award number: FA9550-21-1-02204).

Infrared Optoelectronic and Magneto-Optic Properties in Gd-Doped CdO Angela Cleri, Noel C. Giebink and Jon-Paul Maria; The Pennsylvania State University, United States

CdO is one of the most promising low-loss infrared (IR) plasmonic materials to date. Incorporation of a donor dopant such as Y, In, or F has demonstrated tunable carrier concentration between 10^{19}-10^{21} cm^{-3}, corresponding to mid-IR plasmonic modal frequencies. In addition, high-power impulse magnetron sputtering (HiPIMS) consistently produces epitaxial films with high mobilities between 300-500 cm^2/V-s, minimizing optical losses. We have shown how manipulating donor and acceptor defect chemistry through controlling deposition and post-processing conditions enables one to engineer epsilon-near-zero (ENZ) modes spanning a broad range of the mid- to near-IR (1650-5325 cm^{-1}).

While we have largely explored light confinement in CdO via electron oscillations, we now aim to further manipulate light through magnetism by Gd doping to create a dilute magnetic semiconductor. In this presentation, we show the excellent structural and morphological properties of Gd-doped CdO

across a broad doping range, enabling fine permittivity control with ENZ behavior spanning the mid- to near-IR. Further, we will explore the effect of the ENZ condition on magneto-optic properties.

4:45 PM EQ05.08.04
Bottom-Up Monocrystalline Split Ring Resonators for Enhanced Absorption at Optical Frequency Ibtissem Bouanane[1,2], Judikaël Le Rouzo[1], Olivier Margeat[3], Anna Capitaine[3], Beniamino Sciacca[3], Gerard Berginc[2] and Ludovic Escoubas[1]; [1]Aix Marseille Université, Université de Toulon, CNRS, UMR 7334 – IM2NP, France; [2]THALES LAS, France; [3]Aix Marseille Université, Université de Toulon, CNRS, UMR 7325 – CINaM, France

The opportunity to employ sub-wavelength nanostructures to tune light-matter interaction has triggered tremendous interest in the last decade, thanks to the plethora of optical properties that can be achieved in metamaterials or metasurfaces, that are often not seen in nature. Among those examples, split-ring resonators can display optically-induced magnetic responses with unique possibilities to enhance absorption in the visible and near IR. Tuning the geometric parameters of the nanorings enables for control of the absorption band at optical frequencies, with implication in multiple fields, from thermal solar, to photovoltaic (selective absorbers, anti-reflections coatings, etc.) and optoelectronics (optical coatings, sensitive photodetectors, optical stealth, etc.) [1] [2].

However, whereas design strategies are well established, experimental techniques to fabricate such materials at a large scale and low cost are still in their infancy; they mainly rely on e-beam lithography for the fabrication of small area, high-resolution metasurfaces, or on nanoimprint lithography for larger area. In both cases, several fabrication steps have to be undertaken, including etching steps and metal evaporation steps, that are not easily scalable. In addition, the materials obtained are typically polycrystalline, with negative impact on their optical quality.

The objective of the research is to provide a first proof of concept of tunable silver circular split-rings entirely made by scalable bottom-up approaches, showing enhancement of absorption at optical frequencies.

First, FDTD simulations were performed to realize a parametric study of silver nanoring design in order to optimize its geometric parameters for absorption enhancement (inner, outer diameters, thickness, split-ring gap, array periodicity). This showed full control on resonance peaks and absorbance enhancement in the visible and near IR.

Next, we will show the realization of circular silver split-ring arrays on a large area via bottom-up techniques. Silver single-crystalline nanocubes (synthesized in solution via the polyol process) are self-assembled with high yield (>90%) in PDMS templates previously nanostructured with a pre-defined split-ring motif. Epitaxial nanowelding techniques at low temperature (Sciacca et al. Advanced Materials, 2017) are then employed to connect the individual nanocubes together to obtain a continuous quasi-monocrystalline material. We will show electron microscopy characterization at different steps of the fabrication process to show the high crystalline quality and support our claims.

Finally, we will show measurements of the macroscopic (5 mm^2) optical properties of the split-ring arrays, and compare to those calculated via FDTD simulations.

Our work shows for the first time the realization of a high optical quality metasurfaces at a large scale fully obtained with bottom-up techniques.

Novel Core-Shell Plasmonic Nanoparticles for Hydrogen Sensing Stephen F. Bartolucci, David J. Sconyers, Rosemary L. Calabro and Joshua Maurer; U.S. Army DEVCOM Armaments Center, United States

Noble metal nanoparticles exhibit localized surface plasmon resonance (LSPR) when interacting with light. This property has led to the study of these particles for numerous applications, such as catalysis, biosensing, gas detection, and chemical sensing. One commonly used material in hydrogen sensing is palladium, which can dissociate hydrogen gas and form a hydride, resulting in a shift of the LSPR absorption. The kinetics of hydrogen absorption reaction and desorption in palladium are relatively fast, which is useful for gas sensing in hydrogen economy applications. However, some applications require long-term detection of total hydrogen levels, where fast desorption is not desired. Core-shell nanoparticles consisting of a noble metal core and a shell material, such as a transition metal oxide, could provide a material system for hydrogen detection with a more permanent plasmonic shift during exposure to hydrogen. In this work, we show the synthesis of various noble metal core-shell nanoparticles, including gold-copper (I) oxide and gold-palladium, with spherical and spiked structures and evaluate their ability to detect hydrogen in colloidal suspensions. In addition, we will discuss electrochemical methods to synthesize core-shell nanoparticles and spectroelectrochemistry to characterize the nanoparticles during growth.

EQ05.09.03
Chemical Engineering of Plasmonic Modes in Disordered Cu-Sn Network Metamaterials Jelena E. Wohlwend, Henning Galinski, Alla Sologubenko, Max Doebeli and Ralph Spolenak; ETH Zürich, Switzerland

Design and fabrication of large-area metamaterials is an ongoing challenge for the material science and technological communities. In the present work, we propose a scalable and low-footprint strategy to design large-area, frequency-selective Cu-Sn disordered network metamaterials that exhibit nearly perfect absorption in a given spectral range. These nano-modulated structures exhibit a broadband spectral response, similar to connected wire mesh metamaterials.
We demonstrate that chemical engineering applied to the thin film materials allows the production of nano-modulated networks and allows tuning the

absorption frequencies of the disordered meta-networks to a particular spectral region spanning the near-infrared - UV diapason.
Our approach relies on the establishment of disordered networks of a particular morphology by employing chemical etching to co-sputtered Cu-Sn-Al thin films with the purpose to remove aluminum from the film volume. As a result, the films adopt a particular topological and phase configuration that yield characteristic absorption signals. Moreover, tuning the initial composition of the Cu-Sn-Al thin film during the film production enables the control over the phase state and the spatial modulation period of the porous network which in turn defines the particular set of the plasmon absorption frequencies activated in the system.
Experimental verification of the plasmonic response of the produced networks is carried out in our work by employing electron energy loss spectroscopy (EELS) in the low-loss region. We resolve highly confined gap surface-plasmon (GSP) modes activated at the surfaces of the porous structures due to the near periodic nano-sized topology of the network.

Late News: Plasmonic Enhancement of Strontium Titanate by Galvanic Replacement of Exsolved Ni Nanoparticles with Au Kevin Gregor Both, Xiaolan Kang, Vilde M. Reinertsen, Thomas Aarholt, Truls Norby, Øystein Prytz and Athanasios Chatzitakis; University of Oslo, Norway

Photocatalysis can be regarded as part of the push towards renewable and greener energy production. Water splitting is a suitable example, where the ideal semiconductor has a bandgap of 1.9 – 2.3 eV. However, semiconductors with such a bandgap are usually unstable during photocatalytic water splitting [1]. Extending the absorption spectrum of a catalyst with larger band gaps can be achieved utilizing localized surface plasmon resonance (LSPR). The ability to tune the dominant frequency of the metal particles by changing their geometry and size makes LSPR even more intriguing [1]. The plasmon absorption peak energies of certain metal nanoparticles (NPs) are in the range of visible light, potentially allowing their energy to drive chemical reactions with sunlight or contribute to photovoltaic applications [2]. The plasmonic metal NPs can utilize the energy directly and act as photocatalysts, they can be used in an antenna-reactor setup with catalytically active metallic NPs, or they can transfer the energy to the semiconductor surrounding them [1-3]. The chemical and physical properties of these metal NPs, as well as of the substrate define the type of energy transfer and consequently chemical reaction possible.

In this work NPs of nickel (Ni), copper (Cu), and ruthenium (Ru) were created within strontium titanate (STO) by exsolution in a hydrogen/argon mix (HArmix, 5%) at elevated temperatures (600 °C to 900 °C). Subsequently, the exsolved Ni was replaced by gold (Au) to different degrees by galvanic replacement. The versatility of the technique was demonstrated by using A-site excess and A-site deficient STO, as well as galvanic replacement by platinum (Pt). While Ni, Ru, and Pt are only weakly plasmonically active, their catalytic properties may be used in an antenna-reactor setup. Thin films and powders were synthesized by pulsed laser deposition and solid state reactions methods, respectively. Particles of pure Au, ladybug-like Au decorated Ni particles on STO, and flower-like Au decorated Ni particles on STO, as well as potential antenna-reactor setups, were obtained. The main difference between the ladybug-like and flower-like samples was the size of the Au particles decorating the Ni. In general, shorter galvanic replacement times led to spherical NPs, while prolonged ones yielded (bimetallic) NPs with complex geometries.

Scanning Transmission Electron microscopy (STEM) and energy dispersive X-ray dispersion (EDX) were utilized to determine the structure and chemical environment of the particles. STEM and Electron Energy Loss Spectrometry (EELS) in the low electron energy loss regime were employed to study the plasmonic response on the nm-length scale, directly observing “hot-spots” in the electric field. The STEM-EELS/EDX experiments were performed with a monochromated 300 kV STEM probe with Zero-Loss Peak (ZLP) full-width at half maximum of 110 meV on a FEI Titan G2. The Au nanoparticles exhibited peaks in the EELS spectra between 1.50 and 2.40 eV. While the 2.40 eV peak is well known for Au nanoparticles, a Finite Difference Time Domain (FDTD) approach was used to investigate them further, determining that peaks towards 1.50 eV originate in parts of the particles near STO or with complex geometries. Geometries and the chemical environment of the particles can be used to explain the splitting and shifting of the peaks. Moreover, the PEC performance of samples with partially of fully galvanically replaced Ni NPs by Au, showed a clear improvement compared to samples without NPs.

Late News: Tuning the Plasmonic Properties by Alloying—Insights from a DFT Approach Matej Bubaš and Jordi S. Parramon; Ruder Boskovic Institute, Croatia

Changing the composition of alloy nanostructures can be a way of tuning their plasmonic properties. Rational tuning for a desired purpose requires a method that provides both prediction and the fundamental understanding of the predicted properties. We present an approach based on density functional theory (DFT) calculations coupled with electrodynamics simulations that meets the aforementioned requirements. Our results show the importance of the chosen exchange-correlation functional on the quality of prediction for bulk alloys that becomes critical in the case of nanostructures. Furthermore, we show the value that the fundamental insights provided by DFT have by explaining the causes for predicted low energy interband transitions as an emergent property of alloying. Lastly, we compare our approach to other state-of-the-art methods for computing hot carrier energy distribution and study the possibility of tuning the hot carrier distribution by alloying.

EQ05.09.07
Late News: Simulating Surface Plasmons on Ni and Au Nanoparticles Embedded on a SrTiO3-Surface Made by Exsolution Followed by Galvanic Replacement Vilde M. Reinertsen, Kevin Gregor Both, Øystein Prytz and Athanasios Chatzitakis; University of Oslo, Norway

Local Surface Plasmon Resonances (LSPR) on metal nanoparticles have been found to enhance photocatalysis with the largest enhancement by noble metals. They turn out to have properties which results in a strong LSPR response [1]. However, the catalytic properties of the noble metals are poor due to low adsorption of reactant molecules on their surface [1]. A solution to this issue is to use the LSPR in the noble metal to enhance the photocatalytic abilities of a supporting semiconductor. The semiconductor can be enhanced through different mechanisms including local electromagnetic field enhancement, resonant energy transfer and the generation of hot carriers from LSPR decay [2]. In this contribution, we investigate the latter possibility by calculating the absorption in Ni and Au nanoparticles (NPs) embedded on a $SrTiO_3$ (STO) surface. The hot carrier injection is especially interesting since it enables light absorption below the band gap of STO (E_g^{STO} = 3.25 eV).
The simulations were performed using the finite difference time domain method. The simulated geometries were modeled after the structure of Ni-doped STO thin-films grown by pulsed laser deposition, where subsequent exsolution gave socketed Ni NPs on the surface of the thin-films [3]. Some samples were afterwards treated to galvanically replace the Ni with Au [4]. To investigate the thin-film samples computationally, we compared the plasmonic

response of Au and Ni spherical NPs (5 nm ≤ radius ≤ 15 nm) embedded on the surface of STO in the energy range below the band gap of STO.
The simulations confirmed that the Au NPs have a larger absorption cross section (σ_{abs}) than Ni NPs as expected [5] and validated the galvanic replacement as a method to increase the plasmonic effect in the thin-film samples. In addition, we found that, for both materials, the σ_{abs} increased when the NPs were embedded deeper into the substrate. The increase is probably due to the high refractive index of STO compared to vacuum which redshifts the LSPR peak away from interband transitions at 2.4 eV for Au and 4.7 eV for Ni [6,7]. The redshift therefore works to decrease damping. The σ_{abs} per geometrical cross section (σ_{geo}) peak height seems to increase linearly with the redshift in energy. For Au, a LSPR energy at 2.05 eV gives an σ_{abs} peak height equal to the σ_{geo} and at 1.9 eV σ_{abs} is almost $7\sigma_{geo}$.
For Ni, most of the absorption spectra have the largest σ_{abs} around the interband transitions at 4.7 eV and a smaller peak around 2.5 eV, with a few exceptions. The exceptions have both a large size and are deeply embedded in STO which are two things that redshift the LSPR energy. However, the smaller LSRP peaks, which lie below the band gap of STO, seem to follow the same linear trend as for Au. We observe that with a LSPR energy of 2.55 eV the σ_{abs} peak height is equal to the σ_{geo} and at 2.4 eV σ_{abs} is around $1.4\sigma_{geo}$. If we look at the σ_{abs} per volume, the linear trend is not as clear. The smaller particles have a larger σ_{abs} per volume compared to the larger ones, but the absorption still increases with redshift in LSPR energy.
In conclusion, we have calculated the absorption in Ni and Au NPs embedded on a STO surface, as a first insight into hot electron injection as a way to enhance the photocatalytic abilities of STO. We found that the embedding of the particles deeper into the semiconductor increased their σ_{abs}, and that the $\sigma_{abs}/\sigma_{geo}$ peak height is linearly proportional to the redshift in LSPR energy. These results are a starting point to assess this attempt to photocatalytically enhance STO.

Spectral Robustness of Single Ultrabright Fluorescent Silica Nanoparticles Mahshid Iraniparast, Berney Peng and Igor Sokolov; Tufts University, United States

We present a study of possible variations of fluorescence spectrum between individual ultrabright silica nanoparticles (SiNPs) at the level of single nanoparticles. The extremely high fluorescent brightness of these particles has been created by encapsulating fluorescent dye molecules inside the nanoporous silica matrix of nanoparticles. A specific environment around the dye molecules allows attaining a very high concentration of the dye molecules without quenching of fluorescence. Different dyes can be mixed within each nanoparticle, thereby creating a platform for fluorescent sensors. The ultrabright nature of these particles allows doing measurements using single nanoparticles. For a quantitative study, it is paramount to demonstrate that the fluorescence spectra collected from individual nanoparticles are substantially similar. Encapsulation of multiple dyes within the same particle exhibits Forster Resonance Energy Transfer (FRET), which may cause differences in fluorescence spectra because of the random location of the encapsulated dye molecules inside each particle. .
In this study, direct measurements and simulations were performed to study the possible variation in the fluorescence spectra of individual SiNPs. A confocal fluorescent microscope attached with a single-photon camera was used for the direct measurements. These results were compared to the simulation of fluorescent spectra, which took into account the multiple random positioning of dye molecules inside each particle.
Overall, the direct measurements and simulation were in very good agreement with each other and showed that the spectral variation between single SiNPs was rather small. We can conclude that individual ultrabright SiNPs can be used in a variety of applications as taggants and sensors, including multiplexed biomedical imaging, flow cytometry, and ratiometric fluorescence sensors.

SESSION EQ05.10: Active Control
Session Chairs: Souvik Biswas and Jeremy Munday
Wednesday Morning, December 1, 2021
Hynes, Level 2, Room 210

11:00 AM EQ05.10.02
Dynamic, Electro-Optically Controlled Wavefront Shaping via High Quality Factor Silicon-on-Lithium Niobate Metasurfaces Elissa Klopfer[1], Sahil Dagli[1], David R. Barton[2], Mark Lawrence[3] and Jennifer A. Dionne[1]; [1]Stanford University, United States; [2]Harvard University, United States; [3]Washington University in St. Louis, United States

Dynamic control of wavefront shaping is essential for optical technologies spanning communication, computation, and sensing. Reconfigurable metasurface devices are especially important for lightweight and compact applications, including LidAR, LiFi, and AR/VR systems. However, achieving reconfigurable devices that demonstrate efficient modulation remains an outstanding challenge, due in part to the low electro-optic coefficient of most materials and weak light-matter interactions afforded by traditional metasurfaces. Current reconfigurable metasurface designs optimize for phase contrast and thus generally operate close to absorption peaks, leading to low efficiencies and poor contrast between diffraction orders. Here we present fully reconfigurable, high-efficiency wavefront shaping, exemplified by both high reflection efficiency and a large dynamic tuning range, achieved via high-Q silicon-on-lithium niobate metasurfaces. Our metasurface consists of subwavelength nanobars of silicon, 500 nm wide and 220 nm tall, atop 100 nm thick lithium niobate. Periodic perturbations to the constituent nanobars allow guided modes to couple to free space, with strongly enhanced electromagnetic fields localized in the lithium niobate. These guided mode resonances achieve Q factors exceeding 30,000, enabling strong electromagnetic field confinement without compromising the metasurface transfer function; these high-Q resonances can make the constituent nanoantennas more sensitive to subtle changes in refractive index. Using full-field simulations, we show how applying a voltage across individual nanoantennas shifts the spectral position of the high-Q resonance, modifying the antenna phase and amplitude, and achieving nearly a full 2 pi phase variation with reflectance above 91%. With the ability to individually address metasurface elements through transparent conducting oxide contacts on each antenna, we construct phase gradient transfer functions defined by the applied field, rather than varying the size, spacing, or geometry of the constituent nanoantennas. By changing the nanoantenna biasing configuration, we show a single metasurface can be tuned to switch between multiple transfer functions and steer light to different angles with high diffraction efficiency. We demonstrate how an applied field can modulate the metasurface to act as reflective beamsplitting or beamsteering devices, depending on the biasing conditions,with varying angles and efficiencies as high as 85%. Near-continuous beam-steering can be achieved by modifying the

bias across each antenna; for example, voltages of +14.5, 0, and -14.5 steer to 31 degrees, while applied voltages of +18.6, +2.7, -2.7, and -18.6 and +21.1, +5, 0, -5, and -21.1 steer to 23 degrees and 18 degrees, respectively. Our presentation will discuss not only the design but also fabrication and characterization en route to a versatile metasurface platform that can reconfigurably achieve a variety of transfer functions.

11:15 AM EQ05.10.03
Reflective Optical Limiters Based on Tunable Frequency-Selective Surfaces Modulated by Vanadium Dioxide Chenghao Wan[1], Zhen Zhang[2], Jad Salman[1], Jonathan King[1], Yuzhe Xiao[1], Zhaoning Yu[1], Alireza Shahsafi[1], Raymond Wambold[1], Shriram Ramanathan[2] and Mikhail A. Kats[1]; [1]University of Wisconsin--Madison, United States; [2]Purdue University, United States

Optical limiters are optical devices that utilize optical nonlinearities to achieve decreasing transmittance versus increasing incident optical intensity, which is useful for protecting sensitive detectors or human eyes against high-intensity illumination. Most optical limiters utilize nonlinear absorption to absorb the light when the incident intensity increases significantly. However, such absorptive designs may be suboptimal because the absorption of high-power light may result in damage to the limiter via melting, sputtering, or ablation. Therefore, a more-ideal solution is to make optical limiters that are reflective (i.e., they reflect excess light) rather than absorptive. There have been limited efforts to realize reflective optical limiters, and existing designs have limitations in terms of spectral and angular bandwidth, speed, etc.

In our talk, we will present our design of an ultrathin, broadband reflective optical limiter based on dynamically tunable resonant transmission through metal aperture antennas using thin-film vanadium dioxide (VO_2), an electron-correlated material that features a dramatic change in optical properties across its insulator-metal phase transition (IMT). Specifically, we incorporated gold (Au) frequency-selective surfaces (FSSs), which are metallic arrays of aperture antennas that feature resonant transmission, onto VO_2 thin films on transparent substrates (here, GaAs). The FSS-VO_2 optical limiter can feature high resonant transmission when the VO_2 is in the insulating phase (open state of the device), but reflects light when the resonant transmission is detuned or extinguished by the IMT of VO_2 (limiting state of the device).

We designed and optimized the FSS-VO_2 structure using finite-difference time-domain (FDTD) simulation (implemented in Lumerical FDTD), primarily targeting three figures of merit: a) high open-state transmittance, b) low limiting-state transmittance, and c) low limiting-state absorption. Via varying the FSS geometries, our optimized design can feature a broad open-state transmission band (FWHM > 2 μm) centered at any desired wavelength in the infrared from ~2 to 11 μm and essentially zero transmittance (~0.008) for all wavelengths in the limiting state. Because of the deep-subwavelength thickness and symmetry of the FSS structure, our design works for a large angular bandwidth (up to angle of incidence of 50°) for any polarization.

We used e-beam lithography to fabricate a design that has an open-state transmission band centered at ~10 μm. We measured the transmittance spectrum of the fabricated device for both states using a Fourier-transform infrared (FTIR) microscope, and the results agreed well with our simulations. The limiting performance of the fabricated device was characterized using our intensity-dependent transmission measurement setup with a continuous-wave CO_2 laser operating at λ= 10.6 μm. Note that we needed to preset the device at a higher temperature using a heat stage because the CO_2 laser we used could not provide sufficient power to photothermally trigger the IMT of VO_2 from the room temperature. Our experiments showed that the device was able to feature limiting performance for different incident-intensity ranges by varying the preset temperature. Moreover, the experimental results were well captured by our opto-thermal simulation (implemented in COMSOL Multiphysics) which also provided us insight to the limiting performance of our design regarding the limiting threshold and the device speed. We also used this opto-thermal simulation to explore opportunities for unidirectional limiting (i.e., nonlinear optical isolators).

11:30 AM EQ05.10.04
Photonic Crystal Fabry-Perot Cavities in Thin-Film Lithium Niobate for Tunable On-Chip Photonics David R. Barton, Jeffrey Holzgrafe, Di Zhu, Hana Warner, Neil Sinclair and Marko Loncar; Harvard University, United States

Photonic crystal cavities are ideal for enhancing weak light-matter interactions by simultaneously increasing the residence time of an optical mode while shrinking its mode volume. In addition, these structures can act as high extinction and narrow-band filters due to the optical bandgap formed. This can be used for on-chip filtering and dispersion engineering, both of which are necessary components in integrated photonic circuits. Lithium Niobate has emerged as a strong candidate for integrated photonics due to the ability to fabricate low-loss waveguides and high-quality factor ring resonators on a chip. In addition, its non-centrosymmetric structure allows for second order nonlinear optical effects like three-wave mixing phenomena and the electro-optic effect. Lithium Niobate's strong electro-optic effect is particularly useful, as it allows for tunability and optical modulation at microwave frequencies. Combining photonic crystals in integrated lithium niobate photonics is of great interest for optical technologies spanning nonlinear classical and quantum photonics.

Here, we explore Fabry-Perot cavities integrated in a Lithium Niobate on Insulator platform for tunable on-chip photonics. The mirrors are formed by photonic crystal sections on either side of low-loss waveguides. To reduce unwanted scattering losses, we utilize a "nanofin"-type geometry with alternating regions of wide and thin waveguide sections. We design our devices on uncladded 300 nm and 600 nm Lithium Niobate with underlying silicon dioxide. For 300 nm Lithium Niobate devices, a waveguide width of 1 micron, photonic crystal period of 480 nm, and alternating photonic crystal waveguide widths of 1600 nm and 400 nm forms an optical band gap near 1525 nm. We experimentally demonstrate bandgaps exceeding 80 nm in bandwidth at telecom frequencies and extinction exceeding 50 dB with a photonic crystal less than 30 microns long. By designing mirror segments with tapered sections to reduce impedance mismatch, we further demonstrate Fabry-Perot cavities with quality factors exceeding 150,000. We have also designed and tested devices on 600 nm Lithium Niobate with quality factors exceeding 75,000 in strongly overcoupled cavities, suggesting that much higher quality factors are achievable without sacrificing on transmission efficiency. We characterize the potential loss mechanisms by varying the cavity length and observe linear increases in the quality factor with cavity length, suggesting that mirror reflectivity is the dominant limiting factor in our devices, rather than scattering from waveguide or mirror imperfections. Future designs suggest that quality factors approaching 1 million are possible in devices with mode volumes smaller than typical ring resonator structures.

Coupled with Lithium Niobate's strong electro-optic effect (r_{33} ~ 30 pm/V), the high-Q nature of these devices lend themselves strongly to tunable nanophotonics and nonlinear photonics. We envision these devices in a variety of integrated optical technologies, including optical sensing and detectors, microwave-frequency modulation, and integrated quantum photonics.

Tunable Photonics Enabled by Defect Engineering of Vanadium Dioxide via Ion Implantation Chenghao Wan[1], Martin Hafermann[2], Tae Joon Park[3], Zhen Zhang[3], Jura Rensberg[2], Shriram Ramanathan[3], Carsten Ronning[2] and Mikhail A. Kats[1]; [1]University of Wisconsin--Madison, United States; [2]Friedrich-Schiller-Universität Jena, Germany; [3]Purdue University, United States

Vanadium dioxide (VO_2) has been widely investigated for tunable and reconfigurable photonic devices because it features dramatic changes in its optical

properties across its insulator-metal phase transition (IMT) at ~68 °C. As a strongly correlated material, the IMT temperature of VO_2 is determined by the stability of the electron hybridization, which is sensitive to the strain environment in the thin film, providing opportunities for engineering of the IMT. Most existing methods for modulating the IMT temperature of VO_2 either use different substrate materials or orientations to result in different strain environments in the film, or introduce dopants via physical or chemical processes during growth. Therefore, such methods need to be developed particularly depending on the choice of synthesis method, and the IMT characteristics are predetermined during the growth and fixed in the post-growth films.

In our talk, we present a method to modulate the IMT characteristics (e.g., the IMT temperature, or the temperature range of the IMT, which we refer to as IMT width) by introducing defects into VO_2 films via a post-VO_2-growth ion-implantation process. Our method is applicable for VO_2 films synthesized using different methods, and we demonstrated that such modulation in the VO_2 properties can be achieved even after a nanostructured device has been patterned on top of the VO_2 film.

Under irradiation by high-energy ions (Ar ions in our experiments), vacancies of V and O result from the collision cascade between the impinging ions and atoms of V and O, resulting in changes in IMT characteristics due to the induced changes in the strain and stoichiometry of the VO_2. In our experiments, we used 75-keV Ar ions to irradiate a ~100-nm VO_2 film grown on a sapphire substrate. We irradiated different areas of the film with different ion fluences ranging from $1x10^{13}$ to $2x10^{14}$ cm^{-2}. The IMT temperature and width of all the irradiated regions were characterized using temperature-dependent Fourier-transform infrared (FTIR) reflectance measurements. We also quantitatively extracted the temperature-dependent refractive index throughout the IMT for all irradiated regions using a combination of ellipsometry analysis and effective-medium calculation.

Based on our experiments, we conclude that the IMT characteristics of VO_2 can be grouped into distinct behaviors with respect to irradiation fluences: When irradiated by ion fluences of $<6x10^{13}$ cm^{-2}, the IMT temperature can be continuously lowered by up to ~20 °C with no substantial changes either in the IMT width or in the refractive-index contrast between the insulating and metallic phases. In contrast, for the higher irradiation fluences, though the IMT temperature can be further reduced, it is accompanied by a broadened IMT width and less refractive-index contrast.

The low-irradiation-fluence modulation is generally favorable for reconfigurable photonic designs because it can simply tune the IMT temperature (i.e., device triggering threshold) without trading off the optical contrast between device states. As a demonstration, we fabricated an optical limiter that incorporated gold aperture antennas onto a VO_2 thin film. The device featured a high transparency window centered at λ~4 μm when the VO_2 is in the insulating phase and low transmittance for all wavelengths when the VO_2 is triggered to the metallic phase at 68 °C. By irradiating this device with an ion fluence of $6x10^{13}$ cm^{-2}, we reduced the switching temperature to 52 °C.

SESSION EQ05.11: Fundamental of Plasmonics and Metaphotonics I
Session Chairs: Artur Davoyan and Luca Sortino
Wednesday Afternoon, December 1, 2021
Hynes, Level 2, Room 210

1:30 PM *EQ05.11.01
Quantum Photonics Empowered by Plasmonics and Machine Learning Vladimir Shalaev and Alexandra Boltasseva; Purdue University, United States

We will discuss some recent ideas and developments on how plasmonics and machine learning can be employed to dramatically speed up quantum process to make them immune to decoherence and how they can significantly improve the performance of quantum photonics devices and systems.

2:00 PM EQ05.11.02
Nonlocal and Quantum Effects in Graphene Plasmonic Devices Operating at Short Wave Infrared Wavelengths over Large Scale Areas Joel Siegel, Jonathan Dwyer, Anjali Suresh, Nathaniel Safron, Margaret Fortman, Chenghao Wan, Jonathan Choi, Wei Wei, Vivek Saraswat, Wyatt Behn, Mikhail A. Kats, Michael Arnold, Padma Gopalan and Victor Brar; University of Wisconsin--Madison, United States

Graphene plasmonic resonances have been broadly studied in the terahertz and mid-infrared (MIR) ranges because of their electrical tunability and large confinement factors, which can enable exploration of extreme light-matter interactions, among other optoelectrical applications. Plasmonic resonances occur in graphene when it is patterned into nanostructures (e.g. ribbons) which confine the graphene plasmons and enables coupling to free-space radiation. But an upper frequency limit (MIR) is set by the limits of electron beam lithography, which can make graphene nanostructures as small as 15 nm. In this talk, I will show that nonlocal and quantum effects become significant for graphene nanostructures less than 15 nm. Those changes blue-shift the frequencies of the graphene plasmons, pushing their operational range from the MIR into the short-wave infrared (SWIR). These effects are realized in centimeter-scale arrays of graphene ribbons as narrow as 12 nm created using a novel, bottom-up block copolymer lithography method that allowed for the creation of plasmonic cavities with resonant wavelengths as short as 2.2 μm. The confinement factors of these cavities can reach 135, which, while exceedingly large, is less than what has been theoretically predicted – a result of strong nonlocality. The combined SWIR response and large confinement factors observed in these graphene nanoribbon arrays – combined with the scalable fabrication method used to create them – makes these nanostructures an attractive platform to explore next-generation optoelectrical devices and strongly enhanced spontaneous emission in the SWIR.

2:15 PM EQ05.11.04
A Fluctuational Electrodynamics Approach for Radiative Transfer Modeling of Nanocomposites with Particles of Arbitrary Shape Francisco V. Ramirez[1,2], Gurunatha Kargal Laxminarayana[2], Ivan P. Parkin[2] and Ioannis Papakonstantinou[2]; [1]Universidad Adolfo Ibanez, Chile; [2]University College London, United Kingdom

Composites lie at the core of nanophotonics. Many devices in fields such as photosensing, photochemistry and thermophotonics are based on disordered nanomaterials with arbitrary shaped and randomly distributed structures, where their dispersion, filling fraction and size need to be finely tuned to achieve optimal performance. Although simulations are critical in this task, predicting the optical response of these materials is challenging, given the random orientation and anisotropic morphology of the structures involved. The radiative transfer equation (RTE), while being specifically formulated to describe light transport in random scattering media, becomes computationally expensive to solve when the structures are non-spherical.

In this talk, I will discuss our newly developed universal theory of average light scattering of randomly oriented scatterers (particles or collections of particles), and a practical method for radiative transfer simulations of composite with scatterers of arbitrary morphology. First, I will introduce our

fluctuational-electrodynamics-based theory to compute the average absorption cross section, scattering cross section, and asymmetry parameter of randomly oriented scatterers of arbitrary shape. The three parameters can be directly integrated into traditional RTE solvers, enabling computationally inexpensive radiative transfer simulations. The accuracy of this modeling framework is demonstrated against optical measurements of polymer composites with metal-oxide crystals of irregular morphology.

As I will discuss by the end of this talk, the modeling framework could provide a better understanding of the interrelation between nanoscale electromagnetic interactions and the macroscopic response of disordered nanomaterials, such as the effects of agglomeration of plasmonic nanostars in optical absorption, or the impact of multiple scattering in the light trapping of heterostructured photocatalysts.

3:45 PM EQ05.11.06
Sunlight-Powered Reverse Water Gas Shift Reaction Using a Titania Supported Plasmonic Au Nanocatalyst: Distinguishing between Photothermal and Non-Thermal Contributions Pau Martínez Molina[1], Nicole Meulendijks[1], Man Xu[1,2], Marcel A. Verheijen[3,4], Tim den Hartog[1,5], Francesc Sastre[1] and Pascal Buskens[1,6]; [1]TNO, Netherlands; [2]Delft University of Technology, Netherlands; [3]Eurofins Material Science Netherlands B.V., Netherlands; [4]Technische Universiteit Eindhoven, Netherlands; [5]Zuyd University of Applied Sciences, Netherlands; [6]Hasselt University, Belgium

Plasmon catalysis is an interesting technology concept for powering chemical processes with sunlight. It makes use of the localized surface plasmon resonance (LSPR) of catalytically active metallic nanoparticles. Upon illumination, a coherent electron oscillation occurs in these nanoparticles, which rapidly dephases and generates hot electrons. These can then either be transferred into an electron accepting orbital of an adsorbed molecule, or thermalize due to electron-electron and electron-phonon scattering leading to an increased temperature of the catalyst. Both from a fundamental and application perspective, differentiating between the non-thermal and photothermal contribution is essential.
Recently, we reported the sunlight powered conversion of carbon dioxide and green hydrogen to methane and water – the so-called Sabatier reaction – using alumina supported Ru nanocatalysts [1,2]. Here, we report the sunlight powered conversion of carbon dioxide and green hydrogen to carbon monoxide and water – the so-called reverse water gas shift (rWGS) reaction – using a titania supported plasmonic Au nanocatalyst. The rWGS reaction is endothermic (ΔH_{298K} = 41.2 kJ mol^{-1}) and limited by equilibrium. In the conventional thermal rWGS process, catalysed by *e.g.* Cu, Rh or Pt, temperatures above 800°C are applied to produce CO with an acceptable selectivity (about 80%). In our study, we demonstrate that CO can be formed with high selectivity using only sunlight and without external heating of the reactor. Using mildly concentrated artificial sunlight (1.44 W cm^{-2} equals 14.4 suns) we realized a selectivity of 98% and a CO production rate of 429 mmol g_{Au}^{-1} h^{-1}. Temperature measurements performed with a thermocouple positioned in contact with the bottom side of the catalyst bed indicated a catalyst temperature of 140°C. We expected the top layer of the catalyst bed to have a higher temperature since it is directly exposed to light. Using a simple theoretical model based on Kirchhoff's law and Stefan-Boltzmann's law for macro scale objects, we estimated that the collective temperature at the top surface of the catalyst reached 300°C upon illumination with 14 suns. We furthermore demonstrated that the relationship between the reaction rate and the light intensity is exponential, which points to a strong photothermal component contributing to this reaction.
In reference reactions performed in dark with the same catalyst methane was formed in large quantities, while upon illumination CO was formed with a selectivity of 98% and CH_4 formation was largely suppressed. We propose the promotion of H_2O and CO desorption through charge transfer of plasmon generated charges to explain this difference.
In conclusion, we have demonstrated that plasmon catalysis can be applied to convert the greenhouse gas CO_2 into the valuable chemical intermediate CO using sunlight as sustainable energy source. Further studies on quantification of photothermal and non-thermal contributors and other aspects involving the reaction mechanism as subject of research in our labs.

4:00 PM EQ05.11.07
Exploiting Thermoplasmonics in Dynamic Self-Assembly of Gold Nanoparticles Joscha Kruse[1], Stefan Merkens[2], Andrey Chuvilin[2] and Marek Grzelczak[3,1]; [1]Donostia International Physics Center, Spain; [2]CIC nanoGUNE, Spain; [3]Centro de Fisica de Materiales, Spain

The development of dynamic self-assembly (nano)systems is still a young research area (1) with promising future applications due to the ability of actively rearranging building blocks on the nanoscale. An in-depth investigation of the assembly and disassembly processes is of great importance to gain insights into the intermediate assembly states. Here we show the detailed picture of temperature-driven reversible clustering of gold nanoparticles (gold nanospheres(2) and gold nanorods).
Using in-situ UV-VIS spectroscopy, we revealed the emergence of hysteresis during the cyclic temperature changes. By varying nanoparticles diameter and their surface charge as well as the rate of applied stimulus we were able to describe qualitatively the contribution of thermodynamic and kinetic hysteresis. A particularly intriguing case is the reversible clustering of gold nanorods.They adapt to transient mutual configurations, such as tip-to-tip or side-to-side, enriching the hysteretic response. In addition, the large absorption cross-section of gold nanorods in the infrared spectral range allowed us for taking advantage of their efficient light to heat conversion. Therefore by introducing light as stimulus, instead of an external heating source, we were able to control locally the change of temperature which in turn altered the colloidal stability of the nanorods.
Then, we designed a more sophisticated colloidal system and integrated feedback loops, leading to oscillatory and self-sustained clustering under continuous energy flux. We found that the presence of hysteresis in reversible aggregation is the prime condition to invoke oscillatory clustering otherwise the system adapts to its equilibrium steady state without oscillations.

We foresee that the presented experimental framework offers an exciting playground to study the nature of meta-stable assemblies, and enables possible applications in spatiotemporal catalysis, thermo-mechanical nanotransducers, smart windows, among others.

4:15 PM EQ05.11.08
Understanding the Chemical Mechanism Behind Photo-Induced Enhanced Raman Spectroscopy Junzhi Ye[1,2], Rakesh Arul[1,2,2], Michel K. Nieuwoudt[2], Junzhe Dong[2], Wei Gao[2] and Cather Simpson[2]; [1]University of Cambridge, United Kingdom; [2]The University of Auckland, New Zealand

Photo-Induced Enhanced Raman Spectroscopy (PIERS) is a new surface enhanced Raman spectroscopy (SERS) modality with an order-of-magnitude Raman signal enhancement of adsorbed analytes over that of typical SERS substrates. Despite the impressive PIERS enhancement factors and explosion in recent demonstrations of its utility, the detailed enhancement mechanism remains undetermined. Using a range of optical and X-ray spectroscopies, supported by density functional theory calculations, we elucidate the chemical and atomic-scale mechanism behind the PIERS enhancement. Stable PIERS substrates with enhancement factors of 106 were fabricated using self-organized hexagonal arrays of TiO2 nanotubes that were defect-engineered via annealing in inert atmospheres, and silver nanoparticles were deposited by magnetron sputtering and subsequent thermal dewetting. We identified the key source of the enhancement of PIERS vs. SERS in these structures as an increase in the Raman polarizability of the adsorbed probe molecule upon photo-induced charge transfer. A balance between crystallinity, which enhances charge transfer due to higher electron mobility in anatase-rutile heterostructures but decreases visible light absorption, and oxygen vacancy defects, which increase visible light absorption and photo-induced electron transfers, was critical to achieve high PIERS enhancements.

SESSION EQ05.12: 2D Photonics/Nonlinear Optics
Session Chair: Benjamin Vest

Hynes, Level 2, Room 210

4:45 PM EQ05.12.01
Broadband Electro-Optic Polarization Conversion with Atomically Thin Black Phosphorus Souvik Biswas[1], Meir Y. Grajower[1], Kenji Watanabe[2], Takashi Taniguchi[2] and Harry A. Atwater[1]; [1]California Institute of Technology, United States; [2]National Institute for Materials Science, Japan

On-demand polarization control of light plays a critical role in a variety of classical and quantum optics-based applications such as holography, imaging, dichroism sensing and polarization encoding of qubits. We demonstrate electrically reconfigurable, high dynamic range, broadband polarization conversion with atomically thin van der Waals heterostructures, using tri-layer black phosphorus (BP) integrated in a Fabry-Pérot cavity, at telecom wavelengths. Here, we leverage the exciton-dominated near-unity birefringence in naturally stacked three atomic layers of BP (~1398 nm) which enables a broadband operation window of the entire telecom E, S and C bands (1360-1580 nm). The inherent optical anisotropy of BP, further enhanced by integration into a Fabry-Pérot resonant cavity, allows generation of polarization states over the entire Poincaré sphere via spectral and input azimuthal angle tuning. Furthermore, the extreme polarizability of the exciton to an external electric field provides near-complete suppression of its dipole oscillator strength, enabling active control of the polarization state across nearly half the Poincaré sphere. Specifically, both linear to circular and linear cross-polarization conversion schemes, among numerous other trajectories, were achieved (for example at ~1444 nm) via electrical doping (up to ~$7x10^{12}/cm^2$) demonstrating superior control over the reflected ellipticity and azimuthal angles. Our findings highlight the potential of BP in future chip-based polarization-sensitive electro-optic platforms such as spatial light modulators, variable phase retarders, and sensors.

5:00 PM EQ05.12.02
All-Dielectric Nanophotonics for Enhanced Light-Matter Interaction in 2D Semiconductors Luca Sortino[1,2], Panaiot Zotev[2], Sandro Mignuzzi[3], Stefan A. Maier[1,3], Riccardo Sapienza[3] and Alexander Tartakovskii[2]; [1]Ludwig-Maximillians-University Munich (LMU), Germany; [2]University of Sheffield, United Kingdom; [3]Imperial College London, United Kingdom

High refractive index dielectrics are emerging as a novel platform to shape and control light at the nanoscale by engineering electric and magnetic Mie-resonances in sub-wavelength nanostructures. Between two-dimensional (2D) semiconductors, the family of transition metal dichalcogenides (TMDs) exhibits exceptional optical properties, such as tightly bound excitons and single-photon emitting centers, and unique mechanical properties leading to favorable integration in current nano-photonic architectures. In our work, we integrated single and double layer TMDs WSe_2 with Mie-resonant gallium phosphide (GaP) dimer nano-antennas and demonstrate the enhancement of the light-matter interaction of 2D excitons and native single-photon emitters. At room temperature, we observe an enhancement of the PL up to 10^4, compared to WSe_2 on planar GaP, and show this is a result of increased absorption, enhanced spontaneous emission rate, and emission redirection [1]. Moreover, the nano-structures displace the semiconducting layers in the out-of-plane direction, allowing the tuning of the local WSe_2 bandstructure via strain [2]. At cryogenic temperatures, the strain-induced potential acts as a trap for photo-generated excitons, leading to the nano-scale positioning of bright single-photon emitters in monolayer WSe_2 [3]. We compare the optical properties of quantum emitters on GaP nano-antennas to those positioned on non-resonant SiO_2 nano-pillars. In agreement with our numerical simulations, we observe more than two orders of magnitude enhancement in the collected PL intensity of nano-antenna coupled SPEs, further exhibiting long PL lifetimes - up to 200 ns - and ultra-low PL saturation thresholds. We show this is related to an increased quantum efficiency of the single-photon emission when the TMD layer is coupled to the nano-antenna near-field. We report quantum efficiency with values up to > 80% on GaP nano-antennas, compared to an average of 4% when positioned on SiO2 nano-pillars. Our results highlight Mie resonances in dielectric nanostructures as a novel nanophotonic platform to engineer light-matter interaction in two-dimensional materials and single-photon emitters.

Jariwala[1]; [1]University of Pennsylvania, United States; [2]University of California, United States; [3]The Pennsylvania State University, United States; [4]Aixtron Ltd., United Kingdom; [5]Air Force Research Laboratory, United States; [6]University of Dayton, United States

The ability to arbitrarily stack two-dimensional (2D) crystals have led to new opportunities to design and assemble artificial lattices without the constraints of epitaxy. However, these opportunities are limited by difficulties in controlling the thickness of exfoliated van der Waals (vdW) layers, which prevents the realization of repeat units with high fidelity. Recently, the development of metal-organic chemical vapor deposition (MOCVD) synthesis has allowed the creation of uniform, wafer-scale samples with thickness control. This allows the production of stacks of disparate 2D layers with multiple repeating units, which permits the engineering of electronic and optical dispersions in these heterostructures. We have engineered the optical dispersion in a superlattice structure by alternating layers of 2D chalcogenides and dielectric insulators. We demonstrate 94% narrowband absorption in <6 nm active layer excitonic absorber medium at room temperature through the design of the unit cell parameters. This is accompanied by an enhancement in the photoluminescence of square-centimeter-sized samples. The TMDC-insulators also show evidence of strong light-matter coupling and exciton-polariton formation with a Rabi splitting up to 190 meV. These results demonstrate that it is possible to engineer optical properties in 2D heterostructures and suggest approaches to create a broad class of scalable, designer optical metamaterials from atomically thin layers.

5:30 PM EQ05.12.04
Weyl Semimetal Thin-Films for Nonlinear and Ultrafast Nanophotonics Benjamin Tilmann[1], Amilcar Bedoya-Pinto[2], Gustavo Grinblat[3], Yi Li[4], Stuart Parkin[2] and Stefan A. Maier[1,5]; [1]Ludwig-Maximilians-Universität, Germany; [2]Max Planck Institute of Microstructure Physics, Germany; [3]Universidad de Buenos Aires, Argentina; [4]Southern University of Science and Technology, China; [5]Imperial College London, United Kingdom

Weyl semimetals are a class of materials with unique properties as a results of a single touching point of valence and conduction band and a linear electronic dispersion, where the electrons behave as quasi-massless fermions, comparable to the Dirac cone in graphene. This leads to the formation of Fermi arcs and topologically protected edge states on the surface of Weyl semimetals and gives them a generally high electron mobility, a large magnetoresistance and effects such as the Adler-Bell-Jackiw anomaly. Furthermore, the Weyl semimetal family of transition metal monopnictides, were shown to have outstanding optical properties. Among others, the glass coefficient of TaAs in the near-infrared was measured to be the highest reported so far[1] and the second-order nonlinear coefficient has been measured to be two magnitudes larger than the one for GaAs[2]. These properties make Weyl semimetals promising candidates for optical applications, however, most previous works were limited to bulk crystals that are naturally limited in means of flexibility and device applications.
In this work, we perform first steps towards nanophotonics with Weyl semimetals by characterizing the linear and nonlinear optical response of recently realized epitaxially grown NbP thin films[3,4]. By spectral ellipsometry, we determined the linear refractive index and extinction coefficient with good agreement to theoretical predictions and thereby confirm the semimetallic character of the material. Despite the strong absorption over the visible spectrum, we show strong third-harmonic generation that reaches a maximum efficiency of 10^{-5} % when exciting in the near-infrared. Comparing this to the signal detected from a bulk crystal of the same material, the nonlinear response of the thin film is stronger by more than a factor two. Furthermore, we performed non-degenerate pump-probe spectroscopy with 10 fs temporal resolution. We observe that the ultrafast optical response of the bulk NbP crystal is dominated by electronic absorption processes and subsequent scattering dynamics in the Weyl cone, in good agreement with previous studies on comparable materials. On the other hand, the NbP thin film shows a probe wavelength independent response that is dominated by the nonlinear optical Kerr effect and an ultrafast modulation depth of close to 1%, again a factor of two stronger than the bulk crystal. Undergoing a complete relaxation within less than 50 fs, the NbP film would allow all-optical switching with a full-width half-maximum bandwidth of 10-20 THz. We ascribe the boosted nonlinear performance to the reduced volume that contains only 10-20 unit cells of the material and therefore limits the absorption and electron-electron interactions. In conclusion, our results show that the epitaxial grown NbP thin films inherit the intrinsic optical properties of the bulk crystal but significantly reduce the absorption due to the reduced dimensionality, which further boosts the nonlinear optical interactions. Together with the fact that thin films enable common top-down nanofabrication techniques, this paves the way for various promising applications of Weyl semimetals in the field of nanophotonics.

Third-Harmonic Generation Reveals Strong Sub-Wavelength Optical Confinement in Photonic Gap Antennas Coupled to Epsilon-Near-Zero Thin Films Felix Thouin, David Myers, Ashutosh Patri, Bill Baloukas, Ludvik Martinu and Stephane Kena-Cohen; Polytechnique Montréal, United States

Squeezing light down to sub-wavelength scales allows the emergence of a host of fascinating phenomena in non-linear and quantum optics. These find applications in photonics and quantum information processing to name a few. While such a feat has been realized using conventional plasmonic nanoantennas, the losses inherent to these systems limit the scope of applications by lowering their damage threshold and damping quantum coherences. To this end, epsilon near-zero (ENZ) thin films, with their vanishing real permittivity and relatively low imaginary permittivity, are attractive candidates to tightly confine light with little losses. These have been used in the past in conjunction with plasmonic nanoantennas to reach high levels of confinement. We sought to integrate these materials in dielectric nanoantennas to achieve comparable levels of confinement while maintaining losses low.

We achieved sub-wavelength light confinement with photonic gap antennas (PGAs) consisting of a thin film of indium tin oxide (ITO), an ENZ material, embedded in an amorphous silicon nanopillar. PGAs of various sizes were fabricated with a multilayer deposition process followed by pseudo-Bosch photolithography. The antennas' scattering spectrum was measured using dark field scattering spectroscopy and the resonant character of the light confinement was assessed through third harmonic generation. We interpreted these results in the framework of coupled mode theory and show that the resonances responsible for the light confinement arise from the hybridization of the silicon pillar modes with the epsilon near-zero mode of the ITO thin film. This work opens up the possibility for high efficiency non-linear photonics with high damage thresholds, as well as strong light-matter interaction for the generation of quantum light and ultrastrong light-matter interaction.

Developing ITO Nanolayers for ENZ-Enhanced Nonlinear Responses Wesley Britton and Luca Dal Negro; Boston University, United States

The engineered material dispersion of the thin-film transparent conductive oxide indium tin oxide (ITO) has been proven to exhibit extremely large epsilon-near-zero (ENZ) and low index-driven nonlinear responses. This has enabled the rapid development of compact and integrated CMOS-compatible

devices that perform efficient nonlinear operations such as sub-picosecond all optical modulation, ultra-fast pulse shaping through frequency translation, and optical time reversal. Recent theoretical studies indicate that both bound electrons in the lattice and hot electron contributions significantly drive the nonlinear response of ITO materials. These results strongly motivate the optimization of material structure beyond dispersion engineering to boost nonlinear enhancement using material lattice contributions. Specifically, crystallographic texture describes the tendency for the grains of a polycrystalline films to avoid random distributions in favor of preferred orientations and can profoundly affect the nonlinear optical material properties. We show how modified growth and post-deposition conditions can dramatically modify ITO crystallographic texture and impact the nonlinear properties of ITO films characterized using Z-scan and four-wave mixing experiments.

Evaluation of 2D Transition Metal Carbides and Carbonitrides (MXenes) for SERS Substrates Kateryna Shevchuk, Asia Sarycheva and Yury Gogotsi; A.J. Drexel Nanomaterials Institute, United States

Two-dimensional transition metal carbides and carbonitrides are promising plasmonic materials for surface-enhanced Raman spectroscopy (SERS), allowing sensitive detection of analyte molecules. Their high electronic conductivity and rich surface chemistries enable both SERS electromagnetic and chemical enhancements. We have synthesized seven most common MXenes – Nb_2C, Mo_2C, Ti_2C, V_2C, Ti_3C_2, Mo_2TiC_2, and Ti_3CN with the transversal plasmon resonances ranging from the visible region to NIR. We were able to detect the 10^{-7} M concentrations of Rhodamine 6G dye on MXene substrates, reaching the enhancement factors of 10^5-10^6. The results were compared to the commercially available substrates and showed advantageous performance of Ti_3C_2 compared to gold nanoparticles. We tested the best performing MXene with a variety of dyes, suggesting the versatility of MXene SERS substrates. Due to high charge carrier densities and tunable surface chemistries, MXenes show potential for SERS sensors that are inexpensive, easy to fabricate, and optimize for specific applications.

Improved Performance of Polymeric One-Dimensional Photonic Crystals via High-n Additive Samuel Wallaert, Ali Masud, Hadi Ghasemi and Alamgir Karim; University of Houston, United States

Interest in flexible photonic layers made of polymeric materials is growing as they can find applications to create reflective surfaces for IR reflection, UV reflection, etc. for applications such as thermal management since they can have tunable heat dissipation or shielding properties. One-dimensional photonic crystals, specifically Distributed Bragg Reflectors (DBR) made of alternating high and low refractive index polymeric materials, have attracted research attention for the past few decades in this regard. However, very few materials exhibit the optical properties to function as polymeric DBRs. Major problems encompassing polymer-based DBRs include the low refractive index of the polymer, incompatible optical properties of the polymer, and casting of uniform thickness of alternating layers without damaging the underlying layers. Herein, we explore creating a DBR with high reflective properties developed by applying an additive directly to the high refractive index polymeric material to increase the refractive index difference of the two alternating layers from 0.2 to 0.5. Such enhancements helped us achieve 100% better reflective properties for near and far-infrared regions of the electromagnetic spectrum, with broader reflection bands requiring only half the number of layers than most common DBRs used in the literature. We hope such findings would make polymeric DBR materials useful for defense vehicles and clothing for shielding purposes and heat dissipation as they are flexible and readily integrate into many surfaces.

We acknowledge DoD Grant #W911QY2190015 for support of this project.

Wafer-Scale Synthesis and Optical Characterization of InP Nanowire Arrays for Solar Cells Lukas Hrachowina[1], Nicklas Anttu[2,3] and Magnus T. Borgström[1]; [1]Lund University, Sweden; [2]Åbo Akademi University, Finland; [3]Aalto University, Finland

Nanowire solar cells have the potential to reach the same efficiencies as the world record III-V solar cells by the use of a fraction of the material[1, 2]. For solar energy harvesting, large area nanowire solar cells have to be processed but so far high efficiency nanowire solar cells have been demonstrated only on small areas less than 1 mm^2 [3-5].
In this work, we demonstrate the synthesis of epitaxial, photovoltaic InP nanowire arrays on a 2" wafer. We used talbot displacement lithography and placed black plastic stripes on the phase shift mask to block the UV light in order to define five array areas with different nanowire diameters on the same wafer by sequentially varying the exposure dose. We use a photoluminescence (PL) mapper to characterize the sample with both steady-state and time-resolved PL maps. Subsequently, we compare it to a reference wafer that was exposed homogenously. Furthermore, by the use of a white light source inside the PL mapper instead of the laser diode used for PL, we measure reflectance (R) maps. We created a database for modeled $R(\lambda,D,L)$ for varying λ, D, and L at a fixed period of 500 nm for the hexagonal array of nanowires[6]. Then, we simultaneously extract the diameter and length of the nanowires from the several thousand experimentally measured R spectra over the full wafer, using the modeled R database. The extracted knowledge of large-scale nanowire synthesis will be crucial for the upscaling of nanowire based solar cells, and the demonstrated wafer-scale characterization methods will be central for quality control during manufacturing.

Transparent Luminescent Solar Concentrator with Quantum Dots and Hexarhenium Cluster Enhanced by Energy Transfer Jun Choi and Sung-Jin Kim; Ewha Womans University, Korea (the Republic of)

A luminescent solar concentrator (LSC) photovoltaic (PV) system is a solar light harvesting device that absorb the sunlight by large LSC panel and concentrate photoluminescent light on PV cell placed at the edge of LSC panel to convert it into electricity. The nano-sized inorganic-organic cluster complex $(dMDAEMA)_4[Re_6S_8(NCS)_6]$ (refers as RMC, where dMDAEMA is 2-dimethyl amino ethyl methacrylate) is a good candidate for LSC luminophore due to largely downshifted broad photoluminescence suitable to PV cell. However, the low quantum yield (QY) of RMC limit the performance of LSC. Here, Zn doped CuGaS/ZnS core-shell quantum dots (ZQD) as a Stokes shift engineered donor with high QY was used to improved performance of LSC. These two metal chalcogenide luminophores, RMC and ZQD, are chemically suitable to be dispersed in amphiphilic polymer matrix making clear waveguide with low reabsorption and optically well matched emission resulting high power conversion efficiency (PCE) and optical efficiency (η_{opt}). We achieved maximum η_{opt} of 3.47 % and PCE of 1.26 %, while maintaining high transparency of over 80 % in visible wavelength range. This dual-dye LSC system exhibits reabsorption free and increased emission by isolation of dyes in polymer matrix and energy transfer from ZQD to RMC. This LSC system suggests as a promising candidate for up-scaling building-integrated PVs (BIPV) for use in windows.

EQ05.13.08
Late News: X-Ray Radioluminescent Crystalline Colloidal Arrays—Fine-Tuning ColorCcharacteristics via X-Ray Induced Sequential Förster Resonance Energy Transfer (FRET) and a Photonic Bandgap Haley W. Jones, Iurii Bandera, Eric Zhang and Stephen H. Foulger; Clemson University, United States

Photonic crystals describe a class of periodic dielectric materials that exhibit a photonic bandgap (i.e., rejection wavelength) corresponding to specific wavelengths of light where propagation through the crystal is forbidden. In the past few decades, particular interest has focused on photonic crystals composed of crystalline colloidal arrays (CCAs), which exhibit iridescent structural colors similar to that of the precious opal. These biomimetic colloids are composed of closed-packed, electrically charged particles that self-assemble into three-dimensional periodic arrays due to their repulsive Coulombic interactions. While a CCA does not exhibit a complete photonic bandgap due to a low refractive index contrast, a CCA possesses a rejection wavelength in the visible regime that can be described by Bragg's equation ($\lambda = 2n_c d_{hkl}\sin(\theta)$). The CCA's rejection wavelength (λ) can be shifted across the full visible spectrum by changing the interplanar spacing (d_{hkl}), changing the refractive index (n_c), or a combination of the two parameters.

X-ray radioluminescent CCAs with highly tunable emission colors are synthesized using an emulsion polymerization procedure. An anthracene methyl methacrylate derivative (AMMA) is copolymerized within a poly(styrene-co-propargyl acrylate) (PS-PA) basis to generate an x-ray radioluminescent PS-PA-PAMMA CCA (87 nm), emitter 1 ($\mathbf{E_1}$). Due to the electrostatic repulsive forces between the colloidal nanoparticles, $\mathbf{E_1}$ spontaneously self-assembles into an FCC structure. $\mathbf{E_1}$ possesses a rejection wavelength in the visible regime that can be shifted across the visible spectrum by a change in the interplanar spacing, which is achieved by the addition or removal of deionized water. Typical anthracene radioluminescence spanning 400 – 515 nm, with a maximum at 420 nm, is detected when there is no rejection wavelength interference. However, a decrease in spontaneous emission at the rejection wavelength is observed when the rejection wavelength is shifted within $\mathbf{E_1}$'s radioluminescence. The radioluminescence decrease corresponding to the rejection wavelength can be shifted across the entire radioluminescence of $\mathbf{E_1}$. In this way, the CCA's radioluminescence can be manipulated by photonic means. Furthermore, the CCA's color characteristics can be adjusted across the visible spectrum by x-ray induced sequential Förster Resonance Energy Transfer (FRET). Energy transfer is achieved by copolymerizing one or two additional organic fluorophores that form FRET pairs with AMMA and each other. A naphthalimide methyl methacrylate derivative (NMMA) that absorbs in the blue region where AMMA emits is incorporated within $\mathbf{E_1}$ to generate a PS-PA-PAMMA-PNMMA CCA (125 nm), emitter 2 ($\mathbf{E_2}$). $\mathbf{E_2}$ emits in the green region of the visible spectrum, with a maximum at 535 nm, when pumped with an x-ray source. Additionally, a rhodamine B methyl methacrylate derivative (RMMA) that absorbs in the green region where NMMA emits is incorporated within $\mathbf{E_2}$ to generate a PS-PA-PAMMA-PNMMA-PRMMA CCA (122 nm), emitter 3 ($\mathbf{E_3}$). $\mathbf{E_3}$ emits in the red region of the visible spectrum, with a maximum at 630 nm, when pumped with an x-ray source. In this way, x-ray induced FRET or x-ray induced sequential FRET is achieved, respectively. Furthermore, the rejection wavelength of $\mathbf{E_2}$ and $\mathbf{E_3}$ can be coupled with their radioluminescence to fine-tune the color characteristics of the liquid systems.

EQ05.13.10
A Universal Synthesis Strategy for Chiral Inorganic Nanostructures via Self-Assembled Templates of Achiral Block Copolymers and Racemic Mixtures Minju Kim and Dong Ha Kim; Ewha Womans University, Korea (the Republic of)

Chiral inorganic nanostructures have attracted growing attention due to their potential applications and technological prospects. Even though various strategies have been developed for fabricating chiral inorganic nanostructures, the complex processes and expense of chiral biomolecules and their derivatives remain formidable challenges to realize mass production and large-area fabrication with simple and cost-effective processes. Here, we suggest a generalized protocol for the fabrication of chiral inorganic nanostructures including Au, Ag, Pd, and TiO_2 nanostructures based on achiral templates consisting of block copolymer inverse micelles and racemic mixtures. Self-assembly of poly(styrene-*b*-4-vinyl pyridine) (PS-*b*-P4VP) diblock copolymer inverse micelles containing inorganic precursors and DL alanine additives is shown to exhibit chiral properties in a specific environment in solution, a prerequisite element for the evolution of chirality. Notably, we found the pyridine groups of P4VP interacted more favorably with D-alanine than with L-alanine via hydrogen bonding in non-polar solvents, leading to the chirality transfer from D-alanine to the D-alanine-bonded P4VP micellar cores. In-situ synthesis of nanoparticles (NPs) in the micellar core by a mild reducing agent enabled strong electronic interaction between induced chiral micellar cores and in-situ formed NPs. Therefore, we achieve outstanding chiroptical properties with high anisotropy factors of $8\ 10^{-4}$ although chiral reagents and scaffolds were not involved in any step. Our design concept pinpoints forwarding steps to construct an extended library of viable chiral inorganic nanostructures, ensuring a substantial development in the field of chiroptics.

Nanophotonics for Advanced Space Exploration Artur Davoyan; University of California, Los Angeles, United States

At present deep space exploration is limited by transit time and overall mission costs. Conventional spacecraft make use of chemical or electric engines, which have fundamental limitations on the possible speed one can achieve. Light driven propulsion offers a conceptually different approach to space travel. In this talk I will overview our work on solar and laser driven propulsion for space exploration.

First, I will survey our work on laser driven propulsion. I will outline key requirements and challenges associated with Breakthrough Starshot mission. I will then discuss implications of utilizing smaller and more affordable systems for near-term space exploration. I will show that with relatively moderate laser powers (~1 MW) conceptually new regimes for spacecraft maneuvering and orbiting on interplanetary and Earth orbital missions emerge. Next I will discuss nanophotonic designs that optimize the tradeoff between mass, reflectance and a need for a radiative cooling. I will also summarize challenges and opportunities of laser driven propulsion for space exploration.

Next, I will examine an alternative approach for deep space missions with the use of solar sailing. I will demonstrate that lightweight solar sails are potentially capable of reaching >30 AU/year velocities (i.e., more than 8 times faster than the Voyager – fastest space probe ever built), and can pave the way to fast and scalable exploration of the solar system and beyond. I will then survey material challenges associated with solar sailing and discuss the way nanophotonics can advance solar sail missions. Lastly, I will survey our ongoing experimental effort.

Hydrogel-Encapsulated Crystalline Colloidal Arrays—Coupling the Radioluminescence of an Organic Scintillator with a Rejection Wavelength Sarah Mell, Haley W. Jones, Iurii Bandera and Stephen H. Foulger; Clemson University, United States

A crystalline colloidal array (CCA) is a photonic crystal made of self-assembled colloidal nanoparticles, in which a periodic dielectric structure prohibits the propagation of a particular wavelength of light throughout the material. The blocked wavelength is known as the rejection wavelength, or stopband, of the material. Iridescence is observed in CCAs because of the rejection wavelength located within the visible light spectrum, causing the liquid system to resemble a precious opal. CCAs utilize the long-range electrostatic repulsive interactions between the colloidal particles to induce self-assembly into a crystal-like structure. Bragg's equation can be used to estimate the observed rejection wavelength based on the angle of incident light, interplanar spacing, and refractive index of the material. This dependence on interplanar spacing indicates that the rejection wavelength can be manipulated by adjusting the particle spacing. Incorporating a scintillator into the CCA results in the system exhibiting the typical emission of the scintillator, given that the rejection wavelength does not overlap the range of emission. If the rejection wavelength is located within the emission range of the scintillator, the light at that wavelength is prohibited from propagating and the signal can be blocked. In this work, an emulsion copolymerization was used to synthesize monodisperse, polystyrene-based radioluminescent terpolymer nanoparticles that self-assembled into a face-centered cubic (fcc) structure. Anthracene is an organic scintillator that emits blue light when excited with an x-ray source. During the copolymerization, anthracene was covalently incorporated into a poly(styrene-co-propargyl acrylate) (PS-PA) basis in the form of anthracen-9-ylmethylmethacrylate (AMMA) to form a poly(styrene-co-propargyl acrylate-co-anthracen-9-ylmethylmethacrylate) (PS-PA-PAMMA) liquid CCA. Because liquid CCAs are susceptible to ionic impurities and mechanical stress, the CCA was encapsulated in a hydrogel network. The hydrogel network was photopolymerized in situ with the CCA by mixing the CCA with poly(ethylene glycol) methacrylate (PEGMA), poly(ethylene glycol) dimethacrylate (PEGDMA), and diethoxyacetophenone (DEAP) and exposing the mixture to ultraviolet light. Encapsulating the liquid CCA in a hydrogel network stabilized the crystalline structure and created a more mechanically robust film which was preserved by storing in deionized (DI) water. The hydrogel-encapsulated CCAs exhibited similar rejection wavelength and emission properties to the liquid CCAs. Multiple methods can be used to shift the rejection wavelength of the CCAs. Diluting the liquid CCA with DI water increased the interparticle spacing, red-shifting the rejection wavelength. The rejection wavelength of the hydrogel-encapsulated CCA was tuned by swelling and drying the film. When excited with an x-ray source, the encapsulated CCA exhibited the radioluminescence characteristic of anthracene with a maximum emission at 425 nm. The radioluminescence of the hydrogel-encapsulated CCA decreased when the rejection wavelength was shifted to overlap the characteristic emission. The overall emission of the system can be controlled by coupling the rejection wavelength of the CCA with the emission of the scintillator.

III-Nitride Photonic Crystal Membrane Cavity with Substrate Isolation Ganapathi Subramania[1], Keshab Sapkota[1], Nicholas Karl[1], George Wang[1], Igal Brener[1], Zachary Meinelt[2] and Daniel Feezell[2]; [1]Sandia National Laboratories, United States; [2]The University of New Mexico, United States

On-chip nanophotonics devices such as those possible on Silicon or GaAs for near-infrared frequencies have been challenging to achieve in the visible frequency regime. III-Nitride based materials have excellent material properties for visible frequency nanophotonics such as broad gain regime (e.g., for lasing) and large refractive index for waveguiding visible light. Surface emitting lasers have been demonstrated from photonic crystal (PhC) nanowire arrays [1,2]. Nevertheless, fabricating devices such as cavities, modulators and lasers that can be integrated for on-chip photonics requires light transport to be confined to a submicron sized active layer. This can be done with a low refractive index optical cladding layer separating the active layer from the high refractive index substrate layer. This is achieved in a relatively straightforward manner in Si by using low index SiO_2 buffer layer (silicon-on-insulator) or in GaAs by oxidizing an AlGaAs buffer layer to a low index $AlGa_xO_{1-x}$ layer. Such options are not available for III-nitrides making on-chip integrated photonics in the visible. One approach that can address this challenge is by creating a nanoporous layer of GaN with a reduced effective index between the active region and the substrate. Nanoporous GaN layer produced by electrochemical etching have been used as a low refractive index layer to fabricate a distributed Bragg reflector (DBR) mirror [3] that can be utilized for VCSELS. We will describe fabrication of membrane type PhC cavities using nanoporous GaN as cladding from the high refractive index substrate. We will describe the effects of the porosity on the PhC cavity quality factor and cavity emission wavelength.
Sandia National Laboratories is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

11:30 AM EQ05.14.05
Lattice Coupled Anapole Excitations in Photocatalytic Semiconductor Nanodisks for Improved Solar Light Harvesting Ludwig Hüttenhofer[1], Andreas Tittl[1], Lucca Kühner[1], Emiliano Cortés[1], Ian Sharp[2] and Stefan A. Maier[1,3]; [1]Nanoinstitut Ludwig-Maximilians-Universität, Germany; [2]Walter-Schottky-Institut Technische Universität, Germany; [3]Imperial College London, United Kingdom

Effcient solar energy conversion requires broadband visible light harvesting which is not provided by most semiconductor photocatalysts. The engineering of Mie-Resonances in nanostructures of these materials offers a route for trapping light and expansion of the absorption throughout the visible spectrum. Anapole excitations and associated absorption engineering in dielectric nanoresonators are therefore the key tool of our research due to the intricate combination of nonradiating modes and strong electromagnetic field confinement in the underlying material. We present our studies on engineered nanoantennas composed of photocatalytic dielectrics and demonstrate increased light-harvesting capabilities in otherwise weakly absorptive spectral regions.

We employ anapole excitations in single nanodisks of oxygen-vacancy-rich TiO_{2-x}, a prominent photocatalyst that provides a powerful platform for exploring concepts in absorption enhancement. The arising photocatalytic effect is monitored on the single particle level using the well-established silver reduction reaction on TiO_2. With the freedom of changing the optical properties of TiO_2 through tuning the abundance of oxygen vacancies, we discuss the interplay between cavity damping and the anapole-assisted field confinement for absorption enhancement.

On the route towards upscaling, collective anapole-anapole interactions are investigated in rectangular arrays of nanodisks of GaP, as a high refractive index of the resonator material emerges as favourable. Our experimental findings show that maximum visible light extinction by the array and maximum absorption in the GaP are not achieved by the densest packing of resonators. Counterintuitively, increasing the array periodicities such that collective effects spectrally overlap with the anapole excitation of a single particle leads to an absorption enhancement of up to 300% compared to a single disk. An analysis of coupling in one- and two-dimensional arrays with polarization-dependent measurements and numerical simulations allows us to discriminate between coupling interactions parallel and perpendicular to the polarization axis and evaluate their strengths.

Based on our findings we fabricate large-scale nanoimprinted photoelectrodes that make use of the investigated photonic effects, allowing for the generation of quantifiable catalytic yields. We share our latest results of wavelength dependent photoelectrochemistry on these electrodes and demonstrate a photocurrent enhancement by a factor of 5.7 compared to a planar film under hydrogen evolution reaction conditions.

Our results provide a fundamental understanding of tailored light absorption in coupled anapole resonators and reveal important design guidelines for advanced metasurface approaches in a wide range of energy conversion applications.

SESSION EQ05.15: Advanced Nanophotonic Design III
Session Chairs: Artur Davoyan and Benjamin Vest

1:30 PM EQ05.15.01
Scalable, Nanometer-Precise Engineering of Light-Matter Interactions with Deterministically Patterned Colloidal Plasmonic Structures Weikun Zhu, Peter Satterthwaite, Patricia Jastrzebska-Perfect and Farnaz Niroui; Massachusetts Institute of Technology, United States

Tailoring light-matter interactions with precise yet scalable fabrication of hybrid structures, only few nanometers in size, is essential to advance nano-optics and plasmonics. Conventional top-down fabrication techniques though lack the resolution necessary to achieve such dimensions. Alternatively, colloidal nanoparticles, with controlled size, shape, composition, and crystallinity, can reach unprecedented resolutions while also enabling unique functionalities. However, their current integration suffers from stochastic processing and assembly into passive structures, lacking the positional accuracy and structural complexity essential for functional devices and systems. In this work, we present a fabrication platform in which bottom-up directed assembly is combined with dry-phase transfer printing to achieve deterministic, large-area, and high-throughput patterning of colloidal metallic nanoparticles onto arbitrary surfaces with single particle resolution. This approach provides a versatile platform for colloidal particle integration into next-generation optoelectronic devices. Utilizing gold nanocubes as an example, we discuss fabrication of scalable nanopatch antenna arrays with deterministic and easily tailorable optical response on-demand. By further integrating these structures with molecular emitters, we present controlled enhancements leveraging precise engineering of light-matter interactions towards realizing functional building blocks for diverse quantum optical technologies.

1:45 PM EQ05.15.02
Microcavity Enhanced Raman Spectroscopy of Fullerene C_{60} Bucky Balls Vinayaka H. Damle, Miri Sinwani, Hagit Aviv and Yaakov Tischler; Bar Ilan University, Israel

Raman spectroscopy is a widely used characterization technique in material science. It is a non-destructive tool with relatively simple instrumentation, and provides intrinsic qualitative information of analytes by probing their vibrational modes. In many cases, Raman enhancement is essential for detecting low-intensity signals in high-noise environments, spectrally unresolved features, and hidden modes. Here we present optical and Raman spectroscopic characterization of fullerene C 60 in a gold microcavity. The fabrication of single-layered gold mirrors is facile, low cost and direct but was proven to give considerably significant enhancement. The findings of this work demonstrate the cavity resonance as a powerful tool in obtaining tunability over individual peak for selective enhancement in the tuned spectral range. The PL of the material within the cavity has demonstrated a red shift assumed to be caused by the low-energy transitions. These transitions are induced by virtual low-energy states generated by the cavity. We further observe that adopting this principle enables resolution of active Raman modes that until now were unobserved. Finally, we assigned the new experimentally observed modes to the corresponding motions calculated by DFT.

2:00 PM EQ05.15.03
Low Energy Band Gap Opening in Polymer-Wrapped/Metallic Single-Walled Carbon Nanotube Hybrid Assemblies via Symmetry Breaking Francesco Mastrocinque, George Bullard, Nicholas X. Williams, Aaron D. Franklin and Michael Therien; Duke University, United States

There is an incontrovertible need for low dimension materials that can provide reliable, high performance microelectronics. Single-walled carbon nanotubes (SWNTs) are one-dimensional materials that are ideal for microelectronic applications due in part to their unique optical and electronic attributes. SWNTs possess superior charge carrier mobilities when compared to conventional microelectronic materials such as Si and GaAs, and their π-conduction pathways are impervious to electromigration which is an increasing source of failure as device size decreases. Nanotube based technologies are hindered by the current standards of production, which yield heterogeneous distributions of SWNT diameters or chiralities. These irregular compositions of electronic structures often preclude their inclusion in practical applications such as field-effect transistors (FETs) or optical sensors. To isolate

homogeneous SWNT samples with unique electronic structure, the aqueous two-phase (ATP) separation method gives access to electronically sorted SWNT chiralities that were previously inaccessible. We have adapted and optimized the ATP purification method to isolate a highly enriched (11,11) metallic SWNTs (m-SWNTs). Additionally, we have developed novel compositions of matter that have unique electronic and structural characteristics: SWNTs that are helically wrapped in a single chain fashion by chiral semiconducting polymers. These assemblies provide robust organic and aqueous solvent soluble superstructures featuring exceptional electronic and morphological homogeneity.
Disruption of the highly symmetric electronic structure of (11,11) m-SWNTs through polymer wrapping shifts the allowed wave vectors away from the K and K' Dirac points in reciprocal space, resulting in a metallic to semiconducting phase transition in these m-SWNT assemblies. We have recently demonstrated metal to semiconductor phase transitions in polymer-wrapped m-SWNTs through a number of optical and potentiometric methods in both aqueous solution and the solid state. Results indicate that symmetry breaking of the SWNT electronic structure is accomplished through chiral single-chain helical polymer wrapping at a fixed pitch length that give rise to newly allowed low energy electronic transitions. These noncovalently wrapped polymer/m-SWNT hybrid assemblies do not introduce chemical defects and therefore are practical for applications leveraging electronically homogeneous nanotubes that require high reproducibility, or for devices where band gap magnitudes are tuned on the fly through modulation of electrical or optical fields. These new low energy band gap polymer/m-SWNT compositions provide a new means to manipulate optical and electro-optical function in hybrid nanoscale assemblies.

All-Dielectric Photonic Gap Antennas for Extreme Confinement of Light Ashutosh Patri[1], Kevin G. Cognee[2] and Stephane Kena-Cohen[1]; [1]Polytechnique Montreal, Canada; [2]The City College of New York, United States

The use of optical antennas has been the subject of an increasing number of scientific studies as they can improve the efficiency of a wide range of near-field optical technologies, including light transmission and reception, spectroscopy, sensing, and imaging. Antennas are designed primarily to facilitate efficient energy transfer between a localized source and free space while serving as impedance matching elements. In this regard, most previous studies have focused on antennas made of metals since their surface plasmon polaritons can effectively confine light within deep subwavelength boundaries to enhance the coupling between the source and the antenna. However, plasmonic antennas suffer from ohmic losses, which can lead to considerable heat generation, resulting in melting or irreversible structural alteration of the antenna and thermochemical destruction of the nearby matter. An alternative way to mitigate ohmic losses is to make antennas from dielectrics instead of metals. Indeed, all-dielectric antennas have several advantages over plasmonic antennas, including excellent photostability, low heating, and high radiative quantum efficiency. Unfortunately, the relatively weak spatial confinement offered by the volumetric modes in conventional dielectric antennas makes it difficult to achieve efficient coupling between the source and the antenna itself.

We present here an all-dielectric multilayer antenna configuration that supports strongly confined modes while maintaining unity antenna quantum efficiency. Our antenna design consists of a high-index pillar structure with a transverse gap filled with low-index material. The index contrast between the gap material and the pillar material allows for strong localization of the field within the gap. We provide a detailed explanation of the operation principle of such Photonic Gap Antennas (PGAs) based on Fabry-Perot-like resonances of horizontal slot-waveguides with symmetrically and asymmetrically placed gap layer. We calculate the mode volumes of the PGA based on quasinormal mode theory and obtain mode volumes in the range of $10^{-4}\ \lambda_0^3$ that are on par with plasmonic antennas. We demonstrate that, when acting as a transmitter, the PGA can improve the spontaneous emission rate of a point dipole by ~1300 times that of its emission rate in free space. Reciprocally, when acting as a receiver, the PGA can lead to a near-field intensity enhancement by a factor of ~3000 with comparison to the intensity of the incident plane wave. Moreover, we show that the PGA can operate over a broad spectral bandwidth ($\Delta\lambda \approx 300$ nm at $\lambda = 1.25$ μm), while providing unidirectional out-of-plane radiation.

Bottom-Up Synthesis of Hybrid Dielectric/Metal Nanowires for Low-Loss Plasmonics Corban G. Murphey and James Cahoon; University of North Carolina at Chapel Hill, United States

Confining and guiding light on a deep sub-wavelength scale is a key goal in nanophotonics. Plasmonic materials are used in this respect, but are often limited by large Ohmic absorption losses, resulting in undesirable heating effects and short propagation distances in waveguides. Dielectric materials, on the other hand, have substantially lower losses than metals, but do not confine light on the same sub-wavelength scale. However, by combining these two classes of materials into a single nanostructure, it should be possible to achieve simultaneous low-loss and deep sub-wavelength modes by confining plasmonic resonances in a low-loss dielectric. Here, we show that a simple geometry – a silicon (Si) nanowire (NW) with a uniform gold (Au) shell – can confine NIR light in a NW just 210 nm in diameter. Furthermore, the hybrid dielectric environment produces two unique effects: the high-index Si core allows for the Au plasmon resonances to exist in a much smaller structure and at a substantially lower energy than they would normally occur, and the Si core's Mie resonances blueshift and adopt a Fano lineshape due to coupling with the plasmons. Core diameter and shell thickness are easily tunable and can dramatically shift the positions of the hybrid plasmonic resonances. We combine bottom-up vapor-liquid-solid SiNW growth with metal sputtering to synthesize a vertically aligned, hybrid Si/Au NW - a structure that is not accessible by more conventional lithographic or solution-phase techniques. To measure optical properties, we employ a custom-built supercontinuum laser microscope for single-NW extinction measurements. The tunability of the materials and optical properties of this structure make it an exciting candidate for a range of photonic applications, from sensing to optical computing.

Circularly Polarized Light-Assisted Chiral Superstructure Assemblies on Substrate Ji-Young Kim, Connor McGlothin, Minjeong Cha, Emine S. Turali-Emre and Nicholas Kotov; University of Michigan, United States

Self-assembly of geometrically complex structures has been accomplished in dispersions but not on the surfaces, which is needed for further studies and applications of their intriguing electromagnetic/optical properties. Their successful assembly can be accomplished using intrinsic chirality of the nanostructure and/or exerting local chiral bias. That could be translated to a variety of technologies, from medicinal chemistry to advanced manufacturing. Here, we show that the strong optical activity of plasmonic materials under circularly polarized light (CPL) affords photon-to-matter chirality transfer, fabricating centimeter-scale chiral 3D superstructures. Illuminating CPL on substrate immersed in silver salt solutions induces the formation of nanoparticles (NPs) with 15–20 nm in diameter and subsequent asymmetric deposition/assembly to construct chiral superstructures on the substrate. Circular dichroism (CD) spectra vividly showed opposite polarity after exposure to photons with left- and right circular polarization. The wavelength of the light source determined the size of the final superstructure as well as their surface plasmonic resonance (SPR) and CD band wavelength. Electron microscopy images for its intermediate growth stages showed vivid handedness of the rotational assemblies of NPs. The experimental evolution of CD peaks in different growth stages correlated well with those calculated for assembled nanostructure models with complex geometry, as established by the prediction of deposition/assembly pattern by electromagnetic simulations. The chiral patterns were fabricated on polydimethylsiloxane (PMMA) stamp by CPL exposure time to demonstrate the simplicity and universality of these photosynthetic routes to direct construction of metallic 3D chiral metamaterials

on arbitrary substrates with controlled chirality. These simple and versatile architected metamaterials can be used for extensive applications, including but not limited to photonic, optoelectronic, and electromechanical devices as well as enantioselective catalytic and sensing systems.

Solving Integral Equations in Free-Space with Inverse-Designed Ultrathin Optical Metagratings Andrea Cordaro[1,2], Brian Edwards[3], Vahid Nikkhah[3], Andrea Alu[4], Nader Engheta[3] and Albert Polman[1,2]; [1]AMOLF, Netherlands; [2]University of Amsterdam, Netherlands; [3]University of Pennsylvania, United States; [4]City University of New York, United States

The physical speed and power consumption of conventional microelectronics processors are reaching their limits, and consequently, novel paradigms and approaches for computing and information processing are desired. One such approach, which has gained significant renewed interest recently, is analog optical computing capable of processing large amounts of data with high speed and low energy consumption. Moreover, the tremendous recent advances in the field of metamaterials and metasurfaces have yielded the possibility of shaping optical fields in extreme ways over subwavelength thicknesses. This, in turn, has unlocked new opportunities for all-optical computing strategies and opened entirely new avenues in the field of analog signal processing and computing with waves.
Here, we demonstrate, theoretically and experimentally, a Si-metagrating-based optical platform that combines a tailored scattering matrix design and a feedback system to enable the solution of Fredholm integral equations of the second kind from the far-field
$g(u)=I_{in}(u)+\int_a^b K(u,v)\,g(v)dv$, (1)
where g(u) is the unknown solution of the integral equation, K(u,v) is a function of two variables that acts as the kernel of the integral operator, and $I_{in}(u)$ is an arbitrary input function. This problem can be discretized by sampling the variables u and v over N points in the interval [a,b] to form two vectors, $\underline{u}$ and $\underline{v}$, and recast into a matrix equation

$\underline{g}=\underline{I_{in}}+K\,\underline{g}$ (2)

where $\underline{g}=g(\underline{u})$, $\underline{I_{in}}=I_{in}(\underline{u})$ and $K=K(\underline{u},\underline{v})*(a-b)/N$ where u and v are evaluated as N discrete points. The solution $\underline{g}$ can be thought of as the result of the Neumann series $\underline{g}=\sum_n (K)^{\wedge}n\ \underline{I_{in}}=(I_N-K)^{\wedge}(-1)\ \underline{I_{in}}$ where I_N is the NxN identity matrix. Next, it is possible to think of the N mathematical sampling points as N discrete physical modes, and thus $\underline{g}$ is a vector representing the complex amplitude of these modes on a given plane with a chosen direction. The integral operator can then be represented by a scattering matrix that performs matrix-vector multiplication between these sets of modes and can be mapped onto the reflective part of the scattering matrix of a Si metagrating. Finally, a semi-transparent mirror feeds the signal back into the system mimicking an analog Neumann series.
By means of the adjoint method, it is possible to inverse-design the unit cell of the Si metagrating (not including the mirror) in order to achieve a prescribed S-matrix. The unit cell is embedded in a SiO_2 superstrate. The design wavelength is λ=706 nm while the unit cell is 825 nm wide and 400 nm deep. Next, we include a semitransparent mirror, and hence the feedback system, in the simulation and check how that results in the inversion of the designed S-matrix. From the transmission block of the S-matrix of the entire stack (metagrating, SiO_2 spacer, and semitransparent mirror) it possible to read out the analog solution provided by the structure. At the conference, we will present the comparison between the metasurface-based analog solution and the ideal solution demonstrating good agreement for all the inputs, both in terms of the real and imaginary parts.
To demonstrate these concepts experimentally, the metasurface was fabricated with e-beam lithography on Si-on-sapphire substrate. Next, the sample was planarized with a layer of SiO_2 solgel and an extra layer of sputtered SiO_2. Finally, 15 nm of Au were evaporated on the sample using an organic adhesion monolayer. At each step, the transmission spectrum of the sample was measured and shows a good match with the simulated spectrum. At the conference, we will show the agreement between optical measurements and simulations for the ideal structure that solves the integral equation.
Finally, future applications of these concepts could include TMDCs two-dimensional materials to explore to dynamically tune the encoded mathematical operation, paving the way for all-optical reconfigurable computing circuitry solving problems of further enhanced complexity.

Directing Quantum Dot Emission with Resonant Mie-like Nanocylinders for Luminescent Solar Concentrators Tom Veeken, Kyra Orbons and Albert Polman; AMOLF, Netherlands

Building-integrated photovoltaics (BIPV) has received much attention recently to minimize the use of land for PV systems, decrease the overall system and installation costs due to its multifunctional use, and make PV systems more aesthetically appealing. The luminescent solar concentrator (LSC) is such a building-integrated photovoltaic device, consisting of a glass or plastic waveguide with embedded luminophores and integrated solar cells along the edges or in a matrix. Therefore, the LSC can directly be used as a (vertical) facade or roof and offers more aesthetic options due to its semi-transparent and/or colored surface.
Even though the LSC concentrates sunlight in the waveguide and guides it to solar cells smaller than the top surface area, it cannot surpass the detailed balance limit for a single-junction solar cell. In short, the LSC remains at 1-sun illumination intensity, and the potential V_{OC} increase due to increased J_{SC} (concentration factor) is offset by the coincident increase in the J_0. Thus, the power conversion efficiency (PCE) of the LSC is limited to the typical 34%, while the world record remains at 7.1%, indicating both the poor performance of LSCs so far, but also the significant potential gain. One of the main loss mechanisms in an LSC is the emission of photons through the escape-cone, accounting for about 25% of all lost photons. This is a direct consequence of isotropic luminophore emission and the escape-cone angle of a glass/plastic waveguide in air.
In this work, we use anisotropic luminophore emission to decrease the escape-cone losses in an LSC. We do so by embedding CdSe-CdZnS core-shell nanoplatelets, the luminophores, into high-index TiO2 nanocylinders that exhibit Mie-like resonances. An array of TiO2 cylinders is then incorporated into the waveguide. The shape and size of the cylinders are optimized such that sunlight with energy higher than the luminophore bandgap is resonantly absorbed in the out-of-plane direction, while the Stokes-shifted luminophore emission is resonantly directed in-plane. We use FDTD simulations to find the optimal nanostructure and identify the Mie-like modes that are excited by the incoming sunlight and couple to the luminophore emission. The simulations predict that the escape cone losses are reduced from 25% to 12%.
Arrays of TiO2 nanocylinders were fabricated on top of a glass substrate. First, a multilayer stack of TiO2, CdSe-CdZnS core-shell nanoplatelets, and TiO2 was created. Using e-beam lithography and subsequent lift-off, we created a chromium hard-mask for reactive ion etching of the multilayer. After removal of the chromium, we obtained an array of TiO2 cylinders with 450 nm diameter, 120 nm height, and 1800 nm pitch, with an embedded nanoplatelet layer of 30 nm thick. SEM images and spatially resolved photoluminescence measurements show that the luminophores are only located inside the cylinders as designed.
To demonstrate the directional emission, we measure the luminophore emission in a Fourier-microscopy setup. To emulate the incorporation of the cylinder array inside the waveguide, we used an immersion-oil objective, which also enables the collection of luminophore emission under grazing angles. Besides the use in LSCs, directional luminophore emission has potential applications in LEDs and up- and down-conversion for photovoltaics.

4:15 PM EQ05.15.12

Near-Field Light Concentration with Silicon Light Funnel Arrays Ashish Prajapati and Gil Shalev; Ben Gurion University of the Negev, Israel

Silicon light funnels are three-dimensional subwavelength structures in the shape of inverted cones with respect to the incoming illumination. Light funnel (LF) arrays can serve as efficient absorbing layers on account of their light trapping capabilities, which are associated with the presence of high density complex Mie modes. Specifically, light funnel arrays exhibit broadband absorption enhancement of the solar spectrum. In the current study, we numerically explore the optical coupling between surface light funnel arrays and the underlying substrates. We show that the absorption in the LF array-substrate complex is higher than the absorption in LF arrays of the same height (~10% increase). This, we suggest, implies that a LF array serves as an efficient surface element that imparts additional momentum components to the impinging illumination, and hence optically excites the substrate by near-field light concentration, excitation of traveling guided modes in the substrate, and mode hybridization.

Recent Advances in Mie-Resonant Metaphotonics Yuri Kivshar; Australian National University, Australia

Future photonic technologies underpinning high-performance communications, ultrafast computations and compact biosensing will rely on densely packed reconfigurable optical circuitry based on nanophotonics. For many years, plasmonics was considered as the only available platform for subwavelength optics, but the recently emerged field of Mie-resonant metaphotonics provides more practical alternatives for nanoscale optics by employing resonances in high-index dielectric nanoparticles and their structures such as metasurfaces. This talk aims to discuss recent advances and future emerging directions in the physics of dielectric Mie-resonant nanostructures with high quality factors (Q factors) for efficient spatial and temporal control of light by employing multipolar Mie resonances and bound states in the continuum (BIC), with applications of these concepts to nonlinear optics, active photonics, and topological lasers.

In particular, we discuss the physics of photonic BICs and their applications to metadevices, including enhancement of nonlinear response, light-matter interaction, and development of active nanophotonic devices. We discuss how BIC-empowered dielectric metastructures can be used to generate efficiently high-order optical harmonics from bulk and to boost the intrinsic nonlinearity of transition metal dichalcogenide (TMDC) flakes. We explore TMDC resonators composed of structured dielectric arrays and individual nanoparticles for strong light-matter coupling phenomena. We discuss the extension of metasurface functionalities for biosensing applications in biomarker detection and quantum information processing with entangled photons. Finally, we demonstrate how tunability of BICs in the momentum space can be used to realize a novel type of efficient lasing based on a finite-size cavity with a small footprint.

In addition, we introduce a novel platform for plasmonic metasurfaces empowered by optical BICs, for engineering high-Q optical resonances. Our plasmonic metasurfaces are composed of arrays of vertically oriented pillar meta-molecules covered by a thin layer of gold. We suggest and realize experimentally anisotropic plasmonic metasurfaces supporting high-Q resonances governed by quasi-BIC collective resonant modes. With this platform, we demonstrate several other effects including novel plasmonic metasurfaces for full Stokes polarization perfect absorption in the mid-infrared. In this latter case, the metasurface unit cell consists of coupled anisotropic meta-atoms forming a diatomic metamolecule. The designed plasmonic metastructures provide a strong field enhancement by at least one order of magnitude higher than conventional perfect absorbers.

8:30 AM EQ05.16.02
Experimental Demonstration of Magnetic Purcell Enhancement by Magnetic Resonance of Silicon Nanospheres Hiroshi Sugimoto and Minoru Fujii; Kobe University, Japan

Optical nanoantennas play a central role for enhanced light-matter interactions in modern nanophotonics. Integration of a quantum emitter into a nanoantenna that is capable of increasing local density of optical states (LDOS) results in the enhanced spontaneous emission rate through the Purcell effect. In the past decade, the main focus of the Purcell enhancement has been placed on the manipulation of an electric dipole transition, and less attention has been paid to that of the magnetic dipole and higher order optical transitions. Dielectric nanoantennas have been suggested for manipulating spontaneous emission of a magnetic dipole through the magnetic Purcell effect. However, the experimentally observed enhancement of magnetic dipole emission has been marginal and much smaller than the theoretical prediction. In this work,[1] we develop a composite system, that is, a Si nanosphere decorated with Eu^{3+} complexes, in which magnetic dipole emission of Eu^{3+} is efficiently coupled to the magnetic Mie modes of the nanosphere. By means of single particle spectroscopy, we systematically investigate the light scattering and photoluminescence spectra of the coupled system with diameters of Si nanospheres from 130 to 245 nm. We demonstrate that by tuning the magnetic quadrupole Mie resonance to the $^5D_0$-$^7F_1$ magnetic dipole transition of Eu^{3+}, the branching ratio between the magnetic and electric dipole transitions is enhanced up to 7 times. We also show the magnetic Purcell enhancement in an ensemble of Si nanospheres with size distribution. The observed magnetic Purcell enhancement driven by colloidal Mie resonators offers an opportunity not only to develop novel fluorophores with enhanced magnetic dipole emission, but also to control the excited state of the matter in photochemistry.

Modeling Multi-Level Phase Change Photonics Devices Yunzheng Wang[1], Jing Ning[1], Bosman Michel[2] and Robert Simpson[1]; [1]Singapore University of Technology and Design, Singapore; [2]National University of Singapore, Singapore

Chalcogenide phase change materials (PCMs) have shown many exciting and interesting characteristics, such as non-volatile structure transition, up to trillions of reversible cycles[1], high stability, and large optical and electric differences between their two distinct structure phases. These make them not only been used in existing electric storage[2], but also a potential candidate for reprogrammable photonics devices, micro-electromechanical systems, and tunable radio frequency devices.
An accurate model to describe the PCM switching behavior is necessary for designing programmable photonic devices. The optical properties of PCMs are determined by their crystal microstructures and phase transitions which depend on the heating and quenching conditions. To understand the evolution of a PCM photonics device's optical response during switching, and the conditions that can lead to multi-level optical devices, it is important to know not only the initial and final states, but also how the optical constants evolve during nucleation, crystal growth, and melt-quenching. Therefore, a model that

accurately predicts the optical properties during and after phase transition will be a key enabler of successful photonic device designs, and in particular, phase change multi-level devices.
The existing models, such as the JMAK method and density functional theory, can not satisfy the need of modeling a PCM device in accuracy, cost, time consumption and device size. However, semi-empirical methods can have a good compromise between accuracy, scaling, and performance. Recently, Meyer et al developed a multiphysics model based on phase field method to describe the optical properties of a phase change metasurface perfect absorber but no experiments was conducted to verify the multiphysics model[3].
Herein, we developed an accurate multiphysics framework based on the Gillespie cellular automata (GCA) method to quantitively simulate the evolution of PCM crystal microstructures and optical response of PCM photonics devices. The multiphysics framework self-consistently combines the nanosecond non-isothermal laser heating, non-linear and probabilistic GCA, effective medium theory and the Fresnel Equations together. To prove the accuracy, the framework was applied to a programmable thin-film optical stack, and laser switching experiments and transmission electron microscopy were performed. Comparison between simulation and experimental results shows that the model can accurately predict not only the final optical state, the crystallographic microstructure evolution and the transient optical response, but also multilevel optical reflectivity and transmissivity which corresponds to partial crystallization of the PCM film. Therefore, we foresee the model will be widely applied to optimizing the interconnection weights in all-optical neural network schemes, controllable metamaterial phase arrays, and displays. For this reason, the code is publicly available at the GitHub website[4], and we encourage others to use it.

Plasmon-Induced Electric Effects in Various Materials—Theory and Experiment David Keene[1], Paula Fortuna[1], Maxim Durach[2] and Natalia Noginova[1]; [1]Norfolk State University, United States; [2]Georgia Southern University, United States

Significant photoinduced electric effects observed in nanostructured metal systems are clearly associated with plasmonic excitations. In order to better understand the origin and be able to predict the effect in various materials and geometries, we perform theoretical calculations for the effective "plasmonic pressure" and "plasmonic striction" ("gradient") forces based on the electro-magnetic hydrodynamic momentum loss approach (EHML) in various plasmonic materials, including gold, silver, aluminum and TiN. We show that the wavelength dependence for the pressure force is expected to be weak for most of the optical and near infra-red range with a rapid increase toward the short wavelengths. The opposite (a decrease with decreasing wavelength) is predicted for the striction force. A direct comparison of experimental data to the theoretical calculations offers new insight into the nature of the plasmon drag effect and promises a conclusive answer to which of the proposed forces has a larger impact on the magnitude of the plasmon drag effect. It is the hope of the authors that this more complete understanding of the phenomenon will contribute to the design on devices that will more efficiently utilize the plasmon drag effect for a myriad of applications from environmental sensors to opto-electric interfaces.

9:15 AM EQ05.16.05
Modification of Plasmonic Responses of Doped Semiconductor Nanoparticles by Electron Beam Irradiation Kevin Roccapriore[1], Andrew R. Lupini[1], Shin-Hum Cho[2], Delia Milliron[3] and Sergei V. Kalinin[1]; [1]Oak Ridge National Laboratory, United States; [2]Samsung Semiconductor R&D, Korea (the Republic of); [3]The University of Texas at Austin, United States

Nanoparticles can exhibit exotic physics, display quantum phenomena, and offer opportunities in multiple disciplines and applications. Plasmonics is one field in which nanoparticles has made a large impact, for example in biosensing, the pharmaceutical industry, and quantum optics. Particles are typically chemically synthesized and can be tailored to meet specific plasmon resonance requirements based on the chemical recipe. Resonances of nanoparticles can extend from the near infrared (NIR) to the ultraviolet (UV) spectral regions and can even be spectrally tunable based on the level of incorporated dopants [1]. However, once synthesized, the plasmon response cannot be dynamically modified. Here we report use of the electron beam in a scanning transmission electron microscope (STEM) to modify plasmon resonances of doped semiconductor nanocrystals in both space and energy.
Using the framework of a self-assembled system of nanoparticles, we direct the electron beam at higher-than-normal operating currents in order to intentionally modify individual nanoparticles. Previous work related to the use of an electron beam for modification of structures has shown precise cutting and welding of metallic an silicon nanowires [2], positioning of atoms and dopants within two dimensional materials [3], and sculpting 1D nanowires in 2D materials [4], however, here we focus on the application to nanoparticle plasmonics, and attempt to understand the mechanisms responsible for modification.
We demonstrate that near atomic-resolution sculpting of nanoparticles is possible by selectively removing atomic columns with a converged electron beam in nanoparticles whose thicknesses range from 10-15 nm. Entire particles can also be removed from the array, allowing for plasmonic hotspots to effectively be patterned by the electron beam. The modification to the plasmonic response occurs in both space and energy domains and we explore these modifications on-the-fly with electron energy loss spectroscopy (EELS). Not surprisingly, the altered geometry supports additional localized plasmons, e.g., creation of a hole within a nanoparticle allows for existence of edge plasmons on the edge of the hole. We also observe spectral shifting of plasmon resonances upon electron irradiation in different conditions, and attribute this to element-specific removal of atoms from core-loss EELS measurements. The ability to adjust the particle response on the fly significantly increases the design possibilities for nanostructure development and is key for nanophotonic design.

Electric and Magnetic Dipole Emission of Dense and Diluted Emitter Arrangements in Plasmonic Structures John N. Munga[1], MD Afzalur Rab[1], Maxim Durach[2] and Natalia Noginova[1]; [1]Norfolk State University, United States; [2]Georgia Southern University, United States

Control and enhancement of spontaneous emission of magnetic and electric dipole transitions can be achieved by use of plasmonic structures. In our work,

we study modification in the emission spectra, polarization and radiation patterns of Eu^{3+} ions in very close vicinity of plasmonic films, gratings and cavities. We compare effects observed in dense and diluted arrangements of emitters, and show that on the contrary to theoretical predictions, reduced quenching is observed in monolayers of closely packed EuTTA molecules. Significant enhancement of p-polarized emission is observed at certain angles in gratings for both dense and dilute Eu systems, which is ascribed to decoupling of surface plasmon polaritons excited by the emitters with a different efficiency for electric and magnetic emitters. Effects are considered theoretically based on the Green's function approach. The effects of roughness of metal and mutual emitter coherence of emitters are discussed.

9:45 AM EQ05.16.07
Plasmonic Electrodes with Nanoantenna Lattice Resonances Dominic Bosomtwi[1], Marek Osinski[1] and Viktoriia Babicheva[2]; [1]The University of New Mexico, United States; [2]University of New Mexico, United States

We report on the design of plasmonic nanostructures that enhance the hot-electron generation and can be used as nanoelectrodes. The advantage of the nanostructure is brought about by the periodic arrangement of nanoantennas and the excitation of collective resonances [1,2]. These collective multipole resonances result in a significant field enhancement in the proximity to nanoantenna and, therefore, a more efficient generation of hot electrons. We analyze the case when hot electrons are injected into the aqueous environment and the nanoantennas have a high aspect ratio supporting multipole resonances along the antenna. We show that by selecting structure dimensions and periodic arrangement comparable to the wavelength of Rayleigh anomalies, one can achieve a significant enhancement in the localized electromagnetic field and enhanced hot-electron generation.

Driving Energetically Unfavorable Hydrogenation Dynamics with Plasmonics—From the Single Particle to the Reactor Scale Jennifer A. Dionne, Katherine Sytwu, Daniel Angell, Briley Bourgeois and Dayne Swearer; Stanford University, United States

Nanoparticle phase transformations and their transient states underlie many technologies in energy storage, memory, and catalysis. However, modifying these intermediate states requires bridging the length-scale gap between the atomic-scale structural features (such as atomic coordination number and surface strain) that influence dynamics and the macroscale extrinsic parameters (e.g. temperature, chemical environment) that can be controlled. Optical excitation of localized surface plasmon resonances (LSPRs) offers a solution for overcoming this size mismatch. Here, we use in situ environmental transmission electron microscopy coupled with optical illumination to demonstrate how LSPRs enable spatially-modified phase transformation dynamics in nanoparticles. As a model reaction, we study the gas-phase photocatalytic dehydrogenation of a variety of Au-Pd systems, including Au-Pd crossed-bar systems, and AgPd bimetallic nanoparticles, where [Ag,Au] acts as a plasmonic light absorber and Pd serves as the catalyst. Under controlled hydrogen pressures, temperatures, and illumination conditions, we study the study the kinetics of the hydrogen absorption and desorption reactions triggered by the optical excitation of plasmons. We find that plasmons control photochemistry in four ways. First, plasmons modify the rate of distinct reaction steps differently, increasing the overall rate more than ten-fold. Secondly, plasmons open new reaction pathways that are not observed without illumination. Third, reaction nucleation occurs at electromagnetic hot-spots – even when those hot-spots do not occur in the preferred nucleation site. Finally, through atomic-resolution imaging, we show how plasmons modify sub-surface hydrogen within the first few atomic layers of the nanoparticle. We link our single particle results to reactor-scale nanoparticle performance in reactive hydrogen environments, showing how catalyst sub-surface hydrogenation impacts not only product yield but also product-selectivity.

Plasmonic Nanoparticle Supercrystals Niclas S. Mueller[1], Florian Schulz[2], Emanuel Pfitzner[1], Bruno Vieira[3], Yu Okamura[1], Sabrina Juergensen[1], Georgy Gordeev[1], Patryk Kusch[1], Joachim Heberle[1], Eduardo B. Barros[3], Holger Lange[2] and Stephanie Reich[1]; [1]Freie Universitaet Berlin, Germany; [2]Universitaet Hamburg, Germany; [3]Universidade Federal do Ceara, Brazil

Most materials interact weakly with light, which is why we treat light as an external perturbation. There has been growing interest in systems where light-matter interaction is much stronger so that it becomes comparable to other characteristic energies of the system. In the regime of ultrastrong and deep strong coupling the coupling energy approaches the bare excitation energy of a material. This regime leads to exotic effects like the population of the ground state with virtual photons, phase transitions, and a breakdown of the Purcell effect. Here we discuss how extreme light-matter coupling is systematically achieved in materials. We introduce densely packed supercrystals of gold nanoparticles that have coupling energies corresponding to the visible spectral range.[1,2] We present measurements of their plasmon-polaritons, confirm the breakdown of the Purcell effect as an example of the effects predicted for deep strong coupling, and show how to use such materials as enhancing agents in surface-enhanced vibrational spectroscopy.[1-4] We discuss a universal model to treat light-matter coupling in systems of different dimension and the strongest light-matter coupling we can reasonably expect to achieve in materials.

Late News: Optical Measurement of the Limits of Pseudoelasticity in Gold Nanocrystals K. Anika Harkins, Jonas Boettner and Lindsey Hanson; Trinity College, United States

Pseudoelasticity in metal nanocrystals allows for shape recovery from strains much larger than their bulk counterparts. This fascinating property could be used to engineer self-healing or reconfigurable materials, but to take full advantage of its possibilities a deeper understanding of its mechanism and limitations is needed. For instance, it is unknown whether room-temperature pseudoelasticity can occur in all metal nanocrystals without the introduction of plastic damage. Here we report the use of non-hydrostatic compression of gold nanocrystals in a diamond anvil cell to a range of maximum pressures, up to 11.4 GPa. Optical absorbance spectroscopy of the localized surface plasmon resonance is used to non-invasively monitor changes in particle shape and crystallinity, as indicated by the plasmon resonance peak position and intensity, respectively. We find that while complete shape recovery occurs following compression to all pressures tested, irreversible crystalline defects are only introduced above a threshold of approximately 2.5 GPa. In this way, we establish the capacity of gold nanocrystals to undergo complete pseudoelastic shape recovery following compression under moderate loads, as well as the onset of limited pseudoelastic behavior at higher loads. This work lays a foundation for future all-optical investigations of the limits of pseudoelastic deformation in a wide variety of metal nanocrystals.

Late News: X-Ray Investigations into the Role of Reduction Kinetics in the Atomic Distributions of Bimetallic Alloy Nanocrystals Hannah M. Johnson, Acacia M. Dasher and Liane M. Moreau; Washington State University, United States

The favorable optical and catalytic properties of bimetallic noble metal nanocrystals have been directly attributed to the atomic-scale arrangement of metal atoms. In AgAu nanocrystals, for example, CO oxidation efficacy has been directly attributed to the presence of Ag-Au bonds. Despite the mechanistic hypotheses that atomic scale structure affects observed phenomena, atomic distributions within bimetallic nanocrystals are rarely investigated in tandem with synthetic advances, and often alloy structure is assumed to be homogeneous based on species miscibility alone. While thermodynamic models have suggested that Ag/Au phase segregation is favored under certain nanoscale conditions, the effects of kinetics on atomic distributions within nanoparticle alloys have not been systematically explored. Based on differences in redox behavior between noble metal species, we hypothesize that altering parameters that affect atomic reduction within bimetallic systems will lead to differences in atomic incorporation and distribution within bimetallic nanocrystals.

Herein, a systematic investigation of the effects of reduction parameters on AgAu alloy atomic-scale distributions will be discussed. In particular, the Ag:Au solution ratio, concentration of reducing agent to metal atoms and volume of reductant added have been varied, and the resulting morphology, composition and atomic coordination environments mapped accordingly using X-ray focused approaches. Electron microscopy and small angle X-ray scattering trace differences in particle morphology, X-ray fluorescence determines composition, UV-vis spectroscopy shows changes in the position of the local surface plasmon resonance peak and X-ray absorption spectroscopy reveals differences in atomic coordination environment. Together, these techniques reveal that indeed the parameters that affect reduction kinetics can alter alloy distributions within nanoparticles, even when nanoparticle composition remains constant. Other notable results include trends in Ag underincorporation and the proposal of synthetic methodology that can be employed to encourage the formation of homogeneous alloys. Results have substantial impact on the use of bimetallic noble metal nanoparticles for plasmonic sensors and as substrates for heterogeneous catalysis.

Plasmon Enhanced Photodetection in NbN Superconducting Photodetectors Jingwei Yang[1,2], Tzu-Yu Peng[1,2], Jia-Wern Chen[2], Hao-Chen Yeh[1], Chi-Te Liang[1,1] and Yu-Jung Lu[1,1,2]; [1]National Taiwan University, Taiwan; [2]Academia Sinica, Taiwan

The growth of highly metallic transition metal nitride films has received considerable attention using methods such as RF sputtering, atomic layer deposition, pulsed laser deposition, and molecular-beam epitaxy. Especially, niobium nitride (NbN) is known for its superconducting properties with relatively high superconducting T_c which is crucial for superconducting nanowire single-photon detectors. However, the wavelength sensitive detection with high detectivity remains unexplored. In this work, we demonstrate a plasmon enhanced photodetection in NbN superconducting photodetectors. We deposited niobium nitride (NbN) thin film by radio-frequency (RF) magnetron sputtering on MgO (100) substrate at 800 °C with high crystalline quality. Since the superconductivity of the NbN film can be varied with the argon/nitrogen flow rate, target, RF power, growth temperature, and growth substrate during sputtering. Thus, we optimize the metallicity and superconductivity (with T_c ~16 K) of NbN films by adjusting the argon/nitrogen flow rate. To increase the photodetectivity, we design an Ag nanocube nanoresonator with a strong gap-plasmon resonance in the visible range to further enhance the photoresponsivity by engineering the optical response for the superconducting devices. This is due to the superconducting states are broken down by a localizing strong electromagnetic field. To design the plasmonic nanostructures, we calculated the electromagnetic field distribution of Ag nanocube/Al_2O_3/NbN structure by finite-difference time-domain (FDTD). We observed a strong plasmonic resonance field which tightly confined in the Al_2O_3 layer between the Ag nanocube and NbN film at a resonant wavelength of 532 nm. We will discuss the detailed working mechanism and the potential application of plasmon-enhanced photodetection in NbN superconducting photodetectors.

How Photonic Metadevices Can Perform Mathematical Operations and Analog Computation with Waves Dimitrios Tzarouchis[1], Mario Junior Mencagli[2], Brian Edwards[1] and Nader Engheta[1]; [1]University of Pennsylvania, United States; [2]University of North Carolina at Charlotte, United States

In this talk, we will present an overview of our ongoing work on exploring the theoretical foundations of networks of photonic structures that can perform mathematical operations and analog computation with waves/signals. These structures may include metadevices such as couplers, which can be waveguide-

based or material-based couplers, and reconfigurable multipliers that provide phase shifting and amplification/attenuation of signals. We will discuss some of the mathematical operations such networks of metadevices can perform, including matrix-vector multiplication, equation solving and matrix inversion and related capabilities. Moreover, we will discuss the possibility of generalized inversion (also known as pseudoinversion or Moore-Penrose inversion) of matrices that can be singular and rectangular, leading to possible applications of such metadevices for gradient descent computation. We will discuss our theoretical findings and their physical insights, and we will also mention possible future research directions and applications.

1:30 PM EQ05.18.02

Electron Beam Spectroscopy of a Plasmonic Vertical Split Ring Resonator Isobel C. Bicket[1,1], Edson P. Bellido[1], Sophie Meuret[2], Toon Coenen[3,4], Albert Polman[3] and Gianluigi Botton[1,5]; [1]McMaster University, Canada; [2]CEMES-CNRS, France; [3]AMOLF, Netherlands; [4]Delmic BV, Netherlands; [5]Canadian Light Source, Canada

A swift electron beam can interact with localized surface plasmon resonance (LSPR) near-fields to excite an LSPR, which may then decay and emit a photon into the far-field [1,2]. The initial excitation process is detected in electron energy loss spectroscopy (EELS); the decay and photon emission is detected using cathodoluminescence (CL). The two techniques together provide a powerful combination for studying both the near- and far-field properties of LSPRs.

We use EELS and CL to study a vertical split ring resonator (VSRR), a popular nanostructure for left-handed metamaterial design and an interesting option for dichroic spectroscopy platforms [3]. The VSRR supports an LSPR mode with an electric and magnetic dipole, both in-plane and relatively strongly excited using light [4]. The ~300 nm long gold VSRRs were fabricated using a double-step electron beam lithography process, then characterized using EELS in a monochromated FEI Titan scanning transmission electron microscope, with an energy resolution of ~60 meV. We acquired polarization-resolved CL spectroscopy data in an FEI XL-30 field emission scanning electron microscope equipped with a parabolic mirror, polarization filters, and IR and visible spectrometers. Using six acquisitions with different polarization filter settings, we derive the full polarization state of the emitted light [5,6] from the VSRR LSPRs. Our experimental data is supported by simulations using the MNPBEM toolbox [7] and custom Python data processing code [8,9]. In EELS we identify the magnetic dipolar mode at a free-space wavelength of approximately 1800 nm, and a series of higher order modes in the visible region of the spectrum [10]. We isolate this dipolar mode in our CL acquisition and derive the emission polarization as a function of electron beam location. The CL signal is strongest when the electron beam is located near the tips of the VSRR, overlapping closely with EELS intensity hotspots for this mode. When the electron beam is located far from either of the symmetry axes in the VSRR, we detect a non-negligible amount of circular polarization in the emission.

At higher energies, there are a series of coupled electric dipoles on the rims of the VSRR pillars. These coupled dipoles form bonding and anti-bonding longitudinal and transverse pairs, with corresponding different linear polarization states. Although these modes are heavily intermixed in a small spectral region, they respond to different polarization states and will produce different near-field distributions under photonic excitation, as we determined from the spatially unique EELS and CL maps at different energies. The dependence of the polarization state on the electron beam location reveals that, reciprocally, the near-fields in different locations may respond strongly to different incident polarizations. With regards to assessing the viability of a nanostructure for dichroic spectroscopies, this relationship could be very fruitful.

Acknowledgements

Experimental EELS work was performed in the Canadian Centre for Electron Microscopy, supported by the Natural Sciences and Engineering Research Council of Canada (ICB, EPB, GAB). Experimental CL work was performed at AMOLF, part of the research program of the Netherlands Organization for Scientific Research and funded by the European Research Council (ICB, SM, TC, AP).

Vivid Colour Generation from Disordered Plasmonic Networks with Material Insensitivity Changxu Liu[1], Peng Mao[2,3], Fengqi Song[4], Min Han[4], Richard Palmer[5], Shuang Zhang[2,3] and Stefan A. Maier[1,6]; [1]Ludwig-Maximilians-Universitaet Muenchen, Germany; [2]University of Birmingham, United Kingdom; [3]The University of Hong Kong, Hong Kong; [4]Nanjing University, China; [5]Swansea University, United Kingdom; [6]Imperial College London, United Kingdom

Disordered nanostructures are ubiquitous in Nature, usually generating white or black colours due to their broadband optical response and robustness to perturbations. By manipulating the optical environment, we are able to tune the disordered plasmonic networks from broadband absorption to band-limited reflection through deterministic control of the coupling to an external cavity, producing rainbow-liked colours at will [1]. Counterintuitively, fabrication imperfections (intrinsic disorder) can be harnessed as a beneficial factor to improve the purity of structural colours. More surprisingly, the disorder can disentangle optical responses and material prosperities (refractive indices), in sharp contrast with the traditional belief that optical responses vary with the material. With the assist of random scattering inside disordered structures, the same colour is achieved by metallic nanostructures composed of different noble metals including gold, silver, palladium and platinum [2]. Not limited to fundamental physics, the proposed platform may inspire novel applications ranging from Raman spectroscopy, nonlinear optics, photocatalysis.

Observation of Hyperbolic Polariton Vortices Mingsong Wang[1], Guangwei Hu[1,2] and Andrea Alu[1,3,4]; [1]CUNY Advanced Science Research Center,

United States; [2]National University of Singapore, Singapore; [3]Graduate Center of the City University of New York, United States; [4]City College of the City University of New York, United States

Light can hybridize with low-dimensional materials, forming half-light-half-matter quasiparticles known as polaritons, featuring deeply subwavelength field confinement and broadband responses from terahertz to visible and infrared range. Among them, hyperbolic phonon polaritons (HP^2) in natural materials, especially anisotropic van der Waals (vdW) crystals, are uniquely interesting. Their hyperbolicity originates from the drastic difference in atom interaction strength between in-plane covalent bondings and out-of-plane vdW bondings, and it can support large momentum for enhanced light-matter interactions. Based on these features, directional propagation and dispersion engineering of HP^2 have been demonstrated in hexagonal boron nitride (hBN) and α-MoO_3, facilitating super-resolution focusing and imaging, canalization, molecular sensing, reconfigurability, and other polariton applications. However, current state-of-the-art discoveries in HP^2 have been mostly based on studying the amplitude of polaritons, while other degrees of freedom, such as nontrivial geometric phase, remain largely unexplored. Surface plasmon polaritons (SPPs), a counterpart of phonon polaritons in the visible and near-infrared range, have gained more controllability over their phases, as additional degrees of freedom. In particular, a plasmonic vortex featuring orbital angular momentum (OAM) with spiral phases has been shown to support a large number of states in Hilbert space, thus offering the potential to increase the capacity of optical communication networks. Plasmonic OAMs can also couple to the spin of excitation, inducing spin-orbit interactions, enabling spin-controlled plasmonic applications such as unidirectional propagation, spin-locked optical vortex generation, and chiral information detection. However, plasmonic materials act as conductors in the mid-infrared (mid-IR) range, and graphene, which supports infrared plasmons, has a limited light-matter interaction efficiency due to its atomic thickness. Herein, we report mid-IR deep-subwavelength HP^2Vs with high tunability in pristine hBN flakes. Our system is composed of a substrate gold disk with Archimedean spiral shapes to launch HP^2 in hBN. Via scattering-type scanning near-field microscopy (s-SNOM), HP^2Vs are observed in real space, and the spin-orbit interaction and high tunability of HP^2V are accordingly demonstrated. Our results facilitate effective optical spin-orbit interaction, super-resolution sensing and imaging, enhanced light-matter interaction, and particle manipulation in the mid-IR regime.

Magnetic Dipole Emission and Effect of Gap Plasmons in Metal-Dielectric-Metal Structures MD Afzalur Rab[1], John N. Munga[1], Natalia Noginova[1] and Maxim Durach[2]; [1]Norfolk State University, United States; [2]Georgia Southern University, United States

Gap plasmons allow strong optical field confinement, and has many promising applications in plasmonic circuitry, nonlinear optics, sensing etc. In this work, we study both flat and profile modulated three layers sandwich-like structures made of external plasmonic metal layers and a dielectric layer. The excitation of gap plasmons at specific thicknesses of the intermediate layer is predicted with COMSOL simulations. Introducing Eu^{3+} emitters into the dielectric layer, we show that such structures can provide strong control on magnetic and electric dipole emissions and radiation patterns. The experimental structure is fabricated using thermal evaporation of metal and spin coating of dielectric layer. A clear conformity between experimental observations and theoretical predictions is observed.

Flat Optics for Dynamic Wavefront Manipulation Mark L. Brongersma; Stanford University, United States

Since the development of diffractive optical elements in the 1970s, major research efforts have focused on replacing bulky optical components by thinner, planar counterparts. More recently, dynamic flat optics has been gaining importance and new opportunities are emerging for dynamic wavefront manipulation. I will discuss efforts to realize electrically-tunable flat optics based on metasurfaces that employ nanomechanics, electrochemistry, free-carrier dispersion, phase change materials, and atomically-thin semiconductors.

Defect Engineered Molybdenum Sulfide Nanosheets as Catalysts for Dye-Sensitized Solar Cells Kit Sze, Tyrome Fowlkes, Chiedozie Ogueri, Alexander Nanor, Solomon Tadesse, Saroj Pramanik and Yucheng Lan; Morgan State University, United States

Molybdenum sulfide (MoS_2) shows strong optical absorptions in UV-vis electromagnetic spectrum and high photo-corrosion tolerance, being an excellent photovoltaic and photocatalytic material. Here MoS_2 nanosheets were prepared and defect engineered to tune optical properties. Their microstructures were characterized by diffractions, electron microscopies, and optical methods. The defected nanosheets were then fabricated as electrode catalysts in I^{3-}/I^- -based dye-sensitized solar cells (DSSCs). The defects in MoS_2 nanosheets enhanced the photoelectric conversion efficiencies of the DSSCs. The work is partially supported by DOE grant DE-FE0031906.

WITHDRAWN 12/6/2021 EQ05.19.03 Shape-Effect on Quantum Confinement in Alloy Quantum Dots as Applied to Photovoltaics Nicholas Ulizio and Zubaer M. Hossain; University of Delaware, United States

Alloy quantum dots (aQD) represent a new class of nano-materials whose electron confinement is determined not exclusively by size, but also by composition field. While homogeneous quantum dots have been more widely explored for applications in photonics, optoelectronics, and photovoltaics, aQDs remain less investigated. The differences in both size and composition field across differently shaped aQDs lead to differences in material properties. These variations in material properties present compelling potential applications, specifically in the field of energy generation and photovoltaics. This is primarily because of the complexity in characterizing nonuniform fields and establishing the correlation between inhomogeneity and confinement. In order to effectively analyze the varied electron confinement of these materials, we employ a combination of density functional theory based quantum simulations, and finite element analysis based k.p calculations to determine the electron energy levels for a number of uniform and nonuniform physical variables. As a part of the analysis, composition maps were constructed for each of the four different aQD shapes, namely, the steep cone, normal cone, hut, and dome. Each of these composition's maps was fitted with an analytical function that was then used to analyze the quantum confinement and general electronic properties of the aQDs. Results show that a generic expression for all four of the aQDs exists such that modification of this equation allows each of the disparate aQDs to be modeled.

The steep cone shaped aQD with a 15° sidewall angle corresponds to a composition map where spatial decay occurs from the tip of the cone to the bottom. The normal cone shaped aQD exhibits a similar behaviour, but the sidewall angle is instead 30°, and the fitting function is modified to a product of a quadratic and a linear function. For the hut shaped aQD, the composition map takes the shape of a "hut" where decay occurs from the top edges towards the bottom edges in a non-linear fashion. For the final shape, the dome, spatial decay emanates from the top tip of the dome. The dome is fitted by two sidewalls per side that have angles of 11° and 30° respectively.

For each of the quantum dot shapes above, composition maps obtained are independent of size to determine the singular effects of the compositional variation. Our results suggest that inhomogeneity in composition field has a consequential role in controlling the confinement energy levels, with the highest ground state confinement in the steep cone shape, and the lowest in the hut shape. Thus, the shape of aQDs can play a critical role in tailoring effective electronic behavior. Furthermore, a larger alloy quantum dot can behave electronically like a smaller quantum dot, if the composition field is inhomogeneous. By engineering quantum dots with certain composition maps, the photon absorption properties of the respective quantum dot can thus be tailored substantially. In particular, the most apparent application of this is to solar cells and spintronics; engineering the properties of the quantum dot allows us to increase the absorption efficiency of the photovoltaic cell, which directly leads to greater potential for green energy generation.

Late News: Edge Effect on Light Distribution in Solid State Light Emitting Device Kishore Natarajan, Adam Samuel and Yue Kuo; Texas A&M University, United States

A novel Solid State Incandescent Light Emitting Device (SSI-LED) that was fabricated from the MOS capacitor with the high-k gate dielectric was invented and investigated by Kuo's group (1). Upon the application of a gate voltage to the device, light emission is observed. The principle behind the light emission is the thermal excitation of nano-sized conductive paths, i.e., nanoresistors, formed after the breakdown of the dielectric layer (2). Previously, the light emission from nanoresistors across the gate electrode area was assumed to be uniform (3). However, some experimental results (4,5) showed that the density of nanoresistors near the edge of the gate was larger than that away from the edge.
In this paper, authors utilize the Finite Element method to explore the reason behind the formation of the denser nanoresistors at the circumferential edge of the gate electrode. The current density distribution, which is the foundation behind the generation of the large number of nanoresistors from the dielectric breakdown process, has been simulated using the COMSOL Multiphysics software package and the results are depicted using MATLAB and Python codes. The area circumferential to the gate electrode has a larger density of nanoresistors than the rest of the area due to the accumulation of larger amount of charge carriers before the dielectric breakdown. Possible factors contributing to the uneven distribution of the nanoresistors, such as the dielectric and substrate properties, have been investigated. The substrate-to-gate electrode area ratio has been identified as the key factor in determining the width of the periphery area with the high density of nanoresistors.

5:15 PM EQ05.02.03
Poly(3-hexylthiophene)s with Terminal *N*-Heterocyclic Carbenes as Robust and Conductive Ligands to Stabilize of Gold Nanoparticles Franziska Lissel[1,2]; [1]Leibniz Institute for Polymer Research, Germany; [2]Dresden University of Technology, Germany

Gold nanoparticles (Au NPs) have unique surface plasmonic resonances (SPR) and promise a broad variety of optical applications in sensors and imaging, and combining them with organic components can give electronically functional hybrid materials [1]. In general, protecting surface ligands are required to stabilize the Au NPs and prevent their irreversible aggregation. The ligands carry one or more functional anchor groups with a high affinity for gold. Thiols are the most ubiquitously used anchor group, yet the thermal instability and comparably low conductance of the S−Au contact limit the applications of the resulting Au NPs. *N*-heterocyclic carbenes (NHCs) have been receiving much interest in surface chemistry as an high-performing alternative to sulfur-based ligands: The NHC−Au linkage shows excellent stability under conditions that destroy the S−Au bond (e.g. high temperature, variable pH, and electrochemical redox), and is furthermore highly conductive.

We use NHC anchors as robust and conductive anchors to bind charge-conducting conjugated polymers (CPs) to Au NPs to obtain electronically functional hybrid materials.

Three different Br-NHC-Au-X (X=Br, Cl) complexes with were synthesized in multiple steps. The complexation saturates and stabilizes the NHC, the bromo function on the benzimidazole ring can be used to further functionalize the complexes. 2-Bromo-3-hexyl-5-iodo-thiophene was converted to a Grignard monomer with isopropyl-magnesium chloride, and used for a chain-growth Kumada polymerization starting from the active aryl bromide on the NHC complexes. Using a Ni−bipyridyl complex as intermediate catalyst, P3HTs functionalized with the NHC-Au-X were prepared. The Mn values are in the range of 10k, the head-to-tail regioregularity was visible in ^{1}H NMR. ^{1}H MNR and MALDI MS were used to confirm the terminal NHC units, but also showed unmodified chains due to the tendency of the Ni catalyst to dissociate from the initiators into the reaction solution and initiate the polymerization without functional group.

Direct reduction with NaBH4 directly gave Au NPs with P3HT as surface ligands. For these P3HT-NHC@Au NPs, TEM images showed spherical particles with average diameters of 3.2, 2.5, and 6.5 nm, respectively. The presence of the NHC on the surface was confirmed by XPS.The P3HT-NHC@Au NPs have a remarkable thermal stability up to 24 h in 100 °C toluene solutions, while Au NPs stabilized by sulfur-based PEG fully degrade under the same conditions. Also, continuous CV scans revealed only a slight decay of peak current after 50 cycles, indicating the good electrochemical stability of P3HT-NHC@Au NPs.

To investigate the conductive linker, electrochromism (EC) experiments were carried out. P3HT is electrochromically active, and one can assume that binding the polymer to Au NPs via a conductive NHC anchor group will increase the electrochromic response speed, allowing to estimate the organic/inorganic electron transfer of P3HT-NHC@Au NPs. We found that blending 10% of P3HT-NHC@Au NP into an P3HT-NHC-Au films improves the responsive speed signiffcantly, from 1.21/1.05 s for neat P3HT-NHC-Au to 0.79/0.52 s for the blend.

This is consistent with DFT calculations (B3LYP/6-31g(d,p) for H, C and S; B3LYP/lanl2dz for Au) on a simple model compound (NHC linking tetrathiophene to a single Au0 atom): The electron cloud was found to be delocalized over the gold atom and the NHC in the HOMO orbit, suggesting an efficient electron transfer between Au NP and the conjugated P3HT polymer.

Detection of DNA Bases and Monitoring ssDNA Hybridization by Noble Metal Nanoparticles Decorated Graphene Nanosheets as Ultrasensitive G-SERS Platforms Sanju Gupta; University of Central Florida, United States

Surface- and graphene-enhanced Raman spectroscopy (SERS and G-SERS) are attractive analytical techniques for the detection of chemical and biological molecules at a single-molecule level registering their chemical fingerprints. Graphene-mediated or G-SERS boosted this phenomenon producing signal enhancement from both electromagnetic (EM) and chemical (CE) mechanisms. Graphene oxide (GO) nanosheets coated with silver; Ag (30 nm) and gold; Au (40 nm) nanoparticles were developed smart array of platforms for direct detection and differentiation of DNA bases: Adenine (A), Cytosine (C), Guanine (G), Thymine (T) as well as environmental relevant β-carotene (β-C) and malachite green (MG) biomolecules. The size and interparticle gap of metal nanoparticles were controlled via dispersion and loading on GO to achieve optimal enhancement factors. These substrates were characterized by electron microscopy, atomic force microscopy, and Raman spectroscopy. The Raman spectra consisted of discrete bands characteristic of (A: 732.8 cm^{-1}; C: 792 cm^{-1}; G: 658 cm^{-1}; T: 796 cm^{-1}; β-C: 1416 cm^{-1}; MG: 1174 cm^{-1}), which represent molecular normal modes of vibration and serve as a fingerprint of three-dimensional structure, intramolecular interaction and steady-state dynamics of biomolecule ensemble. The GO-decorated nanoparticles are capable of sensitive biomolecular detection over a broad concentration range of 100nM-100mM with the limit of detection (LOD) noted at <1ppm for A, C, G, T, β-C, and MG. Moreover, the experimental results illustrated five to six-order magnitude signal enhancement in the following order: GO/Ag30>GO/Au40>Ag30>Au40>GO. Moreover, ssDNA probe and complementary strand target DNA were monitored simultaneously during hybridization on the same substrates assigned confidently to base, local structure, and global conformation of dsDNA. The experimental findings suggest (1) a strong GO-nanoparticle coupling leads to interfacial hybridization (charge transfer), polarization, and molecular orientation, and (2) it will help to design ultrasensitive G-SERS platforms covering a range of inorganic nanoparticles and nanostructured organic surfaces for a wealth of biomedicine and environmental applications.

Combined Theoretical and Experimental Study Of Optoelectronic Properties in Transition Metal Nitrites Muhammad U. Javed[1,2]; [1]National Taiwan University, Taiwan; [2]Academia Sinica, Taiwan

We Investigated electronic structure and optical properties of transition metal nitrites i.e. TiN, HfN, ZrN, and their composition, TiZrN and TiHfN by using density functional theory and experimental techniques. These metallic materials are envisaged as alternative plasmonic materials in preference with comparison to conventional nobel metals from optical to the infrared wavelength range. Band structures and density of states are calculated in addition with bulk plasma frequency, absorption-extinction coefficients using ab initio procedure. Evaluation of calculation along experimental results for frequency dependent dielectric functions contributed by their interband and intraband transitions depicted optical losses in these refractory materials. Aforementioned materials with optimized thin films were deposited on suitable substrates of MgO and Si. These stoichiometric thin films were characterized to measure real and imaginary part of dielectric function by spectroscopic ellipsometry (SE). From quantitative analysis of measured and calculated quality factors for localized surface plasmon resonance (Q_{LSPR})and surface plasmon polaritons (Q_{SPP}) it is confirmed that HfN, TiN, TiZrN, TiHfN and ZrN possess excellent mechanical, chemical, and optical properties to be used as an alternative plasmonic material of gold in the visible and near-infrared spectral regions respectively. The photonic energy absorbed by these material is far less than gold (Au) at optical frequency, calculated and demonstrated as concrete evidence in absorption spectrum.

9:10 PM EQ05.20.03
Efficiency Increasing of Photodetectors Based on Two-Dimensional Semiconductors Using Ordered Plasmonic Elements Arseniy M. Buryakov[1], Sergey Lavrov[2], Andrey Guskov[2], Artur Avdizhiyan[2], Rinat Galiev[1], Anastasiya Gorbatova[2] and Elena Mishina[2]; [1]V.G. Mokerov Institute of Ultra High Frequency Semiconductor Electronics of RAS, Russian Federation; [2]RTU MIREA, Russian Federation

The necessity of increasing the optical radiation absorption in two-dimensional semiconductors significantly slows down the possibility of their technological implementation in modern photovoltaic and photosensor applications. In an unmodified transition metal dichalcogenides monolayer, the optical absorption in the visible range does not exceed 7%, which is extremely low for generating a sufficiently high photoelectric effect. There are several approaches, among which the most effective is the use of low-dimensional plasmonic metallic elements. Such structures make it possible to generate local amplification of optical radiation near their surface, leading to a significant increase in absorption in adjacent semiconductor structures.
Here we demonstrate a successful approach for increasing absorption in two-dimensional transition metal dichalcogenides films using ordered matrices of plasmonic elements of various shapes. The monatomic layer WS_2 was used as an active element. To achieve the highest efficiency of photodetectors, theoretical modeling of the plasmonic structures was made. Using this simulation, the optimal parameters of silver nanostructures were determined. Based on the obtained results, a series of experimental photodetectors was made. It was found that the created plasmon detectors have an almost tenfold increase in photosensitivity in comparison with conventional structures. It is shown that such an approach makes it possible to develop polarization-sensitive and spectrally selective optical devices. Moreover, their performance characteristics can be changed in a wide range by varying the geometric parameters of the plasmonic structures.

Differential Enhancement of 2D Raman Band Intensity of Decoupled Multilayer Graphene Mediated by Surface Plasmons from Ag Nanoparticles Suchithra P[1], S Walia[1], U Mogera[1,2] and Giridhar U. Kulkarni[1,2]; [1]Centre for Nano and Soft Matter Sciences, India; [2]Jawaharlal Nehru

Centre for Advanced Scientific Research (JNCASR), India

The coupling physics of localised surface plasmons of metal nanoparticles and phonons of graphene has attracted a great interest in the last few years. Surface-Enhanced Raman Scattering (SERS) is an effective method to probe this effect, where the intensity of the graphene Raman peaks are enhanced by the near field plasmonic effect originating from metal nanoparticles. In this work, we have examined the plasmonic property of the interface of a twisted multilayer graphene system and Ag nanoparticles (~ 100 nm). The twisted graphene produced in the laboratory has been established to possess decoupled layers leading to strong 2D bands [1]. The presence of plasmonic interface is found to cause relative enhancement of the 2D band intensity, the extent of enhancement varying with the nature of the substrate. Further, we have studied the particle size and laser energy dependence on this differential enhancement.

Plasmonic Photothermal Effects of Cotton Fabrics Densely Modified with Metal Nanocrystals Nobuko Fukuda, Muneyasu Suzuki, Kouji Suemori and Konami Izumi; National Institute of Advanced Industrial Science and Technology, Japan

Localized surface plasmon resonance (LSPR) brings about some interaction between metal nanostructures and the surrounding materials. Generation of hot electrons through LSPR allows a lot of applications such as photothermal manipulation of materials surrounding the metal nanostructures as well as promoting photovoltaics and photocatalysis.[1-5] Fabric is very familiar with us in our daily life. We focus on it as an attractive substrate to densely modify metal nanostructures with the viewpoint of the large surface area, chemical resistant property, and flexible workability. In this study, we prepared a gold nanostructure-modified fabric in such a way of dyeing and investigated the photothermal effect on the fabric.
Immersion of tetrachloroauric ions-adsorbed cotton fabric in a heated aqueous solution of sodium citrate gave dark purple color. The coloration is due to strong plasmonic absorption through densely formation of isolated gold nanostructures on the cotton fabric. The X-ray diffraction pattern of the gold nanostructure-modified cotton fabric (Au-cotton) shows peaks assigned as Au(111) and (200) as well as cellulose. The Au-cotton has an absorption band in visible light region with a peak around 550 nm. Irradiation of visible light to the Au-cotton causes the temperature rise at the surface. The largest temperature rise per unit given photon number occurs by irradiation at 550 nm. The rising rate to the light power at 550 nm was estimated to be ca. 0.5 K/mW between 293 and 343 K. The results of the dependence of the temperature rise on the irradiation wavelength suggest that the temperature rise comes from generation of hot electrons based on LSPR.
We demonstrate an interaction between the gold nanocrystals and the surrounding material as an example of the photothermal effect. The Au-cotton soaked with paraffin was placed on a glass plate at room temperature and irradiated with visible light. The paraffin in the Au-cotton melted and seeped out onto the glass surface attributed to the temperature rise of the Au-cotton based on LSPR. When the light irradiation was stopped, the paraffin solidified. Consequently, the Au-cotton adhered to the glass surface.

Bio-Inspired Porphyrin Hybrids for Enhanced Solar Harvesting Jou Lin, Zicheng Deng, Mengyao Lyu and Donglu Shi; University of Cincinnati, United States

One of the key requirements in solar harvesting is to have strong absorptions in the NIR region as the solar spectra provide nearly 50% of the infrared irradiation. In some particular photonic material applications, transparent thin films are desirable especially in dye-sensitized solar cells, therefore requiring high average visible transmittance (AVT). We have developed and synthesized transparent photonic thin films based on a bio-inspired porphyrin compound chlorophyllin that typically exhibits two peaks respectively near 400 nm (blue-violet) and 700 nm (NIR) with a high AVT above 90%. To further enhance NIR absorptions, a unique porphyrin hybrid is developed with systematic additions of another porphyrin compound phthalocyanine with much stronger NIR absorptions. Phthalocyanine has more pronounced UV and NIR absorptions, but a narrower “optical window” as compared to that of chlorophyllin. We have found that congruent mixtures between chlorophyllin and phthalocyanine can result in broader NIR absorptions while maintaining the optical window between 400 and 650 nm. This will provide an ideal spectrum for a highly transparent but strongly UV/NIR absorbing characteristic. We report the optical properties of the porphyrin hybrids based on UV-vis and Raman spectroscopy. Also discussed is the operating mechanism underlying the thermal-photonic behaviors associated with the hybrid structures.

Utilization of Co-Reduction Method in Fabrication of Au@Ag@Pt Multi-Shell Nanoparticles with a Granular Surface Anh T. Dao[1], Yuta Takeuchi[2], Hu-jun Lee[2], Ryo Teranishi[2], Hitoshi Kasai[1] and Kenji Kaneko[2]; [1]Tohoku University, Japan; [2]Kyushu University, Japan

Noble metallic nanoparticles (NPs) become a great scientific and industrial interest due to their unique physicochemical properties, and play important roles for a number of catalytic applications, such as oxidation and reduction reactions, environmental catalyzes, fuel cells and energy storage. Among these, platinum NPs (Pt NPs) have been receiving large attention because they are the most efficient and common catalyst for both anodes and cathodes in fuel cells. Multi-metallic Pt-based NPs were reported for enhancement of catalytic properties in comparison to monometallic Pt NPs, while reducing the Pt consumption [1]. Although possessing such potentials, the synthetic techniques for multi-metallic NPs have not yet achieved the controllability over the NPs morphology and structure, unless going through complex reaction conditions. In this study, Au@Ag@Pt core@multi-shell NPs were synthesized in one-pot by facile co-reduction method, a combination of galvanic replacement reaction (GRR) and a co-reducing agent, to obtain a well-defined nanostructure with enhanced surface area of Pt towards catalytic applications. The as-synthesized NPs were found to have Au core covered by Ag-Pt double-shell, which contained a degree of hollows with the inner surface composed of both Ag and Pt, while the outer surface composed of granular Pt. The shell-formation mechanism will also be discussed in aspect of competition role between GRR and co-reduction reactions, under the influence of unique charge transfer effect from Au core to Ag middle shell [2]. The NPs were characterized with UV-Vis, DLS, and especially high-end electron microscopic techniques, including ADF-STEM and EDS elemental mapping. Through understanding the complexity of the reaction mechanism, one can expect to design and fabricate various types of trimetallic nanoparticles with intricate structures, thus further expanding their nanotechnology and applications.

Structural Colors in Plasmonic Hafnium Nitride Metasurfaces Zong-Yi Chiao[1], Yu-Chia Chen[1], Jia-Wern Chen[1], Yu-Hung Hsieh[1], Yu-Cheng Chu[2], Jingwei Yang[2], Tzu-Yu Peng[2], Li-Chien T. Chang[2] and Yu-Jung Lu[1,2]; [1]Academia Sinica, Taiwan; [2]National Taiwan University, Taiwan

Most common plasmonic materials such as silver, gold, and aluminum have been proven to have excellent localized surface plasmon resonance (LSPR). However, the research for hafnium nitride (HfN) plasmonic nanostructures, one of the alternative plasmonic materials with high chemical stability, high melting point (T~3583 K), still remains unexplored. In this work, we experimentally demonstrated a full-color plasmonic color filter based on HfN metasurfaces with a high melting point. By tuning the LSPR the optical response can be controlled. Thus, we demonstrated full-color imprinted color pixel including red, green, blue, and black in the subwavelength scale. By using finite-difference time-domain (FDTD) simulation, the LSPR can be tuned by the designed HfN nanodisk structure with a diameter varied from 80 nm to 640 nm. The key reason to achieve full-color plasmonic resonance is the HfN has a high bulk plasmon frequency around 3.1 eV (λ_p = 400 nm). This result provides evidence that refractory plasmonic HfN metasurface is applicable in the full-visible spectrum, thus can pave the way in the thermostable optoelectronic applications.

EQ05-Virtual

8:00 AM *EQ05.21.02
From Structured Light to Structured Dark with Metasurfaces Federico Capasso; Harvard University, United States

Recent advances by my group on structuring the wavefront of light and on new optical singularities are presented. Metasurfaces suffer from limited performance and efficiency when multiple functions with large deflection angles are required because the non-local interactions due to optical coupling between nanostructures are not fully considered. Supercell metasurfaces can achieve multiple independent optical functions at arbitrary large deflection angles with high efficiency. In one implementation the incident laser was simultaneously diffracted into Gaussian, helical and Bessel beams over a large angular range. A compact wavelength-tunable external cavity laser with arbitrary beam control capabilities – including beam shaping operations and the generation of freeform holograms has also been demonstrated utilizing supercell metasurfaces.
The majority of structured light work has been concerned with shaping the wavefront in the plane transverse to the propagation direction. Multiple degrees of freedom, such as spin and optical angular momentum, can be controlled simultaneously along the optical path with a single metasurface by sculpting the incident waveform into an ensemble of co-propagating modes with different longitudinal wavevectors which beat along the direction of propagation, thereby modulating the resulting envelope at-will via multimode interference. Note that replicating this behavior with bulk polarization optics or SLMs is inherently cumbersome (if not impossible) as the former can only modify incident polarization globally whereas the latter operates on one incident polarization at a time. Two classes of metasurfaces have been realized for structuring light along the propgation direction: namely: polarization-switchable plates that couple any pair of orthogonal polarizations to two vortices in which the magnitude and/or sense of vorticity vary with propagation, and multifunctional plates that can structure both , spin and orbital angular momentum, independently, along the optical path while operating on incident light of any polarization. Compact and integrated devices of this kind can be exploited in light-matter interaction and imaging and may facilitate new applications that are not accessible with other wavefront shaping tools.
Optical phase singularities are zeros of a scalar light field. The most systematically studied class of singular fields is vortices: beams with helical wavefronts and a linear (1D) singularity along the optical axis. Beyond these common and stable 1D topologies, a broader family of zero-dimensional (point) and two-dimensional (sheet) singularities can be engineered. Sheet singularities are realized by maximizing the field phase gradient at the desired positions. Furthermore, by applying an analogous procedure to the full vectorial electric field, one can engineer paraxial transverse polarization singularity sheets. As validation, the experimental realization of phase and polarization singularity sheets with heart-shaped cross-sections using metasurfaces has been realized. Singularity engineering of the “dark” enables new degrees of freedom for light-matter interaction and can inspire similar field topologies beyond optics, from electron beams to acoustics.

High-Performance Metasurfaces for Wavefront Engineering Amir Hassanfiroozi, Chia-Hsiang Lin, Jhao-Ting Lin and Pin Chieh Wu; National Cheng Kung University, Taiwan

Metasurfaces have attracted a lot of attention because of their great capability to manipulate the attributes of an electromagnetic wave in demand. Thus, nanophotonic metasurfaces provide great flexibility in light management that highly benefits the development of low-profile optical systems. However, metasurfaces severely suffer from high optical losses that highly limit their optical performance. In addition, optical modulation in metasurface unit elements relies on strong resonances at a sub-wavelength resolution. It leads to a significant amplitude variation when a broad phase shift range is obtained. Such amplitude-phase covarying response can further degrade the optical performance of metasurfaces. In this talk, I will present two strategies to realize high-performance metasurfaces. Firstly, I will present a design method that enables a significant enhancement of the optical efficiency in a hybrid plasmonic metasurface. By integrating a solid nano-structure with its inverse complementary, we realized a plasmonic metasurface with a circular cross-polarization conversion efficiency higher than 50% in transmission at near-infrared wavelengths. Such high optical performance metasurface is achieved by simultaneously exciting the electric, magnetic, and toroidal multipolar modes, which satisfies the generalized Kerker condition and improves the transmission efficiency. We further demonstrate a couple of metasurface-based components such as beam deflector and flat focusing lens with record operating efficiency based on the proposed metasurface. Secondly, I will report an unsupervised genetic-type tree search algorithm in a virtual space wherein an automatic inverse design of metasurfaces is achieved with low computational complexity. With the developed method, we design and characterize beam deflection/steering metasurfaces, which are capable of deflecting normally incident light into target directions with minimal sidelobes; other functions of metasurfaces could also be achieved by revising the learning criterion in the virtual space. Due to the co-optimization of amplitude and phase shift, the inversely-designed metasurface possesses higher optical directivity than the forward-designed metasurface.

Efficiency Enhancement of Spin Hall Effect of Light Using Metamaterials Minkyung Kim and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

Spin Hall effect of light (SHEL) refers to a transverse and spin-dependent displacement of light at a planar optical interface. The SHEL is a universal phenomenon that can be readily observed in any interface, but has been neglected mostly due to the subwavelength scale of the shift. Therefore, enhancement of the shift up to wavelength scale and even beyond has been the main trend. However, the enhancement of the shift generally entails degradation of efficiency below 1%. To overcome the limitation, the simultaneous enhancement of the shift and efficiency under horizontal polarization was proposed and demonstrated in the microwave regime by using anisotropic impedance mismatching [1].
Here, we present our second proposal to achieve the large SHEL with high efficiency [2]. In contrast to the first approach, both the shift and efficiency is enhanced under arbitrarily polarized source due to the degenerate reflection coefficients [3]. The principle is a total reflection, in which both s- and p-polarized light is reflected at a denser-to-sparser interface with unity amplitudes. The simultaneous enhancement of the shift and efficiency is demonstrated experimentally using a near-zero-index metamaterial in the microwave regime. The large SHEL with near-unity efficiency under an arbitrarily polarized source will enable highly efficient and versatile devices with spin-selective functionalities.
Furthermore, we extend the recent attempts to achieve the large and efficient SHEL, which have been limited only to the microwave, to the optical regime [4]. The large SHEL with high efficiency can be also realized in the near-infrared wavelength by using an all-dielectric metasurface. A capability of metasurfaces to modulate complex transmission coefficients can be used to design a system that supports the large SHEL with high efficiency. Our recent progress in demonstrating the SHEL using Stokes polarimetry measurement will be introduced.

Near Infrared Absorption and Photocurrent Enhancement by Coupled Toroidal Dipole Modes in Silicon Metasurfaces Hiroaki Hasebe[1], Hiroshi Sugimoto[1,2] and Minoru Fujii[1]; [1]Kobe University, Japan; [2]JST PRESTO, Japan

High index dielectric nanostructures have unique optical responses driven by the Mie resonance, offering a variety of functionalities for directional nanoantennas, metalenses, etc. Recently, in addition to the electric and magnetic multipole resonances, toroidal multipole resonances have attracted much attention as a third multipole family. The lowest-order toroidal dipole (TD) mode is composed of a current loop along a meridian of a torus, which leads to strong confinement of an electromagnetic field in a dielectric nanostructure [1]. The enhanced electromagnetic field associated with the TD resonance has been exploited for the enhancement of nonlinear optical responses, [2] photocatalytic activities, [3] etc.
We have studied a low aspect ratio circular silicon (Si) nanodisk, e. g., ~500 nm in diameter and ~50 nm in thickness, as a nanoantenna supporting the TD mode, and showed that a metasuraface composed of the two-dimensional hexagonal array supports high quality (Q) factor TD resonances arising from coupling of the TD modes of individual nanodisks. [4] The high-Q coupled TD resonance results in narrow-band absorption enhancement in the wavelength range, where Si is almost transparent. This suggests that the Si metasurface supporting the coupled TD resonance enhances responsivity of a Si photodetector in a specific narrow wavelength range depending on the structural parameters.
In this work, we produce a Si nanodisk array metasurface having a coupled TD resonances and demonstrate that the resonant absorption results in the enhancement of the photocurrent in the near infrared range, especially in the wavelength range below the bulk Si band gap. First, we explore the structural parameters of the metasurface by the FDTD simulations, and show that at maximum ~120-fold enhancement of the absorption compared to that of a flat Si film with the same thickness is possible. We reveal from the multipole decomposition that the strong absorption enhancement is due to TD modes having an enhanced electric field within a Si nanodisk (intra-nanodisk TD mode) and between Si nanodisks (inter-nanodisk TD mode). Finally, we fabricate Si nanodisk metasurfaces and demonstrate narrow-band enhancement of the absorption and photocurrent due to coupled TD resonances.

Single-Base-Resolved and Millisecond SERS Sensing of DNA Oligonucleotides Using Gold Nanoparticle Dimers in Aqueous Suspension Nozomi Hagiwara, Keiko Esashika and Toshiharu Saiki; Keio University, Japan

Solid-state nanopore technologies have shown a great progress for developing single-molecule DNA sequencing, in which single-stranded DNA molecules passing through a nanoscale ion channel are observed by detecting current blocking signals. At present, nanopore ionic current detection enables discrimination of four bases (adenine, thymine, cytosine, and guanine) included in DNA, but it is much more challenging to identify chemically modified bases for epigenetic sequencing. Optical DNA sequencing based on surface-enhanced Raman scattering (SERS) is promising as an alternative method for spectroscopic identification of DNA bases. SERS utilizes extremely high field enhancement in a sub-nanometer volume (hot spot) of metal nanostructures to provide single-base spatial resolution and sensitivity. In this study, we develop a method to spontaneously form Au nanoparticle (AuNP) dimers, which sandwiches a single DNA oligonucleotide within a gap of less than 1 nm. SERS measurement of single AuNP dimers in aqueous suspension demonstrates single-base resolution obtained within a 10-ms measurement period.
We formed oligonucleotide sandwich AuNP dimers in aqueous suspension by using colloidal AuNPs with a diameter of 60 nm and oligonucleotides containing adenine (A) and cytosine (C) bases with a sequence of CCCCCCCCCCCCACCCCCCCCCCCC (12C1A12C; 25 mers length). The adsorption of oligonucleotides on AuNP surface and the formation of AuNP dimer was promoted by protonation of oligonucleotides, addition of salt, and incubation at elevated temperature. The conditions are carefully examined and optimized for enhancing the dimerization efficiency and for maximizing the probability

to find the oligonucleotide in the dimer gap, which should be minimized to obtain pronounced SERS activity and single-base resolution. The absorption spectrum of AuNP dimers, which were reproduced from the second band (dimer band) of gel electrophoresis separation after incubation and addition of BSPP into the AuNP dimer suspension, exhibits a large red shift of the longitudinal mode of AuNP dimer, demonstrating a strong coupling of AuNPs due to an interparticle gap smaller than 1 nm.
We performed micro-Raman measurements for oligonucleotide sandwich AuNP dimers under Brownian motion in aqueous suspension. The dimer suspension was diluted such that single dimer spectroscopy could be conducted. The measurement time was set to 100 ms while the dwell time of dimer in the observation volume was approximately 40 ms. By considering the fact that the AuNP dimer experiences rotational diffusion, the effective measurement time should be less than 10 ms. Among a number of Raman spectra obtained from single dimers, some exhibited a characteristic peak purely from adenine (734 cm^{-1}) while others purely from cytosine (800 cm^{-1}). Because we observed nucleotides containing both adenine and cytosine, the SERS signal should in principle always be a mixture of adenine and cytosine even at a single nucleotide observation. The fact that we obtained the SERS signal of purely adenine is clear evidence that the measurement achieved single-base (sub-nanometer) resolution. A similar result was obtained for oligonucleotides containing guanine (G) and cytosine (C) bases.

Implantable Sensors Based on Gold Nanoparticles for Continuous Long-Term Concentration Monitoring in the Body Katja Buder[1], Katharina Kaefer[1,2], Felix Schlapp[1], Hüseyin Uzun[1], Sirin Celiksoy[1], Bastian Flietel[1], Axel Heimann[3], Thies Schroeder[1], Oliver Kempski[3] and Carsten Sönnichsen[1]; [1]Johannes Gutenberg-University of Mainz, Germany; [2]Max Planck Graduate Center, Germany; [3]University Medical Center of the Johannes Gutenberg-University, Germany

Implantable sensors continuously monitor biomarkers in bodily fluids, facilitating chronic disease observation, supporting personalized drug therapy, and enhancing the patient's comfort. Nevertheless, there are two major issues limiting long-term application: Firstly, the sensor must be well integrated into the host tissue to prevent encapsulation, and thus impediment of analyte transport [1]. Secondly, the sensor-element for external signal transduction must be robust against degradation and exhibit a long signal lifetime [2].
To overcome both issues, we have developed an implant based on plasmonic gold nanoparticle sensors embedded in a macroporous polymeric hydrogel [3]. While the hydrogel's macropores allow tissue and capillary ingrowth, the nanoparticles' plasmonic signal exhibits a potentially unlimited lifetime. The nano-sensors are coated with aptamer and show a change of their resonance wavelength upon binding the antibiotic drug kanamycin. We implant our sensor-system subcutaneously in the abdominal skin of live hairless rats and measure the plasmon spectrum with a self-built spectral imaging setup non-invasively through the skin.
Upon administering the drug kanamycin in the rat's tail vein, we can observe a concentration-dependent change of the plasmon signal verifying the drug's presence in the tissue surrounding the implant. Control experiments, where we inject analyte-free saline solution, show no such signal change. The shift of the resonance wavelength is consistent with values we expected from theoretical calculations. Finally, histological sections of the working implants confirm that they are well integrated into the host tissue.
Our sensor design is not restricted to a specific analyte and allows many possible applications due to the versatile functionalization options of gold nanoparticles. The potentially unlimited lifetime of the plasmon signal enables long-term application and is advantageous over e.g. fluorescence-based systems, which are subject to photobleaching. Additionally, the macroporous polymeric hydrogel matrix is well-integratable into the host tissue, preventing encapsulation, facilitating analyte transport, and hence further boosting the service life of the implant.
Taking all these points into account, we believe that our implant paves a realistic way towards a universal sensor-platform for continuous monitoring of biomarkers.

Surface Plasmon Resonance Sensing in Electropolymerized Molecular Imprinted Polymers (E-MIPS) with *In Situ* and *In Operando* Parametrization. Rigoberto C. Advincula[1,2,3]; [1]Case Western Reserve University, United States; [2]The University of Tennessee, Knoxville, United States; [3]Oak Ridge National Laboratory, United States

Plasmonics and metamaterials have a common thread of enhanced phenomena and shape/composition independent dielectric and light behavior. A common application of plasmonic materials in sensing where the "enhanced light" can be used to further the use in detecting low levels of analyte and combined with a waveguide or guided layer detection. This is especially useful when combined with spectroscopic and imaging methods for characterizing the potential for artificial intelligence and machine learning (AI/ML) paradigm. This work will report on the use of plasmon, localized surface plasmon resonance LSPR and SPR waveguiding methods to demonstrate high sensitivity and selectivity for the detection of chemical and biological analytes at a very low level of concentrations. Using electrochemically molecularly imprinted polymers enabling tuning of the dielectric parameters based on the oxidation state of the polymer to facilitate the MIP process and evaluate the figures of merit of a sensor device. The main sensitivity is achieved by the plasmonic enhancement and relationship with multilayer films and dielectric behavior closer to a guided wave platform. Thus there is a high possibility of combining in-situ and in-operando measurements methods that can be relevant for future AI/ML applications.

11:15 AM EQ05.22.05
Polymer-Supported Composite Sensor Particles for Surface-Enhanced Raman Scattering Sensing Nikunjkumar Visaveliya; The City College of New York, United States

Surface-enhanced Raman scattering (SERS) spectroscopy is a very powerful analytical technique for the detection of various analytes in various mediums. For concentrating the electromagnetic waves (laser light), plasmon resonance is a minimum requirement for realizing the SERS effect. Therefore, various types of SERS substrates based on plasmonic metallic were developed since its discovery four decades ago. It is also required that SERS substrates are equipped with a roughened metallic surface with some nanoscale gaps and junctions that create hotspots. SERS techniques enabled the detection at the ultimate limit, *i.e.*, detection of a single molecule. Though solid substrates have potential, the mobile substrate (solution dispersion of nanoparticles) is very promising because of its small size, movability, high surface area, and ability to dealing with light efficiently. In this regard, smaller-sized metal nanoparticles with hotspots are very useful. However, smaller-sized metal nanoparticles are good for one-time use as it is difficult to wash and regenerate the nanoparticles because of their very small size and the possibility of uncontrolled aggregation and oxidation. To avoid such concern and also for regeneration and sequential SERS sensing purpose, polymer-based metal composite particles are very promising. Polymer-supported sensor particles (as substrate) are versatile due to the fascinating characteristics of the polymers such as swellability, porosity, transparency, metal loading ability, and high

surface area. Microfluidics is a promising technique for the fabrication of polymer-supported sensor particles of nanoscale and microscale with uniformity. For nanoscale sensor particles, the metal nanoparticles can be incorporated and anchored at the surface of polymer nanoparticles electrostatically, and a ligand-free metal layer can be deposited by a metal-catalyzed metal enforcement process. Here, the development of the polymer-metal composite particles at nanometer and micrometer length scales, and their applications as sensor particles for SERS sensing are presented. Microfluidic techniques were utilized for the generation of uniform sensor particles with the precise distribution of metal nanoparticles in the interior and at the surface. Furthermore, metal-catalyzed metal enforcement approaches initiated for achieving a ligand-free metal surface for direct analyte interactions, and experimental demonstration of sequential SERS analysis of multiple analytes through microfluidics has been established.

11:30 AM EQ05.22.06
Gold Nanoparticle Incorporated Oxide Thin Films for Gas Sensing at High Temperature Jeffrey Wuenschell[1,2], Youngseok Jee[1,2], Michael Buric[1] and Benjamin Chorpening[1]; [1]U.S. Department of Energy National Energy Technology Laboratory, United States; [2]Leidos, United States

Many applications of high economic value within the energy sector operate at high temperature or under chemically harsh environments, posing a challenge for *in-situ* operation with traditional sensor technology. Oxide thin films as sensing layers for conductive sensors or on the optical fiber platform provide one solution to this problem, as these thin films have the ability to operate at high temperature under a wide range of chemical conditions. The optical fiber platform in particular offers scalable, spatially distributed sensing, with off-the-shelf silica fiber providing stability up to 800 °C under oxidizing and reducing conditions. The incorporation of tailored plasmonic nanoparticles offers an additional response in the visible spectrum which may be utilized to provide enhanced cross-sensitivity discrimination under multi-variate sensing conditions. Gold nanoparticles, for example, have been shown to be stable at high temperature when incorporated within an oxide matrix. However, the plasmonic response can be impacted by the complex interaction between free carriers and atomic vacancies (which may be mobile at elevated temperature).

Computational modeling and experimental results demonstrate the impact of defect chemistry on the high temperature sensing response of the following two model oxides on the optical fiber platform: 1) La-doped $SrTiO_3$, an n-type doped system for sensing reducing gas streams; and 2) Fe-doped $SrTiO_3$, a p-type doped system for sensing oxidizing gas streams. On optical fiber and planar substrates, the interaction between the free-carrier (Drude) response of the oxide film in the NIR and the plasmonic response in the visible spectrum is demonstrated. The dynamics of the combined electronic-ionic-plasmonic physics are also modeled and used as a tool to guide the development of sensing layers with improved sensing response time and reduced drift at extreme temperatures.

Smart-Integration of Organic Light-Emitting Transistors in a Multifunctional System for Plasmonic Sensing Mario Prosa[1], Emilia Benvenuti[1], David Kallweit[2], Paola Pellacani[3], Michael Toerker[4], Margherita Bolognesi[1], Laura Lopez-Sanchez[3], Franco Marabelli[5] and Stefano Toffanin[1]; [1]CNR-ISMN, Italy; [2]CSEM Center Muttenz, Switzerland; [3]Plasmore s.r.l., Italy; [4]Fraunhofer FEP, Germany; [5]University of Pavia, Italy

The integration of multiple devices in a single functional unit is boosting the advent of a series of compact optical sensors for rapid and on-site analysis. In this context, the huge potential of plasmonic-based sensors has been affected by the strict constraints of the detection scheme. The resulting need for laboratory equipment, such as laser sources and expensive prism-based optics, therefore ends up in not-portable systems.
Here, an ultra-compact plasmonic sensor is demonstrated through the smart integration of an organic light-emitting transistor (OLET), an organic photodiode (OPD), and a nanostructured plasmonic grating (NPG). The direct integration of the OPD onto the planar structure of the OLET enabled unprecedented proximity of the light source and light detecting areas, which allowed the exploitation of the angle-dependent sensing characteristics of the NPG.
The most effective 3D layout of integration, including the optimal size and relative positioning of the three elements (i.e. OLET, OPD, and NPG), was unraveled by an advanced simulation tool, which also predicted the signal variation of the sensor under different conditions. Accordingly, the effectiveness of the new plasmonic-based detection scheme was demonstrated by the dependence of the OPD photocurrent on the surrounding environment of the NPG. In particular, a variation of the OPD photocurrent of about 10^{-9} A was recorded when exposing the NPG from water to alcoholic solutions at different concentrations.
A miniaturized plasmonic sensor with a total size of 0.1 cm^3 was therefore obtained through the smart integration of cost-effective, versatile, and nanometer-thick optoelectronic and plasmonic components.

SESSION EQ05.23: Metasurfaces and Metamaterials V
Session Chairs: Ortwin Hess and Giulia Tagliabue

EQ05-Virtual

1:00 PM *EQ05.23.01
Polaritonic Metasurfaces Andrea Alu; City University of New York, United States

In this talk, we discuss our recent progress in the area of polaritonics, and in particular on the role of polaritons in molding the optical wavefront over engineered ultrathin surfaces. We discuss the opportunities of these concepts to manipulate the propagation of light strongly coupled with matter. We will discuss the role that polaritons can have in inducing giant nonlinear responses in metasurfaces, and we unveil the emergence of topological transitions at photonic magic angles enabled by the strong coupling between two polaritonic bilayers with a twist angle between them. We will also discuss other exotic opportunities enabled by lower symmetry materials, such as monoclinic crystals or tailored metasurfaces. During the talk, we discuss the unusual phenomena supported by these structures, and their opportunities for nano-imaging and information transport.

1:30 PM *EQ05.23.02
Metasurfaces for Orbital Angular Momentum Holography and Fiber Optical Imaging Stefan A. Maier; Ludwig-Maximilians-Universität München, Germany

Metasurfaces allow the manipulation of the amplitude, phase, and polarization of light on an ultrathin platform, and have started to be explored also in the context of digitizing optical holograms. To increase the bandwidth of a metasurface hologram, essential for high-capacity holographic memory devices, different properties of light including polarisation, wavelength, and incident angles have been exploited for holographic multiplexing; however, the bandwidth of a metasurface hologram has remained too low for any practical use.

We present the design of a complex-amplitude metasurface hologram for ultrahigh-dimensional OAM-multiplexing holography in momentum space. To realise a complex-amplitude Fourier hologram, we have introduced an OAM diffuser array with a random phase function, capable of scaling down the amplitude variation in a typical Fourier image as well as eliminating the coherence of holographic image channels. We will demonstrate first realizations of holograms based on this concept.
The second part of the talk will focus on demonstration of metasurfaces on fiber end facets for optical trapping and achromatic focusing with record bandwidth over the whole telecom range.

2:00 PM *EQ05.23.03
Frontiers in Nanophotonics—Enabling Technology for Next-Generation Biosensors Hatice Altug; École Polytechnique Fédérale de Lausanne, Switzerland

Biosensors play an essential role in numerous healthcare applications ranging from diagnosis of life-threatening conditions to the management of infectious diseases for preventing pandemics. Unfortunately, current biosensors are lacking precision, bulky, and costly, as well as they require long detection times, sophisticated infrastructure and trained personnel, which limit their use. In our laboratory, we address these challenges by developing next-generation nanophotonic biosensors, bioimaging, and spectroscopy technologies. We exploit nanophotonics using plasmonic and dielectric metasurfaces for achieving high sensitivity, integration and multiplexing. We integrate our sensors with microfluidics for efficient sample manipulation and automation. We use smart data science tools to improve sensor performance. In this talk, I will present some of our recent effort towards developing ultra-compact, portable, rapid, and low-cost nanophotonic biosensor and their use for early disease diagnostics [1-4].

Our lab has been developing various point-of-care (PoC) biosensors with plasmonic nanohole arrays (NHAs) supporting extraordinary optical transmission (EOT) [5-7]. Recently, we showed that gold nanoparticle (Au-NP) bindings on NHAs can dramatically enhanced the sensitivity and enable digital counting of even individual binding events [1]. The detection principle is based on local suppression of the EOT signal. Although the sizes of NPs are subwavelength, their plasmonic interaction with NHAs allows for high-contrast imaging of surface-bound NPs in a bright field optical reader over large field-of-views and eliminates the need for bulky and expensive spectrometry instrumentation. In a follow-up work, we used this new principle to develop a portable PoC device to assist sepsis diagnosis [2]. The optical is made of off-the-shelf optical components and comprises an LED, a simple sample holder, and a CMOS camera. We tested the portable reader in a hospital setting with patient samples and showed detection of two inflammatory biomarkers related to sepsis diagnosis, procalcitonin and C-reactive protein with limit-of-detection down to few tens of pg/mL directly in blood serum. Our sensor provided performance equivalent to gold-standard immunoassay based laboratory tests. Moreover, our results revealed that our sensor can perform rapid tests in less than 15 minutes.

Concurrently, we use low-loss dielectric metasurfaces and exploit their high-Q resonance modes with accessible near-field enhancements for sensing. In one work, we combined silicon-based metasurfaces supporting BIC modes in NIR spectrum with hyperspectral imaging and demonstrated detection limits at the levels of ~3 IgG molecules/μm2 [3]. Recently, we introduced a single-wavelength imaging-based dielectric biosensor for achieving superior sensitivity based on reconstructed spectral shift without requiring wavelength scanning and spectrometers [4]. Here, we employed diatomic metasurfaces and combined them with advanced data processing techniques for aided imaging. Our method acquires large-area intensity images of the metasurface in real-time by using a single wavelength illumination and processes them optimally by a linear estimation algorithm to reconstruct spectral shift data at high accuracy. We integrated the metasurfaces with microfluidics in a microarray format and performed in-flow detection of breast cancer extracellular vesicles (EV), which are important biomarkers for diagnostics. Our optofluidic sensor has enabled real-time quantification of EV bindings from solution at concentrations as low as ~200 femtomolar.

2:30 PM EQ05.23.04
Terahertz Transverse Magnetism in Metasurface-Assisted Hybrid Plasmonic Gratings Subhajit Karmakar[1], Ravendra K. Varshney[1] and Dibakar Roy Chowdhury[2]; [1]Indian Institute of Technology Delhi, India; [2]Ecole Centrale School of Engineering - Mahindra University, India

Plasmonic wire has drawn immense scientific interests since the inception of artificial chiral media [1], which supports dominant electric mode upon applied electric polarization parallel to its axis and does not usually induce non-axial circulating current (i.e., dominant transverse magnetic modes) in it [2 – 6]. To induce transverse magnetic moment (circulating current distribution) in conducting systems, resonator geometry must be suitably tuned to manipulate its charge distribution along a loop (e.g., split- or closed ring, spherical particles, solenoid, toroid, etc.) [2 – 5]. Moreover, plasmonic systems possess inherent ohmic and radiative losses which eventually degrades system performance in large extent. As a result, plasmonic systems like metal wires, nonmagnetic plasmonic gratings were barely used to tailor its magnetic characteristics. Motivated from this viewpoint to excite magnetic resonances in a sole plasmonic wire, a mechanism was proposed recently in periodically arranged electromagnetically coupled plasmonic cut wires with applied polarization along its length [7]. By tuning length of one cut-wire (implying asymmetry), one can effectively transform physical functionality of other wire from being ‘electric’ to ‘magnetic’ in nature at terahertz (THz) regime by interplaying with near-field coupling and lattice coupling. We may highlight, as of earlier literature [1 – 5], realization of artificial transverse magnetism had only been possible by combining or coupling of at least two coupled wires; whereas nature of a single wire (be it isolated or coupled) always remains electric in nature, unlike our case where we break this convention. Moreover, the behavior of continuous wire (constituting grating) would be significantly different than periodically oriented subwavelength cut wires. Thus, we investigated the coupling between a continuous wire (grating) and a cut-wire (dipole) to tune the nature of grating element from electric to magnetic. Hybridization between grating and metasurface responses leads to generation of magnetic Fano and nonradiative anapole modes (i.e., low loss characteristics), makes this hybrid (combination of subwavelength grating (guided mode) and cut-wire dipole (diffractive, metamaterial mode)) plasmonic device useful for prospective THz magnetic applications like realization of femtosecond opto-magnetism, magnetic cloaking, magnetic storage, spin rectification, magnetic imaging, etc.

Energy-Resolved Plasmonic Chemistry in Individual Nanoreactors Eitan Oksenberg[1], Ilan Shlesinger[1], Angelos Xomalis[2], Andrea Baldi[3], Jeremy J. Baumberg[2], Femius Koenderink[1] and Erik C. Garnett[1]; [1]AMOLF Amsterdam, Netherlands; [2]University of Cambridge, United Kingdom; [3]Vrije Universiteit Amsterdam, Netherlands

Plasmonic resonances can concentrate light into exceptionally small volumes, approaching the molecular scale. Such extreme light confinement provides an advantageous pathway to probe molecules at the surface of plasmonic nanostructures with highly sensitive spectroscopies. Beyond the chemical information available through surface-enhanced Raman scattering (SERS), unavoidable losses associated with metals, which are usually seen as a nuisance, encode invaluable information on energy transfer to the adsorbed molecules through the resonance linewidth. We target the sharp gap resonances of gold nanocubes deposited on a gold mirror coated with a thin dielectric layer (NCoMs) and measure a thousand single nanocavities with resonances spanning the orange to red spectral range. We closely monitor changes in linewidth and peak energy of the nanocavities and combine these observations with SERS spectra to monitor, in an energy-resolved manner, energy transfer and plasmon-driven chemical reactions at their surface. Using methylene blue (MB) as a model system, we show how this approach can be used to measure the absorption spectrum of molecules following their adsorption onto a metal surface and reveal a rich plasmon-driven reactivity landscape. We show that within different energy windows distinct reaction pathways dominant: near-field driven desorption at ~1.7 eV and direct charge-transfer driven N-demethylation at ~1.9 eV.

SESSION EQ05.24: Quantum Photonics/Advanced Nanophotonic Design

4:00 PM *EQ05.24.01
Nanoplasmonics as Enabler of Room-Temperature Quantum Nanophotonics Ortwin Hess[1,2]; [1]Trinity College Dublin, The University of Dublin, Ireland; [2]Imperial College London, United Kingdom

Quantum technologies harness quantum effects usually in small and pure arrangements such as through cold atoms or superconducting systems. From the start, photonic quantum effects have played a central role, too, but most photonic solutions and systems based on light-matter interaction also require cryogenic environments. Strong coupling of light and matter at the single emitter level is a fundamental quantum resource offering deterministic energy exchange between single photons and a two-level system, and the possibility to achieve single-photon nonlinearities via the anharmonicity of the Jaynes-Cummings ladder. Until recently, however, the conditions for achieving strong-coupling were most commonly met at cryogenic temperatures such that de-coherence processes are suppressed. As a major step forward, we have recently demonstrated room-temperature strong coupling of single molecules [1] and single quantum dots [2] to ultra-confined light fields in plasmonic resonators at ambient conditions. The fact that strong-coupling conditions may be reached at room temperature is of immense interest because it represents a clear route to a practical implementation and use of quantum behaviour in nanophotonic systems and its application in bio-sensing [3].
Here we discuss the principles of room-temperature single-emitter strong coupling in nanoplasmonics and illuminate perspectives for quantum nanophotonics [4]. We will highlight the physics associated with recently demonstrated room-temperature strong coupling of single molecules in a plasmonic nano-cavity [1] and near-field generated strong coupling of single quantum dots [2] and single quantum emitter Dicke enhancement [5] paving the road towards single-photon quantum nonlinearities. We will also explain near-field enhanced single-photon emission in near-zero index materials and multipartite dynamic quantum entanglement [6].

Photonic Materials by Design—The Role of Chemical Bonding Matthias Wuttig; RWTH Aachen University, Germany

Controlling a state of material between its crystalline and glassy phase has fostered many real-world applications including photonic switches and phase

change materials. Nevertheless, design rules for crystallization and vitrification kinetics as well as the contrast of the corresponding optical properties still lack predictive power. Here, we identify stoichiometry trends for these processes in phase change materials, i.e. along the GeTe-GeSe, GeTe-SnTe, and GeTe-Sb2Te3 pseudo-binary lines employing a pump-probe laser setup and calorimetry. We discover a clear stoichiometry dependence of optical properties and crystallization speed along a line connecting regions characterized by two fundamental bonding types, metallic and covalent bonding. Increasing covalency slows down crystallization by six orders of magnitude and promotes vitrification. The stoichiometry dependence is correlated with material properties, such as the optical properties of the crystalline phase and a bond indicator, the number of electrons shared between adjacent atoms. A quantum-chemical map explains these trends and provides a blueprint to design crystallization kinetics and property contrast.

Engineering the Size, Morphology and Ordering of Metal Nanoparticles on Nano-Dimpled Surfaces Gavin Farmer, Brianna Western, Yan Jiang, A.J. Syllaios, Chris Littler and Usha Philipose; University of North Texas, United States

We present a fabrication technology to produce highly ordered metal nanoparticle arrays on large surface areas of a chosen substrate. The nanoparticles were formed on a nano-dimpled aluminum template which allows for highly ordered nanoparticle distributions and also allows for their direct transfer to a substrate of choice using a polymer lift-off. The influence of several experimental parameters on the nanoparticle ordering was studied. By controlling the dimple size and the thickness of the deposited metal film, it was possible to influence the size of the nanoparticles and its spacing within the array. Post-deposition, the metal film was annealed and the annealing temperature as well as the rate of rise in temperature during the annealing process were factors that influenced the ordering of the metal nanoparticles.
The nano-dimpled alumina substrate was prepared by a two-step anodization method. Three different deposition voltages (40 V, 60 V, and 70 V) were used to study the effects of voltage on pore diameter and the spacing between the metal nanoparticles. It was observed that the pore diameter scales approximately linearly with voltage in agreement with results reported in previous works. By controlling the pore diameters, it was possible to tune the diameters and interpore distance of the metal NP's. Large pore sizes yielded metal nanoparticles with large diameters and smaller interpore distance. Constant DC voltages of 40, 60, and 70 volts resulted in pore diameters of 60 ± 10nm, 100 ± 10 nm, and 120 ± 10 nm respectively.
Following fabrication of an ordered nano-dimpled surface, different metals (gold, silver and indium) were evaporated onto the dimpled surface to form a thin film. The thickness of the metal was varied from 8 nm to 12 nm and its effect on nanoparticle size and morphology was studied. Subsequent annealing of the metal film at different temperatures with varying rates of temperature rise enabled a study of the metal film thickness and annealing parameters on the morphology and ordering of the metal nanoparticles. The inter-particle distance was found to be inversely proportional to the thickness of the metal film. Moreover, rapid thermal annealing resulted in less uniform nanoparticles whereas slow anneal provided much more spherical nanoparticles with hexagonal close-packed ordering. The annealing temperature did not strongly influence the size and morphology of the nanoparticles, but the duration of the annealing process had a greater effect on the result. For gold nanoparticles, the optimum annealing process was a slow anneal at a temperature of about 300 C. Results of fabricating ordered arrays of indium and silver nanoparticles will be presented in this talk.

5:00 PM EQ05.24.04
A Neural Network-Based Approach for Emulating Light-Matter Interactions in Nanostructured, Disordered Photoelectrodes Robert H. Coridan; University of Arkansas, United States

Photoelectrochemical (PEC) solar energy conversion applications rely on chemical reactions driven by photogenerated minority carriers (electrons or holes) at a semiconductor-liquid junction. The optical, electronic, and chemical transport processes characteristic of these PEC reactions occur on independent and generally disparate length scales. Fabricating electrodes with hierarchical structure can optimize the performance for each of these processes simultaneously. Disordered materials with dielectric contrast on the length scales of the wavelength of light can trap light in localized modes. The simplicity of the fabrication alone makes this approach a particularly attractive one for engineering light trapping into scalable photoelectrode structures. One significant issue is that disordered materials can only be defined by ensemble or statistical parameters (pore diameter, scatterer diameter, relative volume fractions) rather than as precise structures, which results in a real, physical variance intrinsic to the ensemble structure. Simulations of the properties of a given ensemble (local light absorption, for example) require a large number of examples for generating statistically accurate measurements for those properties. In this talk, we will describe our recent efforts to use neural network emulation to explore the absorption properties of defects in a simplified, disordered photonic glass. This system provides an apt model for developing mathematical representations for electrode structure (input) and finite element simulation data (output) to interface with machine learning algorithms. It also provides an opportunity to develop appropriate error metrics for quantifying the accuracy of prediction and improve the training of a neural network emulator. We will outline the practical application of these models and show how algorithmic predictions can be used to identify the most efficient ensemble configuration for a given semiconductor photoelectrode.

5:15 PM EQ05.24.05
Semimetal Composite Nanostructures Induced Synergistic Photon Management and Band Gap Engineering of Two-Dimensional MoS2 Xiaoxue Gao[1], Sidan Fu[1], Xiaobai Yu[1], Haozhe Wang[2], Tao Fang[1], Jing Kong[2] and Jifeng Liu[1]; [1]Dartmouth College, United States; [2]Massachusetts Institute of Technology, United States

Photon management techniques are widely applied in solar cells and photodetectors to improve device efficiencies by light absorption enhancement. Conventional photon management strategies like dielectric nanophotonic structures in thin film photonics are limited by complicated fabrication process, incompatibility with Si foundry, high cost of materials, and narrow resonant bandwidth. Surface-textured transparent conducting oxide (TCO) thin films, typically composed of heavily doped wide bandgap semiconductor oxides like indium tin oxide (ITO) [1], are widely developed to overcome the above challenges. However, their sub-micron surface textures tend to weaken the photon management effect on thin absorber with thickness <1 μm. These facts leave the development of photon management strategies for two-dimensional (2D) absorbers such as graphene and molybdenum disulfide (MoS2) an open challenge for the current optics and materials research societies. In this paper, we report two semimetal composite nanostructures designed for 2D MoS2: pseudo-periodic Sn nanodots and SnOx (x<1) core-shell nanoneedle structures. 2D MoS2 shows up to 15x enhancement in absorption at λ=700-1000 nm under pseudo periodic Sn nanodots and 20-30x enhancement with 11% absorption in MoS_2 at λ=700-900 nm under SnOx (x<1) nanoneedles. Both cover broad optical bands from visible to near infrared (NIR) light regimes and are self-assembled from physical vapor deposition without sophisticated nanolithography. The enhanced absorption has been verified by notable increase in Raman scattering and Photo luminance intensities as a result of field enhancement under photon management. One mechanism of light absorption increase is the ultrahigh permittivity of Sn [2]. Same as Si which is the key element for almost all the current electronic and photonic devices, Sn is a group IV semimetal in the chemical periodic table. Compared with other conventional high-index dielectric materials (typically ε=10-15), it has an ultra large dielectric constant of ε > 50 at λ=500-3000 nm to induce strong near field enhancement in the nearby lower index regions according to the boundary condition of Maxwell's equations. Thus, Sn as a type of semimetal itself, could serve as a novel material system beyond plasmonic metals and high index dielectrics for optical interactions. The other unique feature of increased light absorption is that it covers a broadband which even achieve long wavelengths beyond intrinsic inter-band transition in 2D MoS2. This interesting behavior could be explained by local strain induced band gap engineering. Band gap engineering techniques are developed for photoelectronic devices operated at long wavelengths. These devices require especially small bandgap semiconductors. Conventional technique of tuning the stoichiometry of different elements inside a material system would need advanced material processing method like molecule beam epitaxy (MBE) and could only boost the

absorption at a specific wavelength. Our self-assembled nanostructures effectively decrease the band gap of 2D MoS2 by introducing local tensile strain to the material which enable the broadband long wavelength light absorption improvement. Thus, our semimetal composite nanostructures synergistically address the photon management and band gap engineering challenges of 2D MoS2 photonic devices at long wavelength. Besides, the preparation of self-assembled Sn composite nanostructures would not require sophisticated nanolithography which would potentially hinder large-scale manufacture. The compatibility with Si also makes it favorable for current semiconductor foundries. Therefore, our semimetal composite nanostructures would potentially be a good feature on future 2D photonic devices.

Unconventional Metals and Dielectrics for Photonic Devices Peifen Lyu, Tao Gong and Marina Leite; University of California, Davis, United States

The employment of metal thin films and nanostructures in photonic devices has widespread applications in displays, lasers, sensors, electro-optical modulation and photovoltaics. By far, intense research has focused on conventional metals (e.g., Au, Ag and Cu) because of their low optical losses, paramount to achieving excellent plasmonic responses [1]. Yet, these metals are neither CMOS-compatible nor earth-abundant, which constrains their usage in advanced optical devices. Therefore, research for other potential candidates such as non-conventional metals/alloys is called for. Magnesium (Mg), which dissolves in water, is the eighth most abundant material on the earth's crust with confirmed biocompatibility, and has not been explored to its full potential in photonics. By investigating its etching properties with the control of thin film deposition method (radio frequency sputtering, RFS, and electron-beam evaporation, EBE), temperature (10 – 60 ºC) and structural dimension, we demonstrate the promise of utilizing Mg for achieving optical tuning [2]. We fabricate scalable, transmissive color filters formed by triple-stack Mg/MgO/Mg thin films based on Fabry-Perot resonance, which feature tunable optical transmission to any color within the sRGB gamut [3]. Additionally, we fabricate tunable reflective color filters consisting of two stacked metal-insulator-metal layers (top: Mg-MgO-Mg, and bottom: Ag/Al_2O_3/Ag). After immersion in water, dynamic color tuning is successfully achieved (e.g., vivid yellow to pink), conditioned on etching time and temperature. Therefore, the transient properties of Mg-based photonics hold great promise for use in biodegradable color display, data encryption, and anticounterfeiting. Furthermore, we also exploit the modulation of optical properties of other unconventional metals such as Nickel (Ni), Cobalt (Co) and Platinum (Pt) and their alloy systems. Specifically, we implement the dewetting process of thin films to obtain large-area arrays of nanostructures. We characterize their optical behavior by *in-situ* spectroscopic ellipsometry. We establish a platform for engineering these metallic materials with *on-demand* optical responses. Research into these unconventional metals (e.g., Mg, Ni, Co and Pt) and their nanostructures opens up a new opportunity for game-changing nanophotonic components.

Ultrafast Free-Carrier Dynamics in Epsilon-Near-Zero Conducting Oxide Thin Films Sudip Gurung[1,2,3], Subhajit Bej[2,3,4], Francesco Tonelli[5], Zhenhuan Yi[2], Aleksei Anopchenko[1,3], Alessandro Ciattoni[5], Andrea Marini[6] and Ho Wai (Howard) Lee[1,2,3]; [1]University of California, Irvine, United States; [2]The Institute for Quantum Science and Engineering, Texas A&M University, United States; [3]Department of Physics and Baylor Research and Innovation Collaborative (BRIC), Baylor University, United States; [4]Photonics Laboratory, Physics Unit, Tampere University, Finland; [5]CNR-SPIN, c/o Dip.to di Scienze Fisiche e Chimiche, Italy; [6]Department of Physical and Chemical Sciences, University of L'Aquila, Italy

Understanding the ultrafast temporal dynamics of free carriers in epsilon-near-zero (ENZ) materials is important for zero-index nonlinear photonic applications [1]. Unique and fascinating features of ultrathin ENZ materials such as strong field intensity enhancement (FIE) along with high inherent nonlinearity and sub-picosecond temporal response have enabled enhanced high harmonic generation [2] and sub-picosecond optical switching [3]. However, the origin of such giant optical nonlinearity in epsilon-near-zero (ENZ) materials is still not well understood. Additionally, there is a lack of theoretical models that can accurately describe the temporal dynamics of hot electrons, especially in the strong nonlinear optical regime. In this work, we observe abnormal temporal dynamic of hot electrons in ENZ thin films under different pump fluences and excitation angles using a degenerate pump-probe spectroscopy technique. An strong intensity- and angle-dependence (for a TM polarized pump) on the relaxation time of the hot electrons are experimentally observed for the first time. Furthermore, a novel hydrodynamic model [4] has been used to validate the experimental results theoretically.

Two different ENZ materials (ITO with a thickness of 305 nm and AZO with a thickness of 205 nm) are fabricated using magnetron sputtering and atomic layer deposition respectively. The optical properties of the thin films are measured with spectroscopic ellipsometry, showing that the ENZ wavelength is 1190 nm for ITO and 1480 nm for AZO. The ultrafast temporal response of free carriers is measured with linearly polarized femtosecond laser pulses (pulse duration ~70 fs, repetition rate 1 kHz, peak wavelength (λ_p) tunable between 1100-1600 nm). Experiments are performed for normal and oblique incidences of TE/ TM polarized light pulses with different pump intensities and peak wavelengths ($\lambda_p = \lambda_{ENZ}$, $\lambda_p > \lambda_{ENZ}$, and $\lambda_p < \lambda_{ENZ}$). The temporal dynamics of the free carriers are evaluated by the relaxation time of carriers upon fitting the normalized change in probe transmission using the two-temperature model [5] and compared with the theoretical value predicted with the hydrodynamic model. Our results suggest that free carriers' relaxation time are highly dependent on the pump intensity as well as the excitation angles and wavelengths. We believe that our findings on understanding the tunability of the ultrafast free carrier dynamics of ENZ materials will be significant for efficient nonlinear zero-index photonic applications in the strong nonlinear optical regime.

SESSION EQ05.25: Plasmonic Applications IV
Session Chairs: Andrea Alu and Yu-Jung Lu
Tuesday Afternoon, December 7, 2021
EQ05-Virtual

9:00 PM *EQ05.25.01

Flexible Plasmonics Using Aluminum and Copper Epitaxial Films on MIca Le Thi Quynh[1], Chang-Wei Cheng[1], Chiao-Tzu Huang[2], Soniya S. Raja[1], Ragini Mishra[1], Meng-Ju Yu[3], Yu-Jung Lu[3] and Shangjr Gwo[1,1,3]; [1]National Tsing-Hua University, Taiwan; [2]National Chiao-Tung University, Taiwan; [3]Academia Sinica, Taiwan

Gold and silver are the most commonly used plasmonic materials because of their excellent optical properties in the visible and near-infrared spectral ranges. However, realization of wide-spread plasmonic applications requires additional material advantages, such as low cost, material stability, device scalability, spectral tunability, as well as device integration with existing semiconductor technologies. In this work, we demonstrate growth of atomically smooth aluminum (Al), copper (Cu), gold (Au), and silver (Ag) epitaxial films on two-dimensional (2D) layered muscovite (mica) substrates via van der Waals (vdW) heteroepitaxy with controllable film thickness from a few to hundreds of nanometers. In our approach, the mica thin sheet act as a flexible and transparent substrate with an atomically flat surface for vdW heteroepitaxy, which allows for large-area formation of atomically smooth, single-crystalline, and ultrathin plasmonic materials without the conventional issue of film dewetting. The metal thin films grown on mica allow us to design and fabricate well-controlled Al and Cu plasmonic nanostructures (the focus of this work) with tunable localized surface plasmon resonance (LSPR) and propagating surface plasmon polariton (SPP) properties from visible to the near-infrared spectral region. Furthermore, we show that the plasmonic responses of Al and Cu nanostructures fabricated on mica substrates remain unchanged under large substrate bending conditions. Based on these results, we expect that the metal-on-mica vdW epitaxy platform can lead to transformative plasmonic device applications ("flexible plasmonics") based on novel bendable functionalities.

9:30 PM EQ05.25.02
Gram-Scale and High-Throughput Synthesis of Noble Metal Nanoparticles Using Polymerizable Deep Eutectic Solvent Yoon Hyuck Kim and Jae-Seung Lee; Korea University, Korea (the Republic of)

Deep eutectic solvents (DESs) as a new generation of low-melting-point solvents have been used for syntheses of noble metal nanoparticles owing to their unique properties, such as structure-directing abilities, strong solvating power, wide reaction temperature range, non-volatility, and high thermal stability. Despite these advantages, to the best of our knowledge, the high-throughput and large-scale productions of noble metal nanoparticles using DESs have been rarely reported to date. In this work, we present the gram-scale synthesis of various noble metal nanoparticles with controlled shapes and sizes using a polymerizable DES. Acrylamide (AAm) is used to play a role as a hydrogen bond donor in DES and monomer. Importantly, the synthesis of noble metal nanoparticles and the polymerization of AAm take place simultaneously, resulting in the stabilization of highly concentrated nanoparticles in a polyacrylamide (pAAm) solid matrix. In addition, the overall synthesis of the nanoparticles in the polymerizable DES takes only 20 min in one-pot, and can be easily extended to carry out multiple reactions in a high-throughput manner. The intense optical properties of the nanoparticles are investigated, demonstrating the localized surface plasmon resonance of noble metal nanostructures. The molecular weights of the pAAms are investigated using gel permeability chromatography, indicating the roles of the reagents participating in the synthesis reactions. Moreover, alloy nanoparticles are also synthesized in the polymerizable DES. Importantly, we demonstrate that the production of the noble metal nanoparticles using the polymerizable DES could be as large as a few grams, demonstrating that our method could be truly practical for various applications, such as molecular diagnostics and therapeutics. As an example of applications that utilize a large number of nanoparticles, we demonstrate a concept of transparent displays using the synthesized nanoparticles on a round glass plate with a diameter of 10 cm.

9:45 PM EQ05.25.07
Real-Space Imaging of Strongly-Coupled Plasmon-Phonon Modes in Mid-Infrared Antennas Maureen Joel Lagos[1,2], Philip E. Batson[3], Zihan Lyu[1] and Ulrich Hohenester[4]; [1]McMaster University, Canada; [2]Canadian Centre for Electron Microscopy, Canada; [3]Rutgers, The State University of New Jersey, United States; [4]University of Graz, Austria

Strong plasmon-phonon (pl-ph) coupling can modify the energy landscape of mid-infrared antennas, thus providing opportunities to alter the energy states of infrared (IR) polaritons beyond the standard tunability approaches. Optical probes have dominated strong-coupling studies, but they offer limited spatial resolution. Nowadays, atom-wide monochromatic electron beams formed in transmission electron microscopes allow us probing and mapping IR excitations (e.g. plasmon, phonon polaritons) with better spatial sensitivity [1,2]. Here, we present a spectroscopical study of strong pl-ph coupling in mid-IR antennas using spatially-resolved electron energy loss spectroscopy (EELS). We imaged the spatial distribution of strongly-coupled ph-pl modes, revealing unique spatial behavior of polaritonic hybrid modes in mid-IR antennas [3].
We fabricated mid-IR double-antennas with extreme aspect ratio (up to 40) by joining a single rod-like Al plasmonic antenna and a rod-like *a*-SiO_2 phononic antenna, side by side. We adjusted the length of the double-antenna in such a way that the plasmon response of the Al antenna lies within the upper Reststrahlen band (RB) of the SiO_2. Optimal coupling conditions are achieved for antennas of 3 μm in length. The spatially-resolved EELS work was conducted using a transmission electron microscope equipped with an aberration corrector and monochromator that produces a ~ 2 Å electron probe with an energy resolution of ~ 9 meV.
The EELS spectra of the Al/SiO_2 antennas show double-peak resonances as a result of the pl-ph coupling. Each peak in the double-peak resonance is associated with the formation of one hybrid pl-ph mode. We determined the dispersion relationship associated with the polaritonic modes and found Rabi splittings as large as 26 meV within the RB. Our simulations indicate the appearance of only two coupled pl-ph modes, despite the large variety phonon polariton modes involved in the coupling. We measured the coupling constant of the pl-ph interaction (g = 18 meV), indicating that the coupling is in the strong-regime. Despite the modest quality-factor antennas built using low-cost materials, the fabricated Al/SiO_2 antennas equals performance of platforms of different geometries that capitalize on novel materials [4]. Our work suggests that geometry plays a relevant role in the development of strong-coupling hybrid platforms, likely due to the large variety of phonon polariton modes that participate in the coupling.
We mapped out the scattering associated with the strongly-coupled pl-ph modes and found that its spatial distribution is akin to the distribution of dipole optical modes in rod-like antennas. The maps of both coupled modes share several similarities along the double-antenna main axis, however minor variations can be noticed in the transverse direction, likely due to their unique charge configurations. Spatially-resolved EELS measurements across SiO_2/Al interfaces revealed a drastic scattering variation within sub 10 nm distances due to the charge symmetry of each pl-ph mode.
In summary, we have built and probed a double-antenna composed by one plasmonic Al antenna attached to a phononic SiO_2 antenna. We found evidence of strong coupling between plasmon and phonon polaritons, as revealed by the energy split in the dispersion curve. We have imaged strongly-coupled pl-ph modes bringing important physical insights into the local density of electromagnetic states. Our results suggest that geometry plays an important role in the design of hybrid strong-coupling platforms.

Magic-Angle Lasers in Nanostructured Moiré Superlattice Ren-Min Ma; Peking University, China

Conventional laser cavities require discontinuity of material property or disorder to localize a light field for feedback. Recently, an emerging class of materials, i.e. twisted van der Waals materials have been explored for the applications in electronics and photonics. Here, we propose and develop magic-angle lasers where the localization is realized in a periodic twisted photonic graphene superlattices [1]. We reveal that the confinement mechanism of magic angle lasers does not reply on a full band gap but on the mode coupling between twisted two layers of photonic graphene lattice. Without any fine tuning in structure parameters, a simple twist can result in nanocavities with strong field confinement and high quality factor. Furthermore, the emissions of magic-angle lasers allow direct imaging of the wavefunctions of magic-angle states. Our work provides a robust platform to construct high quality nanocavities for nanolasers, nanoLEDs, nonlinear optics and cavity quantum electrodynamics at the nanoscale.

Room Temperature Single-Mode Lasing from Metal Halide Perovskite Nanodisk Arrays Chi-Ching Liu[1,2] and Yun-Chorng Chang[1,2]; [1]Academia Sinica, Taiwan; [2]National Taiwan University, Taiwan

Lead halide perovskites have become promising materials for future lasers and optoelectronic devices. However, the conventional solution-based fabrication process greatly limits the possibility to include precision nanostructures that can further enhance the performance. In this study, we implement thermal evaporation to adapt conventional nanolithography technique, which allow us to construct $MAPbI_3$ perovskite nanodisk arrays. Optical pumped single-mode lasing centered at 785 nm is observed at room temperature. The Q-factors is estimated to be larger than 1500. The lasing peaks corresponds to the lattice mode and can be tuned for at least 20 nm by varying the periodicity of the nanodisk arrays. Results in this study can be extended to obtain perovskite nanolasers with tunable lasing wavelength.

8:45 AM EQ05.26.03
Photoinduced Schottky Barrier Width Modulation and Charge Transfer in Zinc-Tin Oxide and Gold Nanoparticles Hybrid Structure for Multilevel Visible Light Memory Li-Chung Shih[1], Ya-Shan Lin[1], Yen-Cheng Mi[1], Jen-Sue Chen[1], Yen-Hsun Su[1], Jih-Jen Wu[1] and Chao-Cheng Kaun[2]; [1]National Cheng Kung University, Taiwan; [2]Academia Sinica, Taiwan

In recent year, high responsivity and low-cost phototransistors have become prospective for various applications, such as optical communication, imaging, and wearable electronics. While the semiconductor materials will dominate the transistor performances, there have been several studies to develop thin film transistors using zinc-tin oxide (ZTO) due to its high electron mobility and on/off ratio. In addition, ZTO have shown the potential for optoelectronic applications owing to their significant photocurrent arising from generation of electron-hole pairs under UV light illumination. When using the visible light sources, photoexcited electrons can be generated in ZTO via the ionization of neutral oxygen vacancies (V_o) to positively charged oxygen vacancies (V_o^{2+}) and the photoexcited electrons under illumination of visible light of wavelength less than 450 nm. However, it will be difficult to get significant light response of ZTO at wavelengths of greater than 500 nm because the neutral oxygen vacancies are mostly locating at deep levels (>2.5 eV) within the bandgap.
In order to expand the light responding spectrum of ZTO, in this work, we report a hybrid device by embedding gold nanoparticles (Au NPs) in the zinc-tin oxide (ZTO) thin film transistor. Integrating with plasmonic metals provides a promising approach for visible light photodetectors and photocatalysis since the photocurrent can be enhanced by hot electrons generated by local surface plasmon resonance (LSPR). Au NPs may act as the charge trapping/detrapping media to further control the electron concentration in ZTO via gate bias modulation. As a result, the responsivity and sensitivity of ZTO/Au NPs phototransistor depend on the gate bias under illumination and the wavelength of the light. Compared to the same lighting condition without applying negative gate bias, the responsivity and the sensitivity of ZTO/Au NPs hybrid device can be greatly increased by 5 and 200 folds, respectively, with the application of negative gate bias under 405 nm light illumination. Similar enhancement effects are also observed under illumination using 520 nm and 635 nm light, which is partially attributed to LSPR effect of Au NPs. The key factor to generate the higher photocurrent with applying negative gate bias is that the charged oxygen vacancies (V_o^{2+}) will accumulate at the ZTO/Au NPs interface, and thus form a build-in electric field to induce the electrons to tunnel from Au NPs into ZTO.
A superb memory retention performance upon light/bias operation can be achieved in ZTO/Au NPs hybrid phototransistor since the electrons tunneling from Au NPs are excessive as compared to the charged oxygen vacancies (V_o^{2+}) in the ZTO channel. As a result, the recombination process is minimized, and the current is retained. Multiple memory state can be achieved by repeated programming operation and the memory states can be erased by applying positive gate bias which trigger the recombination/trapping of photocarriers. Therefore, this novel ZTO/Au NPs hybrid phototransistor exhibits broad spectrum photoresponse and multi-level photo-memory performance that highlights the promises for optical communication and computation technologies.

Electrical Tuning of Dynamic Organic Polymer Plasmonic Nanoantennas Akchheta Karki, Giancarlo Cincotti, Shangzhi Chen, Chuanfei Wang, Mats Fahlman and Magnus P. Jonsson; Linköping University, Sweden

Light-matter interactions with conventional metal nanostructures can be limiting as it is unduly challenging to modify their static properties after fabrication. To circumvent this issue and open up avenues to dynamically control light at the nanoscale, research is shifting towards dynamic plasmonic systems with switchable states. Our recent study showed for the first time that nanodisks of the highly conducting polymer, poly(3,4-ethylenedioxythiophene:sulfate) (PEDOT:Sulf), can function as dynamic nano-optical antennas with plasmonic resonances that are tunable via gas- or liquid-induced chemical redox reactions. Here, we take the next crucial step and present the first electrically tunable conducting polymer nano-optical antennas. In addition to switching the antennas on and off, we demonstrate gradual tuning of the plasmonic resonances by careful electrical modulation of the mobile polaronic charge carrier density. The concept can facilitate many future applications such as smart windows with tunable plasmon-induced heating or ultrathin optical components with tunable focal lengths and beam steering. Moreover, tailoring of the polymer antenna geometry enabled a significant blue-shift of the resonance peak from a previously reported lower limit of ~1800 nm to ~1270 nm, opening up the possibility to use such nano-

optical antennas for applications in the visible to near-infrared ranges.

9:30 AM EQ05.26.06
Focus-Tunable 2D Lens by Carrier Control Seong Chan Jun; Yonsei Univ, Korea (the Republic of)

Owing to the tremendous demands for high-resolution thin lenses, ultrathin flat lenses, which are different from conventional lenses, have been extensively investigated with various applications in telescopes, aerospace technology, holograms, and glasses-free 3D displays. However, such ultrathin flat lenses need some characteristics such as thickness and tunable focal length to satisfy the requirement of various applications. So, realize these characteristics of ultra-thin flat lenses, diffractive optical elements or metasurfaces are being used. In particular, Fresnel zone plates which is comprised of a set of concentric rings using diffraction to focus light can be designed as thin, low-volume for applications in various fields. In this study, ultrathin flat lenses based on Fresnel zone plates using graphene have demonstrated high focusing efficiency and broadband performance. Unlike in most other 2D material, graphene which has a very thin thickness of per layer is intrinsically an ideal conductor with zero energy bandgap. How the transmittance change when a DC voltage is applied to ultrathin flat lens by experiments and COMSOL simulations. The result indicates that the transmittance is the lowest at 0 V and increases as the magnitude of the voltage bias is increased in either direction. Furthermore, as the voltage bias increases, the carrier density increases at the edge of the pattern leading to the shift in Fermi level which results in the difference in absorption of the incident light and thus the reduction of the Fresnel zone plate ring width. Our ultrathin flat lens is able to modify the focal length while achieving high transmission efficiency and nanoscale thickness. This study will be the cornerstone of the development of ultra-thin variable focus displays in the future, and it will be able to develop into a hologram display, reducing weight and increasing efficiency of glasses-free 3D displays and multi-focusing display for vehicles.

9:45 AM EQ05.26.07
Plasmonic Upconversion Lasing from Single-Crystal Lead-Free Perovskite Nanowire Chih-Ang Lin[1], Jung-Chan Lee[1,2], Yu-Cheng Chu[1,2], Li-Chien T. Chang[1,2], Yu-Hung Hsieh[1,3], Ming-Yen Lu[3], Chih-Wei Chu[1], Tzung-Fang Guo[4] and Yu-Jung Lu[1,2]; [1]Academia Sinica, Taiwan; [2]National Taiwan University, Taiwan; [3]National Tsing Hua University, Taiwan; [4]National Cheng Kung University, Taiwan

Lead halide perovskite materials have been proven to be promising candidates for laser application owing to their extraordinary optical properties. However, the environmental pollution risk of lead-based devices has become a challenge. Thus, searching for non-toxic, lead-free perovskite materials is essential. Here, we report a plasmonic upconversion laser from a lead-free halide perovskite $CsSnBr_3$ nanowire which synthesized at room temperature. The length of $CsSnBr_3$ nanowires ranging from 5 to 10 mm, and the width is from 100 nm to 1 mm. We characterized the spontaneous emission rate using time-resolved photoluminescence (PL) and PL measurements and observed an emission centered at 675 nm from the $CsSnBr_3$ nanowire. However, we only observed spontaneous emission from $CsSnBr_3$ nanowires due to their low PL quantum yield. Hence, we designed a plasmonic nanocavity to enhance the two-photon absorption rate and photon emission rate to reach the lasing action. The plasmonic upconversion nanolaser consists of a nanowire on a sputtered plasmonic hafnium nitride film with a thin Al_2O_3 capping layer by using atomic-layer-deposition. We will discuss the potential applications of lead-free halide perovskite $CsSnBr_3$ nanowire lasing such as nonlinear optics, optical communication, information processing, and sensing.

SESSION EQ05.27: Low Dimensional Photonics

10:30 AM EQ05.27.01
Late News: 2D Semiconductors as Highly Tunable Optoelectronic Building Blocks Tony F. Heinz[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

2D semiconductors in the transition metal dichalcogenide family (MoS_2, $MoSe_2$, $MoTe_2$, WS_2, WSe_2) have attracted much recent attention because of their direct-gap character at monolayer thickness and the pronounced role of excitons in these systems. In addition, the possibility of combining them in vertical stacks creates a wide range of new properties, such as the emergence of interlayer excitons. In this paper, we will highlight some the distinctive ways in which these robust building blocks for optoelectronic devices can be tuned, often in ways not available or practical in bulk materials. In particular, large and spatially localized strain fields can be used to modify the gaps and to localize excitation. Also, the external dielectric environment can modify the electrical and optical gaps of these materials at monolayer thickness. Finally, in monolayers and especially in heterostructures, electrical gating can be used to tune the material properties both through doping and the Stark effect. We will give an overview of these distinctive properties and how they might be harnessed in a device context.

11:00 AM EQ05.27.02
Direct Observation of Photoinduced Charge Transfer in Intermediate Coupling of MoS_2 Monolayer Min-Wen Yu[1,2], Satoshi Ishii[2], Shisheng Li[2], Ji-Ren Ku[1], Jhen-Hong Yang[1], Kuan-Lin Su[1], Takaaki Taniguchi[2], Tadaaki Nagao[2] and Kuo-Ping Chen[1]; [1]National Chiao Tung University, Taiwan; [2]National Institute for Materials Science, Japan

In exciton-polariton coupling, the understanding of electronic energy exchange in Rabi splitting is crucial. The favorite structures that have been adopted to study such coupling are “nanoparticle-on-mirror”. Integrating with transition metal dichalcogenide (TMDC) monolayers can realize large Rabi splitting. However, such a hybrid system has a significant localized electric field in out-of-plane that cannot satisfy the couple with in-plane exciton dipole of TMDC. Here, we propose one-dimensional plasmonic nanogrooves integrated with MoS_2 monolayers. The strongly localized fields are parallel with MoS_2 exciton orientation can address the aforementioned issue. As a result, a significant Rabi splitting (65 meV) in the intermediate coupling regime is demonstrated. In addition, Kelvin probe force microscopy is used to image charge transportation in the hybrid system. We directly observed the surface potential change on the proposed system via photo-excitation caused by the charge rearrangement. Furthermore, the giant photoluminescence enhancement can be attributed to the parallel exciton-polariton interactions. Our findings can provide great potential for improving the performance of plasmonic-TMD heterodevices in the field of photoconversion.

11:15 AM EQ05.27.03
Near-Field Probing of Image Polaritons in van der Waals Crystals Sergey Menabde[1], Jacob T. Heiden[1], Jongtae Ahn[2], Sergejs Boroviks[3], Kenji Watanabe[4], Takashi Taniguchi[4], N. Asger Mortensen[3], Do Kyung Hwang[2] and Min Seok Jang[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of); [3]University of Southern Denmark, Denmark; [4]National

Institute for Materials Science, Japan

Polaritonic modes in van der Waals crystals provide an unexcelled degree of field confinement and a superior capability for light manipulation at nanoscale. Very recently, a new class of polaritonic modes has been spotlighted as a superior platform for low-dimensional nanophotonics: the image polaritons, supported by a polaritonic material in proximity to a metal when the polaritonic mode couples with its mirror image.
We use scanning scattering-type near-field optical microscope (s-SNOM) to study the hyperbolic image phonon-polaritons (HIP) in hexagonal boron nitride (hBN) on gold. In our experiments, atomically flat gold crystals are used as a substrate, eliminating any roughness-mediated scattering of HIP. In such system, HIP dispersion properties can be accurately measured by the near-field mapping of their interference fringes. We use the polariton propagation length in optical cycles as a figure of merit (FOM).
We observe the first-order HIP mode with FOM of 6.5, independently of hBN thickness, while its wavelength varies from 192 nm in a 30 nm-thick hBN slab to 565 nm in an 88 nm-thick slab, all measured at 1480 cm^{-1} in the upper reststrahlen band. In agreement with theory, measured FOM is 1.8 times larger than that of hyperbolic phonon-polaritons in the same hBN on a typically used SiO_2 substrate. At the same time, HIP possess an impressively 3.9 times shorter wavelength. While the hBN used in our experiments has isotope composition of $^{10}B/^{11}B \approx 82/18$, we note that FOM of the HIP in the isotopically pure hBN with $^{10}B = 98.7\%$ is expected to be as high as 19.
Our results are even more interesting in a context of the recent work by Menabde *et al.* reporting on the experimental observation of significantly improved FOM of the mid-infrared image (also called acoustic) graphene plasmons. Near-field probing has revealed image plasmon mode that is twice as compressed and has 1.4 times higher FOM compared to graphene surface plasmons under similar conditions. Importantly, these results have been obtained with a large-area, chemically grown graphene, suggesting that image graphene plasmons are less sensitive to loss in graphene. This can be explained by the field distribution of the image plasmons which is mostly confined within the dielectric spacer, in contrast to the surface graphene plasmons localized at the graphene plane.
Summarizing, the direct near-field probing of image polaritons in van der Waals materials clearly demonstrates their superiority over pristine polaritonic modes in terms of both FOM and field confinement, promising the ultra-compact photonic devices where the wave phenomena and the exceptionally strong light-matter interaction can be put to work together.

11:30 AM EQ05.27.04
Ultrafast Exciton Dynamics in Millimeter-Scale, Continuous, Janus WSeS Monolayer Ching-Wen Chan[1], Chih-Wen Yang[2], I-Hung Ho[3], Hyeyoung Ahn[3], Vincent Tung[2] and Yu-Jung Lu[1,4]; [1]Research Center for Applied Sciences, Academia Sinica, Taiwan; [2]King Abdullah University of Science and Technology, Saudi Arabia; [3]National Yang Ming Chiao Tung University, Taiwan; [4]National Taiwan University, Taiwan

The exciton dynamics in layered transition metal dichalcogenides (TMDCs) have spurred immense interest for next generation optoelectronics. Many works regarding this topic have been reported on either mechanically exfoliated TMDCs or monolayer flakes made via the chemical vapor deposition (CVD). Meanwhile, the exciton dynamics in Janus TMDCs monolayer with structural symmetry-breaking remains unexplored in any scalable fashion. Here, we report the ultrafast exciton dynamics in millimeter-scale Janus WSeS monolayer grown by chemical vapor deposition with H_2 plasma strip method. We performed PL measurement, Raman mapping, and steady-state absorption measurement to study the optical properties of the Janus WSeS monolayer. The ultrafast carrier dynamics of A/ B /C excitons were studied by using pump-probe transient absorption spectroscopy with a broadband white-light probe beam. The transient absorption pump-probe spectra of Janus WSeS varying with pump fluences and time delay will be discussed. We find that the relaxation of A exciton in Janus WSeS follows a triple-exponential decay process of approximately 1.1 ps, 14.4 ps, and 52.4 ps, respectively. We compare the carrier dynamics in Janus WSeS monolayer to the symmetric WSe_2 and WS_2 monolayers. We conclude that the short exciton lifetime in the Janus structure is due to the built-in dipole moment. The findings provide fundamental insight into the optical properties of 2D materials. We will discuss the practical applications in the field of 2D optoelectronics and ultrafast 2D photonics.

11:45 AM EQ05.10.01
Late News: Electrically Switchable Plasmonic Nanoantennas—Active Metasurfaces for Beam Steering and Metalensing Harald Giessen, Julian Karst and Mario Hentschel; University of Stuttgart, Germany

Metasurfaces based on plasmonic materials have revolutionized nanooptics [1]. The ability to shape beams with surfaces that are only a few hundred nanometers high has added tremendous design freedoms and functionalities to optics. In principle, plasmonic metasurfaces are the ultimate spatial light modulators that include amplitude and phase control on a deep subwavelength scale. The combination of propagation phase with geometrical phase allows for a full 2π phaseshift for each individual spatial element.
The forefront of metasurface research is geared towards active metasurfaces. These devices allow for changing their functional properties. Examples include beam steering with varying angles, bifocal and zoom lensing, and, ultimately, switchable spatial light modulation.
Several approaches have been brought forward: Liquid crystals or polymers have been combined with plasmonic nanoantennas or high-index dielectric resonators, and an electric field can switch the refractive index next to the nanoantennas, hence shifting the resonance wavelength. Phase-change materials such as GST have been used in hybrid or high-index Mie resonator fashion to create metasurfaces in the infrared. Typically, materials of the GST family are switched by heat, as they can shift their refractive index drastically, depending on whether they are in the amorphous or crystalline state, which can be switched depending on heating and cooling parameters [2]. Another approach uses materials such as ITO which can shift its refractive index in the infrared depending on its charge carrier densitiy. In combination with a perfect absorber geometry, this results in electrical switchable functionalities such as beam steering for LIDAR applications. Other possibilities include metal-to-insulator transition materials such as Mg or VO_2, which can be switched by proton incorporation or heating [3].
All of the previous approaches have their individual benefits and drawbacks. Hybrid approaches often suffer from the fact that the plasmonic resonances are shifted only spectrally, hence influencing other wavelengths. This holds true also for several of the GST approaches. Perfect absorber geometries that can in principle give the full 2π phaseshift and can be electrically switched commonly work in reflection geometries with very low reflectances, hence making applications such as LIDAR difficult. Nanoantennas that can switch plasmonic resonances on or off have switching speed issues, as incorporation of protons from the hydrogen gas phase often requires palladium as molecule splitting catalyst and hence results in switching times of seconds [4].
Here, we present a completely different and novel approach to the above problem: We present electrically switchable nanoantennas whose plasmon resonance can be switched on and off electrically and individually. We demonstrate video-rate switching times, hence overcoming the previous speed issues.
In order to validate our concept, we combine our electrically switchable plasmonic nanoantennas in functional metasurfaces. In one implementation, we demonstrate beam steering. In another example, we demonstrate a flat metalens whose focusing ability can be switched on and off electrically. Our system can be operated in transmission as well as in reflection geometry.
Our approach represents the breakthrough that will ultimately enable spatial light modulators with densities higher than 1000 lp/mm. This is the crucial element to make possible high-angle variable beam steering, electrically adressable zoom metalenses, and, ultimately, wide-angle holographic videos. These devices are key to enable compact augmented and virtual reality devices.

High-Momentum 2D Exciton-Polaritons in Monolayer Semiconductors Itai Epstein[1] and Frank Koppens[2]; [1]Tel Aviv University, Israel; [2]ICFO–The Institute of Photonic Sciences, Spain

Highly-confined or large-momentum polaritons are usually associated with transverse-magnetic (TM) surface modes residing at the interface between two bulk materials. Commonly, the condition for the existence of such a mode is that one of the materials exhibits a permittivity whos real part is negative, while the other is a dielectric. For example, electron in metals give rise to the existence surface-plasmon-polariton (SPP) at a metal/dielectric interface, and optical phonons give rise to the surface-phonon-polariton in polar dielectrics. Both exhibit a negative real part of the permittivity in a certain spectral range, and the response holds also for 2D monolayers with the same properties [1, 2]. In that aspect, up until recently, monolayer TMDs have been known to exhibit a positive real part of their permittivities and thus in principle, should not support such a polaritonic mode.

In this work [3], we predict the existence of a highly-confined exciton-polariton mode, which propagates in-plane and confined to the monolayer in the out-of-plane direction. It belongs to the same family of polaritons mentioned above, only here the oscillations of the impinging TM electromagnetic light field couples with collective oscillations of the TMD excitons, and indeed exhibits the known signature of negative real part of its permittivity. The latter is attainable by encapsulating the monolayer TMD with hBN and cooling down to cryogenic temperatures. We show that owing to the resonant nature of the excitonic optical response in TMDs, the formation of the 2DEP and its detection strongly depend on achieving extremely narrow excitonic linewidths.

From experimental data, we extract the temperature-dependent real part of the permittivity, for an hBN-encapsulated WS2 monolayer, obtained from reflection measurements, and find that it can sustain increasingly negative values with decreasing temperature. We analyze the 2DEP properties under these conditions at the lowest temperature and compare them to those of SPPs at the same spectral range. We find that the 2DEP exhibits over two orders of-magnitude larger wavelength confinement.

Such highly-confined polaritons in the visible spectrum can pave the way to new light-matter interaction possibilities, based on 2D-materials, and compete with current SPP-based applications.

Surface Nonlinear Optics with Two-Dimensional Materials Andrea Marini; University of L'Aquila, Italy

Optical nonlinearity in photonic materials enables a large number of applications such as frequency conversion, all-optical signal processing, and non-classical sources of light. The speed of solid-state electronic devices, determined by the temporal dynamics of charge carriers, could potentially reach unprecedented petahertz frequencies through direct manipulation by optical fields, consisting in a million-fold increase from state-of-the-art technology. In graphene, charge carrier manipulation is facilitated by exceptionally strong coupling to optical fields, from which stems an important back-action of photoexcited carriers. Here we report the instantaneous response of graphene to ultrafast optical fields, elucidating the role of hot carriers on sub-100 fs timescales. The observed nonlinear response and its dependence on interaction time and field polarization reveal the back-action of hot carriers over timescales commensurate with the optical field. An intuitive picture is given for the carrier trajectories in response to the optical-field polarization state. We note that the peculiar interplay between optical fields and charge carriers in graphene may also apply to surface states in topological insulators with similar Dirac cone dispersion relations. Furthermore, we report harmonic generation and saturable absorption in graphene, discussing free-carrier generation and their ultrafast temporal dynamics in the atomically thin material. We further discuss the nonlinear optical properties of transition metal dichalcogenides, illustrating cavity-enhanced second-harmonic generation and parametric down-conversion and demonstrating that phase-matching free operation can be achieved in photonic micro-cavities embedding two-dimensional semiconductors as nonlinear optical media. Our results are promising for the development of integrated optical parametric oscillators and micro-sources of entangled photons.

1:30 PM EQ05.28.03
Third-Order Nonlinear Optical Response of Embedded Arrays of Plasmonic Gold Nanoparticles Synthesized by MeV Ion Implantation José-Miguel Zárate-Reyes[1], Oswaldo Sánchez-Dena[2], Erick Flores-Romero[3,1], Jorge-Alberto Peralta-Angeles[1], Jorge-Alejandro Reyes-Esqueda[1] and Juan-Carlos Cheang-Wong[1]; [1]Instituto de Física, Universidad Nacional Autónoma de México, Mexico; [2]Instituto de Ingeniería y Tecnología, Universidad Autónoma de Ciudad Juárez, Mexico; [3]CONACYT, Instituto de Física, Universidad Nacional Autónoma de México, Mexico

Arrays of plasmonic gold nanoparticles, embedded in fused silica plates, were prepared by implanting 2 MeV Au^+ ions through a silica particle lithographic mask. The nonlinear optical response of these periodic arrays was experimentally investigated using the z-scan technique at 532 nm with 26 ps pulses from a Nd:YAG laser. The open-aperture z-scan measurements were performed following different linear polarization angles for the incident light beam. A strong saturable absorption and a very clear nonlinear dichroic behavior were determined, the latter indicated by a sinusoidal modulation of the nonlinear absorption coefficient β (up to about 20% of its absolute value) as a function of the polarization angle. This result gives clear evidence of the formation of ordered arrays of embedded Au nanoparticles, corresponding to a honeycomb lattice symmetry with a modulation period of 30°.

Simulating Diffuse, Glossy and Specular Albedo Materials for Enhanced Bifacial Solar Module Output Shweta Pal and Rebecca Saive; University of Twente, Netherlands

Simulating diffuse, glossy and specular albedo materials for enhanced bifacial solar module output.

An effective way of improving photovoltaic (PV) yield while keeping the costs low is by using bifacial modules. As opposed to conventional monofacial modules, bifacial modules produce electricity by accepting solar irradiance from the front and the rear side. A crucial element in enhancing the bifacial output is the ground reflectance, *i.e.*, albedo. The module output strongly depends on the angle and wavelength of the incident irradiance and many nanophotonic light management strategies are particularly sensitive to these parameters [1, 2, 3, 4, 5]. Thus, understanding the spectral and angular albedo of the ground-reflector becomes important for the accurate understanding of albedo-dependent module output. Various sophisticated models [6, 7, 8, 9] help in calculating the bifacial output due to albedo but often use wavelength and/or angle averaged albedo.
To overcome this, we developed an albedo-centric reverse ray-tracing algorithm that can simulate short-circuit current density of a bifacial module under the influence of albedo materials with complex spectral and angular reflectance. The software can model a wide range of reflectors, *i.e*, diffuse, glossy [10], specular, and a combination of the three. It can also accommodate custom reflectors like metamaterials or free-space luminescent solar concentrators [11]. The algorithm also accepts any spectral and angular irradiance and tailored PV modules, while accounting for self-shading.
Our study shows that under AM1.5G illumination at 85° relative to the horizontal, a diffuse reflector outperforms a specular reflector for any value of module height and tilt. A diffuse reflector also proves to be more robust to the changes in module orientation and consequently, self-shading.
Such an approach can help in the fundamental understanding of the influence surface properties of a reflector on a solar module. It can facilitate in assessing the performance of currently existing natural and artificial reflectors and inspire ideas to devise novel albedo materials for higher bifacial output. Furthermore, when combined with the open-circuit voltage and local spectro-angular irradiance [12] measurements, the above methodology can assist in selecting the best module-albedo pair and their optimal configuration.

Two-Dimensional Fluorescence Mapping (2DFM) for the Non-Destructive Analysis of Band-Gap and Defect States in Inorganic and Organic Semiconductors Carole C. Perry, Daniel J. Oliver and Victor V. Volkov; Nottingham Trent University, United Kingdom

We report a novel approach to analyze bandgap and defect states within semiconductors by fluorescence spectroscopy using a plate reader conventionally used for the study of biological samples in solution. We use two-dimensional fluorescence mapping (2DFM) to deconvolve spectral signatures that would be superimposed in 1D-spectral space; for example, the 570nm emission peak in ZnO whose emissive state is of a different physical nature depending upon the excitation wavelength used. The broad applicability of the technique is shown for a library of widely studied inorganic semiconductors CdS, CdSe, ZnS, ZnSe, ZnO (analytical standard and nanorods) & TiO_2. Anthracene is also included as a representative example of an organic semiconductor. The 2DFM approach is able to identify spectral features from the bandgap, defects and trace impurities. The technique has applicability in both academic and industrial settings for semiconductor studies and quality control (QC) applications.

2:15 PM EQ05.28.06
Au Nanoparticles Embedded in ZnO Microstructures for Optical Security Applications Daniel J. Oliver, Victor V. Volkov and Carole C. Perry; Nottingham Trent University, United Kingdom

Composites of ZnO-Au are promising materials for use in optical security applications due to multiple aspects of the materials fabrication process impacting its spectral fingerprint. We report a one-pot strategy to synthesize ZnO-Au hetero-structures using a peptide chimera with sequence GLHVMHKVAYSSGAPPMPPF (ZA2). The novel ZA2 chimera combines most of a ZnO binding sequence, G-12 (GLHVMHKVAPPR) and a gold binding sequence, A3 (AYSSGAPPMPPF) that has been extensively studied in the literature. The one-pot peptide mediated synthesis was performed in the presence and absence of $HAuCl_4$ to separately determine the impact of the peptide and gold inclusions on the structural and electronic properties of the ZnO component. Using a combination of optical spectroscopy and electron microscopy we show that both spherical and non-spherical gold nano-inclusions were successfully embedded within the ZnO forming Ohmic contacts. Simulation of the plasmon resonance of nanoscale gold inclusions in ZnO using Mie theory and finite difference time-domain (FDTD) numerical approaches report on collective plasmon phenomena from embedded inclusions suggesting an inter-inclusion spacing of 10 nm or less and informs on the tuneable spectral nature of these materials. Spectra calculated using the FDTD approach show the synthetic approach described here has the potential to generate a library of materials with varying spectral features that could be used for identification purposes.

Enhancing Classical and Quantum Effects with Epsilon-Near-Zero (ENZ) Materials Jeremy N. Munday; University of California, Davis, United States

Materials whose dielectric functions approach zero have many unique properties ranging from enhanced non-linear behavior to suppression of quantum electromagnetic fluctuations. Beyond these interesting physical phenomena, epsilon-near-zero (ENZ) concepts can be applied to devices to exploit these effects. In this talk, I will discuss our recent work on the development of devices that take advantage of these effects to create super-absorbing optical films for novel photodetectors and hydrogen sensors, modified thermal emission, and quantum effects that can be exploited using ENZ materials. Two examples

of the later are the suppression of spontaneous emission and modifications to the Casimir force, a force that it purely quantum in nature and is related to the electromagnetic boundary conditions placed on vacuum fluctuations. We will conclude with an outlook for this emerging area of research.

Emission Control with Dielectric Metasurfaces Igal Brener; Sandia National Laboratories, United States

The spontaneous emission rates of emitters can be manipulated by tailoring the optical density of states of its local environment. Traditionally, this has been achieved through interaction of emitters with different types of photonic cavities. Using the same principles, metasurfaces and other types of nanostructured media have been used to control spontaneous emission of single and ensembles of quantum emitters. In this talk I will give an overview of the control and manipulation of spontaneous emission from different types of emitters (dopants in carbon nanotubes, excitons in two dimensional materials and epitaxial/colloidal quantum dots) using dielectric metasurfaces. Finally, I will describe how semiconductor metasurfaces can be used to control the directionality of spontaneous emission at ultrafast time-scales.

4:30 PM EQ05.29.02
Exciton-Polariton Lasing from a Bound State in the Continuum Fabrizio Riminucci[1], Vincenzo Ardizzone[2], Monica Lorenzon[1], Luca Francaviglia[1], Camille Stavrakas[1], Stefano Cabrini[1] and Daniele Sanvitto[2]; [1]Molecular Foundry, Lawrence Berkeley National Laboratory, United States; [2]CNR Nanotec, Italy

The achievement of thresholdless lasing is a long-sought goal for many applications. Yet, the inherent working principle behind lasers hinders its realization, due to the necessity to reach population inversion. An interesting strategy to overcome this limitation is based on exciton-polaritons. These hybrid light-matter excitations can undergo a phase transition to a coherent state, known as Bose-Einstein condensate, eliminating the requirement for population inversion.
In order to undergo this phase transition that leads to the emission of laser-like light, exciton-polaritons need to live long enough to macroscopically occupy a single quantum state. Up to now they have been mainly studied in vertical microcavities but their lifetime is usually limited by the quality of the mirrors and deep etching processes.
In this work we show exciton-polariton lasing from a bound state in the continuum (BIC), obtained via shallow patterning of a GaAs/AlGaAs slab. The extremely long lifetime of the BIC, alongside the high-quality post-processed cavity, allowed us to achieve an ultra-low lasing threshold in state-of-the-art polariton lasers. We focus on the impact of the nanofabrication processing over the polariton lasing from a BIC, leading to low threshold polariton condensation, and we characterize its emission in both real and reciprocal space.
In conclusion, this work unveils new possibilities of energy efficient coherent light sources to be used in future integrated photonic devices. Our new approach to achieve exciton-polariton lasing shows several advantages over the more classical vertical microcavities, since no mirrors are required and the etching needed to manipulate the photonic mode is only a few tens of nanometers. Aside from the interesting technological advantage, bosonic condensation in symmetry-protected photonic eigenmodes could also bring new topological properties onto macroscopic quantum states, which could give new insights on the spatial properties of BIC states.

4:45 PM EQ05.29.03
Controlling the Effective Bandgap of Epsilon-Near-Zero (ENZ) Nanoparticles Coupled to Quantum Emitters Tao Gong[1,1], Inigo Liberal[2], Miguel Camacho[3], Benjamin Spreng[1], Nader Engheta[4] and Jeremy N. Munday[1]; [1]University of California, Davis, United States; [2]Public University of Navarre, Spain; [3]University of Seville, Spain; [4]University of Pennsylvania, United States

Epsilon-near-zero (ENZ) materials have drawn significant research interest in recent years, owing to their unique electromagnetic/optical properties at the frequencies of vanishing real part of permittivity. Effects include negligible phase advances, strong spatial coherence, and enormous field enhancement at the interfaces with dielectric materials. They have found extensive applications in supercoupling, nanocircuit boards, ultrafast optical nonlinearity, perfect optical absorption, etc. In addition, ENZ materials have also been successfully exploited to modulate the spontaneous emission intensity, including the spectrum and directionality, of quantum emitters (QEs). Here we propose the concept of electromagnetic “bandgaps” for nanoparticles comprising an ENZ material. Depending on the frequency, the spontaneous emission of a QE in close proximity to a nanoparticle can be either substantially enhanced (as a result of the coupling into surface plasmon or dielectric resonances) or significantly suppressed (due to the lack of modes available for excitation around the ENZ frequency). Our theoretical results show an enhancement factor of ~38000 for the total emitted power at the surface plasmon resonance frequency and of ~0.002 for the radiatively emitted power around the ENZ frequency from a QE placed in close proximity of a low-loss ENZ sphere with a diameter of 600 nm, compared with that placed in free space. Even for realistic ENZ materials (e.g. ITO), enhancements of ~1610 and suppressions of ~0.13 are predicted. The effective bandgap of the nanoparticles can therefore be probed by tracking the radiated power from the emitter. Our research provides an alternative perspective to explore the correlation between plasmonic resonances, ENZ behavior, and spontaneous emission dynamics of quantum emitters.

5:00 PM EQ05.15.09
Neural Network Based Inverse Design of Organic Light-Emitting Diode Structures Sanmun Kim[1], Jeongmin Shin[1], Jaeho Lee[2], Chanhyung Park[1], Songju Lee[1], Juho Park[1], Dongjin Seo[1,3], Sehong Park[2], Chan Y. Park[3] and Min Seok Jang[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]LG Display Co., Ltd., Korea (the Republic of); [3]KC-ML2, Korea (the Republic of)

Organic light-emitting diodes (OLED) are widely used light-emitting diodes that utilize the light emission from an electron-hole annihilation inside an organic material. In an OLED device, the multiple reflections and the light interference inside a layered structure cause its optical characteristics to depend heavily on the device shape. Also, it leads to an angle dependence of the emission spectra while narrowing down the emission spectra. In this manner, an optimization process is required for any OLED device for the maximization of light extraction efficiency and color gamut. Some classical approaches have been made to optimize the structure but the results are hardly global optima since the global optimization requires heavy computation.
In the meantime, it has been reported that the neural network works as an excellent platform for calculating optical response of photonic devices, and tackling photonic inverse design problems[1,2]. In the field of OLED, machine learning techniques have also been performed to facilitate material screening processes[3]. However, no approach has been made to address the link between the device design parameters and the light extraction efficiency (LEE) of a

given OLED device for the purpose of the inverse design and optical performance optimization.

In this work, we present a neural network that receives the layer thicknesses and refractive indices as the inputs and predicts the LEE response of a given OLED structure. The network is trained with a dataset containing 260,000 structure parameter-LEE pairs which were obtained from the in-house Chance-Prock-Silbey (CPS) model[4]. The neural network was able to complete the spectrum predictions with 4×10^6 faster rate than the rigorous electromagnetic simulation based on CPS formulation depending on the degree of parallelization with RMSE of 1.86×10^{-3}. Two different routes were taken for the inverse design of LEE responses. One was the inverse neural network built by joining additional layers to the pre-trained forward neural network and the other was the neural network assisted genetic algorithm (NNGA) which uses the forward network as the platform for LEE prediction. NNGA showed superior performances in the inverse design of both existing and non-existing LEEs whereas the inverse neural network was unmatched in terms of the computation speed. The NNGA also successfully solves two representative OLED optimization problems: maximizing LEE and minimizing angle-dependent white color variation. Considering that both problems possess large design spaces that are difficult to be addressed by conventional numerical approaches employing rigorous electromagnetic simulations, the neural network-based methodology presented in this work provides a promising platform for tackling computation-heavy optimization tasks with one-time computation cost. Furthermore, different aspects of the neural network including its one-to-many mapping behaviour, extrapolability, and comparison between the inverse design methods were investigated extensively.

Fast and Rigorous Electromagnetic Simulation of Dipole Emission in a Periodically Corrugated Light-Emitting Diode Structure Based on Diffraction Tracking Chanhyung Park, Jeongmin Shin, Sanmun Kim, Juho Park and Min Seok Jang; KAIST, Korea (the Republic of)

Organic light-emitting diodes (OLED) have become one of the major light sources for display use due to high color accuracy and luminosity. The external light efficiency of conventional OLEDs ranges around 20% while the internal quantum efficiency approaches ~100%, which is sufficiently low. The discrepancy arises from the total internal reflection and a relatively large refraction index of emission layers. It has been reported that the external light efficiency of an OLED can be improved by introducing a periodically corrugated layer boundary [1, 2], but the effect has not been analyzed quantitatively. Electromagnetic analysis of a dipole layer in a periodically corrugated LED has been done previously [3], but the approach used in that work cannot deal with the emission from a single dipole, which is crucial for analyzing a periodically corrugated dipole layer. In this work, we demonstrate how the emission from a single dipole in a periodically corrugated LED structure can be calculated by diffraction tracking. We decomposed the light emission of a point dipole source into plane waves, and tracked each wave to calculate light emission. We tracked the diffraction and polarization conversion at a periodically corrugated layer boundary. Diffraction efficiency was calculated by rigorous coupled-wave analysis method (RCWA) [4]. We have confirmed that the results from our calculation model agree well with the simulation values from finite-difference time-domain method (FDTD) in terms of far-field image and light extraction efficiency (LEE) while alleviating the computational load by a significant amount. We even showed that the results from our calculation model agree well with FDTD methods at two-dimensional periodically corrugated layer boundary. We also implemented direct calculation of incoherent dipole layer in a periodically corrugated OLED, which makes our method more time efficient.
The advantages of our method become clear during the OLED structure optimization process. The diffraction coefficients obtained from the RCWA calculation depends only on the shape of the corrugation, hence the calculation for different dipole vertical/horizontal position, dipole orientation and different emission layer thicknesses can be completed with minimal computation. Also, the analysis involving multiple dipoles can be calculated in parallel, facilitating the optimization task even more.

Spin-Valley Locking Edge States Through Staggered Chiral Photonic Crystals Yeseul Kim, Minkyung Kim and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

Topological photonics mimic the topological condensed matter physics to transport the photons efficiently and robustly. In this poster presentation, we present spin-valley locking of edge states through staggered chiral photonic crystals in the two-dimensional honeycomb lattice. We demonstrate the bulk band dispersion with a bandgap in the spin-valley locked edge states and by using a coupled dipole method. And the spin-valley locking characteristics can be observed when the staggered chirality breaks the inversion symmetry.

Self-Assembled Soluble Organic Semiconductors John Anthony; University of Kentucky, United States

Solubilization of organic semiconductors is critical to enable a wide variety of deposition technologies. However, the selection and location of solubilizing groups must be made with great caer, to avoid disrupting critical intermolecular interactions. This talk will address weak, non-covalent interactions that can be used as supramolecular synthons to induce or enhance crystallization in organic thin films. I will also describe current efforts to harness computation and machine learning to enhance the design of high-mobility organic semiconductors.

11:00 AM EQ06.01.02
Controlling Structure-Property Relationships of Organic Semiconductor Thin Films Using Tunable, Highly-Ordered Self-Assembled Monolayers Ashley Conley, Joshua Choi and Gaurav Giri; University of Virginia, United States

Organic semiconductors are competitive with conventional amorphous silicon due to their solution processability at room temperature, which allows for the inexpensive, high-throughput fabrication of lightweight, flexible optoelectronic and electronic devices. Organic semiconductors are applicable in optoelectronic devices such as organic light emitting diodes, organic solar cells, and organic field effect transistors. An inherent disadvantage of organic semiconductors is their propensity to adopt multiple molecular packing motifs, a phenomenon called polymorphism, which can yield highly-contrasting charge transport capabilities and optoelectronic characteristics. More specifically, singlet fission, a photophysical process whereby one exciton is converted into two, has a significant dependence on molecular packing. However, controlling the molecular packing of organic semiconductors is difficult because the underlying crystal structure is dictated by weak Van der Waals forces, and thus, variability in the molecular packing arises from even minute changes in processing conditions.

In this study, the molecular packing of TIPS-pentacene (a small molecule organic semiconductor) was finely-tuned using highly-ordered, tunable self-assembled monolayers. TIPS-pentacene thin films were deposited from solution using solution shearing and subsequently relaxed on top of five ordered self-assembled monolayers. Through this method, various interface-stabilized polymorphs of TIPS-pentacene were isolated. Grazing incidence X-ray diffraction was used to characterize the distinct crystal structures, revealing repeatable and controllable, precise structural changes spanning less than 2 percent shift from bulk crystal structure. Photoluminescence spectroscopy and UV-Vis spectroscopy were used to discern structure-property relationships. We discovered changes in the bandgap transition energies as well as relative changes to the steady-state photoluminescence, suggesting that these interface-stabilized polymorphs have significant differences in intermolecular interactions.

Singlet fission is an exciting area of study that could result in the breaking of the Shockley-Quessar limit and be the basis for next generation solar cells, and are strongly influenced by intermolecular interactions. Singlet fission rates as a function of polymorph have been studied by other researchers; however, the polymorphs had significantly different crystal structures. Here, the finely-tuned interface-stabilized polymorphs puts us in a unique position to obtain a deeper understanding of the sensitivity of singlet fission on crystal structure by experimental means through the systematic structural changes. In conclusion, this work provides a novel method to control and explore structure-property relationships through the fine tuning of the molecular packing of small molecule organic semiconductors using highly-ordered, tunable self-assembled monolayers.

11:15 AM EQ06.01.03
Remarkable In-Plane Alignment Enabled by Unique Thermomechanical and Packing Behavior of the Conjugated Polymer PBnDT-FTAZ Harry Schrickx[1], Somayeh Kashani[1], Lauren Buck[1], Jeromy Rech[2], Wei You[2], Lee Richter[3], Harald Ade[1] and Brendan T. O'Connor[1]; [1]North Carolina State University, United States; [2]University of North Carolina at Chapel Hill, United States; [3]National Institute of Standards and Technology, United States

In-plane alignment of conjugated polymers leads to anisotropic optoelectronic properties that can be exploited for multiple applications, including polarization sensitive photodetectors, light emitting devices, and thin film transistors. For example, intramolecular charge transport along the polymer backbone is typically favored, and thus promoting alignment can improve charge mobility. Given that the primary optical transition dipole moment is oriented along the polymer backbone, the greater alignment leads to increased polarized light sensitivity in detectors or polarized light emission in OLEDs. Seeing as performance metrics improve as the degree of alignment increases, maximizing in-plane alignment is highly desirable. A popular strategy for aligning conjugated polymers is straining the film on an elastomer, however the degree of alignment achieved is often modest. To maximize the degree of anisotropy, we leverage the unique thermomechanical behavior and molecular structure exhibited in PBnDT-FTAZ by applying a combination of strain and post-strain thermal anneal. The annealing process leads to optical dichroic ratios surpassing 30, the highest known reported dichroism in conjugated polymers indicative of the remarkable alignment achieved.

To better understand the mechanism behind this striking film alignment, we conducted a detailed structural analysis. In-situ UV-Visible spectroscopy reveals the change in absorption anisotropy when the films are annealed past a temperature associated with aggregate relaxation. In addition, the formation of strong vibronic features observed under parallel polarized light and a shift in the absorption spectra indicate a transition to improved packing order. In-situ GIWAXS scans further confirm the increased packing order, as sharp peaks form through annealing and subsequent cooling of the film. These scans unearth a unique packing arrangement, as two populations of crystalline order appear with distinct out-of-plane tilts in the lamellar stacking direction. The dramatic shift in film morphology with thermally annealing is further uncovered with AFM scans, which show the formation of distinct plateau-like domains. Finally, we report how the molecular structure of PBnDT-FTAZ lends itself to the reported packing behavior. Through this work, we uncover how molecular structure and thermomechanics drive packing behavior, which can guide conjugated polymer design to realize films with exceptional in-plane polymer alignment.

11:30 AM EQ06.01.04
Enhancement of Electrical Conductivity in Conjugated Polymers by Post-Processing Side Chain Removal James Ponder, Shawn A. Gregory, Amalie Atassi, John R. Reynolds and Shannon K. Yee; Georgia Institute of Technology, United States

The processability and electronic properties of electroactive conjugated polymers (CPs) have become increasingly important due to the utility of these materials in numerous redox and solid-state devices. While the π-conjugated backbone structure is considered primarily responsible for imparting the core optoelectronic and electrochemical functionality of the material, solubilizing chains - appended to the backbone for processability - also play a significant role in tuning the morphological, redox, and electronic properties. To solubilize CP backbones, the side chains must be relatively long and are typically branched to induce many degrees of conformational freedom. Such side chains reduce the relative fraction of active material in the film, potentially obstructing π-π intermolecular interactions leading to increased localization of charge carriers, and compromise many of the desirable properties of the material (such as electrical conductivity). To reduce the deleterious effects of side chains, we report that post-processing side chain removal, exemplified here via ester hydrolysis, significantly increases the electrical conductivity of chemically doped CP films with a corresponding decrease in Seebeck coefficient. Using a variety of methods, we demonstrate that this change is not due to an increase in degree of doping, but an increase in charge carrier density and reduction in charge localization. Application of this method to high-performance ProDOT/EDOT copolymer structures yield significantly higher average conductivities, even outperforming any currently reported oligoether/glycol-based CP system. Finally, further structural modification yields a highly soluble material that can be processed from a wide range of solvents with an optimized conductivity of > 800 S/cm in thick films after post-processing side chain removal.

11:45 AM EQ06.01.05
Efficient Electronic Transport Through the Insulator-Rich Phase in PEDOT:PSS Blends Scott T. Keene[1], Wesley Michaels[2], Armantas Melianas[2], Tyler J. Quill[2], Elliot J. Fuller[3], Alexander Giovannitti[2], Iain McCulloch[4,5], Christopher J. Tassone[6], A. A. Talin[3], Jian Qin[2], Alessandro Troisi[7] and Alberto Salleo[2]; [1]University of Cambridge, United Kingdom; [2]Stanford University, United States; [3]Sandia National Laboratories, United States; [4]University of Oxford, United Kingdom; [5]King Abdullah University of Science and Technology, Saudi Arabia; [6]SLAC National Accelerator Laboratory, United States; [7]University of Liverpool, United Kingdom

Conductive polymers rely on side-chains[1] or blending[2] to improve solubility and processibility to fabricate thin films showing efficient electronic charge transport. One such blend, poly(ethylene dioxythiophene):poly(styrene sulfonate) (PEDOT:PSS), has become the most widely utilized conducting polymer because of its ease of processing, air stability, transparency, high electronic conductivity,[3] and more recently for its mixed ionic and electronic conduction.[4] However, the role of the PSS, which makes up 71% of the blend by weight, on the high conductivity is still unknown.[5] Like other conducting polymers, PEDOT:PSS phase segregates, leading to a semi-ordered, semiconductor-rich component (PEDOT-rich grains) which are surrounded by a less conductive insulator-rich matrix (PSS-rich matrix).[6] Here, we investigate the fundamental electronic charge transport through the insulator-rich phase to provide a more wholistic understanding of transport in PEDOT:PSS. We decrease the concentration of the conductor, PEDOT, by adding excess PSS and observe an exponential dependence of conductivity on PEDOT weight fraction. Surprisingly, a PEDOT:PSS blend consisting of < 3% PEDOT by weight displays a moderate mobility comparable to polyaniline. Using electrical characterization combined with molecular dynamics simulated microstructures, we show that inter-grain electronic transport through PSS-rich regions occurs via highly efficient tunneling between neighboring PEDOT chains. The results demonstrate the importance of the sidechain or blending polymer on efficient electronic transport and provides a framework for the molecular design of new conducting polymer systems.

1:30 PM *EQ06.02.01
Formation, Growth and Applications of Microcrystalline Organic Semiconductors Barry P. Rand; Princeton University, United States

Even though record organic semiconductor mobilities are reported for organic semiconductor single crystals, making thin film crystals remains challenging. We will present our efforts to understand crystal formation, and growth (epitaxy) of pinhole free films of numerous organic semiconductors with grains with dimensions of 100s of microns. We will explain how materials that undergo a transition from amorphous to crystalline correlate well with thermal properties. Homoepitaxial studies uncover evidence of point and line defect formation in these films, indicating that homoepitaxy is not always strain-free, but films always remain remarkable smooth (rms roughness never exceeds 5 nm). Transistors made out of large-grained films of rubrene display charge carrier mobility of up to 3.5 cm2 V–1 s–1, very close to single crystal values, highlighting their potential for practical application. Finally, we will show efforts in achieving heteroepitaxial growth of a different molecular material on top of a crystalline organic template.

2:00 PM EQ06.02.02
High Performance Molecular Rectifiers Based on Mixed Self-Assembled Monolayers Ryan Sullivan, John T. Morningstar, Mark E. Welker and Oana D. Jurchescu; Wake Forest University, United States

The chemical composition and degree of order in self-assembled monolayers (SAMs) is critically important to the properties of molecular electronic devices. We report on the synthesis and electrical response of a series of molecular rectifiers based on benzalkylsilanes in the form of SAMs anchored to a silicon substrate and tested with an Eutectic Gallium-Indium (EGaIn) top electrode. Mixed SAMs were formed via the co-absorption method by incorporating controlled amounts of different aliphatic silane-based additives into the film of the host SAM. The impact on the current-voltage characteristics, breakdown voltages, and static contact angle measurements provided insights into the degree of order and uniformity of the mixed SAM films. We discovered that despite a reduced degree of order introduced within the SAMs, small amounts of (3-aminopropyl)triethoxysilane (APTES) enhanced the current rectification of several materials, whereas, the other additives (such as n-propyltriethoxysilane) decreased the current rectification. We attribute this behavior to the APTES molecules acting as a dopant, thus allowing more efficient charge transport under forward bias. On the contrary, under reverse bias, the shorter dopant molecules do not make intimate contact with the top electrode, decreasing the effective surface area and overall conductance of the monolayer. The most significant improvement was measured in (E)-1-(4-carbomethoxy-phenyl)-N-(3-(triethoxysilyl)propyl)methanimine, where a three-fold increase in the rectification was found when mixed with APTES at an optimized 2:1 ratio, yielding an average rectification ratio of 4500, one of the highest reported values to date for molecular diodes on silicon.

2:15 PM EQ06.02.03
Quantifying Polaron Density in Molecularly Doped Semiconducting Polymers Adam J. Moule[1], Tucker L. Murrey[1], Goktug J. Gonel[1], Meghna Jha[1], Michael Berteau-Rainville[2], Nikolay Shevchenko[1], Jan Saska[1], Raja Ghosh[3], Alberto Salleo[4], Mark Mascal[1], Ingo Salzmonn[2] and Frank Spano[3]; [1]University of California, Davis, United States; [2]Concordia University, Canada; [3]Temple University, United States; [4]Stanford University, United States

Sequential solution doping is a processing technique that allows a conjugated polymer film to be doped from a solution that will not dissolve the polymer. We present here a method to predict the film doping level in cm^{-3} from the solution concentration used to dope the film. We show using four polymers and three newly synthesized molecular dopants that the doping level can be modeled using a simple Langmuir isotherm and fit to a single equilibrium coefficient. Analysis of the free energy derived from Keq yields a consistent thermodynamic model for molecular doping in polymers. We show that 50-75% of the polymer sites can be doped from solution. We compare Fermi level filling and electrochemical models for ionization efficiency of the dopant. In addition, analysis of the UV/vis/NIR and mid-IR spectra allows analysis of both the polaron sites and the neutral sites as a function of doping level. We show distinct differences between the spectral changes for polymers that when neutral formed H-aggregates rather than J-aggregates for both the neutral sites and the resulting polaron sites. Taken together we demonstrate a consistent and quantitative model for molecular doping that can be applied across different polymer and dopants.

2:30 PM EQ06.02.04
Polaron and Bipolaron Characteristics in Doped Conjugated Polymers Joel H. Bombile and Chad Risko; University of Kentucky, United States

Molecular doping is a powerful method to tune the electronic properties of solution-processed semiconductors based on π-conjugated polymers (CP), enabling high performance thermoelectric devices and thin film transistors. Despite the importance of doping, it is still challenging to predict how a given dopant will influence charge-carrier transport in semiconducting polymers. An accurate description of charge transport in these materials necessitates a good understanding of how polaron and bipolaron characteristics are affected by dopant counterions. We use first-principles calculations based on density functional theory (DFT) and time-dependent Density Functional theory (TD-DFT) with an optimally-tuned hybrid functional to determine various polaron characteristics in CP's with and without dopant counterion present. We find that the coulomb interaction between the polaron and the dopant counterion dictates the polaron size and is the dominant contribution to the polaron binding energy, exceeding polarization and nuclei reorganization. Both polaron size and binding energy play an important role in charge transport. We also find that the location of the induced charge along the polymer chain follows the counterion. As such bipolaron, which leads to faster charge transport, become more stable than polarons when the distance between dopant counterions is sufficiently reduced.

2:45 PM EQ06.02.05
The SLoT Model—A Language for Quantifying Fundamental Charge Transport Parameters in Chemically Doped Semiconducting Polymers. Shawn A. Gregory, Riley Hanus and Shannon K. Yee; Georgia Institute of Technology, United States

In this talk, I will present on the semi-localized transport (SLoT) model and demonstrate its ability to quantitatively compare fundamental charge transport parameters in semiconducting polymer-dopant-processing systems (see Gregory, Hanus, *et al.*, *Nat. Mater.* (2021)). The SLoT model spans the spectrum and captures both localized (hopping-like) and delocalized (metal-like) contributions to the observable electronic and thermoelectric properties by bridging the mathematical and physical formalisms from both polaronic transport models and the Boltzmann transport equations. Using the SLoT model, we can quantify fundamental transport parameters, such as the carrier ratio (carrier density) needed to exceed the transport edge, to what extent does localization (and its activation energy) decrease with increasing carrier density, and what is the hypothetical maximum electrical conductivity in the absence of localization. Although the SLoT model currently lacks chemical and structural predictive ability, the SLoT model provides quantitative transport parameters for each system that can be related to chemical and structural features; this enables a deeper understanding for why one system obtains different transport properties compared to another and could eventually lead to predictive ability. Lastly, I will compare the chemical, structural, and charge transport properties among several systems, which will illustrate the benefit to quantifying charge transport and developing structure-property relationships with the SLoT model.

4:00 PM *EQ06.03.01
The Role of Device and Semiconductor Fabrication in Measurement Development Emily G. Bittle; National Institute of Standards and Technology, United States

Enhancements or tailoring of organic device performance using unique physical effects requires benchmarking measurements that can be used across labs. Specific unique physical processes, such as singlet fission or dynamic disorder, are difficult to probe directly using standard electrical measurements. To develop new metrics that reflect unique physical processes, devices with researcher-defined properties are required to show reproducibility and reliability. Controlling device and semiconductor properties through fabrication is therefore extremely important. In this talk I will cover how we use controlled fabrication to develop measurements to look into device and semiconductor physics in working organic semiconductor transistors and light emitting diodes, including dynamic disorder, contact resistance, and singlet fission/triplet fusion.

4:30 PM EQ06.03.02
Spectroscopic Characterization and Electronic Transport in Conjugated Polymers Undergoing Post-Processing Side Chain Removal Amalie Atassi, James Ponder, Shawn A. Gregory, Natalie Stingelin and Shannon K. Yee; Georgia Institute of Technology, United States

Conjugated polymers are an increasingly important materials class for organic electronics mainly because of their immense chemical versatility. Generally, side-chains are introduced to induce straight-forward processability, *e.g.*, from solution. However, these chemical modifications also tend to affect local assembly and, in turn, specific optoelectronic properties such as charge transport. As a consequence, sample-to-sample variation can be significant. Here, we report an alternative pathway frequently used in the semiconducting small molecule area: side chain removal through post-processing hydrolysis. We selected a series of poly(dioxy thiophenes) as a model system and employed spectroscopic techniques utilizing X-ray, ultraviolet, and visible sources in combination with thermoelectric measurements to quantify the effects of side-chain removal on the extent of doping and charge transport properties. We find that cleaving the side chains does substantially alter the carrier density and increase the electrical conductivity. Additonally, through tuning of the repeat unit structure, different temperature dependencies in the electrical conductivity are found. Since X-ray photoelectron spectroscopy (XPS) suggests that tuning the repeat unit structure also affects core-level electron interactions, we will discuss the observed differences in the temperature-resolved electrical conductivity and extent of doping with the use of the semi-localized transport model. Moreover, by comparing the side-chain-cleaved systems to materials with complex, insulating side chains, we argue that the former polymers may provide a route towards semiconducting plastics of high processing reliability and a high conjugated backbone fraction.

4:45 PM EQ06.03.03
Nonlinear Impedance Spectroscopy to Characterize Hole Transport and Recombination Dynamics in Organic Semiconductor Devices Robin Rice; University of Vermont, United States

Impedance Spectroscopy (IS) is an increasingly common technique to characterize both solid state and electrochemical systems including solar cells and light emitting diodes (LEDs). However, IS relies on a system response being linear with its input such that a time invariant impedance can be defined. This is usually achieved by a small amplitude input. However, doing so suppresses responses of the nonlinear processes which are of considerable interest to those designing and optimizing these devices, such as charge carrier recombination and space charge effects. This investigation employs the recently developed nonlinear extension to IS (NLIS) based in Fourier analysis of the measured harmonic current such that a nonlinear definition of higher harmonic admittance (inverse impedance) is established. By relating Fourier coefficients of the measured current with derivatives of the voltage specific transfer function we may extract valuable physical parameters of the system in question. Benchmark tests of this technique on systems of known transfer functions will be presented specifically measuring hole mobility from space charge and the diode ideality factor from recombination limited current regimes. Finally, NLIS is used to characterise 2-(7-{4-N,N-Bis(4-methylphenyl)aminophenyl}-2,1,3-benzothiadiazol-4-yl)methylenepropanedinitrile (DTDCPB), a promising novel intramolecular charge transfer (CT) organic semiconductor (OSC). The first known report of DTDCPB hole mobility is presented.

5:00 PM EQ06.03.04
Can Vitrification Lead to Polymer:Dopant Glasses with High Electrical Conductivities and Low Thermal Transport? Hongmo Li[1], Olivier Bardagot[2], Stephen Barlow[1], Alejandro Vega-Flick[1], Juan Jose Alvarado-Gil[3], Renaud Demadrille[2], Seth Marder[1] and Natalie Stingelin[1]; [1]Georgia Institute of Technology, United States; [2]Univ. Grenoble Alpes, CEA, CNRS, IRIG, SyMMES, France; [3]Cinvestav Merida, Mexico

Here, we demonstrate that we can use vitrification at eutectic compositions as a tool to produce homogeneously intermixed, doped organic semiconductors with high electrical conductivity from solution. Doped organic semiconductors have found broad use as interlayers for organic light-emitting diodes (OLED), photovoltaic cells (OPV) and photodetectors. Doping, often, is achieved via addition of another species, an oxidizing or reducing agent – i.e., a dopant. However, many semiconducting polymer:dopant systems are not highly miscible, leading in many cases to undesirable phase separation and, thus, inhomogeneous film formation. As a consequence, polymer films are commonly doped via sequential doping methodologies, to achieve more homogenous dopant dispersion and, in turn, higher electrical conductivity. By using vitrification at eutectic compositions, we simplify the procedure towards homogeneously intermixed, high-conductivity polymer:dopant blends. We show that the highest electrical conductivities are found in the most vitrified regime, attributed to enhanced charge-carrier densities at these compositions as deduced from the spin densities measured in electron paramagnetic resonance. The question that remains is whether this eutectic vitrification also assists in keeping the thermal transport in such polymer:dopant blends low. For this purpose, we present thermal transient grating measurement data. Our work, thus, starts to provide a window towards a generally applicable structure/processing/property relationships to electron and charge transport in multicomponent macromolecular matter.

5:15 PM EQ06.03.05
Simulation-Guided Design of Organic Transistors for Cost-Effective, Scalable Electronics Matthew Waldrip[1], Yue Yu[1], Hamna Haneef[1], Iain McCulloch[2] and Oana D. Jurchescu[1]; [1]Wake Forest University, United States; [2]University of Oxford, United Kingdom

Interest in organic electronics is driven in large part by the applications they can address, yet a complete set of device fabrication design rules is still absent for the devices intended to fulfill those roles. Progress is assisted by general guidelines such as minimizing the Schottky barrier at injection interfaces or reducing defect states in the semiconductor layer, but improvements are achieved mainly through experimental trial-and-error, which is time, cost, and material intensive, and yields incremental results most of the time. Here we use physically-based numerical simulations to explore a vast parameter space with high throughput in order to generate rules for material processing and device design, with the goal of optimizing charge mobility and injection. We

then use these predictions to evaluate a “window” of device design where certain parameters can be relaxed in favor of cost effectiveness, but without a penalty in device performance. Examples include the contact interface and the quality/purity of the semiconductor, which we show can be compensated through adjustment of another parameter. We investigated the impact of the trap density of states (t-DOS) and the injection barrier on the charge carrier mobility in organic field-effect transistors (OFETs) for both high- and low-capacitance dielectric devices, in co-planar and staggered architectures. The simulations revealed that lowering the dielectric capacitance results in a device that is more permissive to an injection barrier, but that is also more sensitive to changes in the t-DOS; the reverse is true for increasing the dielectric capacitance. Additionally, the staggered architecture outperforms the co-planar structure when an injection barrier is present. These trends outlined a processing window for staggered-structure devices, wherein by tuning the dielectric capacitance one can raise the tolerance of traps or poor contacts. To test these predictions and take advantage of this processing window, we fabricated and characterized a variety of OFETs. We tuned the injection barrier via self-assembled monolayers (SAMs) while the trap density of states (t-DOS) was modified by altering the semiconductor film microstructure through processing and purity by synthesis method. Beginning with the case of OFETs with high-work function (SAM-treated) contacts and typical semiconductor processing, mobility changed very little with dielectric capacitance, in accordance with simulation: the high-capacitance devices (ca. 4 nF/cm^2) had mobilities of 1.5 ± 0.1 cm^2/Vs (average obtained on over 100 devices), while the low-capacitance devices (1.7 nF/cm^2) had mobilities of 1.6 ± 0.3 cm^2/Vs. In the low-capacitance devices, a nominal 0.4 eV injection barrier was introduced and devices still retained 80% of the average mobility value. (This is compared with a decrease in mobility of over 50% in the high-capacitance devices.) We then took advantage of the high capacitance window to fabricate OFETs with a low sensitivity to traps: mobilities varied by less than 15% even when the characteristic density of traps increased by over 40%. In summary, we have shown that the low-capacitance design window relaxes the requirement for a high contact work function, allowing the selection of more cost-effective and scalable materials, while the high-capacitance devices grant more lenient requirements for the quality of the semiconductor film.

Tuning the Peierls Bandgap in Planar, One-Dimensional Photonic Crystal OLEDs David Allemeier and Matthew S. White; University of Vermont, United States

Asymmetric optical properties of mirror electrodes in stacked microcavity OLED photonic crystals induces a Peierls bandgap in each photonic band. Here we explore the influence of the anode and cathode thicknesses on the bandgap and the bandwidth of the two sub-bands that result from the asymmetry. In the context of our device geometry, the silver anodes are shown to primarily control the Peierls bandgap and the aluminum cathodes are shown to tune the bandwidth of the upper and lower sub-bands. These effects are explained conceptually, modeled computationally, and resolved experimentally in the electroluminescence spectra.

EQ06.04.03
Late News: The Role of Molecular Aspect Ratio in the Roughness Evolution of Organic Thin-Film Crystal Growth Jordan Dull[1], Holly Johnson[1], Maria Clara Otani[1], Frank Schreiber[2] and Barry P. Rand[1]; [1]Princeton University, United States; [2]University of Tübingen, Germany

The roughness of a series of crystalline organic thin films are measured as a function of film thickness. From these data, the growth exponent of each material is extracted and plotted against the molecular aspect ratio. We find that more three dimensional molecules (low aspect ratio) tend to remain smooth as film thickness increases, in contrast to planar or rod-like molecules (high aspect ratio) which quickly roughen. This suggests that the average Ehrlich–Schwoebel barrier at a molecular step edge for low aspect ratio molecules is smaller than it is for high aspect ratio molecules. These results point to the use of low aspect ratio molecules in crystalline organic electronics because of their ability to remain smooth as thickness is tuned.

EQ06.04.04
Late News: Synthesis of an Organometallic Aluminum Compound for Monolayer Doping of Silicon Wafers Alex J. Taylor, Santosh Kurinec and Scott Williams; Rochester Institute of Technology, United States

Synthesis of an aluminum complex containing a functional mordant group will be presented. The functional vinyl group is designed to coordinate with silicon radicals on the surface of an etched silicon wafer. This process is called monolayer doping. FTIR, Raman, and NMR spectroscopy were used to analyze the different organometallic dopant compounds. A dried derivative of aluminum isopropoxide was found to have FTIR and Raman Peaks of 1612 and 3116(1/cm), which are indicative of the presence of a vinyl group. NMR spectroscopy shows peaks around 6.4ppm which is also indicative of a vinyl group on the compound. Tris(2,4-pentanediono) aluminum(III) was synthesized with aluminum chloride and acetylacetone in an aqueous solution. The reaction between the dopant and the silicon radicals creates a uniform layer of dopant-wafer bonds on the wafers surface. Silicon wafers have been successfully doping using this method. The doped wafer is washed and dried to remove any non bonded dopant from the surface of the wafer. A 70nm capping oxide is applied to the wafer using Plasma Enhanced Chemical Vapor Deposition (PECVD). The wafer is then heated to 1100 degrees Celsius for a variable amount of time between 10 to 40 seconds using Rapid Thermal Annealing (RTA). This drives the dopant into the lattice of silicon wafer and turns the wafer into a p-type semiconductor wafer. Resmap sheet resistance analysis of doped wafers has shown that there is an inverse relationship between annealing time and surface resistance.

EQ06.04.05
Late News: Seed-Induced Crystallization of Molecular Thin Films via Physical Vapor Deposition for Versatile Optoelectronic Applications Kwang-Won Park, Raaghesh Vijayan and Trisha L. Andrew; University of Massachusetts Amherst, United States

Growth of molecular semiconductor thin films with better ordering and uniformity is crucial for devising organic optoelectronics with better performance. A highly ordered and crystalline organic semiconductor thin film can be an ideal active layer owing to its charge transport ability. However, luminescence materials become less efficient when fabricated into solid films, which is known as aggregation-caused quenching. Thus, the luminescent materials are often doped in host materials or remained amorphous to suppress the aggregate formation, even though crystalline films have higher charged carrier mobilities. To address this issue, luminescent molecular rotors have been suggested, that exhibits aggregation-induced emission behavior, which is opposite to the aggregation-caused quenching effect. Nevertheless, for some organic molecules, it is challenging to form crystalline thin films upon substrates, and

their unique optoelectronic properties can be ignored.
Here, we investigate the thin films of 5,11-diphenylindeno[1,2-*b*]fluorene-6,12-dione (**Dp-IFD**) prepared by physical vapor deposition. Because pristine **Dp-IFD** thin films barely crystallize even after thermal treatment and have poor optical as well as electrical properties, **Dp-IFD** thin films have not been exploited to date. However, we discovered that crystalline **Dp-IFD** thin films can be readily achieved by sequential deposition of coronene seed layer and **Dp-IFD** molecules without breaking vacuum. Current atomic force microscope (c-AFM) measurement and space charge limited current (SCLC) devices showed that crystalline **Dp-IFD** can support 4 orders of magnitude higher electron mobility. Crystalline **Dp-IFD** thin films also exhibited brighter fluorescence emission with longer lifetime than their amorphous counterparts. Furthermore, we demonstrated versatile applications of the **Dp-IFD** thin films, such as organic solar cells (OSCs) and light emitting diodes (OLEDs), owing to its veiled superior optoelectronic properties.

EQ06.04.06
Late News: Self-Assembly of Block Copolymers for the Formation of Electronic Devices Using DNA Origami Dulashani Ruwanthika Ranasinghe Weerakkodige, John N. Harb, Robert C. Davis and Adam T. Woolley; Brigham Young University, United States

DNA origami is a powerful method to create structurally versatile, highly addressable, and distinct nanoscale objects to facilitate the field of electronics. Controlled placement of DNA origami is essential to build functional devices like biochips, electronic circuits, sensors, and optical or photonic devices. Block copolymer (BCP) self-assembly can be utilized for next-generation lithography for the advanced nanopatterning of surfaces. Here we present a method of using a BCP as a mask to create a patterned surface, rendering it capable of selective attachment of DNA origami that will eventually become the base of the electronic device. We use a polystyrene (PS) co-poly(methylmethacrylate) (PMMA) block copolymer, PS(S-b-MMA), which has cylindrical nanodomains of PMMA. These cylindrical nanodomains can be oriented normal to the surface with controlled interfacial interactions. Exposure to UV radiation then degrades the PMMA and crosslinks the PS matrix, resulting in a nanoporous film on silicon surfaces after sonicating with acetic acid and oxygen plasma etching. We investigated the process window for forming ordered arrays of nanoscale polymer cylindrical domains perpendicular to the thin films, including the effect of substrate surface treatment, spinning conditions, annealing conditions, and film thickness. The cylindrical nanodomains that are perpendicular to the film surface have ~15 nm diameter. We will use the etched PS-PMMA thin films as a mask for gold deposition. DNA origami modified with thiol groups can then be used to attach to these surface-patterned gold islands selectively. The ability to position DNA origami in a controllable manner will facilitate the integration of DNA-based materials into nanoelectronic and sensor devices where we will deposit electrically conductive metallic or/and semiconducting materials. The electronic characterization will be performed to reveal the ability to use these devices in the future. This work will contribute to the field of using organic BCP and hybrid materials contribution for future electronic and sensor devices.

EQ06.04.07
Electrodeposition of Silver Nanowire-Based Transparent Conductive Flexible Electrode for Organic Light-Emitting Diodes Sy H. Pham[1,2], Anthony Ferri[2], Antonio D. Costa[2], Rachel Desfeux[2] and Philippe E. Leclere[1]; [1]University of Mons, Belgium; [2]Université d'Artois, France

The transparent conductive electrode (TCE) based on a silver nanowire network (AgNW) has demonstrated high optical transparency, low sheet resistance and shows a range of potential applications in flexible electronics. However, the number of junctions and the junction resistance are the parameters governing the conductivity of the electrode and eventually limiting the applications of AgNW networks if left as it. In this work, the electroplating method was employed to decorate an Ag thin layer on AgNW-junctions to improve the contact resistance of the network. As a result, the AgNW-TCE on flexible PET substrate exhibits a sheet resistance as low as 10 Ohm/sq associated with a transmittance larger than 90% measured at $\lambda = 550$ nm by optimizing the experimental conditions. The contribution of the decorated-AgNWs network on the electric behavior of the electrode was also highlighted at the nanoscale using the conductive Atomic Force Microscopy (c-AFM). The obtained results allow us to propose a feasible process for the preparation of TCE using flexible displays, organic light-emitting diodes, and thin-film solar cells

EQ06.04.08
Functional Polymer Semiconductors from a Universal Approach for Human-Integrated Electronics Nan Li, Yahao Dai, Yang Li and Sihong Wang; The University of Chicago, United States

Polymer semiconductors based on π-conjugated structures have shown distinct promise for the development of human-integrated electronics, owing to their solution processability for large-area fabrication, mechanical softness and even stretchability, as well as low cost. However, among the wide range of functional properties required for this application domain (including, but not limited to, biochemical sensing, chemotherapeutic property, bio/immune-compatibility, micro-patternability, stimuli-responsiveness), a number of them face synthetic challenges to be imparted onto conjugated polymers and thus combined with efficient charge-transport property. Here, we develop a “click-to-polymer” (CLIP) synthesis strategy for conjugated polymers, which enables the use of a click reaction for the facile and versatile attachment of diverse types of functional units to a pre-synthesized conjugated-polymer precursor. This can be utilized to realize both bulk and surface functionalization in/on the deposited thin films. Through demonstrating the applicability on four types of functional groups that each carry distinct emerging properties, for instance, ion conduction and immune-modulation, we show that functionalized polymers from this CLIP method can still retain good charge-carrier mobility above 0.1 square centimeters per volt per second. On the other hand, the surface functionalization does not cause any influence on the mobility. We take two of the realized polymers to showcase the capability of imparting new functions to conjugated polymers: photo-patternable property and biochemical sensing function, both of which advance the state of the art of realizing these two types of functions on conjugated polymers. In the future, we expect the expanded use of this synthesis approach will largely enrich the functional properties from conjugated polymers and facilitate the electronic-biological interfacing.

Thermodynamic Study of Nucleation and Growth Process During Preparation of Manganese-Cobalt Oxide Supercapacitor Electrodes by Photonic Curing Najma Khatoon, Madhu Gaire and Douglas B. Chrisey; Tulane University, United States

Metal oxide-based nanomaterials are an important class of materials because of their unique physical and chemical properties. Various techniques are being used to synthesize metal oxide-based nanomaterials. Gaire *et al.*[2] reported binder free manganese-cobalt oxide supercapacitor electrodes with ultra-long cycle life. In this work, we employed photonic curing using PulseForge 1300 (NovaCentrix, Austinx, TX) to synthesize manganese-cobalt (Mn-Co) mixed oxide nanostructures and monitored the process of nucleation and growth during the synthesis process. A mixture of Mn and Co organometallic precursor was deposited on Pt-Si substrate using an air-spray, and processed using PulseForge in ambient conditions. To study the effect of processing conditions on nucleation and growth of nanostructures, processing parameters, such as power and number of pulses were varied while overall pulse fluence was kept constant. We varied power from 400 V to 700 V and number of pulses from 1 to 7 to achieve constant overall fluence of 16 J/cm^2 for each sample. A simulating tool for photonic curing based on transient 1-D heat conduction model (SimPulse) is used to simulate the temperature dependent thermal and material properties. SimPulse provided real time thermodynamic profile of Mn-Co mixed precursors as a function of thickness of the films. Our results give an insight into the nucleation and growth process of thin films as a function of energy per pulse and shows that by varying the fluence per pulse and number of pulses, nucleation, and growth changes. At high-energy fluence per pulse, the first pulse causes photodecomposition of the organometallic

precursor, and subsequent pulses result nucleation and growth, and high-temperature chemical reactions to form crystalline non-equilibrium states of metal oxides within a porous film. We observed that pulse design plays a crucial role in the nucleation and growth of nanostructures, even when overall fluence is kept constant. Our study shows that photonic curing can be utilized as a technique to tune the properties of the nanostructures by controlling nucleation and growth. It provides better understanding of nanometric control of complex materials for next generation energy applications.

Multisource Vacuum Deposition of Methylammonium-Free Perovskite Solar Cells Yu-Hsien Chiang, Miguel Anaya and Samuel D. Stranks; University of Cambridge, United Kingdom

Organic-inorganic halide perovskites of the form ABX_3 have shown outstanding properties for solar cells. The popular compositions consist of mixtures of A-site cations methylammonium (MA), formamidinium (FA) and cesium, and X-site iodide and bromide ions, and are produced by solution processing. It is an open question whether solution processing could produce sufficient spatial performance uniformity for photovoltaic modules or compatibility with multilayered tandem solar cell deposition. In addition, the volatile MA cation presents long-term thermal stability issues. Here, we report the multisource vacuum deposition of $FA_{0.7}Cs_{0.3}Pb(I_{0.9}Br_{0.1})_3$ perovskite thin films with high-quality morphological, structural, and optoelectronic properties. We find that the controlled addition of excess PbI_2 during the deposition is critical for achieving high performance and stability of the absorber material, and we fabricate *p-i-n* solar cells with a power conversion efficiency of 20.7%. Also, the operational stability test shows ~95% of its initial efficiency after 100 hours. We also reveal the sensitivity of the deposition process to a range of parameters, including the type of substrate, annealing temperature, evaporation rates, and source purity, providing a guide for further evaporation efforts. Our results demonstrate the enormous promise for MA-free perovskite solar cells employing industry-scalable multisource evaporation processes.

EQ06.04.12
Rapid Photonic Sintering of Printed Inks to Control Thermal Effects in FHE Substrate Materials Charles Trudeau[1], Bilge Nazli Altay[2], Patrick Beaupré[1], Sylvain G. Cloutier[2] and Martin Bolduc[3]; [1]INO, Canada; [2]École de Technologie Supérieure, Canada; [3]UQTR, Canada

Additive manufacturing has been evolving towards flexible substrates for the fabrication of printable and flexible hybrid electronic (FHE) devices and circuits. Generally flexible thin polymer or paper-based, these emerging substrates suffer from their heat sensitivity and/or low glass-transition temperatures. Photonic and laser sintering has shown great promise in maintaining the integrity of the substrates without structural degradation due to shrinkage, charring or decomposition. The rapid sintering process arises from microseconds to milliseconds at high temperatures onto printed functional ink traces, in order to reduce the thermal diffusion occurring into the thermally sensitive substrate materials. The minimum sheet resistance value of the conductive traces is then obtained after the proper sintering process. These results are supported by numerical models using finite element methods of the optical wavelength induced thermal dynamics in materials.

In this paper, flash lamp [1] and laser sintering [2] techniques show optimized sheet resistance values for inkjet and screen printing silver and copper inks from 0.2 Ω/sq on PET to 4 Ω/sq on SBS paper obtained at very high speed and spatial precision in comparison with conventional oven annealing. In addition, both these techniques provide a greater control over the electronic properties of the resulting conducting ink traces, while providing a more energy-efficient process within rapid processing times. The simulation results suggest that carefully controlling the heating rates within the ink volume is critical to avoid structural surface defects and achieve optimal sheet resistance values for the sintered functional inks. The research is presented in a perspective of a technology applications development for next generation of FHE sensors and interconnectors.

EQ06.04.14
Complete Haze and Transparent Film by Embedding Air-Gaps for Elimination of Angular Color Shift in Organic Light-Emitting Diodes Wonseok Cho[1], Jae Yong Park[1], Sangwon Baek[1], Kihyon Hong[2] and Jong-Lam Lee[1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Chungnam National University, Korea (the Republic of)

Top-emitting organic light-emitting diodes (TOLEDs) are preferred over bottom-emitting structures in terms of high aperture ratio and switching circuit integration. The device structure of typical TOLEDs consists of a metallic electrode on the top and another on the bottom, with organic layers sandwiched between them. Such electrodes induce a Fabry-Perot resonance, which is called the microcavity effect; it gives high device efficiency and high color purity. However, in most TOLEDs show viewing angle (*v*) dependence of luminance spectrum; the emission peak tends to be blue-shifted with increasing *v*. This phenomenon occurs strongly in white-color displays, which are achieved by combining red, green, and blue (RGB) sub-pixels: this is called white angular dependency (WAD). It distorts the color gamut as *v* increases, thus should be eliminated from TOLED displays.
Several methods have been introduced to reduce WAD in TOLEDs. One is to detune the thickness of the microcavity structure. However, tuning the thickness of active layers requires multiple masking processes, and reduces device efficiency. Another approach is to apply a light-scattering layer on top of the TOLEDs without otherwise changing device structure. The light that passes through the scattering layer spreads in random directions, and lights emitted at different angles are merged, so averaged light is extracted regardless of *v*, resulting in suppressed WAD. The light-scattering layers can be achieved by producing nanostructures on the film, but it could be easily damaged and scratched by external mechanical stimuli, resulting in degraded optical properties.
By embedding a high refractive index (RI) nanoparticles in polymer film could be a solution to get a robust property of the scattering film. In fact, there was a trade-off relation between haze and total transparency. Namely, the haze increases with the density of nanoparticle, but total transparency decreases, and vice versa. Such problems could be solved by employing a scattering center with RI = 1.0, air-gap embedding polymer film. The air-gap with RI=1.0 could act as not only a scattering center due to the difference of RIs between the air-gap and its surrounding polymer, but also optically transparent one. Here, we design the optimal size and distribution of air-gap to suppress WAD in RGB TOLEDs, and demonstrate the air-gap embedded hazy film (AEHF). To design the air-gap, rigorous coupled-wave analysis (RCWA) was systematically calculated with respect to the various geometries of the air-gap such as size and period. Based on the simulation results, we demonstrated the AEHF by coating the viscous resin, poly(dimethylsiloxane) (PDMS), on the patterned polymer substrate. By using patterns with a high aspect ratio (AR) during the coating procedure, the geometries of embedded air-gap were increased compared with using patterns with low AR. From the several experimental data, the geometries of the air-gap which were embedded between high AR patterns were similar to the simulation results, realizing a high haze of ~100% while retaining a high average total transmittance of 88%. Consequently, the hazy film is utilized in TOLEDs and the WAD can be dramatically reduced about > 90 % in the RGB wavelength.

EQ06.04.15
Variations in Surface Morphology and Thin Film Properties of Thermally Damaged Top-Emission Organic Light-Emitting Diodes Changmin Lee, Wonho Lee, Geon Woo Jeong, Dong Hyun Kim, Dong Hyun Choi, Tae Wook Kim, Hyung Ju Chae, Amjad Islam, Sung Tae Shin and Seung Yoon Ryu; Korea University, Korea (the Republic of)

In the past few years, several properties of organic layers used for thermally damaged top-emission organic light-emitting diodes (TEOLEDs) have been investigated. However, the surface morphology of organic layers has not been fully explored yet. In this work, surface morphology of stacked layers and cathode used for thermally damaged TEOLEDs are evaluated. Thermal damage is caused by the exposure temperature obtained from the Cu deposition on TEOLEDs, which affects device performance. Because of the low glass transition temperature (T_g), the phosphorescent host material 4,4′bis(N-carbazolyl)-1,1′-biphenyl (CBP) is rapidly degraded to a large extent, changing its surface morphology, optical and geometrical properties.
A severe morphological change due to thermal damage occurred in the excitons blocking layer, tris(4-carbazoyl-9-ylphenyl)amine (TCTA), even below its T_g, owing to the intense variation in the refractive index. Therefore, both the optical and surface morphological properties of TCTA were affected under thermal damage, whereas only the surface morphological properties of the hole-transport layer, N,N′-di(1-naphthyl)-N,N′-diphenyl-(1,1′-biphenyl)-4,4′-diamine (NPB), were changed. However, the optical properties of the thick NPB remain constant despite a lower T_g than that of TCTA. Unexpectedly, increasing temperature has an effect on the hole-transport layer (NPB), the excitons blocking layer (TCTA) and the overall electroluminescence spectra and micro-cavity without affecting device performance much. The surface morphology of upper electrode (Mg:Ag) was cracked due to the difference between the thermal expansion coefficients. Moreover, electrical property of cathode was also affected by thermal damage with increasing its sheet resistance. The wrinkle structure from the full-stacked organic layer was observed, which greatly affected to the micro-cavity and optical properties. Hence, this study reveals that besides T_g, the surface morphologies and thicknesses of the organic layers are also important factors in the annealing process and play a vital role in causing thermal damage to TEOLEDs. To avoid film morphological changes, these findings highlight the need of adopting thermally stable materials in TEOLED devices.

EQ06.04.16
Late News: Highly Bendable Piezoelectric Sensor Fibers via Thermal Drawing Method Seungmin Lee, Quang V. DUONG, Namhun HER, Nhi T. LAM and Seung Tae CHOI; Chung-Ang University, Korea (the Republic of)

Fiber rather than other structures and morphologies such as films or membranes is a promising path for wearable electronic systems, because this long and flexible fiber can be weaved or knitted easily, seamlessly into multifunctional fabrics. Among various fiber-based sensors, piezoelectric fibers, based on polyvinylidene fluoride (PVDF) and poly(vinylidene fluoride-trifluoroethylene (P(VDF-TrFE)), are especially attractive, since they are sensitive and reliable, and show high durability in a compact structure. Recently a novel fabrication technique, named thermal drawing (TD) technique, has been frequently performed to fabricate piezoelectric fibers. TD of multimaterials having different flowability at drawing temperature requires amorphous cladding such as polycarbonate (PC) or poly(ether-sulfone) (PES), of which melting temperature is higher than the other materials, to stabilize the TD process. However, these claddings greatly reduce the mechanical flexibility of fibers at room temperature, and it is difficult to selectively remove them for additional treatments such as electrode interconnection.
In this study, we propose a highly amorphous P(VDF-HFP) copolymer as the cladding material for piezoelectric sensor fibers, of which melting temperature and yield strain are known to be 122 °C and about 18%, respectively. Preform fabrication must be preceded to draw fiber through the TD process. P(VDF-TrFE) film is sandwiched between two electrically conductive composite sheets made of carbon black (CB) and polypropylene (PP), and the piezoelectric device is cladded in P(VDF-HFP) copolymer. Incompatibility of flow characteristics at drawing temperature among P(VDF-HFP), P(VDF-TrFE), and CB/PP composite requires optimization of preform geometry and TD parameters. The preform is transformed into a fiber of length more than 50 m via the TD process. The drawn fiber is stored at 140 °C for 12 hours to increase the crystallinity of the P(VDF-TrFE) polymer. The high solubility of P(VDF-HFP) to polar solvents such as acetone facilitates electrical interconnection through selective etching. The drawn piezoelectric fiber can be directly poled through the two CB/PP electrodes with the electric field of 40 MV/m for 45 minutes. The fabricated piezoelectric fiber produces about 5 V (V_{pp}) under 5% tensile strain and 0.5 V (V_{pp}) under bending deformation with a radius of curvature of 10 mm. Furthermore, the piezoelectric fiber can withstand large bending deformation of 1 mm radius of curvature without any severe degradation in the output voltage.

EQ06.04.18
Late News: Effect of Solvents on the Performance of Solution-Processed Organic Light-Emitting Diodes Taesoo Lee[1], Jaehoon Kim[2], Changhee Lee[3] and Jeonghun Kwak[1]; [1]Seoul National University, Korea (the Republic of); [2]Los Alamos, Korea (the Republic of); [3]Samsung Display, Korea (the Republic of)

The solution-processed organic light-emitting diode (s-OLED) is being actively studied for its advantages such as low-cost fabrication and large area application, but the efficiency and stability of s-OLEDs are still lag behind those of the evaporated devices (e-OLEDs). Many articles point out the film aggregation and pinholes as the main reason for the inferior properties of s-OLEDs, but here we highlight the chemical influence of solvents on the organic materials composing the emissive layer (EML). The investigation on the device performance of s-OLEDs is conducted with two different solvents dissolving CBP:$Ir(ppy)_3$—chloroform (CF) and tetrahydrofuran (THF). Comparing the device performance of s-OLEDs with e-OLEDs, the CF-based device exhibits remarkably degraded properties whereas THF-based device shows less deviation from e-OLEDs. With the Fourier-transform infrared spectroscopy (FTIR) measurement, we analyze the device degradation of CF-based devices in detail. The FTIR results strongly imply that the residual CF solvent can accelerate the chemical degradation of the emissive layer, changing the bond length and force constant of CBP:$Ir(ppy)_3$ film. Although further researches are required to perfectly unveil the mechanisms of CF-related degradation, our work will provide useful insights into realizing the commercialization of s-OLEDs.

Morphological and Electrochemical Properties of Vanadium Pentoxide Thin Films Deposited by Ultrasonic Spray Deposition Method Yusuf Tutel[1], Mete Batuhan Durukan[1,1], Seyma Koc[1], Serkan Koylan[1], Huseyin Cakmak[2], Yusuf Kocak[2], Farzaneh Hekmat[1,1], Emrah Ozensoy[2,2], Ekmel Ozbay[2,2], Levent K. Toppare[3] and Husnu E. Unalan[1,1]; [1]Middle East Technical University (METU), Turkey; [2]Bilkent University, Turkey; [3]Middle East Technical University(METU), Turkey

In the past decades, metal oxide semiconductors have received significant attention due to their unprecedented properties to be used in applications like electronics, optoelectronics, electrochemistry, sensors, and catalysis. Among them, vanadium pentoxide (V_2O_5) shows promising thermal, chemical and electrochromic properties as it is the most stable phase within other vanadium-oxides with an oxidation state of 5. Electronic applications of V_2O_5 films necessitate deposition of thin, homogeneous and crack-free layers thus they show low resistance and high carrier diffusion lengths. To date, various methods were used to deposit V_2O_5 thin films such as thermal evaporation, chemical vapor deposition, sputtering, sol-gel process and spray pyrolysis. Ultrasonic spray deposition (USD) method is another technique that allows the deposition of thin films over large areas. Moreover, this method is significant candidate to deposit thin films due to its good properties such as high material utilization, relatively low-cost processing and non-vacuum

requirement. Besides, it allows repeatable build-up of high-purity thin films. In this work, V_2O_5 thin films were deposited onto pre-heated fluorine-doped tin oxide/glass substrates using USD method. The effect of post deposition annealing temperature on the structural, morphological, optical and electrochromic properties of V_2O_5 thin films have been systematically investigated. Upon annealing over 450 °C, all films showed crystalline morphology while as-deposited films were in amorphous nature. XPS analyses demonstrated the oxidation state of vanadium ions of all deposited films following post deposition annealing was +5. Films have shown visible transmittance with optical band gap values in the range of 2.57 to 2.66 eV as a function of annealing temperatures. Deposited V_2O_5 thin films were also electrochemically tested. Cyclic voltammetry (CV) results with a fast scan rate of 100 mV/s showed that the color of the electrodes was initially yellow and then turned into blue and green at the reduced state for the annealed films. CV results proved the multichromic nature of V_2O_5 thin films. The cycling performance of the V_2O_5 thin films was assessed by assembling an asymmetric cell, which showed promising cyclic stability up to 1000 cycles. Results provided herein indicated that USD method is highly suitable for the deposition of functional V_2O_5 thin films over large areas.

Semiconducting—Insulating Polymer Blends Targeted for Flexible Optoelectronic Applications Natalie Stingelin; Georgia Institute of Technology, United States

In recent years, immense efforts in the flexible electronics field have led to unprecedented progress and to devices of ever increasing performance. Despite these advances, new opportunities are sought in order to widen the applications of organic-based technologies and expand their functionalities and features. For this purpose, use of multicomponent systems seems an interesting approach in view of, *e.g.*, increasing the mechanical flexibility and stability of organic electronic products as well as introducing other features such as self-encapsulation. One specific strategy is based on blending polymeric *insulators* with organic semiconductors; which has led to a desired improvement of the mechanical properties of organic devices, producing in certain scenarios robust and stable architectures. Here we discuss the working principle of semiconductor:insulator blends, examining the different approaches that have recently been reported in literature. We illustrate how organic field-effect transistors (OFET)s and organic solar cells (OPV)s can be fabricated with such systems without detrimental effects on the resulting device characteristics even at high contents of the insulator. Furthermore, we review the various properties that can be enhanced and/or manipulated by blending including air stability, mechanical toughness, H- *vs.* J-aggregation, *etc.*

11:00 AM EQ06.05.02
3D Printed Flexible Polymer Light Emitting Diode Displays Ruitao Su[1], Sung Hyun Park[2] and Michael C. McAlpine[1]; [1]University of Minnesota, United States; [2]Korea Institute of Industrial Technology, Korea (the Republic of)

Additively manufacturing light emitting diode (LED) arrays entirely on 3D printers will enable a new and unprecedented capability to create large scale displays in a freeform manner, untethering the process from highly specialized microelectronic fabrication facilities. Fully 3D printing optoelectronics further allows for a high adaptability to varying device form factors and fabrication scales. However, current material systems and printing methods for optoelectronics present several issues to fully 3D printed LED arrays. First, the fabrication of electrodes and encapsulation layers composed of metal-oxides or solid-state metals requires sputtering or vapor deposition processes that are not compatible with 3D printing platforms. Second, active layers that are printed by solution deposition possess a high degree of layer nonuniformity as a result of the directional mass transport within the printed droplets driven by the capillary flow. Lastly, creating repeatable and stable polymer-metal junctions between the emissive layer and cathode at room temperature has proven to be challenging on 3D printers, which should also set the stage for mechanically and electrically interfacing the cathode arrays with spatially structured interconnecting wires.

Here we report a novel device configuration and a multimodal 3D printing methodology that leads to fully printed, encapsulated and highly flexible organic LED (OLED) displays. To solve the previous printability issue for electrodes and encapsulation materials, we select inks that are in the states of solution, liquid, paste and resin. While the electrodes are extrusion printed with metallic nanoparticles and a eutectic liquid metal, the active layer is spray printed with a semiconducting polymer, poly2-methoxy-5-(3′,7′-dimethyloctyloxy)-1,4-phenylenevinylene (MDMO-PPV). Compared to extrusion printed devices, OLEDs with spray printed active layers demonstrated an improved irradiance and lifetime, attributable to the reduced barrier to charge transport, along with tunable electrical characteristics via the layer thickness. Further, by leveraging the yield-stress behavior of the oxide shell that wraps the liquid metal droplets, we implement a mechanical compression process to reconfigure the morphology of the cathode array and yield an improved contact area for the polymer-metal junction. The repeatable reconfiguration process creates a spatially uniform liquid metal array to be interfaced with the extrusion printed top interconnects. Finally, the device was encapsulated with polydimethylsiloxane (PDMS) that is cast into an extrusion printed silicone holder to form a flexible and transparent top layer. This novel device structure and 3D printing approach lead to a proof-of-concept demonstration of a flexible 8×8 OLED display with a 100% pixel working rate.

11:15 AM EQ06.05.03
Solution Processed Stretchable Organic Field Effect Transistor Touch Sensors Employing EHD Printed Ag NWs Electrodes and a Porous Elastomer Gate Dielectric Runqiao Song, Ping Ren, Yuxuan Liu, Yong Zhu, Jingyan Dong and Brendan T. O'Connor; North Carolina State University, United States

Stretchable touch sensors are attractive for a number of applications including wearable electronics and soft-robotics. In flexible and stretchable devices, all materials including conductors, semiconductors, and insulators must all be effectively integrated to avoid mechanical failure during repeated loading. While there have been a number of touch sensors demonstrated, they often lack mechanical stability necessary for long term application. Here, we introduce an all-solution processed stretchable touch sensor array that employs embedded Ag NW electrodes and a porous elastomer dielectric with stable operation under a strain range of over 50% and a large pressure sensitivity. Ag nanowires (NWs) are chosen as the electrodes as they provide high electrical conductivity and mechanical durability. However, achieving high pattern resolution can be a challenge. We demonstrate an effective processing strategy of printing Ag NWs through electrohydrodynamic (EHD) jet printing to achieve precise and complex patterns. The EHD printed Ag NWs were then embedded in a thin polyimide (PI) substrate providing physically stable electrodes. The Styrene-ethylene-butylene-styrene (SEBS) gate dielectric is printed on the PI substrate followed by polymer semiconductor film and finally the Ag NW source/drain electrodes. Touch sensing was introduce into the devices by forming a nano-porous SEBS layer employing a breath figure method. Through introducing the porous SEBS the transistors become effective

touch sensors. We demonstrate that the porous structure can be tuned to vary pressure sensitivity and operating range. We then transform the ultraflexible touch sensors to stretchable touch sensors through employing a kirigami cut pattern to the PI substrate through laser ablation. One strength of this approach that the EHD can be used to pattern the electrodes to compliment the kirigami cut pattern. The resulting transistors show consistent performance during hundreds of cycles of bending or stretching. In addition, the porous SEBS touch sensors can sense a wide range of pressure from 80 Pa to 19 kPa.
In summary, in this talk we highlight the novel EHD Ag NW printing process, the formation of nano-porous SEBS thin films, and kirigami cut design and processing to achieve physically robust stretchable touch sensors. Using our unique processing methods, we are able to demonstrate an ultra-thin flexible pressure sensing transistor array. The combination of EHD printing and porous SEBS dielectric hold great potential for achieving high performance touch sensors with excellent sensitivity and mechanical robustness.

11:30 AM EQ06.05.04
Comparison of the Mechanical Properties of a Conjugated Polymer Deposited Using Scalable, Roll-to-Roll Compatible Deposition Processes Alexander Chen; University of California, San Diego, United States

One reason why semiconducting (π-conjugated) polymers are amenable to the manufacture of large-area devices is because they are solution processable, making them compatible with ink-based printing or roll-to-roll deposition processes. However, the majority of literature on the mechanical properties of conjugated polymers deposit films by spin coating, a non-continuous, non-scalable process. Different deposition processes inherently have different processing conditions (and likewise, there exists a semi-infinite permutation of processing parameters) that affect the physical properties of the resulting polymer film. These morphological characteristics in turn affect the mechanical and electronic properties of the conjugated polymer film. It is currently unclear how different scalable deposition processes affect the mechanical properties, electronic properties, and morphologies of conjugated polymer films. In this talk, we compare poly(3-heptylthiophene) (P3HpT) films deposited by three roll-to-roll deposition processes – interfacial spreading (i.e., "floating film-transfer method"), solution shearing (i.e., "blade coating"), and spray coating – to those produced by spin coating. We find that the deposition process significantly affects the mechanical and electronic properties of the resulting films. We attribute these differences to changes in the amorphous and crystalline morphologies of the P3HpT films, which holds significant implications for considering how conjugated polymer films are deposited for different applications.

11:45 AM EQ06.05.05
Solid-Phase Deposition—Conformal Coverage of Light Trapping Surfaces with Stretchable Semiconducting Polymers for Photovoltaic Applications Guillermo Esparza and Darren J. Lipomi; University of California, San Diego, United States

Light trapping with textured surfaces is an important technique in photovoltaics used to increase the optical path length without increasing the thickness of the absorber. However, the use of texture limits the application of this strategy in organic and tandem silicon/perovskite photovoltaics, among others. This limitation arises because, while there are a variety of methods available for forming thin films of electronic polymers, very few of them can form thin and conformal coatings on surfaces bearing relief structures on the micron scale. Of the methods that are capable of conformal coverage of such topography, most are applicable only to coatings that can be polymerized in situ—for example, by chemical vapor deposition—and are, thus, not amenable to polymers with complex molecular structures, such as π-conjugated (semiconducting) polymers. This presentation describes a method termed solid-phase deposition (SPD). The SPD process is a variant of water transfer printing whereby a thin film of a semiconducting polymer is suspended on water and taken up by a substrate bearing micron-scale relief structures (in this case, random pyramids such as those used for light management in silicon photovoltaics). Under ambient conditions, solid films that are sufficiently compliant (thin, ductile, or of low modulus) can coat these surfaces readily. Stiffer films comprising higher modulus polymers can be made amenable to the process by the application of heat or solvent vapor. We successfully formed coatings from films of poly(3-alkylthiophenes) spanning the range from glassy (alkyl = butyl) to rubbery (alkyl = heptyl), along with the low-bandgap polymers DPP-DTT and PTB7-Th, on textured silicon and indium tin oxide (ITO) surfaces.

SESSION EQ06.06: Device Applications

Printed and Biodegradable Sensors for Real-Time Monitoring of Soil and Plant Conditions Gregory L. Whiting[1], Eloise Bihar[1], Elliot Strand[1], Madhur Atreya[1], Anupam Gopalakrishnan[1], Yongkun Sui[1], Charlotte Bellerjeau[1], Vaidehi Salway[1], Robert McLeod[1], Jason Neff[1], Ana Claudia Arias[2], Payton Goodrich[2], Carol Baumbauer[2], Raj Khosla[3], Subash Dahal[3] and Wub Yilma[3]; [1]University of Colorado Boulder, United States; [2]University of California, Berkeley, United States; [3]Kansas State University, United States

Understanding soil and plant properties in real-time and at high-spatial resolution is critical for optimizing agricultural input use, and for evaluating soil and plant health. Obtaining such information in real-time and at high spatiotemporal resolution can be a challenge due to limited functionality and high costs when large numbers of devices are used, thereby limiting management approaches and potentially leading to excess input and energy use. As such novel instrumentation that can directly sample soil at high spatial density (10s-100s of meters) is needed to capture current conditions and enable optimized management strategies.

In this report three device types for monitoring soil and plant properties will be described. 1) Capacitive moisture and potentiometric nitrate sensors fabricated from biodegradable materials (conductors, substrates, encapsulants, etc.). The use of transient biodegradable materials enables large numbers of devices to be widely distributed in a field without the need for maintance or collection. 2) Fuse-like microbial activity sensors based on biodegradable materials that enable in-situ determination of the activity of microbes in soils which is important for understanding soil health. 3) Ion selective organic electrochemical transistors (OECTs) for determining the concentration of target ions of interest direclty in whole plant sap. In all of these cases the sensors are fabricated using printing techniques, primarily screen and ink-jet printing, as additive manufacutuing approaches readily enable creation of large numbers of devices, are compatible with a wide range of materials, and assists integration into complete measurement systems.

2:00 PM EQ06.06.02
Printed Organic Photovoltaic Modules on Transferable Ultra-Thin Substrates as Additive Power Sources Mayuran Saravanapavanantham, Jeremiah Mwaura and Vladimir Bulović; Massachusetts Institute of Technology, United States

Thin-film photovoltaics with functional components on the order of a few microns, present an avenue towards realizing additive power onto any surface of interest without excessive addition in weight and topography. To date, demonstrations of such ultra-thin photovoltaics have been limited to small-scale devices on glass substrates, fabricated through vacuum deposition or with only some of the device layers solution-processed. Furthermore, such ultra-thin devices show limited mechanical integrity for everyday human handling. The solution-processability of such device architectures presents an avenue for integration into rapid manufacturing processes and their translation from lab-scale demonstrations into consumer ready technologies. In this work we demonstrate ultra-thin organic photovoltaic (OPV) modules produced fully through scalable solution-based processes (slot-die coating and screen printing). We further demonstrate integration onto light-weight (<15 g/m^2) and high-strength (5kN/m tensile strength) composite fabrics, resulting in large-area (> 10cm x 10cm) prototypes of durable fabric-PVs capable of withstanding over 500 roll-up cycles. Such processing presents a path towards realizing solar technologies with sufficient mechanical integrity for applications requiring ultra-lightweight form-factors including tents, sails, drones, micro-robots and wearables.

2:15 PM EQ06.06.04
High Density, High Performance, Low Leakage Internal Ion-Gated Organic Electrochemical Transistors (IGTs) Claudia Cea, Richard Yao, Zifang Zhao, Jennifer Gelinas and Dion Khodagholy; Columbia University, United States

Organic material-based conformable electronics are optimal candidates for components of bioelectronic circuits due to their inherent flexibility and soft nature. We have shown that internally ion-gated organic electrochemical transistors (IGTs) operate by leveraging ion reservoirs inside their channels to dramatically improve the operation speed and integration capacity of this ion driven transistor. In order to establish IGTs as versatile building blocks of bioelectronics, it is critical to establish fabrication strategies to enable IGT-based high-density integrated circuits for creation of electronic components such as operational amplifiers, multiplexers and logic gates. Here, we report a fabrication process that enables creation of IGTs with channel length of < 500nm, that have high transconductance (> 10 mS) and high speed (< 1 µs). This vertical fabrication strategy allows effective isolation of adjacent transistors, minimizing potential for cross-talk and gate current leakage. Furthermore, it is possible to encapsulate the circuit using long-term implantable grade (parylene C) material. Furthermore, we developed a micron-scale perforation strategy to ensure intact hydration paths for transistor channels while maintaining a low leakage current. We used these transistors to develop high density (IGTs)-based digital logics, voltage amplifiers, operational amplifiers and multiplexers. Overall, the high speed and transconductance of IGTs along their ability to be densely fabricated with minimal crosstalk facilitates their applicability to a broad range of flexible and conformable electronics.

Click Chemistry Derived Polymer Ceramic Nanocomposites with Modified Interface and Improved Breakdown for Energy Storage Applications Binod Subedi, Christopher Keller, Madhu Gaire, Joshua Shipman, Scott Grayson and Douglas B. Chrisey; Tulane University, United States

Tailoring the structure of interface between polymer and ceramic nanoparticles is considered as one of the key approaches to achieve high energy density in next generation dielectric capacitors. To achieve high energy density, we have attached surface engineered barium titanate nanoparticles (~100 nm) to polymer by forming covalent bonds between the nanoparticles and polymer matrix. Nanoparticles used for this work are surface engineered by using a three-step process. The first step of hydroxylation attaches -OH groups which are the reactive sites for the second step of silane treatment. The third step of monomer grafting ensures the formation of covalent bond between the nanoparticles and monomers and provides higher mobility to reactive terminations on nanoparticle surface. Thiol-ene matrix is prepared by a radical mediated process from a mixture of monomers Pentaerythritoltetrakis (3-mercaptopropionate), 2,4,6 Triallyloxy-1,3,5- triazine and 1,3- Diisopropenylbenzene. The monomers and nanoparticles undergo *click reaction*s without the need of photo-initiator when the mixture is processed with an intense pulsed light from a xenon flash lamp. We compare two different routes of surface engineering: an alkene-ended silane (3- Acryloxypropyl trimethoxysilane) treatment followed by thiol monomer grafting, and a thiol ended silane (3 Mercaptopropyl trimethoxysilane) treatment followed by alkene monomer grafting. Nanocomposites with significantly higher electrical breakdown (~5 MV/cm) are prepared which implies an improved interface with reduced defects. The as prepared nanocomposites show energy density as high as 26 J/cm^3 while the dielectric loss is maintained below 0.2. The results from this study show that interface can be improved by increasing the surface density and mobility of the reactive terminations on nanoparticle surface. Photonic curing process utilized in this work is a roll-to-roll amenable, rapid, and high-throughput method. The ability to tailor the interface to obtain desired properties while preparing nanocomposites in large scale using a cost-effective method provides an easy route to an industrial scale method for the preparation of high-energy density nanocomposites.

Functionalized Polymer Dielectrics for Low-Operating Voltage Organic Field-Effect Transistors John Barron, Jaewon Lee, Payal Bhattacharya and Suchismita Guha; University of Missouri–Columbia, United States

The design of appropriate dielectrics plays a crucial role in the performance of organic field-effect transistors (FETs). Along with the active semiconductor layer, the dielectric-semiconductor interface dictates charge transport properties in FETs. Polymer ferroelectric dielectrics with their high dielectric constants are attractive for low-operating voltage FETs. Another route for enhancing the dielectric constant of polymer dielectrics is via the incorporation of semiconducting and insulating nanoparticles. Amongst magnetic nanoparticles, cobalt ferrite ($CoFe_2O_4$ or CFO) has received a lot of interest in sensing and biomedical applications. Its insulating property is attractive in polymer gate dielectrics. CFO magnetic nanocrystals, soluble in organic solvents, were synthesized by a thermal decomposition method and coated with polymers such as poly(vinyl alcohol) (PVA). Improved performance of organic FETs (both small molecule and polymer) using CFO incorporated non-ferroelectric dielectrics are observed. In particular, the threshold voltage and the subthreshold swing are lowered in pentacene and other organic FETs using CFO incorporated cross-linked poly(4-vinyl phenol) (PVP) dielectric. The application of an external magnetic field allows for another parameter to tune the device performance. We will further discuss a nonlinear optical probe for investigating carrier transport in such FETs.

Photonic Band Structure in One-Dimensional Crystals of Stacked Microcavity OLEDs Matthew S. White[1], David Allemeier[1], Benjamin Isenhart[1],

Ekraj Dahal[1], Yuki Tsuda[2] and Tsukasa Yoshida[2]; [1]University of Vermont, United States; [2]Yamagata University, Japan

A microcavity OLED, consisting of a conventional OLED stack with two metallic mirror electrodes, shows narrow-band emission centered around specific peak resonant wavelengths. These cavity modes are analogous to the energy states found in any resonator system, including musical instrument strings and 1-dimensional quantum square wells. The first three cavity modes are directly pumped by varying the thickness of the microcavity structure. The impact of the location of the dipole emitter within the microcavity on outcoupling efficiency and polarization is explored. The microcavity OLED is then used as a unit cell in a planar, 1-dimensional photonic crystal. Stacking *N* microcavities splits the resonant modes into *N* discrete states; a photonic band centered at the single microcavity state. Devices are fabricated by thermal evaporation with in-vacuo shadow mask transfers to enable parallel-connected unit cells. The photonic density of states is controlled by varying the thickness of the semistransparent metal mirror electrodes. A photonic Peierls bandgap is tuned by varying only alternate mirror thicknesses. Device parameters, including *N*, the thickness of the semi-transparent metal electrodes, and dipole emission position are correlated to emission properties such as peak wavelength, FWHM, and Q-factor for each of the photonic states. The experimental results are guided by a predictive computational modelling tool, which is critically important for the complex-architecture devices.

4:45 PM EQ06.07.03
Effect of Emulsified Polymer Particle Thin-Film Deposition on LED Device Performance Buang Zhang and Adrienne Stiff-Roberts; Duke University, United States

Film morphology plays a major role in polymer LED device performance. As an example, blue LEDs fabricated using polyfluorene (PFO) have shown an increase in luminance efficiency with the presence of minimal crystalline domains of a specific phase.[1] Previous work has demonstrated that PFO deposition via resonant infrared, matrix-assisted pulsed laser evaporation (RIR-MAPLE) promotes this crystalline β-phase formation in PFO while maintaining device-quality film surfaces.[2] RIR-MAPLE is a unique variation of pulsed laser deposition featuring an Er:YAG laser (peak wavelength of 2.94 microns) that is resonantly absorbed by the hydroxyl bond vibrational mode.[3] Therefore, PFO deposition occurs by formation of a frozen “oil-in-water” emulsion target in which the polymer is dissolved in primary solvent trichlorobenzene (TCB), and dispersed within the water matrix that resonantly absorbs the incident laser energy. Phenol is added as a secondary solvent to lower the emulsion vapor pressure, and minimal surfactant is added to help emulsion formation. The resonant laser absorption sublimates the water-ice matrix and transfers intact emulsified polymer particles directly from the complex emulsion to the substrate without degradation. Therefore, the morphology of the complex emulsion determines the film morphology. [2,4] In this work, the impact of the complex emulsion morphology on LED device performance is investigated.

Given that the complex emulsion target used in RIR-MAPLE contains multiple components (polymer, primary solvent, secondary solvent, surfactant, and water), the existing two-phase emulsion theory cannot predict accurately the resultant morphology. Empirical studies of RIR-MAPLE deposition have shown that an emulsion recipe with a concentration of 0.83 mg/ml PFO in water yields device-quality, pinhole-free films containing around 6% crystalline β-phase.[2] Two different emulsion recipes that maintain this specific polymer concentration in water but change the total water content in the emulsion were developed. The emulsion recipe with high water content contains 5mg/mL PFO in TCB with emulsion ratio of 1:0.5:6 (TCB:phenol:water), and low water content recipe has 2.5 mg/mL PFO in TCB with emulsion ratio of 1:0.25:3 (TCB:phenol:water). Despite having a drastic difference in emulsified particle size (dynamic light scattering), two outcoming films showed similar surface roughness and morphology determined by atomic force microscopy.[4] Further, cryo-transmission electron microscopy images of the frozen emulsions showed that the observed difference in particle sizes resulted from large agglomerations of emulsified particles occurred in the low water content emulsion.[4] While these differences in emulsion morphology did not impact the overall film morphology, it is not known how these features could impact LED performance. It is anticipated that the networked emulsified particles of the low-water content emulsions will yield better LED performance due to better charge injection.

Therefore, this work will investigate the impact of PFO complex emulsion morphology, as determined by the overall water content, on LED performance for active region films deposited by RIR-MAPLE. The LEDs will be fabricated using the following device heterostructure: ITO/PEDOT:PSS/PFO/LiF/Al. LED device characterization will include current density vs. voltage, luminous flux, and electroluminescence spectra. This work will reveal the relationship between polymer emulsion morphology and PFO LED device performance, thereby providing a guide for future RIR-MAPLE-deposited PFO devices. This work is supported by the National Science Foundation under Grant No. NSF CMMI-1727572.

Multifunctional Flexible Electronics Manufactured by Ultrafast Corona-Enabled Electrostatic Printing Zijian Weng and Ying Zhong; University of South Florida, United States

Flexible electronics have attracted a significant attention in the recent years due to their high demands in a variety of fields such as medical field, sports field, cosmetic field and so on. A number of manufacturing technologies have been developed to fabricate the flexible electronics based on different functional materials. However, there are quite a few challenges in current techniques such as high costs, time consuming and difficult scale-up process, making it hard to produce a large amount of high-quality flexible electronics. Here we reported a novel Corona-enabled Electrostatic Printing (CEP) technology to manufacture flexible electronics in an ultrafast manner of which the printing time can be down to 100 ms. A detail mechanism study is shown in this paper to demonstrate the printing principle of CEP by using simulations and experimental studies. With the help of CEP, a variety of functional material such as graphene, PEDOT: PSS and CNT were able to be fast printed to fabricate flexible multifunctional sensors that can detect strain, temperature and humidity signals. And CEP could also be integrated with roll-to-roll (R2R) process for ultra-fast mass production. The binder-free feature of CEP enables a fast, simple and pure printing process, producing high quality flexible electronics such as graphene-based sensors that possess high sensitivity and acoustic signal detection capabilities.

Blue Light Emission from a p-i-n $POPy_2$ Large Band Gap Homojunction Diode Hannah L. Smith[1], Jordan T. Dull[1], Swagat Mohapatra[2], Stephen Barlow[2], Seth Marder[2], Barry P. Rand[1] and Antoine Kahn[1]; [1]Princeton University, United States; [2]Georgia Institute of Technology, United States

p-Doping organic semiconductors with high ionization energy (IE) remains challenging, as these materials require dopants with correspondingly high electron affinity (EA). Recently, an organic molecular p-type dopant, hexacyano-trimethylene-cyclopropane (CN6-CP) was synthesized and shown to have an EA of 5.87 eV measured by cyclic voltammetry (CV), almost 300 meV higher than other known high EA molecular dopants. In this work, we measure the EA of CN6-CP using inverse photoelectron spectroscopy (IPES) and confirm a high value of 5.88 eV in condensed phase. We then use CN6-CP to

dope phenyldi(pyren-2-yl)phosphine oxide ($POPy_2$), a wide energy gap (3.6 eV), large IE (5.87 eV), organic semiconductor and demonstrate a more than two order of magnitude increase in film conductivity. Using CN6-CP and (pentamethylcyclopentadienyl)(1,3,5-trimethylbenzene)ruthenium $(RuCp^*Mes)_2$, a highly reducing n-dopant capable of n-doping a low EA (2.2. eV) material such as $POPy_2$, we build a rectifying p-i-n homojunction with a 2.9 eV built-in potential. We demonstrate blue emission from this p-i-n structure, indicating both hole and electron injection into this large gap diode through the n- and p-doped regions.

Vacuum Deposition and Stencil Lithography for Flexible Organic Transistors and Complementary Circuits Hagen Klauk and Ute Zschieschang; Max Planck Institute for Solid State Research, Germany

Organic thin-film transistors (TFTs) are being developed for flexible electronics applications, such as rollable or bendable active-matrix displays and conformable sensor arrays. The deposition and patterning of the various transistor components (gate electrode, gate dielectric, source/drain contacts, organic-semiconductor layer) can be accomplished using a wide range of methods, which are often categorized into vacuum-based and solution-based approaches. All of these have real or perceived advantages and drawbacks, which are often related to the anticipated costs of large-scale commercial manufacturing. A lot about these can be learned by analyzing the present-day commercial manufacturing of active-matrix organic light-emitting diode (AMOLED) displays for mobile phones and television sets. All of the OLED and TFT components in these displays are deposited by vacuum-based methods, while patterning is accomplished by optical lithography (TFT stack, anodes, interconnects) or stencil lithography (OLED semiconductors and cathodes). The only process steps involving the use of liquid organic solvents are those in which the surface is coated with polyimide (to create the flexible substrate) or photoresist (in preparation for optical lithography). By keeping the use of organic solvents, which are often toxic, carcinogenic and environmentally harmful, to an absolute minimum, the costs of proper solvent management and disposal and thus the total manufacturing costs are kept as low as possible. The commercial manufacturing of organic TFTs based on small-molecule semiconductors can potentially be even less expensive, since these TFTs can be fabricated entirely without organic solvents, simply by depositing and patterning all materials in vacuum directly on the flexible substrate. Following this general proposition, organic TFTs as well as unipolar and complementary circuits with good static and dynamic performance can successfully be fabricated on a variety of flexible substrates, including plastics and paper.

11:00 AM EQ06.08.02
Continuous and High-Speed Printing of Semiconducting Polymer Line Arrays by Meniscus Oscillation Self-Assembly (MOSA) Jeong Jae Wie[1], Jisoo Jeon[1], Alvin T. Tan[2] and John Hart[2]; [1]Inha University, Korea (the Republic of); [2]Massachusetts Institute of Technology, United States

Evaporative self-assembly of semiconducting polymers has been studied extensively in order to attain a facile and low-cost means of preparing hierarchical micrometer and nanometer-scale features. Yet, solvent evaporation is often a time consuming kinetic process that limits any potential for practical applications toward organic and printed electronics. In this presentation, we introduce a novel high-throughput and continuous printing technique for semiconducting polymer via a modified doctor blading technique with oscillatory meniscus motion, termed meniscus-oscillated self-assembly (MOSA). The oscillatory meniscus motion of the roller regulates a periodicity of the stick-slip phenomenon between the roller and polymer solution that can continuously output semiconducting polymer line arrays. These printed lines demonstrate highly defined boundaries and drastically enhanced crystallinity via shear-induced crystallization. This novel continuous printing technique has the capacity to pave a new path forward for practical applications in printed electronics.

11:15 AM EQ06.08.03
Rapid, High-Resolution, Large-Area Patterning of Semiconducting Polymers Using Projection Photothermal Lithography Tucker L. Murrey[1], Alice S. Fergerson[1,2], Meghna Jha[1], Justin T. Mulvey[1,3], Sarah E. Dolan[1], Daniel Tiffany-Appleton[1] and Adam J. Moule[1]; [1]University of California, Davis, United States; [2]Princeton University, United States; [3]University of California Irvine, United States

Semiconducting Polymers (SPs) have received widespread attention due to their promising qualities like superior absorbance/emission, easy chemical tunablity, low-temperature solution processing, lightweight and flexible substrates, and low environmental toxicity. A significant obstacle for the industrial development of SPs is the lack of a patterning technology that is inexpensive, rapid and viable and capable of producing sub-micron features. Photomask lithography is impossible because the SPs cannot withstand the processing steps. The Moule group recently developed a new photopatterning concept that enables micropatterning of SPs. We present a novel solution based optical patterning method that is compatible with any non-cross linked SP, termed Projection Photothermal Lithography (PPL). We have built a lab scale PPL microscope and demonstrated rapid ($\sim 4 cm^2 hr^{-1}$), large single exposure area ($0.21\ mm^2$), sub-μm patterns can be obtained optically. Selective polymer domains are removed as a photo-induced temperature gradient enables selective dissolution. We estimate the commercial patterning throughput of ($\sim 5\ m^2 hr^{-1}$) can be obtained through optimization of optical components.

11:30 AM EQ06.08.04
Universal Electrode for Ambipolar Charge Injection in Organic Electronic Devices Tanmoy Sarkar and Gitti L. Frey; Technion--Israel Institute of Technology, Israel

Ambipolar transistors, i.e. transistors with symmetrical n- and p-type performances, open new venues for the design and integration of high-density, efficient and versatile circuits for advanced technologies. Their performance requires two processes: efficient injection of holes and electrons from the metal electrodes into the semiconductor; and transport of both carriers through the semiconductor. Organic semiconductors (OSC) support ambipolar transport, but charge injection is strongly asymmetric due to inherent misalignment of the electrode work function with both conducting levels of the OSC. Here we will introduce a new electrode concept capable of efficiently injecting both type of charge carriers into OSCs. The electrode has a mosaic-like structure composed of islands of two metals with high and low work functions, in this case Al and Au, respectively. Under suitable applied bias the Au (Al) domains in direct contact with the OSC allow efficient hole (electron) injection into the HOMO (LUMO) level. Implementing this electrode as both source and drain in organic filed effect transistors (OFET) lead to fully balanced ambipolar performance while maintaining high ON/OFF ratios. We then used the ambipolar OFETs to significantly simplify circuit design and fabrication of digital and analogue elements, i.e. digital inverter and an analogue phase shifter, composed of one type of transistor only. Finally, we demonstrate that a single ambipolar OFET can replace several unipolar transistors to fabricate

digital transmission gate circuits that utilize one transistor only. The new electrode design concept can include other metal combinations and compositions to balance ambipolar injection, and the use of the mosaic electrodes can be extended to other electronic devices that require ambipolar charge injection such as light emitting transistors, memory devices etc.

11:45 AM EQ06.08.05
TCO-Based Scribing Mechanism for High-Throughput Perovskite Module Manufacturing Austin Flick and Reinhold H. Dauskardt; Stanford University, United States

Small area (~0.1cm^2) hybrid organolead-halide perovskite solar cells have recently approached efficiencies near that of single crystalline silicon cells. Scalable methods such as slot-die coating and spray coating offer the possibility of high quality large-area perovskite deposition at these performance levels; however, resistive losses across the transparent front electrode highlight the need for alternative architectures and designs. A variety of alternative designs are explored—gridline, module, and hybrid designs—to mitigate front electrode resistive losses, employing laser-scribing to achieve both controlled gridline deposition and monolithically integrated series interconnections. We have developed a laser scribing mechanism to achieve gridline patterning and removal of the electrodes and active material utilizing a single wavelength (1064nm) pulsed laser at ultrafast processing speeds (>1m/s). This process coupled with improved module design enables high throughput device and module development.

Our work first develops the primary scribing mechanism employed: TCO-based lift-off. We demonstrate the unique characteristics of this scribing method as it interacts exclusively with the front electrode transparent conducting oxide (TCO) material to perform all the necessary scribes between both the gridline and module architectures. With a single wavelength source, controlled removal of either the front electrode or active layers is achieved to perform each scribe step: front electrode patterning (gridline patterning, module P1), creating the series interconnection channel (module P2), and rear electrode patterning (module P3). The unique lift-off mechanism results in particularly improved P2 performance via reduced contact resistance and increased short-circuit current and fill factor compared to traditional P2 ablation mechanisms that often require ultra-short laser pulses to avoid residual thermal damage to the perovskite layer. By avoiding interactions with the perovskite entirely, the TCO-based lift-off mechanism is compatible with lower cost, longer pulse duration laser systems and is capable of complete device and module patterning on a single system.

Following the development of a uniquely broadly applicable laser-scribing mechanism, gridline, module, and hybrid designs are considered for large-area perovskite photovoltaic applications. Resistive losses of each of the dominant components (front electrode, gridlines, scribed interconnections) are evaluated against geometric design considerations to find the optimal device and module geometries. Reductions in resistive and geometric losses motivate the selection of an optimal architecture, though alternative designs are considered for potential compatibility with projected processing challenges.

SESSION EQ06.09: Processing and Applications I

1:30 PM EQ06.09.01
Photonic-Induced Conversion of Semiconductor-Based Inks and Its Use for Flexible Hybrid Electronic Sensor Integration Jaime Benavides-Guerrero[1], Luis Felipe Gerlein[1], Arjun Wadhwa[1], Debika Banerjee[1], Martin Bolduc[2] and Sylvain G. Cloutier[1]; [1]Ecole de Technologie Superieure, Canada; [2]Université du Québec à Trois-Rivières, Canada

In this work, we present our recent progress on the photonic-induced conversion of new semiconducting ink materials and their use for the fabrication of new hybrid opto-electronic sensor platforms. First, we will present the manufacturing-ready photonic curing process and its key advantages for high-speed treatment of large surfaces compared with standard laser-induced conversion. Most importantly, simulations will be used to demonstrate how photonic sintering can achieve high-temperature conversion of the functional inks without compromising the structural integrity of low-temperature substrates. Then, we will illustrate how slurries of silicon-based particles can also be sintered by photonic curing. Altogether, we will describe how we used a thorough understanding of the chemistry combined with a cutting-edge photonic curing expertise to enable novel sensor designs and their integration in fully-autonomous flexible hybrid electronic sensor platforms. Most importantly, we will show how we modified the chemistry of a sol-gel TiO_2 precursor in order to generate high concentrations of oxygen vacancies and describe how this modified chemistry can allow a conversion from amorphous to anatase and rutile polymorphs at room temperature and in ambient environment using low-power photonic irradiation [1]. As a result, unique multi-morphic film architectures are achieved using digital additive manufacturing strategies coupled with both low-power laser irradiation and photonic curing [2].
In turn, these unique metal-oxide film structures enable new printable devices architectures for a wide range of applications from biomedical to energy harvesting. We will show a few concrete examples in this presentation [4-5].

Effect of the Dipole Position on the Emission Characteristics in Microcavity Organic Light Emitting Diodes Ekraj Dahal, David Allemeier and Matthew S. White; University of Vermont, United States

Organic light emitting diodes (OLED) employing two planar metallic electrodes encasing the organic layers form a microcavity etalon. This structure allows a control on the output emission characteristic of the light source resulting in a significant narrowing of the emission bandwidth and angular dispersion of light. We investigate the emission spectra using a single organic emitter molecule, by engineering the position of the dipole emitter in the microcavity structure. The position of the dipole was varied by varying the relative thickness of the electron transport layer ETL and hole transport layer HTL in fixed total thickness and fixed optical pathlength device structures. The output characteristic of a microcavity OLED is affected by its optical path length. Here we test this hypothesis that a fixed optical pathlength generates the same optical characteristics even with the changing dipole position. Varying the thickness of the ETL and HTL layers without changing the total optical pathlength of the device in principle generates the same output characteristic of light. We find that fixing the optical pathlength in the cavity functionally fixes the peak emission wavelength, but the dipole position

within the cavity has strong impact on the efficiency of outcoupling of light and on the polarization.

2:00 PM EQ06.09.03
Controlling Catalyst-Support Interactions via Modifying Metal-Organic Frameworks Won Ho Choi and Kyung Min Choi; Sookmyung Women's University, United States

The development of support materials is one of the most critical challenges in a wide range of fields including energy, the environment, and catalysis. This is because support materials can endow guest materials with new properties. In catalysis, the catalyst–support interaction influences the catalytic performance, so it is urgently required to create a high-affinitive sites in porous supporting media. Among the promising candidate support materials, highly porous and crystalline metal–organic frameworks (MOFs) have received considerable attention. Although many MOFs have been successfully utilized as supports, their metal sites have weak affinity for the guest material due to blockage by organic linkers. We hypothesized that the affinity could be increased by tearing the MOFs into smaller pieces based on this intrinsic limitation. Accordingly, we developed a new pathway for producing metal–organic fragments by tearing MOFs via hydrogen plasma bombardment. The hydrogen plasma exposed more metal nodes and created more delocalized electrons, resulting in high-affinity sites within the metal–organic fragments. Furthermore, metal-organic polyhedra (MOP), are distinct from MOFs, have opened up a possibility for controlling catalyst-support interactions. Here, we focus on the opportunity to use the pore structure without the hindrance to electron transfer by using MOP. As a result of this strategy, the metal–organic fragments and MOP were successfully applied as highly affinitive support.

2:15 PM EQ06.09.04
Simultaneous Control of Crystallinity and Molecular Alignment in Semiconducting Polymer Films Through Tailored Thermal Annealing Alessandro Luzio[1], Jaime Martin[2,3,4] and Mario Caironi[1]; [1]IIT CNST, Italy; [2]Universidade da Coruña, Spain; [3]University of the Basque Country UPV/EHU, Spain; [4]Ikerbasque Basque Foundation for Science, Spain

Semiconducting polymers with satisfactory charge transport properties are demanded to meet the requirements for a vast range of applications in the field of flexible and printed electronics.[1] However, their effective integration into electronic devices is still hampered by a partial understanding of the interplay between microstructure and transport. Starting from 2009, the investigation of innovative donor-acceptor copolymers led to evidences of efficient transport in apparently poorly ordered films,[2] subverting the old perception of long-range crystallinity as the key for transport efficiency. Lately, evidences for well interconnected and efficient charge percolation pathways within otherwise disordered films was consistently reported in high mobility polymer field-effect transistors (FETs);[3] this is made possible by polymers inherent anisotropy, enabling long-range alignment of molecular backbones within thin films microstructure and improved unidirectional film interconnectivity along the same direction. Accordingly, strong transport anisotropy is realized, where transport is maximized in the direction of backbone alignment and improved interconnectivity.[4] Nevertheless, a substantial gap remains to be filled between emerging models for transport, mostly accounting for short range interactions, and the actual charge transport mechanism occurring within the multi-phase percolation paths of aligned FET channels.
Here we report on a post-processing methodology enabling control on those microstructural features that are critical for polymer transport, i.e. molecular alignment, degree of interconnectivity and crystalline structure. We show that a systematic lamellar thickening and improved molecular alignment can be induced upon the accurate choice of thermal post-processing temperatures, tailored to the actual thermal transitions of solution processed thin films. In fact, annealing at a temperature at which only the smaller crystals melt but the larger ones are maintained, allows for the thickening of non-molten crystals and the epitaxial growth of the molten fraction of molecules on the non-molten surface, thereby guiding molecular alignment of newly formed crystals.[5]
We show that our post-processing strategy represents an effective tool for charge percolation optimization, up to the demonstration of ideal, single crystal-like FETs characteristics and drastically reduced thermal barriers to transport. Validation tests were carried out on two paradigmatic *n*-type molecular systems: a diketopyrrolopyrrole-based copolymer, where electrons delocalization within crystalline domains can take place, and a series of naphthalene-diimide bithiophene copolymers, conversely characterized by a strong intra-chain charge localization at any aggregation state. Such a diverse investigation allows for a better understanding of the effect of critical chemical features for a polymeric semiconductor, like electronic structure, molecular conformation and solubilizing side chains, on charge percolation efficiency within aligned films, paving the way toward a more efficient design of polymeric semiconductors for printed electronics applications.

Structures and Mechanisms of Self-Doping N-Type Organic Semiconductors from Aqueous Solutions Lewis M. Cowen and Bob Schroeder; University College London, United Kingdom

N-type dopants for organic semiconductors with reasonable ambient stability have been difficult to develop. In addition to this, dopant and organic semiconductor pairs often exhibit morphological incompatibilities. One promising, yet relatively unexplored, tactic for avoiding morphological disruption to the semiconductor after doping is to covalently bind a doping functionality to the conjugated section. Quaternary ammonium hydroxide groups have previously been bound to rylene diimides and high n-type conductivities (≈ 0.5 S/cm) and thermoelectric power factors were observed after film-formation and annealing.[1, 2] It is likely that the active dopant is a tertiary amine,[3] however multiple routes of quaternary ammonium hydroxide decomposition have been shown to lead to tertiary amine products.[4] Any chemical transformations, such as quaternary ammonium breakdown, can have a significant effect on the morphology of the doped film and complicates any investigation into the doping mechanism.

A water-soluble and air stable naphthalene diimide molecular semiconductor, called NDI-OH, has been synthesised which is covalently bound to a quaternary ammonium hydroxide group. When thin-films were formed by drop-casting absorption features consistent with doping were observed. The chemical structure of the dopant precursor was determined for the first-time using NMR and mass spectrometry. It was seen that the ammonium hydroxide precursor is a product of ring-opening hydrolysis on the imide functionality of the naphthalene diimide. After treatment at high temperature it was found that the reverse hydrolysis reaction also took place. The dynamic nature of this ring-opening reaction was found to have a significant effect on the chemical composition of the doped films.

A steady increase in electrical conductivity was observed with increasing temperatures of drop-casting in NDI-OH thin-films. Spectroscopic structural analysis of the conducting films revealed changes to both the quaternary ammonium moiety and the NDI ring-system at higher drop-casting temperatures. These structural changes lead to large differences in film morphology, doping efficiency and therefore conductivity in films prepared at different

temperatures. Film morphology was probed using a combination of atomic force microscopy and X-ray scattering. A combination of EPR and UV-vis absorption spectroscopy was also used to determine the amount and type of charge carriers generated. The results presented show that the functionality of this promising group of water-soluble conducting organics must be carefully tuned by considering atleast two different chemical transformations. The extent and direction of the dynamic hydrolysis reaction plays a role in the film morphology while the breakdown of the quaternary ammonium group contributes to the generation of the active dopant.

Tracing Channel Potentials in Organic Transistors—Theory, Experiments and Applications Chuan Liu; Sun Yat-sen University, China

Detection and understanding of unipolar and ambipolar charge accumulation and transport is the key to understand intrinsic performance of organic field effect transistor (OFET). However, it is difficult to determine the motion of the carrier with regular electrical tests. In this paper, the generalized gated four probe (G-GFP) technique [1] is extended to employ to investigate both few-mono-layer organic small molecular semiconductors and ambipolar polymer semiconductors in transistors.
For the p-type semiconductor, we fabricated monolayer semiconductor C8-BTBT films by shearing method and investigate the impacts of film thickness, contact metal, dielectric materials, and etc. by systematically monitoring the channel potentials. For the ambipolar transistors, we fabricated iketopyropyrrole thieno [3,2-b] thiophene copolymer (DPPT-TT) and studied the motion of carriers in the ambipolar regimes. For both types of OFETs, the evolution of local potential is monitored in the channel to establish a clear quantitative image of the accumulation and transmission of carriers during device operation. Both simulation and experimental results confirm that G-GFP is a suitable and feasible method to extract the carrier mobility and to reveal the key limiting factors that induce the non-ideal effects in OFETs.[2] Also, the ambipolar device with G-GFP structure can work as a single OFET inverter [3], which shows that G-GFP can be used as an effective tool for bipolar transistor analysis and help to realize logic functions.

Organic Doping at Ultra-Low Concentrations Raj Kishen Radha Krishnan[1], Drona Dahal[1], Paudel Pushpa[1] and Bjorn Lussem[1,2]; [1]Kent State University, United States; [2]Universität Bremen, Germany

Organic Doping is widely used for tuning the Fermi level of organic semiconductors. The precise control in the charge carrier density facilitated by doping allows to maximize the efficiency of organic optoelectronic devices [Walzer, K. et al., *Chem. Rev.* **107**, 1233–1271 (2007)]. However, doping concentrations used in most studies are high (in the wt.% range), which limits the doping process itself resulting to a low doping efficiency [Tietze *et al., Adv. Funct. Mater.* **25**, 2701–2707 (2015)]. In addition, these high doping concentrations can lead to large off-currents when used to dope the channel of Organic Field-Effect Transistors [Liu et al., *ACS Applied Materials & Interfaces* **12**, 49857 (2020)].
In this presentation, we discuss the design of a rotating shutter system that is capable of controlling doping concentrations in vacuum processed films down to the 100 ppm level [R. K. Radha Krishnan *et al. Adv. Opt. Mat.* in press (2021)]. The increased control over the doping concentration is used to study doping at ultra-low concentrations in C_{60} Metal – Oxide - Semiconductor (MOS) junctions. A small-signal drift-diffusion model is presented and used to determine the doping efficiency and activation energy of the doping process. With the help of a statistical model [Tietze *et al., Phys. Rev. B* **86**, 035320 (2012)] the observed trends are fitted and design rules for future dopant/matrix combinations with higher doping efficiency are proposed.
Based on the results of the MOS study, C_{60} OFETs doped at the 100ppm level are designed that operate at ultra-low voltages of 800mV only and retain an on/off ratio of up to 10^7 despite doping. The devices have low subthreshold swing in the range of 80 mV/dec and a transconductance of up to 8 mS/mm.
To demonstrate that our results can be generalized, we will discuss the effect of ultra-low doping not only on the archetypical n-type semiconductor C_{60}, but study doping of the high-performance p-type organic semiconductor, dinaphtho[2,3-b:2',3'-f]thieno[3,2-b]thiophene) DNTT as well. Here, doping enables a balanced ambipolar device characteristic with average electron and hole mobilities of approx. . Hole and electron injecting contacts are used to study the mechanism of majority and minority charge carrier generation inside the doped films.
Overall, it will be argued that doping is a key technology for organic field-effect transistors [Lüssem, B. *et al., Chem. Rev.***116**, 13714–13751 (2016)], and allows not only to reach high performance, but to realize new device structures and to study mechanisms of charge carrier generation in organic semiconductors as well. The use of ultra-low doping concentration broadens the potential use of doping in OFETs, which will help to move the field further towards larger scale integration.

9:00 AM EQ06.10.03
Reduction of Persistent Photoconductivity Effect of Zinc Oxide Ultraviolet Photoconductors by Polymer-Assisted Deposition Method with Deep Ultraviolet Photoactivation Jun-Gyu Choi, Won-June Lee and Myung-Han Yoon; Gwangju Institutes of Science and Technology, Korea (the Republic of)

In this study, we developed zinc oxide (ZnO) based ultraviolet (UV) photoconductor devices with low persistent photoconductivity (PPC) effect by introducing polymer-assisted sol-gel precursor with deep-UV (DUV) photoactivation. The influence of DUV photoactivation on polymer-oxide complexes was investigated by comprehensive characterization analyses. Unlike poor current recovery of conventional oxide photoconductors with ohmic-contact, the

ZnO films cast with polymer-mixed precursor solution exhibited much improved PPC effects with full current recovery, especially for the films irradiated by DUV followed by thermal annealing. The polycrystalline ZnO films in the photoconductor of reduced PPC effect exhibited larger grain sizes as well as fewer defect sites deriving poor recombination of photo-excited carriers. UV photoconductors based on PEI-involved ZnO films under DUV photoactivation showed excellent device performance represented by large photocurrent (~4 μA), rapid response/recovery time (21 s and 40 s), and enhanced on-off current ratio (~ 3.7) in combination with the reduced PPC effect.

9:15 AM EQ06.10.04
Interfacial Control of Organic Semiconductor/Electrode Contact Characters Using Additive-Metal Interaction for Top-Contact Organic Transistor Giheon Choi[1,2], Seungtaek Oh[1,2], Jungyoon Seo[1,2] and Hwasung Lee[1,2]; [1]Hanyang University, Korea (the Republic of); [2]BK21 FOUR ERICA-ACE Center, Hanyang University, Korea (the Republic of)

One of the important factors to improve the performance of organic field-effect transistors (OFETs) is an effective charge carrier injection from the metal electrode to organic semiconducting layer, and thus various studies have been conducted so far to improve this. In this study, the organic semiconducting layer was formed by blending the thiol SAM materials with PBTTT-C14 solution to control the nature of the charge carrier injection in the top-contact bottom gate (TCBG) structure of the OFETs, for which a spontaneously generated SAM was produced through annealing process on the electrodes. This result is simple and applicable on the TCBG-structured OFETs, which is impossible to be applied with SAM treatment until now. The field-effect mobility of PBTTT-C14 FETs blended with 1-dodecanethiol was improved from 0.025 to 0.063 cm^2/Vs as compared to that without blending, and the threshold voltage was shifted from 15 to 0 V, which is closed to an ideal onset operation of the device.

9:30 AM EQ06.10.06
Understanding Marangoni Flow-Driven Solidification of Polymer Semiconducting Films on an Aqueous Substrate Seungtaek Oh[1,2], Giheon Choi[1,2], Jungyoon Seo[1,2] and Hwasung Lee[1,2]; [1]Hanyang University, Korea (the Republic of); [2]BK21 FOUR ERICA-ACE Center, Hanyang University, Korea (the Republic of)

Here, in the context of the polymer film on an aqueous transfer process, the value of spreading coefficient (S) plays an important role in spreading the polymer solution droplet on the base media. A high S is key to improving the polymer film uniformity and crystalline structure, which affect the organic field-effect transistor (OFET) device performance. In addition, the films floating on the base media were transferred either upward (UST) or downward (BST) to differ their solidified orientations. The differences between the UST and BST cases confirmed that the solvent in the polymer solution droplet was rapidly extracted at the interface with the base media and was slowly evaporated near the air interface with the polymer solution. The results induce rapid solidification with poor structural properties at the base media interface and slow solidification with good structural properties at the air interface. The surface properties of the polymer semiconducting films were advantageous in the vicinity of the air/polymer solution interfaces for use as a channel active layer, resulting in good OFET device performances for the UST case.

Organic Dyes Derived from Molecules in Cacao Beans for Use in Lighting Applications Christine Luscombe[1,2]; [1]University of Washington, United States; [2]Okinawa Institute of Science and Technology, Japan

LEDs are the foundation of lighting and display products surrounding us. While they have obtained great success in the commercial market, related research and development activities remain highly active aiming to enhance factors such as energy efficiency, stability, and environmental sustainability. Currently, commercial LED products are comprised of two key components: an indium gallium nitride e LED backlight with emission centered at 450 nm to cover the blue region of the visible spectrum, and powder inorganic phosphors on top converting blue light into longer wavelengths (e.g., green and red) to tune the emission of the device. A drawback of inorganic phosphors is that scattering of the emission from the micron-sized phosphor powders leads to substantial backscattering and subsequent absorption of the emission into the LED chip, and reabsorption losses in the phosphor itself, both of which reduce the overall light output of the final LED device. Organic dyes possess environmental advantages over inorganic phosphors because they are pi-conjugated molecules made from abundant elements (C, H, N, O, etc.) and are potentially bio-sourced. In this talk, I will present dyes that have been developed from theobromine, derived from cacao beans. When blended within an industrial polymer, poly(styrene-butadiene-styrene) (SBS), their enhanced solubility enables the formation of highly transparent films, crucial for reducing scattering loss in LEDs. Furthermore, resultant dye-SBS films achieved photoluminescence quantum yields (PLQYs) of around 90% under ambient conditions. Taking advantage of their transparency and solution processability, we fabricated a waveguide with this theobromine-dye-SBS composite, which was subsequentially assembled into an edge-lit LED device of no glare and enhanced aesthetics.

11:00 AM *EQ06.11.02
Designing Functional Polymers for Organic Electronic Devices Michael L. Chabinyc; University of California, Santa Barbara, United States

Polymers are essential materials for wearable electronic systems and soft robotics as active and passive materials. We will discuss our recent work on polymer architectures that lead to control of electronic and mechanical responses of organic electronic devices. First, we will discuss how single ion conducting polymers, known as polymeric ionic liquids (PILs), can be used as electrolytes in organic electrochemical transistors. PILs provide a unique method to control the current voltage characteristics of electrolyte-gated transistors. By appropriate molecular design of the PIL, the operation of polymer transistors can be switched from conduction at an electrical double layer to conduction in the bulk by infiltration of counter ions. The behavior of transistors with PIL gates reveals the differences in the electrical conductivity of semiconducting polymers at the surface and in the bulk at high charge carrier concentrations. Second, we will discuss how polymers with a bottlebrush architecture can be used to form super-soft elastomers useful for pressure sensors. The low mechanical modulus of bottlebrush elastomers, which is comparable to that of hydrogels, allows for the formation of capacitive pressure sensors with sensitivity comparable to human touch. These studies reveal the importance of molecular design on the development of new organic electronic devices.

11:30 AM EQ06.11.03

Enhancing the Performance of State-of-the-Art Photo Cells Using Universal Hole Extraction Structure Hela Fadool[1], Young-Jun Yu[2], Jung-Il Jin[2], Dong Hoon Choi[2] and Nir Tessler[1]; [1]Technion, Israel; [2]Korea University, Korea (the Republic of)

Organic sensors, photodiodes, and solar cells have attracted much interest in recent years for their unique properties such as flexibility, lightweight, and the low cost and ease of their fabrication processes. While not destined to replace silicon-based technology, organic-based devices provide a promising technology for wearables, windows, as well as lightweight constructions that cannot hold the current massive photovoltaic (PV) modules.

A previous work done by our group[1] presents a device engineering approach to enhance the OPVs' performance using modulation-doping of the hole transport layer (HTL). A planer heterojunction device was investigated using two well-studied materials 1,1-bis [(di-4-tolylamino) phenyl] cyclohexane (TAPC) as a hole transporting material, C_{70} as the accepting material, and P-type dopants, $C_{60}F_{48}$. The dopants were induced in a δ-doped layer of 10 nm width within the TAPC layer. The presence of the doped layer within the device induces an internal electric field at the junction leading to enhanced charge separation efficiency, reaching 50% enhancement in the current at the maximum power point and 30% at $0.8V_{oc}$.

To extend the applicability of the design to solution-processed cells and make it universal to (almost) any donor-acceptor pair, we developed a strategy based on a cross-linkable high band-gap polymer matrix[2] where the donor material of choice can be blended at ~20w% to serve as the charge transporting/extracting level.[3] Being insoluble it can be considered as part of the substrate and the flexibility in choosing the transport material makes it universal.

We will first describe the general properties of the enhanced charge-extraction structure utilizing Poly (vinyl carbazole) bearing cinnamate pendants (PVK-cin [50%]) as the x-linkable matrix, Poly[bis(4-phenyl) (2,4,6-trimethylphenyl) amine (PTAA) as the transport/extraction material, and $C_{60}F_{48}$ doped PTAA as the δ-doped layer. Next, we describe the properties of a complete cell that is based on PBDB-T-2F (PM6) and Y6 (BTP-4F) as the donor-acceptor pair, respectively. [4, 5] To place the experimental results in perspective, we conduct a detailed device simulation and compare the experimentally measured enhancement to the maximum theoretical prediction.

Doping and Extraction of Small Molecules in Semiconducting Polymer Films—Insights from Studies of Fluorescent Chemical Sensors Graham A. Turnbull, Iain A. Campbell, Edward B. Ogugu and Ross N. Gillanders; University of St Andrews, United Kingdom

The presence of extrinsic dopant molecules can have a strong impact on the photophysical or electronic properties of organic semiconductor thin film devices. For example, Extrinsic dopant molecules present at low/ medium density can greatly enhance charge transport in p-i-n OLEDs, or provide recombination sites in the emissive layer. Dopants can act as charge traps, or exciton quenchers for study of transport phenomena in organic thin films. The presence of extrinsic analyte molecules in thin film chemical sensors can either modify the properties of photoluminescence (for example through fluorescence quenching) or electrical conduction. In device studies and applications, the dopants are conventionally introduced via co-deposition with the host material; whereas in chemical sensors, the analyte molecules are absorbed from either the surrounding vapour or solution phase after the film is formed.

In this paper we present study of the process of introduction and removal of small molecules into/from thin films of semiconducting polymers. We use photoluminescence quenching chemical sensors as a model system that can provide a platform for more general study of molecule transport in polymer films. We will describe a combined approach of experiments and simulations to explore molecular doping from the vapour and solution phases; The transport of sorbed molecules under the influence of diffusion and binding processes; and the retention and thermal desorption of the dopant.

We use a computational rate equation approach to model the binding and 1-dimensional diffusion of extrinsic molecules and estimate their populations within the film. We couple Fick's laws of diffusion to chemical binding rate equations for arbitrary analyte diffusion constants and binding rates. We relate the extrinsic dopant molecule populations within the film to the film luminescence and study the influence of the molecular interaction constants on the time-dynamics of fluorescence quenching in the film. We calculate the transport of dopant molecules through the thin film when driven by a positive or negative diffusion gradient at the film surface, observe a strong asymmetry in the fluorescence quenching signal between the in-diffusion dynamics of the dopants and the desorption of stored dopants from the film.

We compare the computational study with experiments of the sorption and transport of nitroaromatic molecules in thin films of the commercial semiconducting polymer Merck Super Yellow and non-conjugated polymers AFLAS and poly(bisphenol A-co-epichlorohydrin. We study the doping of dinitrotoluene over a range of concentrations in the polymers when introduced from acetonitrile solution and from the vapour phase. Measurements of the retention of the dopant at room temperature and at elevated temperatures are made using a combination of absorption and photoluminescence spectroscopy. Combined with the computational model these experiments provide insight to the process and time dynamics of introducing extrinsic molecular dopants in thin polymer films, their distribution and long-term stability.

12:00 PM EQ06.11.05
Strategies for the Mitigation of Ion Migration in Hybrid Perovskite Field-Effect Transistors Amita Ummadisingu, Youcheng Zhang and Henning Sirringhaus; University of Cambridge, United Kingdom

Hybrid perovskites which are composed of both organic and inorganic components, have recently been found to possess excellent optical and electronic properties making them highly suitable for applications such as solar cells, light-emitting diodes, and thin film field-effect transistors (FETs) (1, 2). However, a deeper understanding of the complex charge transport in thin films of these hybrid materials is currently lacking. Here, we fabricated three-

dimensional perovskite FETs in the bottom-contact top-gate and the bottom-contact bottom-gate architectures using solution processing via the anti-solvent method (3) and identified unusual transfer characteristics that result in a lower than predicted field-effect mobility as well as unwanted hysteresis. To tackle these issues, we explore the effect of perovskite stoichiometry on the transfer characteristics of both methylammonium lead iodide and complex triple-cation perovskite FETs (3, 4). Those insights are correlated with the perovskite microstructure and local compositional information obtained using characterization techniques such as photoluminescence imaging, x-ray diffraction measurements and scanning electron microscopy, to unravel the central role of iodide ions in disrupting the expected FET transfer characteristics by partially screening the applied gate field. Furthermore, for each of the architectures, we present individual strategies in the perovskite processing methodologies and post-deposition cleaning protocols (5) that successfully suppress the unwanted ion migration. Our triple-cation-composition based FET device, optimized using Design of Experiments (DOE) principles, exhibits stable transfer characteristics with n-type behavior and remarkably low hysteresis even at room temperature. It also shows a good saturation electron field-effect mobility and an on/off ratio of ~10^4 at room temperature. Our work presents effective strategies to manage the ion migration and obtain improved device performance in organic-inorganic perovskite FETs, taking a step towards the realization of the predicted charge transport characteristics for these hybrid materials for use in different optoelectronic applications.

Electropatterned and Molecularly Imprinted Conjugated Polymers—Sensors and Nanostructured Devices Rigoberto C. Advincula[1,2,3]; [1]Case Western Reserve University, United States; [2]The University of Tennessee, Knoxville, United States; [3]Oak Ridge National Laboratory, United States

Conjugated polymers and their use in organic electronics and have long been recognized and have made advances in display and electronic solid-state devices. The use of electropolymerization and electrodeposition have enabled the layering and formation of ultrathin functional polymer films useful for the transistor, display, and sensor devices. Utilizing control of the solution and electrochemical dielectric parameters, it is possible to tune and pattern surfaces where the polymer formed have controlled oxidation and reduction behavior which mediates the film workfunction and optical parameters. In this work, we report on the methods to prepare ultrathin dielectric and electronic materials of conjugated polymers primarily by electrochemical methods, highlighting the ability to pattern and control transport behavior up to the nanoscale. This will be demonstrated in the following: 1) electronanopatterning using SPM methods to prepare conjugated polymer network circuits, 2) electrodeposition in colloidal particle arrays and electropolymerization, and 3) electrochemically molecularly imprinted polymers. The results are devices that enable memory devices, mediated ion transport gates, and chemical and biological sensors respectively utilizing ultrathin film geometries, electrochemical control and surface characterization methods in devices.

Low Cost Manufacturing of µLED Display by Fluidic Self-align Assembly (FSA) Technology Using Known-Good-µLED Jong-Jan Lee; eLux, Inc., United States

Direct emission displays made with inorganic µLEDs can potentially challenge LCD and OLED displays with better performance, efficiency and lifetime. Markets where microLED displays are likely to first appear are large information displays requiring high brightness, home theater applications benefitting from increased dynamic range and automotive displays in which high contrast and reliability are necessary. These displays are made possible by the integration of two mainstream technologies, namely GaN LED developed for general lighting and the large area active matrix backplanes developed for LCD displays.
The unique manufacturing challenge for µLED displays is development of a technology to position and connect millions of small devices with zero defects and low cost. Conventional pick and place tools are capable of positioning µLEDs, but the throughput of serial assembly is inadequate while mass-transfer methods have difficulty changing the pixel pitch. To address these challenges eLux has developed a massively parallel Fluidic Self-align Assembly (FSA) technology which positions each µLED by capture of the device in a well structure that also contains the connecting electrodes.
FSA uses simple low-cost equipment to achieve assembly rates up to 50 million µLEDs per hour and it is anticipated that production equipment could assemble an 8K display with 100 million LEDs in a few minutes. The technology is suitable for µLEDs from 10 to 200 µm diameter offering flexibility to make a wide variety of displays with resolutions from 400 to 10 ppi or larger. Similarly, the microLED emitter area can be adjusted independently of the assembly technique to increase brightness and it is possible to produce displays over 5,000 cd/m^2. Fluidic assembly applies relatively low force on the device so brittle materials such as red µLEDs fabricated from AlGaInP can be assembled in the same way as blue and green emitting GaN µLEDs.
A fully integrated manufacturing system for µLED fluidic assembly will ensure that the assembled µLEDs have acceptable performance with special emphasis on eliminating shorted or high resistance devices. Testing and binning used in the general lighting industry are not practical at the micron scale, so wafers are mapped by cathodoluminescence to identify defective µLEDs. Based on the defect map, a selective harvest technique diverts bad µLEDs from the suspension so only known good die are used for assembly. FSA relies on an excess of µLEDs to ensure sufficient capture attempts for complete assembly, so it is also necessary to capture, filter and recycle unassembled µLEDs.
With a suitable choice of complementary characteristic for the device and the trap site, it is possible to use fluidic assembly techniques to position nanowires or nanoparticles as well as µLEDs. The presentation will give an overview of the integration issues with some suggestions for other possible applications and approaches.

1:30 PM *EQ06.12.02

Development of Ocean Chemical Sensors and Soft Actuators Through Printing Customizations Shuoen Wu, Yichen Zhai and Tse Nga Ng; University of California, San Diego, United States

With our marine ecosystems under threat from climate change, there is an urgent need to continuously monitor marine conditions. One key indicator is the dissolved oxygen level, but existing sensors are limited by size and costs that preclude widespread non-intrusive monitoring. We present a new dual-gate design based on printed organic electrochemical transistors (OECTs) to track dissolved oxygen concentration in seawater, a highly challenging matrix owing to its high ionic strength and multitude of chemical interferents. The sensor achieved a detection limit of 0.3 ppm dissolved oxygen concentration in seawater. The device demonstrated reliable operation over five days and was capable of monitoring oxygenation changes arising from the photosynthesis cycles of saltwater macro-algae. In addition to oxygen, the dual-gate modulation principle is generalizable to other analytes with high redox potentials such as nitrates and dissolved carbon dioxide, and it offers a new design to realize compact, highly sensitive, economical in-situ sensors for harsh marine environments.

In addition to sensor fabrication, printing approaches can lead to devices that are readily customizable and economical for everyone to explore potential benefits and create new robotic applications. We demonstrated the printing integration of multi-material actuators, with an eye toward improving the fidelity and robustness of the printing process. We achieved compact soft actuators by using liquid-crystal elastomers (LCE) patterned by extrusion. An adjustable load was attached on the probe to control the pressure applied on the film. During the LCE alignment process, the probe velocity and load were tuned for gradient controls of alignment strength with various actuation strains based on different tool path strategies. The actuated samples were recorded with a 3D scanner to compare with the original 3D model. The quantitative results displayed a good index of 84.47% in structural similarity, successfully demonstrating the high fidelity of this approach.

2:00 PM EQ06.12.03
Increasing Photostability of Inverted Nonfullerene Organic Solar Cells by Using Fullerene Derivative Additives Marcella Günther[1], Dominic Blätte[1], Anna Lena Oechsle[2], Sergio Sánchez Rivas[1], Amir Abbas Yousefi Amin[1], Peter Müller-Buschbaum[2,2], Thomas Bein[1] and Tayebeh Ameri[3,1]; [1]Ludwig-Maximilians-Universität München, Germany; [2]Technische Universität München, Germany; [3]University of Edinburgh, United Kingdom

With efficiency now above 18%, organic solar cells are well on their way to commercial application. However, there are still major stability issues that drastically limit their lifetime. One problem that has recently become more apparent originates from the commonly used electron transport layer (ETL) zinc oxide. Although this material has very advantageous properties, such as low price, transparency and good conductivity, it has one major drawback, namely its photocatalytic activity, which degrades many good absorber materials. Typically, this problem is solved by adding a protective layer between the ETL and the absorber layer, however this results in a much more challenging manufacturing. A simpler approach would be to mix a protective compound directly into the absorbing layer. In this work we use a ternary approach by adding three different fullerene derivatives – $PC_{71}BM$, ICMA, and BisPCBM – to a PBDB-TF:IT-4F system in order to suppress the photocatalytic degradation of IT-4F on ZnO via the radical scavenging abilities of the fullerenes [1]. We show that already an addition of 5% fullerene can quintuple the lifetime of the solar cells under UV illumination. We attribute this improvement to a reduced photocatalytic decomposition of IT-4F in the ternary system, which results in a decreased recombination. We propose that the added fullerenes protect the IT-4F by acting as a sacrificial reagent, and thereby suppress the trap state formation. Furthermore, we show that the protective effect of the most promising fullerene ICMA is transferable to two other binary systems PBDB-TF:BTP-4F and PTB7-Th:IT-4F. Importantly, this effect can also increase the air stability of PBDB-TF:IT-4F. This work demonstrates that the addition of fullerene derivatives is a transferable and straightforward strategy to improve the stability of organic solar cells.

2:15 PM EQ06.12.04
Combining Screen and Aerosol Jet Printing Techniques for the Manufacturing of Organic Electrochemical Transistors (OECTs) for Utilization in Logic Circuits and Sensor Applications Anatolii Makhinia, Kathrin Hübscher, Jan Strandberg, Marie Nilsson, Valerio Beni and Peter Andersson Ersman; RISE Research Institutes of Sweden, Sweden

The reported study demonstrates a novel fabrication approach that combines the versatility of screen printing and the high resolution of aerosol jet printing to manufacture reliable and fast all-printed organic electrochemical transistors (OECTs) on PET substrates. For OECTs, both the area and physical thickness of the channels are of critical importance for rapid switching response. As a result, we take advantage of a robust screen printing process to fabricate all the layers, except for the channel that is deposited by aerosol jet printing technology. This fabrication strategy reduces the PEDOT:PSS-based channel volume by up to a factor of 15 compared to screen printed channels, giving rise to a faster switching response due to lowered device capacitance. The switching performance has been confirmed by dynamic and transfer sweep measurements for all-printed standalone OECTs, OECT-based inverters and 5-stage ring oscillator circuits. Remarkably fast switching response and propagation stage delays of just above 1 ms for all-printed OECT-based inverter and ring oscillators have been achieved, despite using a screen printed electrolyte layer solidified by UV curing. In contrast, previously reported fully screen printed OECT-based inverters and 5-stage ring oscillators exhibited propagation stage delays of ~50 ms and ~100 ms per stage, respectively [1]. Additionally, the all-printed OECT devices reveal a high ON/OFF ratio of 10^3-10^4, while keeping low switching voltages. This is evidenced by the fact that the input voltage window for the OECT-based inverter circuit was reduced to 1 V (square wave signal fluctuating between 0 V and 1 V), thereby prolonging the operational lifetime.
The results reported herein pave the way towards a cutting-edge fabrication approach that can tailor-made the device architecture to reveal the best possible match for various applications, depending on the requirements. The proposed approach was applied for the manufacturing of high-performance OECT-based devices, exemplified by OECT-based logic circuits with remarkable switching response as well as in sensor applications utilizing the high amplification in all-printed OECTs.

Transport Regimes, Material Utilization Efficiency and Film Production Rate in Low Pressure Organic Vapor Phase Deposition Ikenna H. Ozofor, Cecelia Kinane, Giselle Roca, Boning Qu, Stephen R. Forrest and Max Shtein; University of Michigan, United States

Organic vapor phase deposition (OVPD) is a technique for depositing active layers in organic optoelectronic devices, including OLEDs. In OVPD, organic material is evaporated into a stream of carrier gas, which transports it toward a cooled substrate, where organic vapor can be made to condense into a

smooth film. This approach decouples evaporation from transport and deposition, thereby offering increased stability of the deposition rate and doping ratio compared to the classical method of vacuum thermal evaporation (VTE). Thus, OVPD is a promising technique for low-cost volume production of multi-layer tandem OLEDs, where the number of active layers can exceed 25 in number. To advance deposition process and hardware design, we analyze transport mechanisms in OVPD, identifying key conditions and dominant factors. For a given hardware configuration, we show that diffusion dominates over convection in the upstream zone at carrier gas flow rates ≤ 50 SCCM and in the downstream zone when flow rate < 400 SCCM. These parameters can be scaled to hardware of different sizes. We also show how organic material flux, which determines film production throughput, can be extrapolated from convenient laboratory-scale experiments and computational fluid dynamics simulation. We further introduce a model that predicts material utilization efficiency, independent of organic vapor concentration. Results from this model compare well with experimental values, and they present pathways for process optimization and material waste minimization.

Emergent Opto-Electronic Properties in Molecular-Metal Polymer Nanocomposites Raphael Pfattner, Elena Laukhina, Marta Mas-Torrent, Elena Laukhina, Concepcio Rovira and Jaume Veciana; Institut de Ciencia de Materials de Barcelona (ICMAB-CSIC) and Networking Research Center on Bioengineering, Biomaterials and Nanomedicine (CIBER-BBN), Spain

Developing smart materials that can respond to an external stimulus is of major interest in artificial sensing devices able to read information about the physical, chemical and/or biological changes produced in our environment. Additionally, if these materials can be deposited or integrated on flexible, transparent substrates, their appeal is greatly increased.
The first [BEDT-TTF = bis(ethylenedithio)- tetrathiafulvalene based quasi-twodimensional organic superconductor β-(BEDT-TTF)$_2$I$_3$ was first reported back in 1984.[1] Soon it became clear that ion radical salts (IRSs) derived from BEDT-TTF exhibit tuneable electronic band structures; therefore, such molecules are excellent building blocks for engineering a rich and diverse family of organic crystalline metals and semiconductors. Thanks to strong electron−electron and electron−phonon couplings, their anisotropic electronic structures exhibit many fascinating electronic and structural phase transitions, which can be controlled by external stimuli such as light, temperature, strain, pressure, and humidity, among others. Nevertheless, it is necessary to engineer these crystals into a proper material for sensing applications. This is done by forming polycrystalline layers of IRSs, derived from BEDTTTF-based conductors, in nanocomposite bilayer (BL) films.
Such systems can be further tuned by choosing the nature of the IRSs enabling high sensitivity towards strain, pressure, temperature or even contactless radiation sensing *i.e.* bolometers.[2,3] In another very recent example, bilayer films, composed of conducting polycrystalline layers of two dimensional BEDT-TTF-IRSs, hydroresistive sub-micron sized crystals on top of a polymeric host matrix permit to electrically monitor relative humidity in a stable and fully reversible fashion.[4] At the percolation threshold, fascinating novel optoelectronic properties emerge (Insulator semiconductor-like metal transition).[5] Mechanisms of responses are discussed and correlated with fundamental properties of charge transport in these systems. This sensor platform enables combining high electrical performance of single crystals with processing properties of polymers towards a simple, low-cost and highly sensitive platform for applications in robotics, biomedicine and human health care.

Electron/Hole Transport Layer Work Function in Organic Devices Dalil Oussalah[1,2], Jérôme Vaillant[1], Benoît Racine[1], Jacques Baylet[1], Romain Paquet[1], Coralie Sésé[1], Christelle Laugier[1] and Raphael Clerc[2]; [1]Univ. Grenoble Alpes, CEA, Leti, France; [2]Univ. Lyon, UJM-Saint-Etienne, CNRS, IOGS, Lab. Hubert Curien UMR5516, France

Introduction: Doped Hole (resp. Electron) Transport Layers HTL (resp. ETL) are commonly used in evaporated organic devices to achieve high work function hole contact (resp. low work function electron contact): in OLED to inject large current [1], in solar cell to increase the open circuit voltage Voc [2], and in photodetector to minimize the dark current [3]. However, the thickness of the HTL/ETL results from a delicate trade off. Indeed, on one hand, to minimize the detrimental impact of HTL/ETL on light absorption and series resistance effects, HTL/ETL must be kept as thin as possible. On the other hand, it is easier to reach an efficient work function by doping thicker layers. This later point is investigated more specifically in this work: an analytical model, numerical simulation and experiments are combined to identify this minimum acceptable thickness.

Simulation & Modeling: As it is surrounded by other materials with different work functions, the built in electric field within the HTL is never negligible, even in absence of applied voltage. In consequence, the Fermi level in ultra thin HTL layer, adjusted by doping, may differ from its (ideal) bulk value. A model has been derived to capture the impact of doping and thickness on the calculation of the HTL work function in two configurations: when the HTL is surrounded by two metals, when it is surrounded by a metal and an undoped organic semiconductor. Results, validated by numerical simulations, allows to determine the minimum acceptable thickness versus doping and electrostatic environment.

Experiments: Moreover, experiments were performed on a p-only structure (Ag/STTB:F4TCNQ (p-doped HTL)/ZnPc:C60 (active zone)/TiN) fabricated using common organic OPD/OLED materials. Samples feature different levels of doping and thickness. I-V curves has been fitted by a coherent set of physical parameters, confirming the capability of simulation of reproducing experiments. To extract the work function in situ, an innovative technic using I-Vs curves was implemented, following the work of X. Wei & al [4]. The results obtained clearly confirm the trend of the work function versus thickness curve predicted by theory. In high doped layers (1019 cm-3) a thickness of 10 nm is required to reach a suitable work function, while more than 20 nm is needed for lower doping (<1018 cm-3).

Conclusion: In summary, the impact of thickness and doping on the HTL work function in p-only template devices has been investigated in three complementary approaches: analytical modelling, numerical simulations and experiments. Results obtained proved that the obtainment of an efficient high work function HTL layer requires a minimum non negligible thickness, between 10 nm and 20 nm depending on doping level.

4:30 PM EQ06.13.03

Tunable and Narrowband Organic Photodetectors for Miniaturized Spectrometers on a Single Chip Shen Xing[1], Jonas Kublitski[1], Donato Spoltore[1], Koen Vandewal[2], Hans Kleemann[1], Johannes Benduhn[1] and Karl Leo[1]; [1]IAPP, TU Dresden, Germany; [2]Institute for Materials Research (IMO-IMOMEC), Belgium

Organic photodetectors (OPDs) are candidates for numerous novel applications including wearable electronics and biometric monitoring. Despite significant development, it is still challenging to simultaneously achieve tailorable optoelectronic properties and faint light sensitivity. Here, we propose a new concept by combining a transmission cavity structure with organic absorbers to achieve tunable and narrowband OPDs via a full-vacuum process. Benefiting from this strategy, remarkable performance such as narrowband photoresponse (full width at half maximum of around 40 nm), a large tunability from visible to near-infrared region, fast response speed, and ultrahigh specific detectivity (> 10^{14} Jones) are simultaneously realized. To prove the potential application of this concept, multiple transmission cavity OPDs are integrated to be a miniaturized spectrometer whose performance is demonstrated. This novel concept extends the state-of-the-art OPDs, rivals silicon photodetectors, and will mature the spectroscopic photodetection for mobile applications.

4:45 PM EQ06.13.04

Innovative Fabrication and Processing Methods for Organic and Hybrid Electronics Christopher Landorf, Vijaya Kayastha, Rebekah Baggett, Anish Thukral and Marriana Nelson; Brewer Science, Inc., United States

Previously Brewer Science has reported on the solubilization of pristine carbon nanotubes in water, alcohols, and glycols through the use of super-acids and polyaromatic hydrocarbon derivatives. The goal of that research was to produce inks that allowed for rapid manufacturing of carbon-nanotube-based conductive thin films. These films do not require any post-processing steps, such as washing, to get rid of surfactants, and since the solubilizing functionality is non-covalently bonded to carbon nanotubes, the electronic structure of the carbon nanotube is preserved.
In addition to enabling the production of films with excellent conductivity, these dispersions of carbon nanotubes also provide us with a unique environment to further explore reactivity for carbon nanotube functionalization. The lack of surfactants means that the surface of the tube is still accessible as a reactive surface, and since these carbon nanotubes are still highly conductive, further functionalization doesn't degrade the electrical properties.
Carbon nanotubes have been exploited for their sensitivity to a variety of analytes, including gases; however, gas selectivity can be a challenge. In order to improve selectivity, carbon nanotubes can be functionalized through various means to target specific analytes. Using the unique reaction environment that Brewer Science has developed, we have successfully coated carbon nanotubes with a disordered tin oxide layer characterized as mixed oxides by Raman spectroscopy to target combustible analytes. Other metal oxides, including vanadium and titanium, have been reacted similarly. SEM images of films of the functionalized tube sets demonstrates that the metal oxide is deposited on the carbon nanotube surface, and minimal free metal oxide is observed.
The resulting inks can be screen-printed between electrodes, allowing rapid manufacture of hundreds of devices. A thin layer of palladium is deposited as a catalyst, and with electronics developed by Brewer Science, the tin oxide-doped carbon nanotube films easily detect 100 ppm of carbon monoxide in our screening efforts. This same sensor, as printed, does not respond to other gases typical of tin oxide, such as methane. A sensor manufactured without either the tin oxide or the palladium does not respond to carbon monoxide.

5:00 PM EQ06.13.06

Enhanced Brightness Solution-Processed $CsPbBr_3$ Perovskite LEDs Using a Composite PEG-PVP Matrix Parvez Akhtar[1], Nidhi Dua[1], Raman Agrawal[2] and Madhusudan Singh[1]; [1]Indian Institute of Technology Delhi, India; [2]IIT Delhi, India

Imperfect surface coverage, pinholes and other defects in solution-processed pervoskite ($CsPbBr_3$) thin films limit the radiative efficiency and stability of corresponding perovskite light-emitting diodes (LEDs). Significant effort on refinement of various deposition techniques, chemical compositions, functionalization and surface treatments have been reported in literature. In this work, we report on use of two inexpensive polymers - poly(ethylene) glycol (PEG) and polyvinylpyrrollidone (PVP) as a composite matrix for $CsPbBr_3$ to enhance surface coverage and uniformity of the deposited films in LEDs. A transparent perovskite precursor solution was prepared by mixing CsBr (99.999%, Sigma-Aldrich) and $PbBr_2$ (99.99%, Sigma-Aldrich) in DMSO with an optimized molar concentration ratio of 1.5:1 (0.2M) in a nitrogen glove box (Inert PureLab). After filtering, this solution was blended with separate PEG and PVP solutions (in dimethylsulfoxide (DMSO) and dimethylformamide (DMF), respectively, concentration > 5mg/ml) with a 6% net loading of the polymer solution to form the active ink. The ink was spin-coated on glass for film characterization. An orthorhombic phase (JCPDS(06-153-3063)) for $CsPbBr_3$ was confirmed using X-ray diffraction (Rigaku Miniflex, Cu-Kα, 1.54Å), with the elemental composition confirmed using energy dispersive X-ray analysis (EDX). UV-Vis spectrometry (Perkin-Elmer) was used to infer a band gap of 2.38±0.015 eV. Photoluminescence spectra (Horiba Labram, with a 325 nm source) yield a single highly intense peak at 520 nm (FWHM: 20 nm). For polymer LED fabrication, indium tin oxide (ITO) coated glass substrates were cleaned in a standard multistep process prior to spincoating poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS, Baytron PVP), dehydration bake in air (120C), followed by spin-coating of perovskite ink under nitrogen, and an anneal at 75C. Samples were transferred under nitrogen for thermal evaporation at $2.3x10^{-6}$ Torr (Angstrom Engineering) of 2,2',2"-(1,3,5-Benzinetriyl)-tris(1-phenyl-1-H-benzimidazole) (TPBi, 300 A), LiF (8A) and Al (1000 A) to complete the devices with a shadow-masked top contact of area 0.3 x 0.3 cm^2. Control devices (no polymer additive) were processed at the same time under identical conditions. Current-voltage (J-V) and light-intensity-voltage (L-V) characteristics were acquired using a Keithley 2450 SMU and a calibrated Si photodiode. The test ($CsPbBr_3$-PEG-PVP) perovskite device exhibited a lower turn-on voltage (4.1V vs 3.2V), higher luminance (392 cd/m^2 vs 1070 cd/m^2), current efficiency (0.150 cd/A vs 0.254 cd/A), when compared to the control device. Electroluminescence spectroscopy measurements (Ocean Optics HR4000) reveal in an emission at 518 nm (FWHM=17 nm) with Commission Internationale de l'éclairage (CIE1931) coordinates (0.13,0.75), in close agreement with measured PL. To study the likely source of these enhancements, we carried out comparative film analysis of test and control devices using field-emission scanning electron microscopy (FESEM, JEOL JSM-7800F Prime) and atomic force microscopy (AFM, Asylum Research MFP3D-SA). A reduced crystal grain size (204.1 nm to 101.1 nm) and nearly 100% surface coverage (compared to 81% found for control devices) found using FESEM suggests that the improved overall morphology and surface coverage plays a significant role in the improved performance. Further, a reduction in surface roughness (5.8 nm to 3.2 nm) and formation of a pinhole-free film is observed to increase yield by 20%. We are currently carrying out initial measurement of device lifetimes under accelerated test conditions under nitrogen and in air (after encapsulation) to further elucidate the relative prevalence of various device failure mechanisms in the test and control LEDs. We expect that these enhanced devices would find extensive applications in personal lighting, and transparent flexible display applications.

5:15 PM EQ06.13.07

Hybrid Organic-Inorganic Thin-Film Multispectral Photodetector Vladimir Pejovic[1,2], Epimitheas Georgitzikis[1], Itai Lieberman[1], Pawel Malinowski[1], Paul Heremans[1,2] and David Cheyns[1]; [1]imec, Belgium; [2]KU Leuven, Belgium

Optoelectronic devices based on thin-film materials such as organic polymers and small molecules, colloidal quantum dots (CQDs), and perovskites have been demonstrated as a promising route to bring disruptions in various consumer and industrial domains. Thin-film photodetectors are emerging as new imaging technology, thanks to their versatile large-area and room-temperature fabrication. Highly sensitive organic photodetectors (OPDs) enable flexible image sensors and co-integration with OLED displays. However, no organic semiconductors have been synthesized so far that can offer competitive quantum efficiency in infrared beyond 1 μm wavelength – the same limitation associated with silicon photodiodes. On the other hand, the facile bandgap tunability of CQDs made them a promising alternative to conventional infrared image sensors based on compound semiconductors. Thanks to a possibility for monolithic integration with CMOS electronics, CQDs offer low-cost, high-throughput fabrication and unprecedented resolution in infrared, which is expected to enhance the development of industries such as autonomous driving, augmented/virtual reality, and others.
Here, we present our work in which we combine the two thin-film technologies in a single photodetector in order to leverage the best features of both, such as high visible sensitivity of OPDs and high infrared sensitivity of CQDs. The photodetector contains two stacked photodiodes connected in a back-to-back serial configuration. Each photodiode can be activated separately by selecting the bias voltage polarity, offering a multispectral capability. One photodiode is based on a solution-processed organic bulk heterojunction made of PTB7-Th and IECO-4F, and it exhibits sensitivity up to 1 μm wavelength, with high external quantum efficiency (EQE) of more than 60% at 700 nm and a low dark current density of 30 nA/cm^2 at 1 V reverse bias. The other photodiode is based on solution-processed PbS CQDs with their size tuned for absorption up to 1600 nm and it exhibits a dark current density of 800 nA/cm^2 at 1 V. We perform optical simulations based on a transfer matrix method and find that an intermediate thin silver layer can reduce the optical crosstalk between the two channels. Moreover, this thin film enables tuning of the CQD photodetector's response thanks to a strong optical cavity created with the back metal electrode, giving rise to a high EQE of more than 20% at different wavelengths in the 1-1.6 μm range. Transient measurements reveal a fast switching speed between the two photodiodes in the order of 10 μs.
By combining solution processing and physical vapor deposition, we developed a room-temperature, large-area compatible process that allows us to integrate polymers, CQDs, metal oxides, and metals in a single device. To ensure efficient charge carrier transport and low levels of dark current, we carefully engineered the device stack by controlling the surface passivation of CQDs and the energetic alignment at the interfaces. The presented photodetector is a two-terminal device that is compatible with the developed methods for integration of thin films with CMOS readout electronics, whereas its vertically stacked structure provides high spatial resolution for imaging. The presented photodetector has the potential to enable low-cost, high-resolution multispectral imaging and demonstrates how thin-film technologies can be exploited for new applications and functionalities.

6:30 PM EQ06.14.01
A Highly-Oriented Fibril-Like Rigid N-Type Polymer with High Electrical Performances Marc-Antoine Stoeckel[1], Han-Yan Wu[1], Chi-Yuan Yang[1], Ziang Wu[2], Yang Lu[3], Jian Pei[3], Han Young Woo[2], Magnus Berggren[1] and Simone Fabiano[1]; [1]Linköping University, Sweden; [2]Korea University, Korea (the Republic of); [3]Peking University, China

Conjugated polymers are an enabling technology for numerous optoelectronic, bioelectronic, and energy harvesting/storage applications. The conductivity of several solution processable conjugated polymers, and therefore the performance of many of the corresponding devices, can be enhanced by molecular doping. For practical applications, both hole-transporting (p-type) and electron-transporting (n-type) conducting polymers are usually required. Unlike p-doped polymers that exhibit conductivities typically > 1000 S/cm, most n-doped polymers suffer from conductivity values < 1 S/cm. Various polymer design strategies, including planarization and stiffening of the polymer backbone, engineering of the donor–acceptor character, and control of the molecular dopant counterion-polymer side-chain miscibility are being explored. Despite great progress, n-doped conducting polymers do not yet meet the performance comparable to the best p-doped polymers. Here, we constructed highly ordered polymeric films, with thickness approaching unit cell dimension, and investigated their electrical properties. We used Langmuir-Schaeffer (LS) deposition technique to manufacture highly oriented polymeric monolayers with a low degree of defects. We used a combination of scanning probe microscopies, optical spectroscopy, GIWAXS, NEXAFS and electrical measurements to characterize the polymeric energetics, structural, and thermoelectric properties. We optimized the electrical performances of the ultra-thin films by n-doping them with strong reducing agents, reaching n-type conductivities of 4 S/cm, and a power factor of 1.5 μW/mK^2.

6:35 PM EQ06.14.02
Effect of Polymer Backbone on Optoelectronic Properties of Metallopolymers Nese Guven[1], Hajar Sultanova[2], Burak Ozer[1], Baris Yucel[2] and Pinar Camurlu[1]; [1]Akdeniz University, Turkey; [2]Istanbul Technical University, Turkey

Metallopolymers are a new generation of hybrid materials containing a transition metal complex and a π-conjugated backbone. Ruthenium complexes between transition metal complexes are extremely important with their stable redox transitions and electrochromic properties. Herein, monomers containing the redox active $[Ru(bpy)_2pytri]^{2+}$ complex and various polymerizable thiophene derivatives such as SNS, EDOT and ProDOT were synthesized via click chemistry. As a result of electrochemical polymerization of monomers, new electrochromic metallopolymers based on polythiophene were obtained.
It was determined that polythiophene derivatives, which consist of the same complex unit and different polymerizable units, exhibit different band gaps and color properties depending on the backbone of the polymers. The band gaps of PSNS, PEDOT and PProDOT were calculated 2.44 eV, 1.84 eV and 1.94 eV, respectively. The neutral colors of the PSNS-Ru, PEDOT-Ru and PProDOT-Ru metallopolymers were determined yellow, green and orange, respectively. The switching times of PSNS-Ru, PEDOT-Ru and PProDOT-Ru were determined as 5.14 s, 2.52 s and 3.70 s, respectively.
All polymers showed their respective redox activities of both conjugated main backbone and metal complex indicating the effective manipulation of redox behavior of conducting polymers through engineering of the monomer structure.

6:40 PM EQ06.14.03

Late News: Effect of Water Treatment on Enhancing the Performance and Stability in Slot-Die Coated Organic Solar Cells Nara Han[1], Youn-Jung Heo[2], Yeonsu Choi[1] and Dong-Yu Kim[1]; [1]Gwangju Institute of Science and Technology, Korea (the Republic of); [2]Korea Institute of Industrial Technology, Korea (the Republic of)

In the field of organic electronic devices, it is generally unusual to use polar solvent in organic solvent-based active solution for improved efficiency and stability. Residual water in active solution has also been reported to adversely affect organic electronic devices. For blocking the contact of moisture, many researchers prepare and store organic electronic devices under nitrogen (N_2) atmosphere. However, we found that various hydrophilic solvents, such as water, methanol and isopropanol, as additives have an unexpectedly positive effect for enhanced efficiency and stability of solar cells. In this study, the D-A blend films (**ref-1**: PTB7-Th:$PC_{61}BM$, **ref-2**: PTB7-Th:EH-IDTBR and **ref-3**: PM6:Y6) with water treatment were slot-die coated and optimized for up-scaling production. Furthermore, we confirmed that the bulk heterojunction morphology and power conversion efficiency depend on the quantity (0~20 v/v%) of water introduced as a solvent additive. The effects of water addition were analyzed by using AFM, TEM, FT-IR and 2D GIWAXS measurements. As a result, enhanced efficiencies of 12% (ref-1/WT), 11% (ref-2/WT) and 12% (ref-3/WT) compared with efficiency of reference cells were achieved from the water addition. In addition, the improved stability (RH 60 % and room temperature in air) of the water additive incorporated devices was demonstrated as compared with reference cells, showing the excellent potential of eco-friendly and morphology-controllable additive for the printable organic solar cells.

6:45 PM EQ06.14.04
Improved Optical Confinement in Ambipolar Field-Effect Transistors via High Refractive Index Cladding Layers Towards Electrical Injection Organic Lasers Yun Li[1], Randy Sabatini[2], Shyamal Prasad[3], Evan Hockings[1], Timothy Schmidt[3] and Girish Lakhwani[1]; [1]The University of Sydney, Australia; [2]University of Toronto, Canada; [3]University of New South Wales, Australia

Electrical injection organic solid-state lasers (OSL) promise easily processable devices for chemical sensing, point-of-care diagnostic and applications requiring wavelength tunable sources. While significant progress has been made with OSL's, persistent issues such as optical losses and short operational lifetimes in the devices prevent the realization of practical application. To circumvent these issues, novel injection architectures have been proposed. One such structure is the ambipolar field-effect transistor (FET).

In our work, mode-solver calculations demonstrate that improvements to optical confinement are possible in FET geometries, by using high refractive index cladding layers. Optical experiments show an increase in amplified spontaneous emission (ASE) efficiency and lowered ASE thresholds, which we attribute predominantly to the increased confinement. The results suggest that the structure can be potentially used to improve lasing characteristics for both optically pumped, and electrical injection organic lasers where thin, low refractive index active materials are required.

6:50 PM EQ06.14.05
The Shrink Film Scale Down Fabrication Method of the Low Voltage Operate Organic Field-Effect-Transistor Shui Hong Siddhartha Dai[1,2]; [1]Hong Kong University, Hong Kong; [2]Advanced Biomedical Instrumentation Centre, Hong Kong

Organic Field-Effect Transistors (OFETs) have been developed for different applications including bio-sensors, flexible memory, display drivers and etc. To enhance the functionality of OFET devices, downsizing the OFETs and increases their packing density are required. However, the traditional scaling-down fabrication method demands more involved fabrication processes such as photolithography, deep X-ray lithography, or e-beam lithography. To avoid these complicated processes, the current work presents an approach to downsize the OFETs by using the pre-stressed polystyrene (PS) shrink film substrates. It is a brand-new strategy for downsizing and improves the electrical performance of organic drivers. This method only needed common equipment (such as the oven or hot plate) and provided time effective downsizing fabrication process. After heating the film to 160 ^{o}C, over the glass transition temperature of PS, the shrink film will release its pre-loaded stress and the OFET devices will follow the shrink film substrates to shrink. The projective area of the device was reduced by 75%. The wrinkled structure can amplify the electrical field at the channel area and reduce the subthreshold voltage of the transistor. By using the AlO_x dielectric layer, the subthreshold voltage of the transistor is shifted from -1.44 V (before shrinking) to -0.18 V (after shrinking) with the subthreshold swing of 74 mV/dec and intrinsic gain of 4.151 x 10^4. This study shows that fabricates OFET devices onto the shrink film substrate can provide a low cost and time-saving scale down method and the wrinkled structure would be one of the designs for the low voltage operated OFETs.

6:55 PM EQ06.14.06
Flexible High-Mobility, Bias-Stable Monolayer Organic Transistors Developed by Lamination Method Zhenfei He and Paddy K. L. Chan; The University of Hong Kong, Hong Kong

Solution processing is a facile fabrication method for large area, low-cost organic field-effect transistors (OFETs). Highly crystalline organic thin film by solution shearing offers a decent mobility, on/off ratio and subthreshold swing which are all important parameters to advance the OFET applications. To increase the device operation stability, self-assembled monolayers (SAMs) with low surface energy are usually used to eliminate the interface trap states locating at the semiconductor-dielectric interface. However, low surface energy which impedes solution wetting is a big challenge for the growth of highly crystalline thin film. To overcome the limitation, we replace the traditional fabrication method of in-situ growth of organic thin film by a transfer method. The high crystalline monolayer was grown on a high surface energy template substrate and transferred onto the low surface energy dielectric by using a temporary carrier. Both the morphology and the electrical property of organic monolayer remained undamaged during the transfer process and high mobility of 10 $cm^2V^{-1}s^{-1}$ on SiO_2 was maintained. We further demonstrated a flexible, low-operation voltage OFET device with zero turn-on voltage, high on-off ratio 10^7, and high mobility of 7 $cm^2V^{-1}s^{-1}$, by transferring the high-quality active layer onto low surface-energy fluorinated-based SAM modified high-κ AlO_x dielectric and laminating source-drain electrodes. The transferred OFETs show a significant improvement against the bias stress effect. The device only showed 200mV threshold voltage shift after 10000s bias stress test. The fabrication method extended the application of highly crystalline organic active layer to flexible and conformal organic electronics.

7:00 PM EQ06.14.07
Feasibility of Fabricating High Mobility and Low Contact Resistance N-Type Polymer Field-Effect Transistors via Doping and Meniscus-Guided Coating Method. Wanli Yang[1], Paddy K. L. Chan[1] and Xugang Guo[2]; [1]The University of Hong Kong, Hong Kong; [2]Southern University of Science and Technology, China

Despite the great progress have been made recent years in organic field-effect transistors (OFET), the n-type organic semiconductors with high mobility and reliability are still scarce. Doping of the meniscus-guided coated organic semiconductors (OSCs) is powerful technique for tuning the electrical properties of the active channel layer. Herein, towards the classic n-type polymer semiconductor P(NDI2DO-T2) (N2200), the better quality of the metal-organic interface between the N2200 and Au was achieved via employing cesium fluoride (CsF) doping and blade shearing method, respectively. Notably, when utilizing the CsF dopants at a low concentration (0.5wt%), the saturation mobility can be significantly

improved from 0.23 to 0.61 $cm^2 V^{-1} s^{-1}$ as well as the threshold voltage from 29.7 to 10.1 V on glass substrate with CYTOP dielectric. In addition, a strong correlation between the contact resistance and the solution shearing speed is well observed with resistance decreasing from 7.9 kΩ cm for samples prepared under 0.005 mms^{-1} to 3.1 kΩ cm for samples prepared by 5 mms^{-1} shearing speed. Taking good advantages of these two techniques, a maximun electron mobility of 3 $cm^2 V^{-1} s^{-1}$ and 1.23 $cm^2 V^{-1} s^{-1}$ are achieved for the saturation and linear region operation, respectively. These results show the feasibility of alkali metal salt CsF as dopants and high-speed Meniscus-guided coating regulating the orientation of polymer fibers and demonstrate their promising applications in organic electronics.

Ultra-Thin and Conformable Two-Dimensional Organic Thin-Film Transistor via Layer-by-Layer Transfer Deng Zou[1,2] and Paddy K. L. Chan[1,2]; [1]The University of Hong Kong, Hong Kong; [2]Advanced Biomedical Instrumentation Centre, Hong Kong

Two-dimensional (2D) atomic crystals are extensively studied in recent years due to their exciting physics and device applications. However, there are still a number of technical challenges in achieving active layers with mono or bi-layer thicknesses while the electrical performance does not deteriorate. Here, we focus on organic field-effect transistors (OFETs) and fabricate them by a layer-by-layer transfer method with bottom-to-top 2D layers. The graphene bottom gate is atomically smooth and has few nanometers in thickness, which affords a pristine bottom interface for constructing upper 2D layers. High-quality C_{10}DNTT molecular crystal is deposited on fluorophlogopite mica by blade coating method, with precisely controlled thickness down to monolayer. Moreover, the van der Waal electrode is applied to ensure a clean and non-destructive interface for metal-semiconductor contact. As a result, the 2D OFET has a channel down to 1 mm length and the total thickness of the device is less than 200 nm. Simultaneously, the 2D OFET with ultra-thin fluorophlogopite mica dielectric shows high carrier mobility up to 12 $cm^2V^{-1} s^{-1}$, operating voltage within 1 V and decent subthreshold swing of 100 mV dec^{-1}. These electrical properties and the thickness allow them to conformally adhere onto non-planar surfaces for multifunctional applications, including electrophysiological signal detection on human. Our work unveils an exciting new class of two-dimensional OFETs for flexible electronic and photonic applications.

Low Operating Voltage Organic Memory Transistor Based on Polymorphs of the Active Layer Lizhi Yan and Paddy K. L. Chan; The University of Hong Kong, Hong Kong

Organic memory transistor (OMT) is a promising candidate for the next generation memory devices towards human-machine interface applications. In this study, we developed nonvolatile optical memory transistor with [1]Benzothieno[3,2-b]benzothiophene (BTBT)-based p-type organic semiconductor as the active layer. We found that the polymorphs density of the active layer is corresponding directly to the OMT memory performance. The processing parameters, including deposition temperature (T), surface energy (γ), surface roughness (r) and film thickness (t), are pivotal to achieve fine control over the polymorphs of the deposited organic active layers and therefore, investigations of these parameters are highly desired. Here, we explore the effects of the processing factors mentioned above on the polymorphs morphology of the active layer under thermal evaporation and the memory performance of OMT. It is verified that T and γ are key parameters connected to the density of thin film polymorphs; r and t are also important in tuning the polymorphs density. Combining with the high-k dielectric material Al_2O_3, the memory transistor can operate at a low voltage during optical programming and electrical erasing process. Additionally, the transistor shows a field effect mobility up to 2.5 $cm^2V^{-1}s^{-1}$ and excellent data retention for more than 12 hours with a current ratio higher than 10^4 between the two binary states, which is a promising value for the OMT. Our findings provide valuable information in understanding the polymorphs morphology and the corresponding memory performance of BTBT-based organic semiconductor under thermal evaporation, which is believed to be with high potential in approaching next generation neuromorphic devices.

7:15 PM EQ06.14.10
A Dielectrophoresis-Chip with an OFET Array for Cell Trapping and Sensing Piao Yingzhe[1,2], Paddy K. L. Chan[1] and Xin Cheng[2]; [1]The University of Hong Kong, China; [2]Southern University of Science and Technology, China

Microfluidics for cell trapping and pairing has become a very powerful platform for in vitro cell analysis. In many topics like the immune system and cancer biology, etc, using microfluidics chips to trapping cells and analyzing their behavior is very effective. Dielectrophoresis (DEP) with its compatibility with living cells is one of the mostly used method for cell manipulation. By integrating a FET sensor array into the DEP-chip, we can realize the combination of cell trapping and sensing. By using the organic field-effect transistors (OFETs) sensor array to measure the impedance of cells, we can monitor whether every trapping points which are designed and fabricated in the chip have successfully trapped a cell and the cell status (alive or dead). After identifying the successfully tapping, we can continue with subsequent manipulation like cell fusion, cell lysis, and DNA detection. . It will be a very powerful platform for bio- and biomedical science.

Solvent Toolkit for Electrochemical Characterization of Hybrid Perovskite Films Jason D. Slinker[1], Sauraj Jha[1] and Alexander Zakhidov[2]; [1]The University of Texas at Dallas, United States; [2]Texas State University, United States

Organohalide lead (hybrid) perovskites have emerged as competitive semiconducting materials for photovoltaic devices due to their high performance and low cost. To further the understanding and optimization of these materials, solution-based methods for interrogating and modifying perovskite thin films are needed. In this work, we report a hydrofluoroether (HFE) solvent-based electrolyte for electrochemical processing and characterization of organic-inorganic trihalide lead perovskite thin films. Organic perovskite films are soluble in most of the polar organic solvents, and thus they were not considered suitable for electrochemical processing until now. We have enabled electrochemical characterization and demonstrated a processing toolset for these materials utilizing highly fluorinated electrolytes based on a HFE solvent. Our results show that chemically orthogonal electrolytes based on HFE solvents do not dissolve organic perovskite films and thus allow electrochemical characterization of the electronic structure, investigation of charge transport properties, and electrochemical doping of the films with in situ diagnostic capabilities.

7:25 PM EQ06.14.12
Electrochromic Properties of PEDOT Derivatives Containing Ru(II) Complex Nese Guven[1,1], Hajar Sultanova[2], Baris Yucel[2] and Pinar Camurlu[1,1]; [1]Akdeniz University, Turkey; [2]Istanbul Technical University, Turkey

In this study we display electrochromic properties of PEDOT derivatives containing Ru(II) complex which were synthesized through electrochemical homopolymerization of EDOT-Ru and copolymerization of EDOT-Ru with EDOT. All the metallopolymers revealed reversible electrochemical activity both in anodic and cathodic regions. Optoelectronic properties of metallopolymers were investigated by cyclic voltammetry, spectroelectrochemistry, kinetic and colorimetry measurements.

The band gap, optical contrast, switching time and coloration efficiency of the homopolymer (PEDOT-Ru) were determined as 1.77 eV, 33.72 %, 1.39 s

and 156.21 cm^2/C, respectively. PEDOT-Ru exhibited multichromic behavior, displaying purple, green, yellow and transparent colors. The studies on copolymerization demonstrated that the electrochromic properties of the copolymers could be changed through comonomer feed ratio. All copolymers displayed multichromic behavior. The neutral state colors of $P(EDOT\text{-}Ru\text{-}co\text{-}EDOT)_1$, $P(EDOT\text{-}Ru\text{-}co\text{-}EDOT)_2$ and $P(EDOT\text{-}Ru\text{-}co\text{-}EDOT)_3$ copolymers were appeared as green, dark green and blue, respectively.

7:30 PM EQ06.14.13
Late News: Chalcogen Atom Substitution Effect in Novel Quinoidal Conjugated Polymers for Organic Field-Effect Transistors Yeonsu Choi[1], Yunseul Kim[1], Yina Moon[1], In-Bok Kim[2], Nara Han[1] and Dong-Yu Kim[1]; [1]Gwangju Institute of Science and Technology, Korea (the Republic of); [2]Research Institute of Solar and Sustainable Energies, Korea (the Republic of)

The field of semiconducting π-conjugated polymers (SCPs) have undergone fast development in recent decades due to their various applications in organic electronics, such as organic photovoltaics (OPVs), organic light emitting diodes (OLEDs), thermoelectrics and organic field-effect transistors (OFETs). In order to accomplish the high performance devices, a number of organic molecular building blocks based on aromatic rings have been designed and synthesized. Recently, the quinoid-type molecules have been considered as a promising candidate for active materials of organic electronics due to their superior electrical properties derived from more electron delocalized atmosphere facilitating efficient charge transport.
In this work, a novel quinoidal building block incorporating 3,4-ethylenedithiothiophene (EDTT) inducing intermolecular interaction *via* sulfur-sulfur interactions were designed and successfully synthesized. In addition to such intermolecular attraction, it has been reported that the conjugated molecules containing thioalkyl group show unique optoelectronic properties compared to molecules containing oxyalkyl group. Therefore, quinoidal polymeric semiconductors PmQEDTT-T2 and PmQEDOT-T2 that is 3,4-ethylenedioxythiophene (EDOT) incorporated structure instead of EDTT were copolymerized by Stille polymerization. The prepared quinoidal conjugated polymers exhibited significantly different properties such as electronic, optical properties and vibronic structures. Organic field-effect transistors were fabricated using PmQEDOT-T2 and PmQEDTT-T2 polymers as active layers, the highest hole carrier mobilities of 0.13 and 0.02 cm^2/Vs were obtained, respectively. In this study, we will explain the substitution effect of atoms on quinoidal conjugated polymers in relation to microstructural analyses and molecular packing structures of thin films as well as thermal, optical, electrical and electrochemical properties.

Late News: Flexible Glucose Biosensing via Carbon Nanotube-Based Electrodes on Elastomer Polymer Substrate Anthony Palumbo[1], Chenguang Zhao[1], Shichen Fu[1], Siwei Chen[1], Zheqi Li[1], Haoyu Wang[1], Kalle Levon[2] and Eui-Hyeok Yang[1]; [1]Stevens Institute of Technology, United States; [2]New York University, United States

Electrochemical wearable biosensors are suitable for diverse skin-attachable applications owing to their high performance, inherent miniaturization, and low cost [1], [2]. Incorporating flexible and stretchy materials enables electrochemical biosensors to impact a wide range of developing applications, including electronic skins [3], smart sensor bandages [4], and implantable medical devices [5]. Flexible/stretchable sensors need to be capable of accommodating various mechanical disturbances such as large bending, twisting and stretching, while retaining their performance for numerous cycles [6]. Though extensive efforts have been made, the performance of such flexible/stretchable electrodes under dynamic deformations issue need further studies , not only in scientific studies but also in any practical device applications.
Here, we study a flexible glucose sensor which can be subjected to various lateral strains via stretching, while providing reliable electrochemical sensing of biomarkers on a patient's skin, undeterred by daily activity and repetitive impacts. Vertically aligned carbon nanotubes (CNTs) grown via chemical vapor deposition (CVD) are embedded onto suspended polydimethylsiloxane (PDMS). The CNTs are coated with a conjugated polymer transducer layer via electropolymerization of polypyrrole (PPy), doped with glucose oxidase (GOx). The sensor is exposed to iterative concentrations of glucose, and GOx reacts in the presence of glucose, resulting in a concentration-dependent change of measurable current. For this sensor, we have developed CNT-based sensing electrodes on flexible substrates that exhibit reliable and stable performance under stretching up to 75%. Skin-attachable devices for continuous monitoring of patients will directly benefit the medical field, with potential applications towards smart sensor bandages, critical wound monitoring, and glucose detection for diabetes.

7:40 PM EQ06.14.15
CNT-Based Flexible Electrodes Towards Sensors and Energy Storage Anthony Palumbo, Runzhi Zhang and Eui-Hyeok Yang; Stevens Institute of Technology, United States

Flexible electronics requires conformable substrates for a wide range of applications [1]. Conventional high-performance electronic materials such as silicon are not flexible, whereas many flexible materials, such as conducting polymers, are often characterized by poor electric properties [2]. Carbon nanotubes (CNTs) are promising owing to their excellent electronic properties and flexibility owing to their small diameter.
Here, we present stretchable electrodes composed of opposing layers of vertically aligned CNTs (VACNTs) partially embedded in a polydimethylsiloxane (PDMS) substrate; the tips of CNTs are partially embedded into PDMS. This unique synthesis permitted a rapid and facile integration of a flexible and stretchable platform for sensors and energy storage. VACNTs were grown using atmospheric-pressure chemical vapor deposition (APCVD) on a Si/SiO2 substrate and transferred onto PDMS as a stretchable electrode. A liquid mixture of PDMS base and curing agent were mixed with a ratio of 10:1 and degassed under reduced pressure in a vacuum environment to remove gas bubbles. The liquid PDMS was heated on a hot plate at 65 °C for approximately 30 min to a state of partially cured PDMS. The CNT carpet was placed face-to-face onto the partially cured PDMS, and PDMS infiltrated between each individual carbon nanotube, owing to the capillary effect and the viscoelastic property of PDMS. As a result, tips of interwoven CNTs were embedded into PDMS. The CNT−PDMS sample was left in an ambient condition to fully cure PDMS. Two such CNT-PDMS electrodes were placed face-to-face and change of resistance occurs due to the external pressure applied orthogonal to the surface.
Here, we demonstrate a pressure sensor and a pseudocapacitor using VACNT/PDMS. To detect the pressure, two CNT-PDMS electrodes are arranged in a face-to-face configuration, so the increased pressure is directly proportional to a detectable change in resistance, enabled by increased contact between the opposing electrode surfaces. The measured resistance was maintained at stretching up to 180%, with a rapid response time during loading and unloading.

The sensor showed a stable performance for 10,000 loading/unloading cycles with the resistance retention of 82%. As a proof-of-concept, the sensor was successfully tested for measuring biological signals of a person, including pulse signature, muscle flexing, and step count/intensity. Towards an energy storage application, the CNT-PDMS electrode underwent electropolymerization of dodecylbenzene sulfonate polypyrrole (PPy(DBS)) to conformally coat individual CNTs, followed by deposition of a gel electrolyte, to create an all-solid state pseudocapacitor. In addition to high stretchability and stability, the pseudocapacitor exhibited a stable cyclic behavior up to 10,000 cycles of galvanostatic charge/discharge measurement. These novel CNT-based flexible electrodes demonstrated towards flexible sensor and energy storage devices . are very promising for wearable applications. This work will directly impact the development of biomedical and e-skin applications.

ZIF—Silane Modified Electrochemical Lead Ion Sensor Jinu Joji and Praveen Ramamurthy; Indian Institute of Science Bangalore, India

The advancement in technology in the field of energy has contributed by different kinds of materials. Which includes polymer composites, metal derivatives, etc. There is a considerable increase in the usage of metal and its different structural derivatives. Heavy metals have been widely used for device applications. Hence contamination of natural resources by heavy metals is a major issue. Different sources like textile effluents, electronics industry, mining, industrial wastewater, are contributory. It causes adverse effects on health once it enters the food chain. So, great attention is required for the detection and removal of these metal ions.
Several methods have been explored for the removal and detection of heavy metals. Methods of removal include Adsorption, Ion exchange, Electrodialysis, Nanofiltration, etc. For the detection, electrochemical and spectroscopy methods, etc have been used. Materials like carbon nanostructures, polymer attached platforms, conjugated polymer, metal-organic frameworks (MOF's), covalent organic frameworks (COF's), etc. are act as receptors for metal ions. Further tunability of structure and functionalization could enhance the sensitivity. The current emerging materials of interest include framework structures like MOFs and COF s due to their ease of synthesis, scalability, stability, selectivity, and sensitivity. These porous architectures hold a high surface area. The change in electronic properties upon adsorption can be attributed to a sensing mechanism.
Zeolite imidazolium frameworks are a group of MOF's which are widely used for the adsorption of a wide range of analytes. Electrochemical device-based sensors based on MOF's are least explored. Modification of these frameworks has been done in numerous ways such as functionalization with various ligands, intercalation of ZIF in other MOF's, nanocomposite with graphene oxide, CNT, graphene, and other materials has shown improved sensing.
In this study, ZIF- 67 has been chosen as a sensing platform for lead ion detection. It is a cobalt metal-centered methyl imidazolium-based framework. Already it has shown good adsorption towards lead ions. Integrating it into a sensing platform is quite challenging. Cyclic voltammetric study in KCl/ $K_4Fe(CN)_6$ exhibit ZIF- 67 holds good catalytic behavior and sensitivity towards lead ions. Modification of ZIF- 67 with 3-aminopropyl trimethoxysilane could increase sensitivity and selectivity due to the amine group's affinity towards lead ions. The sensitivity enhances with the incorporation of aminomethane siloxane compared to neat ZIF. The synthesized ZIF-67/ 3-aminopropyl trimethoxysilane was fabricated into a carbon paste electrode for further electrochemical sensing mechanism studies for lead ions detection.

Flexible Multichannel Neural Probe Developed by Electropolymerization for Localized Stimulation and Sensing Na Xiao[1,2,3], Gary K.K. Chik[1,2], Jianni Deng[1,2], Chung Tin[3] and Paddy K. L. Chan[1,2]; [1]The University of Hong Kong, China; [2]Advanced Biomedical Instrumentation Centre, China; [3]City University of Hong Kong, China

Neural probe application has gotten more and more attention due to its advantages in microscale, material biocompatibility and flexible fabrication technology. Varies kind of biocompatible materials and electrochemical deposition methods were adopted to develop the neural probes so that it can minimize damage to the brain tissue and reduce the impedance for in-vivo applications. Here we designed a highly flexible gold electrode array, using SU8 and Parylene as supporting layer, coated with PEDOT:PSS to reduce the impedance and pHEMA to increase the bio-compatibility. We characterized the electrical performance of the probe for signal quality before in-vivo testing and then the probe was employed in the rat for signal acquisition and bio-compatibility test. The length of the probe was tailor made for applying to different brain regions, including primary motor cortex, hippocampus, paraventricular thalamus and cerebellum, of the rat to record the single neuronal spike and local field potential. From both acute recording in anesthesia rats and 3 months long-term chronic recording in awake animals with implantation, our probes shown a good quality with the signal to noise ratio up to 20. The post-experiment dissection and immunohistochemistry staining illustrated a minor tissue damage and immune response comparing to the commercial metal electrode arrays. The proposed probe can be applied to variety of brain regions which provide a broad application in animal electrophysiological investigation and potential clinical usage.

Late News: Novel and Exact Figure of Merit for Transparent Conductive Electrodes Aman Anand[1,2], MD Moidul Islam[1,2], Rico Meitzner[1,2], Ulrich S. Schubert[1,2] and Harald Hoppe[1,2]; [1]Laboratory of Organic and Macromolecular Chemistry (IOMC), Germany; [2]Centre for Energy and Environmental Chemistry, Germany

Photovoltaic technologies depend largely on transparent conductive electrodes (TCEs). TCEs should, in theory, have the highest light transmission and conductivity. Both traits, however, must be balanced. The selection of the best TCE depends on the photovoltaic material system and is evaluated using so-called figures-of-merit (FOM). A novel and exact FOM is introduced here that explicitly analyzes the impact of TCEs on photovoltaic performance. This unique FOM has several important properties: normalization to the theoretically ultimately attainable photovoltaic performance, proportionality to the solar device's potential power output, and, thus, significant direction for the development of advanced TCEs. Here we evaluated TCE requirements for various photovoltaic material systems in relation to the spectral range in which they operate. Additionally, we also reassessed and compared a variety of realized state-of-the-art semitransparent electrodes.

Mechanics of 2D Materials and Interfaces Rui Huang; The University of Texas at Austin, United States

Atomically thin materials such as graphene and other 2D materials are promising for a wide range of applications. Among many unique and attractive properties of 2D materials, mechanical properties play important roles in manufacturing, integration and performance for their potential applications. Mechanics is indispensable in the study of mechanical properties, both theoretically and experimentally. This tutorial aims to summarize the current understanding on the mechanics of 2D materials including linear and nonlinear elasticity, strength and toughness, as well as mechanical interactions such as adhesion and friction at the interfaces of 2D materials. Theoretical and computational models will be presented along with experimental methods for predicting and measuring the mechanical and interfacial properties of 2D materials.

Outline:
Linear and nonlinear elasticity
Strength and toughness
Adhesion and friction

3:30 PM
Electronic Properties of Moiré Superlattices Allan H. MacDonald; The University of Texas at Austin, United States

When two or more van der Waals material layers are overlaid with small differences in lattice constant are overlaid with small relative twist angles they form two-dimensional moiré superlattices with unit cell areas that can be thousands of times larger than the unit cell areas of the underlying two-dimensional crystals. When the moiré superlattice materials are semiconductors or semimetals, low-energy electronic properties are accurately described by low-energy models that have the periodicity of the superlattice. These moiré materials act like crystals with artificial giant atoms. One of the most attractive properties of moiré materials is that the number of electrons per unit cell can be changed by more than one using electrical gates. I will survey the electronic properties of moiré materials, focusing on systems that have been achieved experimentally, including graphene bilayers and multilayers and systems based on tradition metal dichalcogenide layer building blocks.

Strain and Defect Engineering of van der Waals Materials for Quantum Straintronics and Nano-Photonics Nai-Chang Yeh, Chen-Chih Hsu, Duxing Hao, Deepan K. Kumar, Stella Wang, Jiaqing Wang and Marcus L. Teague; California Institute of Technology, United States

Two-dimensional (2D) van der Waals materials exhibit a rich variety of properties that can be further tailored to achieve novel functionality by strain and

defect engineering. Here we describe a new paradigm of *quantum straintronics* based on strain engineering of monolayer (ML) graphene and 2H-phase transition metal dichalcogenides (TMDs), as well as novel photonic phenomena based on defect engineering of quasi-one dimensional (1D) graphene nanostripes (GNSPs).

Theory and experimental studies have found that non-trivial nanoscale strain in ML graphene can give rise to giant *pseudo-magnetic fields* (PMF) that dramatically modify the local electronic properties of graphene. Nonetheless, no realistic devices with spatially scaled-up PMF had been demonstrated until our recent work that achieved periodic graphene "wrinkles" by placing ML graphene on substrates with arrays of nanostructures and then by developing the strained graphene wrinkles into valley-Hall transistors *via* e-beam lithography. We found that the periodic graphene wrinkles formed a *valley splitter* that separated the K/K'-valley Dirac fermions and preserved the valley polarization. We further observed a wealth of novel quantum and topological phenomena, including flat bands of quantized Landau levels, spontaneous symmetry-breaking and spin polarization in the strong correlation limit, as well as quantum valley Hall and quantum anomalous Hall effects with different Chern numbers in the ballistic limit. Controllable electronic correlation could be further achieved by designing the magnitude and spatial distribution of strain and by varying the back-gate voltage. These findings suggest that nanoscale strain-engineering of ML graphene provides a new platform to control the topological electronic states and electronic correlation in 2D materials.

For ML semiconducting 2H-TMDs (*e.g.*, MoS_2 and WS_2) with strong spin-valley coupling, strain has been shown to induce variations in the optical bandgaps and exciton lifetimes. Our molecular dynamics simulations revealed additional symmetry breaking effects, suggesting that nanoscale strain engineering of ML TMDs may be employed to design the landscape of optical bandgaps and to lift the valley degeneracy to produce valley-polarized excitons for topological photonics and opto-valleytronic/spintronic device applications.

For quasi-1D GNSPs directly grown on silicon by PECVD, we found a number of novel photonic phenomena: [1] The GNSPs exhibited strong and wavelength independent optical absorption (absorption coefficient ~ 10^6 cm^{-1}) from IR to visible light (Vis). [2] The photoluminescence (PL) spectra revealed an emission gap around the excitation frequency as well as both red- and blue-shifted broadband signals. [3] Unusually long carrier lifetimes (up to ~ 12 ns) were found from the time-resolved PL studies with Vis lasers, and the lifetimes were nearly independent of temperature (from 15 K to 300 K). [4] The PL emissions were coherent, as manifested by the second-order temporal correlation function and the spatial interference patterns of the PL maps. [5] Under strong CW excitations, lasing phenomena with sharp peaks (FWHM linewidths < 0.1 THz) at discrete frequencies from FIR to Vis were observed. We attribute these phenomena to the presence of topological defects that either naturally formed during the PECVD synthesis or engineered in the material by selective plasma radiation. These defects behaved like two-level color centers that coupled strongly to the high-mobility GNSPs, and the GNSPs provided significant confinement of photons due to strong subwavelength scattering and internal reflection. The GNSP matrix thus acted as an effective optical cavity for the color centers, and the observed photonic phenomena were consistent with cavity-QED. These findings suggest that defect engineering of quasi-1D GNSPs on silicon is a promising new approach for on-chip nano-photonics that are compatible with CMOS technologies.

Layered Quantum Materials—A New Platform for Quantum Technology Andrea C. Ferrari; University of Cambridge, United Kingdom

Layered Materials (LMs) have potential for quantum technologies, as scalable sources of single photon emitters (SPEs)[1,2]. LM heterostructures can be built with tuneable properties depending on the constituent materials and their relative crystallographic orientation[3,4]. Quantum emitters in LMs hold potential in terms of scalability, miniaturization, integration. Generation of quantum emission from the recombination of indirect excitons in heterostructures made of different LMs is also promising. I will discuss how LM combinations can be used to generate SPEs and confinement of interlayer excitons[5].

Quasi-1D Exciton Channels in Strain-Engineered 2D Materials Florian Dirnberger[1], Jonas D. Ziegler[2], Paulo E. Faria Junior[2], Rezlind Bushati[1,3], Takashi Taniguchi[4], Kenji Watanabe[5], Jaroslav Fabian[2], Dominique Bougeard[2], Alexey Chernikov[2,6] and Vinod Menon[1,3]; [1]The City College of New York, United States; [2]Universität Regensburg, Germany; [3]The Graduate Center, United States; [4]International Center for Materials Nanoarchitectonics, Japan; [5]Research Center for Functional Materials, Japan; [6]Institute for Applied Physics, Germany

The gap between light-based communication technology and state-of-the-art electronic devices on the nanoscale constitutes a major obstacle towards integrated optoelectronic circuits. Two-dimensional transition metal dichalcogenides (2D TMDCs) harbour an enormous potential to bridge that gap by unifying strong light-matter interaction with exceptionally robust and simultaneously highly mobile exciton quasiparticles. However, steering these neutral quasiparticles along predesigned pathways has proven to be exceptionally challenging and only recently strain was identified as a key element in 2D TMDCs to gain real-space control over the exciton flow. Here, we demonstrate guiding of excitons along strain-engineered quasi-one-dimensional (1D) potential channels by combining mechanically flexible van der Waals heterostructures with single-crystal nanowires in hybrid 1D/2D systems. Using ultrafast, all-optical injection and time-resolved readout, we show near 100% anisotropy in the exciton propagation both at cryogenic and room temperatures. The vanishing diffusivity of excitons perpendicular to the channels highlights their efficient localization by the simultaneous action of confinement potentials and reduced scattering in strained regions. Such artificially induced anisotropy in a pristine, otherwise fully 2D semiconductor offers a highly promising, non-invasive platform to steer the flow of optical excitations and opens a path towards rich quasiparticle transport phenomena in 1D.

Late News: Mechanical Tuning of the Electronic and Vibrational Properties of Epitaxial MoS2 Through Ion Beam Modification Shayani Parida[1], Matt Chancey[2], Yongqiang Wang[2], Tanushree H. Choudhury[3], Joan M. Redwing[3], Avinash Dongare[1] and Michael Pettes[2]; [1]University of Connecticut, United States; [2]Los Alamos National Laboratory, United States; [3]The Pennsylvania State University, United States

Atomically thin transition metal dichalcogenides (TMDs), like MoS_2, with high career mobilities and tunable band gaps, are great candidates for next-generation optoelectronic devices. This study demonstrates the use of relatively low power (100 keV) ion beams to control the point defect levels in single and bilayer films of MoS_2. The use of ion irradiation towards controlling the localized strains and defect densities in TMDs is systematically probed to provide opportunities towards tuning the electronic and optical properties, like resistivity, and absorption and emission spectra. The use of relatively low power beams provides the scope to explore the novel phenomenon of ion implantation in 2D materials. Slight changes in the vibrational states and more significant changes in the photoluminescence (PL) of MoS_2 have been observed which might be explained by substrate straining as the ions penetrate the

2D materials before being trapped by the sapphire substrate. The effect of these strained microstructures on the vibrational states of the MoS_2 lattice is studied using PL and Raman spectroscopy. Recent unpublished alpha particle bombardment studies performed on WS_2 thin films also showed significant shifts in PL peaks (~5 nm). This novel capability provides insights into discerning the links between ion bombardment-induced mechanical straining of lattice and the emergent quantum properties. The study also combines experimental characterization with quantum mechanical simulations performed using density functional theory (DFT) framework to quantify the defect density and distributions; as well as further our understanding of the modifications observed in the optical and electronic band alignments with varying levels of atomistic defects.

Emergent Axion Field Effects in Dynamically Deformed 2D Materials Ioannis Petrides and Prineha Narang; Harvard University, United States

In recent years, dynamical systems have proven to be a highly versatile platform for hosting exotic quantum phenomena. Specifically, high-dimensional topological physics, initially developed out of pure theoretical interest, has now been experimentally observed in physical systems, ranging from cold-atoms, to photonics, metamaterials and electrical circuits. At the heart of these experiments, the spatio-temporal evolution of the system's parameters induces a response proportional to a topological index defined in higher dimensions [1,2]. Drawing on this correspondence, we present a dynamical realization of an Axion field in a 2D material where strain is utilized towards engineering a controlled evolution. Such an approach extends the traditional description of 3D Axion insulators to lower-dimensional dynamical systems, in addition to predicting emergent responses in novel platforms.

Even though Axions are yet to be observed in particle physics and cosmology, they naturally arise in condensed matter systems. Specifically, recent research into the topological aspects of three-dimensional semiconductors and insulators has shown that electrons in certain materials are nontrivially coupled to an Axion field. Apart from the interesting responses to electromagnetic fields, e.g., fractional quantum Hall effect on the surface and magneto-electric polarizability, Axion field effects can be employed in numerous other fields, such as testing fundamental physics with dark matter detectors [3] or controlling electronic properties for technological applications [4]. Here, we present these effects in a completely different setting: in dynamical systems where physical observables are shown to depend stroboscopically on an Axion field defined over a higher-dimensional manifold – the phase-space of the system, i.e., the combined position, momentum and time coordinates.

Designing materials that can be easily controlled is of paramount importance when proposing realistic experiments. To this end, coupling electronic properties to strain offers a promising route towards tailoring dynamics. In particular, piezo-electromagnetic and deformation-induced symmetry breaking effects were shown to significantly change the electronic structure of materials. Here, we exploit such properties towards engineering systems that can be externally controlled via weak deformation fields.

Late News: Pressure Activated Diamond Phase in 2D Materials Martin Rejhon and Elisa Riedo; New York University Tandon School of EngineeringCh, United States

Controlling phase transitions in 2D materials and switching between structures opens uncharted avenues in the use of 2D materials in mechanical, optical, electronics, and thermal applications. The first demonstration of a metastable phase transformation in bilayer graphene into an ultra-stiff single layer diamond phase has been recently achieved in ambient conditions and room temperature, with the solely application of a localized pressure [REF}, this new phase was called diamane. This new single layer diamond phase is obtained in two-layer (one layer plus buffer layer) epitaxial graphene grown on SiC without chemical functionalization, and it is reversible to graphene upon release of pressure. Besides graphene, other 2D materials possess the structural characteristic necessary for sustaining a similar pressure-induced sp2-to-sp3 phase transition. In particular, two- and three-layer hexagonal boron nitride (h-BN) is shown to be convertible in a stable cubic phase (c-BN) under pressure. Furthermore, we conduct an electrical and mechanical investigation of 2D diamond phase formation as observed through pressure activation in hBN, single-layer epitaxial graphene, and quasi-free-standing H-intercalated two-layer graphene on SiC. In particular, we fabricate metal contacts on epitaxial graphene and hBN to study the change in electrical and optical properties before, during, and after the phase activation. This also allows to observe the time stability of the pressure-activated phase formation after the release of pressure.<script id="th-iframe-script" src="chrome-extension://ofdopmlmgifpfkijadehmhjccbefaeec/assets/comms/commsiframe.js"></script>

Designing the Bending Stiffness of 2D Heterostructures Edmund Han[1], Jaehyung Yu[1,2], Mohammad A. Hossain[1], Kenji Watanabe[3], Takashi Taniguchi[3], Elif Ertekin[1], Arend van der Zande[1] and Pinshane Y. Huang[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]The University of Chicago, United States; [3]National Institute for Materials Science, Japan

The bending stiffness of 2D materials and heterostructures governs their deformability, reconfigurability, and 3D structure. In particular, interlayer interactions play a major role in governing the bending of 2D materials, where they lead to an unusually low bending stiffness in few-layer graphene and a curvature-dependence of the bending stiffness [1]. The key role of interfaces in the bending of 2D multilayers also indicates potential methods to tune the deformability and 3D structures of 2D systems though interfacial engineering.

In this talk, we use aberration-corrected scanning transmission electron microscopy (STEM), density functional theory (DFT) simulations, and continuum mechanical models to examine the bending of 2D multilayers and heterostructures. We investigate the bending stiffness of graphene and MoS_2 multilayers, comparing the properties of stacks containing aligned, twisted, and heterointerfaces. We find that the bending properties of 2D materials and heterostructures is strongly tuned by the atomic arrangement of the interfaces present. For example, we find that the bending stiffness of 4-layer heterostructures containing two layers each of graphene and MoS_2 can be tuned from 20 eV to 80 eV by simply changing the order and interfacial atomic registry of the layers present. In addition, our measurements show that 2D heterostructures containing only misaligned interfaces exhibit ultra-low bending

stiffnesses that are the linear sum of the bending stiffness of each constituent monolayer, reaching the theoretical lower limit for stiffness in 2D materials. These properties arise from the low interlayer friction and sliding energy barrier of crystallographically misaligned interfaces, which DFT simulations indicate are two orders of magnitude lower in misaligned interfaces than in 2H-stacked MoS_2. Using these observations, we develop a model to predict and design the bending stiffness for arbitrary heterostructures as a function of thickness, system size, and the number and location of incommensurate interfaces [2]. Our techniques should enable the rational design of the out-of-plane structure of devices based on 2D materials, including illustrating how to incorporate slippable interfaces and create ultra-low bending stiffness structures for deformable, stress-resilient electronics.

Poking and Bulging of 2D Crystals Nanshu Lu; The University of Texas at Austin, United States

Recently, nano-tents and nano-bubbles formed by two-dimensional (2D) materials have seen a surge of interest because they are able to induce in-plane strain as well as strain gradient via out-of-plane deformation.[1] Our previous work has unveiled what sets the in-plane strains in terms of the shape characteristics of nano-tents and nano-bubbles.[2-4] Moreover, out-of-plane poking or bulging, also known as indentation or blister tests, are popular methods for the measurement of in-plane elasticity of thin sheets. For linear elastic sheets, a load-cubic deflection relation has been frequently assumed so that the stiffness of the sheet could be readily extracted. However, we find that recent results of indentation and bulge tests on 2D materials do not follow this relation, which can be attributed to the slippage of atomically smooth 2D materials against their supporting substrates.[5, 6] Besides, the interfacial slippage could cause instabilities in the sheet such as radial wrinkles in suspended region, with finite lengths.[4] To gain a quantitative understanding, we assume constant interfacial shear traction and study the wrinkling extent and the effective stiffness of thin sheets upon poking and bulging. We identify a single dimensionless parameter governing these mechanical responses—the sliding number—defined by comparing the sheet tension (that drives the slippage) with the interfacial traction (that resists the slippage).[7] We discuss several useful asymptotic behaviors emerging at small and large sliding numbers. These understandings are helpful for determining when the effect of the interfacial slippage (as well as other substrate-associated subtleties) can be neglected in these tests. At the end, we propose a simple poking/bulging methodology immune to the complexities caused by the slippage, pretension, Poisson's ratio, substrate roughness, etc., enabling a robust and accurate measure of 2D material stiffness.

***In Situ* Strain Engineering of Monolayer MoS_2 Photodetectors for High Photoresponse** Ye Seul Jung and Yong S. Cho; Yonsei University, Korea (the Republic of)

Although strain engineering in 2D transition-metal dichalcogenides (TMDs) has been emerged as a critical way to control the electronic/optoelectronic properties, the presence of an in-situ compressive or tensile strain-applied in the flat state of 2D materials has never been reported in terms of photo-detecting capability. Herein, we propose a technical way of inducing intentional stress during the wet-transfer method of MoS_2 monolayer by using the pre-bent PET (polyethylene terephthalate) substrate for the photodetector of Au/MoS_2/Au structure, ultimately to investigate the strain-dependent photosensitivity modulations. As a highlight, the photocurrent reached a maximum value of 1.48 AW^{-1} with an in-situ tensile strain of +1.08%, which corresponds to nearly 8 times increment compared to the reference sample. The enhancement originates from realigned energy bands at the MoS_2-Au interface through the strain-induced bandgap modulation. It is assumed that the in-situ tensile strain promotes the separation of photo-generated charge carriers and facilitates their transport. With extra strain imposed by post-bending of the in-situ strained sample, the photocurrent performance was further found to be improved to 1.77 AW^{-1} due to the lowered Schottky barrier by the known piezophototronic effect.

SESSION EQ07.02: Poster Session
Tuesday Afternoon, November 30, 2021

EQ07.02.01
Direct Determination of the Linear Coefficient of Thermal Expansion of Low-Dimensional MoS_2 Kory Burns[1,2], Benjamin Bischoff[3], Khalid Hattar[2] and Assel Aitkaliyeva[1]; [1]University of Florida, United States; [2]Sandia National Laboratories, United States; [3]The University of Utah, United States

Low-dimensional Molybdenum Disulfide has shown remarkable potential for applications in flexible electronics and nanoscale photonics. However, a fundamental property that needs to be explored is the thermal expansion coefficient on free-standing MoS_2 because it is instrumental to the thermal management of nanomaterials. Currently, Raman spectroscopy methods and first-principles calculations provide order-of-magnitude differences, likely from the difficulty in obtaining accurate experimental measurements on 2D materials. In this contribution, we couple in-situ transmission electron microscopy (TEM) to supply uniform heating with selected area electron diffraction (SAED) patterns to analyze the defined regions upon heating. Next, we integrate advanced image analysis techniques to precisely align the diffraction pattern, outline Bragg peaks, and calculate the spacing of the d_{100} and d_{110} peaks. Through analysis of the uniaxial and biaxial changes of in-plane spacing, we show that properly indexing SAED peaks is a reliable tool to

investigate some thermal properties of MoS_2.

Ferroelectric Polar Domain Dynamics in Twisted Bilayer Transition Metal Dichalcogenides Philip Kim; Harvard University, United States

Controlling the interlayer twist angle in an artificial two-dimensional (2D) van der Waals (vdW) interface offers an experimental route to create a moire superlattice. One can create exotic electronic states by minimizing electronic bandwidth with a tunable moire length scale. However, in the small twist angle regime, vdW interlayer interaction can cause significant structural reconfiguration at the interface, creating the arrays of domain structures. Particularly, in the crystal symmetry engineered twisted bilayer polar crystals, unconventional ferroelectricity can arise to exhibit the ferroelectric switching mechanism. Here we performed an in-situ transmission electron microscopy (TEM) investigation on dual gated twisted bilayer transition metal dichalcogenides (TMD) devices that enable real-time observation of polar domain dynamics in a 2D system. In combination with the theoretical investigation, we find the polarizability of the twisted bilayer TMD sensitively depends on the moire length and the domain shapes. We also report on the angle-dependent development of ferroelectricity and unconventional domain antiferroelectricity in the twisted bilayer TMD that exhibits intriguing distinction from conventional ferroelectricity and antiferroelectricity.

2:15 PM *EQ07.03.03
Nanometer-Scale Engineering and Analysis of Transition Metal Dichalcogenides with Atomic Force Microscopy Matthew R. Rosenberger; University of Notre Dame, United States

Two-dimensional materials (2DM) are atomically thin materials with extraordinary mechanical, electrical, and chemical properties that make them promising for next generation technologies in quantum communications, sensing, flexible and transparent electronics and optoelectronics, and energy conversion. The realization of new technologies based on 2DM requires both fundamental research on the materials science of 2DM and research that aims to bridge the gap between materials science and the engineering of real devices and systems. In this talk, I will describe our recent work on using atomic force microscopy (AFM) in conjunction with optical spectroscopy and transmission electron microscopy to understand the physics of strain and heterostructure interfaces in 2DM and leveraging that understanding to control material behavior. In the first part of this talk, I will discuss our work on using the AFM tip to write strain gradients into 2DM semiconductors with nanometer-scale precision. Briefly, we use the AFM tip to indent 2DM placed on top of a thin polymer layer, which results in strain texturing. We use this technique to deterministically place single photon emitters (SPEs) in WSe_2.[1] We find that electrical gating can lead to improved purity of SPEs created with this method. In the second part of the talk, I will discuss our investigations of the interfaces between 2DM layers, with a particular focus on the relative twist angle between layers. I will present experimental evidence of atomic reconstruction in $WSe_2/MoSe_2$ and WS_2/MoS_2 heterostructures.[2] We confirm the presence of atomic reconstruction through a combination of AFM and transmission electron microscopy. We find that the reconstructed domains have a pronounced dependence on the relative crystal orientation of the layers in the heterostructure. We also find intriguing electronic behavior of the domain boundaries between reconstructed domains. We use density functional theory modeling to understand the origin of the electronic behavior of the domain boundaries. These calculations suggest that flat bands in the conduction band may explain the observed electronic behavior.

Strain Localization of $MoSe_2/WSe_2$ Interlayer Excitons Imaged by Scanning Tunneling and Nano-Photoluminescence Microscopies Thomas P. Darlington, Sara Shabani, Emanuil Yanev, Abhay Pasupathy and Peter Schuck; Columbia University, United States

Strain in the context of transition metal dichalcogenides (TMDs) has been shown to have a significant impact on the physics of both intralayer and interlayer excitons (ILE), e.g. in the former inhomogeneous strain can trap excitons in deep potential wells forming quantum-dot like localized states. For the monolayer TMDs these strain-induced electronic states have been investigated heavily with optical probes, revealing the emergence of single-quantum emitters at the inhomogeneous strain sites when cooled to cryogenic temperatures. However, to date strain induced localization of ILE's has predominately been investigated by broad far-field probes which obscure significant features of the strain field at the nanoscale. Because of the dramatic effect of strain on the opto-electronic properties of the ILE states, a detailed understand of the nanoscale variations present in heterolayers is crucial.
In this presentation I will detail a combined nano-PL and STM study of nanobubbles in $MoSe_2/WSe_2$ heterostructures. Utilizing scanning tunneling and the nano-PL spectroscopies we find a consistent shifting of the indirect gap and ILE photoluminescence from the edge of the nanobubble to the center. Our hyperspectral STM imaging further shows the emergence of a strain-induced in-gap state at the nanobubble edge, that to our knowledge has not been observed in the literature. Our results demonstrate the dramatic effect of, and importance of, nanoscopic strain on the interlayer excitons in theses state-of-the-art heterostructures.

Inhibited Nonradiative Recombination at All Exciton Densities in Monolayer Semiconductors Shiekh Zia Uddin[1,2] and Ali Javey[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

The upper limit of efficiency that any semiconductors can achieve in a light-emitting device is directly dictated by photoluminescence quantum yield (PL QY), which is a strong function of photocarrier density. Optoelectronic devices that are ubiquitously used for display or lighting applications such as light-emitting diodes (LEDs) often operate in a high photocarrier density regime, where all semiconductors experience elevated nonradiative carrier recombination, and thus diminished PL QY. Previously we have shown that, although 2D transition metal dichalcogenide (TMDC) monolayers exhibit near-unity PL QY at low carrier densities, their PL QY lowers significantly at high carrier densities like all other semiconductors. Despite extensive research to advance their material quality and device architecture, the inherent PL QY degradation in 2D TMDC monolayers at high exciton densities remains a major challenge for their utility towards high-performance optoelectronic devices. At low densities, neutral excitons in monolayer semiconductors recombine entirely radiatively even in the presence of a high native defect concentration. However, at high densities, recombination of neutral excitons is dominated by exciton−exciton annihilation (EEA), where an exciton nonradiatively recombines while colliding with another exciton. We show that EEA is resonantly amplified in TMDC monolayers by van Hove singularities (VHSs) present in their joint density of states. Logarithmically divergent VHSs are a topological hallmark of two-dimensional semiconductors, arising from saddle points in the energy dispersion. By applying small mechanical strain, we shift the EEA process away from the VHS resonance and circumvent the enhanced nonradiative EEA that plagues the PL QY at high exciton densities, leading to near-unity PL QY at all exciton densities in 2D TMDC monolayers (e.g. MoS2, WS2, WSe2). This simple, scalable method suppresses all nonradiative recombination at all generation rates for both exfoliated and CVD-grown centimeter-scale TMDC monolayers, as long as they are direct, and their Fermi level is in the middle of the bandgap by electrostatic or chemical doping. Our results constitute the first critical step towards optoelectronic devices that retain their high efficiency at high carrier concentrations and put forth TMDC monolayers as a key material of choice for next-generation optoelectronic applications.

Deterministic Creation of Quantum Defects in van der Waal Materials Han Htoon; Los Alamos National Laboratory, United States

Quantum defects of vdW materials have advanced to the forefront of quantum communication and transduction research due to their unique potential to access the valley pseudo-spin degree of freedom and facilely integrate into quantum-photonic, electronic and sensing platforms via the layer-by-layer-assembly approach. Strain localized to a nm scale region of vdW has emerged as an effective means of creating quantum defects in vdW materials. This approach allows only a limited degree of control on placement, emission wavelength and quantum coherence properties of defects. Quantum defects realized to dates emit at wavelengths shorter than 1 micron while the defects operating in telecommunication wavelength range are highly desirable. More importantly, how and why localized strain creates the quantum defects is poorly understood. Studies have suggested that strain simply activates the optical properties of naturally existing point defects.[1] Aiming to address these issue, Center for Integrated Nanotechnologies is developing novel strain engineering approaches in conjunction with ion beam implantation capabilities for deterministic creation of defects in vdW materials. Here in this talk I will provide an overview of these capabilities development efforts and recently discovered novel quantum defects: telecomm quantum emitters of $MoTe_2$[2] and quantum defects of TMD/2D magnet heterostructures realized via local strain engineering.

11:00 AM EQ07.04.02
Defect Engineering of 2D van der Waals Materials for the Site-Selective Nucleation of Metal Nanoislands Vera Zarubin[1], Kate Reidy[1], Yang Yu[2], Ilya Charaev[1], Joachim D. Thomsen[1] and Frances M. Ross[1]; [1]Massachusetts Institute of Technology, United States; [2]Raith America, Inc., United States

The controlled formation of structural defects, ranging from single-atom vacancies to nanopores, has been broadly implemented as a method of modulating the properties of two-dimensional materials (2DMs). Moreover, theoretical studies predict that point defects in 2DMs provide nucleation sites for metal adatoms and clusters[1,2] and that nanopores in graphene facilitate the growth of metal islands.[3] These suggest that defect engineering may be extended to the site-selective growth of metals on 2DMs, enabling applications that require deterministic patterning of nanoscale features. Focused ion beams (FIBs) are well-suited for patterning 2DMs with nanometer precision and can be used to mill point defects[4] and sub-10nm features[5] in suspended 2DMs by tuning irradiation parameters that influence the ion dose and beam profile. To optimize the irradiation parameters for deterministic metal nucleation sites, an experimental investigation of defect creation mechanisms and metal-2DM interactions is required.

Here, we study the structural modifications that arise from FIB patterning of suspended 2DMs and the effects of patterning on subsequent metal nucleation and growth. Obtained by mechanical exfoliation of bulk crystals, layered 2DMs (graphene, MoS_2, WSe_2) are transferred to holey Si_3N_4 transmission electron microscope grids and annealed in ultra-high vacuum (UHV) to remove surface adsorbates, resulting in nearly pristine suspended membranes. Ions are delivered to the 2DM surface as arrays of spots and lines using He^+ in the Zeiss ORION helium ion microscope and Si^{2+} and Au^{2+} in VELION FIB-SEM. Ion doses are calibrated and the resulting defects and nanopores are characterized with aberration-corrected scanning transmission electron microscopy. We evaporate metals (Au, Ti) onto the patterned 2DM surface in UHV and study, post-deposition, the extent to which the defects, ion species, dose rate, and 2DM thickness affect the metal nucleation and growth. We also heat the samples post-deposition to examine with *in situ* UHV transmission electron microscopy the effect of post-deposition annealing on island shape and size. The island geometry is well suited for automated image analysis to obtain statistics of the nucleation density and location. The materials preparation and analysis technique can be generalized to the site-selective growth of other materials, such as Si and Ge via chemical vapor deposition or metals via thermal and e-beam evaporation. This templating and nucleation control strategy opens routes towards the directed self-assembly of 3D nanoislands on 2DMs and other mixed-dimensional heterostructures.

11:15 AM EQ07.04.03
Atomically Resolved Imaging of Electronic Defects in a CVD Grown Transition Metal Carbide: α–Mo_2C Saima A. Sumaiya[1], Omer Caylan[2], Goknur Buke[2] and Mehmet Baykara[1]; [1]University of California, Merced, United States; [2]TOBB University of Economics and Technology, Turkey

There is a continuous pursuit for new materials to enable the development of small-scale, power-efficient electronics for next generation devices and applications. During the past decade and a half, two-dimensional (2D) materials have received particular attention in this regard with their extraordinary electronic characteristics. Defects in the form of vacancies, interstitials etc. have a profound influence on carrier transport and local conductance in these materials and as such, would constitute a key factor affecting device performance. Therefore, it is of critical importance to experimentally study defects in 2D materials, in terms of their atomic structure and influence on surface electronics. Motivated in this fashion, we present here an atomic-resolution study of native defects in thin crystals of α–Mo_2C, an emerging 2D transition metal carbide with attractive physical properties and potential to be employed in electronic applications. In particular, we perform conductive atomic force microscopy (C-AFM) experiments on α–Mo_2C crystals grown on copper foils via chemical vapor deposition, revealing the presence of two types of defects that either enhance or inhibit the local conductivity in their vicinity (referred to as "bright" and "dark" defects, respectively), over a lateral span of 2 to 10 nanometers. The simultaneous recording of topography maps together with atomic-resolution conduction maps allow us to make conclusions about the structure and location of defects in the crystals. Specifically, no features are detected in topography maps near both types of defects, suggesting that they are located below the top surface of the crystals. Additionally, while the influence of dark defects on the electronic landscape are diffuse such that the regular atomic structure of Mo_2C appears mainly undisturbed in conductivity maps, bright defects significantly distort the local conductivity, hinting at a stronger influence on local density of states. The findings presented here have the potential to provide critical fundamental information not only for electronic applications but also for other fields ranging from energy storage to catalysis where 2D transition metal carbides are envisioned to be used.

SESSION EQ07.05: Emerging Properties of vdW Materials I

Layered Graphenic Structures for the Next Generation Lithium-Ion Batteries Tereza M. Paronyan; HeXalayer LLC, United States

Rechargeable batteries are considered the key energy storage for portable electronics due to their ability to restore the charge and provide consistency in the voltage. Carbon-based materials remain the safest, cost-efficient, and environmentally stable anode material providing high-power density and energy compared to any other active materials.
I will discuss the advantageous layered graphenic structures versus commonly used graphitic negative electrodes in Lithium-ion batteries (LIB). The focus will be the study of interlayer structural features of multilayered graphene and its direct impact on Lithium intercalation. As-synthesized layered graphene with rotated layers is studied revealing that broken Van der Waals forces preceded intense Lithium diffusion and intercalation reaching up Li_2C_2 component formation. A large Li/electrolyte interface brings an enhanced charge-transfer kinetics resulting in effective charge/discharge cycling throughout hundreds of cycles with over 1800 mAh/g specific capacity.
This graphene anode's feasibility allows developing over 500 Wh/kg energy density in LIBs.

2:00 PM *EQ07.05.02
Direct Electron Imaging of Magnetic Topological Structures using 4D-STEM Kayla Nguyen; University of Illinois at Urbana-Champaign, United States

Emerging 2-dimensional (2D) magnets provide opportunities for reducing magnetism to atomic length scales. For 2D magnets, investigations of their local magnetic structure will be important for future generations of magnetic memory storage, where current technologies utilizing ferromagnetic materials will soon reach fundamental scaling limits. In particular, 4-dimensional scanning transmission electron microscopy (4D-STEM) with the electron microscope pixel array detector (EMPAD) have provided ways to image magnetic domains, topological structures such as skyrmions and local chirality. In my talk, I will highlight new developments for imaging magnetic structures with 4D-STEM and how we can apply these new techniques to the investigation of magnetic properties in 2D materials.

2:30 PM EQ07.05.03
Magnetic Proximity Effect in TMD/2D-Magnet Heterostructures Xiangzhi Li, Andrew C. Jones and Han Htoon; Los Alamos National Laboratory, United States

Van der Waals 2D magnets are recently discovered and have triggered significant research interests. These Magnetic 2D materials provide unique properties to study the magnetism response in the 2D limit, and thus an ideal platform for the integration with other atomic thin semiconductor heterostructures to explore the manipulate spin and photon degrees of freedom (DOF), facilitating control of spin degeneracy and light-matter interactions of well-defined quantum states. Magnetic proximity effect between monolayer transition metal dichalcogenides (TMDs) and 2D magnets have been proved in a few heterostructures (WSe_2/CrI_3 and $MoSe_2$/$CrBr_3$) based on manipulation of the PL intensity/linewidth and valley Zeeman splitting [1-3]. 0D strain-induced quantum emitters in WSe_2 are also employed to determine the proximity exchange interaction in WSe_2/CGT, WSe_2/FGT, and WSe_2/CrI_3 devices [4-6]. Band alignment and spin-dependent interlayer charge transfer are crucial for this effect which also strongly depends on the distance between layers due to the short range of the electronic wave function at the interface. However, most 2D magnets are sensitive to air which hinders the application of spintronic devices. In contract with these extremely air unstable magnetic 2D materials, multiple 2D magnetic materials including the MPS_3 family (M= Mn, Ni, Cr, Co, Fe), $CrPS_4$, and CrSBr have emerged as environmentally stable materials providing a new opportunity for assembling air–stable devices. Moreover, the observation of magnetic exciton in $CrPS_4$, $NiPS_3$, and CrSBr with strong anisotropy also expands research possibilities of band alignment and many-body exciton interactions between them and TMDs. Here, we use monolayer WSe_2 as a probe to investigate the interplay between the magnetic proximity effect and valley pseudospin dynamics in air-stable 2D antiferromagnetic magnets ($NiPS_3$, $CrPS_4$, and CrSBr) heterostructures via polarization-resolved low-temperature PL, time-resolved PL, and magneto-optical spectroscopies. We will also report the interesting properties of strain-induced quantum defects created in TMD/2D magnet heterostructures.

Defect-Mediated Thermo-Mechanical Behavior of 2D Hybrid Organic-Inorganic Perovskites Doyun Kim[1], Eugenia S. Vasileiadou[2], Ioannis Spanopoulos[2], Mercouri G. Kanatzidis[2] and Qing Tu[1]; [1]Texas A&M University, United States; [2]Northwestern University, United States

2D hybrid organic-inorganic perovskites (HOIPs) are low-cost, high-performance semiconductor materials with great potential demonstrated in various fields, including photovoltaics, light-emitting diodes, lasers and field-effect transistors. During device fabrication and device operation, 2D HOIPs will go through various temperature statuses. Because of the hybrid organic and inorganic nature, the temperature fluctuation will cause significant influence on the mechanical behavior of 2D HOIPs, which is vital for material processing and device durability, but is largely unknown. We measured the in-plane elastic modulus *E* of a prototypical 2D HOIP, $(C_4H_9\text{-}NH_3)_2(CH_3NH_3)_4Pb_5I_{16}$ (abbreviated as C4n5) as a function of temperature across a range of technological interest (*i.e.*, -15 °C to 65 °C) by AFM stretching suspended 2D HOIP nanosheets. Unlike their 3D counterpart, $CH_3NH_3PbI_3$, which shows negligible temperature-dependent mechanical property, C4n5 exhibits a strong thermo-mechanical response in the tested temperature range. *E* is a non-monotonic function of temperature, which peaks slightly above room temperature, but are lower both at high and low temperature range. This trend clearly deviates from the general anharmonic expectation of the thermo-mechanical behavior for materials. Further structural analysis suggests that the observed thermo-mechanical behavior is due to the formation of gauche defects in the organic spacer molecules at the van der Waals interfaces, which mediates the mechanical coupling between the 2D layers. We further demonstrated that exposure to moisture results in defects in the 2D HOIP nanosheets and the defect density can strongly modulate the thermo-mechanical behavior of C4n5, probably due to a mix-phase of 2D and 3D HOIPs.

SESSION EQ07.06: Emerging Properties of vdW Materials II

2D Materials and Heterostructures—From Property Engineering to Emerging Memory and Neuromorphic Applications Feng Miao; Nanjing University, China

Two-dimensional (2D) materials and van der Waals (vdW) heterostructures have emerged as promising candidates for post-Moore electronics due to their unique electronic properties and atomically thin geometry. In this talk, I will start with an important type of in-memory computing device, robust memristors with excellent memory performance and thermal stability, which can be created from a vdW heterostructure composed of graphene/$MoS_{2-x}O_x$/graphene.[1] I will then discuss a prototype reconfigurable neural network vision sensor that operates via the gate-tunable positive and negative photoresponses of a WSe_2/BN heterostructure.[2] A neuromorphic vision system with brain-inspired visual perception can be further realized by networking such retinomorphic sensors with a memristive crossbar array.[3] Our latest results on an electrically tunable homojunction for reconfigurable circuits,[4] as well as a scalable massively parallel computing scheme in crossbar arrays[5] will be presented in the last part of my talk.

8:30 AM *EQ07.06.02
Graphene Interfaces for Electronics, Optoelectronics and Bio-Devices Vikas Berry; University of Illinois at Chicago, United States

The presentation will outline several chemical manipulation techniques developed in our laboratory to control the properties of graphene, including non-destructive functionalization, nanoparticle incorporation and biomolecular interfacing. The following topics will be discussed: (i) modification of phononic energy of antibody-coupled graphene when it interfaces with SARS-CoV-2 spike protein. (ii) phononic energy's modification with ionic flow over graphene, (iii) unique eta-6 organometallic approach to functionalize graphene in a vapor-phase process, while retaining its structural and electrical properties and offering chemical sites for nano-interfacing of plasmonic centers for enhanced photovoltaics; (iv) biointerfacing of graphene with electrogenic bacteria for microbial energy devices; and (vi) Photovoltaics via electronic coupling of graphene atop a bulk semiconductor to induce interfacial energy-band reorganization for light-sensitive junctions only one atom below the front surface.

9:00 AM EQ07.06.03
Late News: Long-Range Transport of 2D Excitons with Surface Acoustic Wave Ruoming Peng, Adina Ripin, Yusen Ye, Jiayi Zhu, Ting Cao, Xiaodong Xu and Mo Li; University of Washington, United States

Interlayer excitons in 2D semiconductors have emerged as a promising candidate for engineering excitonic devices, due to the strong coupling with light, large exciton binding energy, and gate tunability. However, the exciton is a charge-neutral particle that can not be controlled by the in-plane electric field

and thus inhibits the study of the exciton transport. Here, we demonstrate the directional transport of interlayer excitons in bilayer WSe_2 driven by the dynamic piezoelectric field induced by surface acoustic waves (SAW) on LiNbO3. We show that at 100 K, the SAW-driven excitonic transport is activated above a threshold acoustic power and reaches a distance up to 20 um which is far beyond the diffusion length, and only limited by the device size. Our work shows that acoustic waves are an effective contact-free approach to control exciton dynamics, which can provide a novel physical platform for the study of 2D excitons such as the exciton valley hall effect and also be promising for realizing 2D materials-based excitonic devices such as exciton transistors, switches, and transducers.

9:15 AM EQ07.06.04
Submicron Bi_2Se_3-WS_2 Pixels with Large (39.4%) Selectable Circular and Valley Polarization at Room Temperature Zachariah Hennighausen[1], Kathleen McCreary[2], Darshana Wickramaratne[2], Hsun-Jen Chuang[2], Bethany Hudak[2], Todd Brintlinger[2], Mehmet Noyan[2], Jisoo Moon[2], Berend Jonker[2], Rhonda Stroud[2] and Olaf van't Erve[2]; [1]National Research Council at Naval Research Laboratory, United States; [2]U.S. Naval Research Laboratory, United States

Measuring and manipulating circular polarization is central to numerous existing and emerging technologies, including spintronics, bio-inspired navigation, valleytronics, quantum computing and communications, and spectroscopy. Here, we demonstrate a method to tune the photoluminescence (PL) intensity (factor of x161), peak position (38.4meV range), and degree of circular polarization (DoCP) (39.4% range) with extraordinary precision using a low-power laser in Bi_2Se_3-WS_2 2D heterostructures. Few-layer, crystalline Bi_2Se_3 is grown on monolayer WS_2 using chemical vapor deposition (CVD). The Bi_2Se_3 grows at a ~0° twist angle, and density functional theory (DFT) calculations predict a coupling between the layers that possibly facilitates non-radiative recombination. The as-grown 2D heterostructure PL intensity is low; however, when exposed to a low-power laser (0.8mW) in ambient, the PL smoothly increases intensity, the peak position shifts, and the DoCP decreases. Atmospheric measurements suggest oxygen is absorbing into the 2D heterostructure. We use first-principles calculations to elucidate the role of oxygen incorporation on the electronic structure. We show that the intensity and peak position changes can be reversed by desorbing the oxygen using a laser in a nitrogen (N_2) environment, and that it can be reused. Our technology can be used to locally modify the valley polarization with submicron precision, a promising advancement for spintronics and valleytronics applications.

Nano-Photoluminescence Mapping of Room-Temperature Strain-Localized Excitons in Array-Guided Nanowrinkles Emanuil Yanev[1], Thomas P. Darlington[1], Matthew Strasbourg[2], Nicholas Borys[2], James Hone[1] and Peter Schuck[1]; [1]Columbia University, United States; [2]Montana State University, United States

Quantum systems, and the field of quantum information science, are quickly becoming a hotbed for technological breakthroughs. At the heart of many of these technologies is the single-photon source (SPS). While a variety of systems are currently used for this purpose—from quantum dots to nitrogen-vacancy centers in diamond—they are not without their limitations. Often, cryogenic temperatures are required, tunability is lacking, or integration with other components is difficult. In an attempt to address some of these challenges, we examine a solid-state system with the potential of realizing tunable SPSs at room temperature by locally inducing large amounts of strain in a monolayer sheet of WSe_2. Due to the very low defect density and single crystal nature of the material, it is able to strongly conform to patterned substrate features. In so doing, nanoscale wrinkles are formed on, around, and in-between the structures, with orientations influenced by the patterned array. These highly strained regions can effectively localize excitons and produce room temperature low-energy emission, similar to that reported in our previous work on strained nanobubbles. When cooled to cryogenic temperatures, a rich milieu of sharp spectral features is revealed in these areas, which suggests that the emission seen at room temperature is quantum in nature and tunable with strain.

9:45 AM EQ07.06.06
On the Origin of Raman Peak Splitting in Monolayer 2D Materials—Metal Interfaces: MoS_2/Au Mirjana Dimitrievska, Akshay Balgarkashi, Jin Jiang, Elias Stutz, Mitali Banerjee and Anna Fontcuberta i Morral; École Polytechnique Fédérale de Lausanne, Switzerland

Monolayer (ML) transition-metal dichalcogenides (TMDs) exhibit a direct bandgap and a relatively high carrier mobility. This makes them as excellent building blocks for applications in optoelectronics, photovoltaics and catalysis.

Electronic and optoelectronic applications with TMDs rely on the good functioning of the junction with metals. While the van der Waals nature of TMDs should in principle imply absence of states in the middle of the TMD bandgap, vacancies and point defects in the material may result in atom exchange and thus doping of the TMD by the metal. Chemical interaction at the interface, such as creation of metal-chalcogenide bonds, could lead to a configurational change in the TMD. In addition, ML TMDs can be easily perturbed by strain or charge transfer from the underlying layers due to their ultra-thin nature. Similar to classical low-dimensional structures, the physics of the metal- semiconductor junction shall dictate the behavior of the device. A fundamental understanding of the metal-TMD junction is thus extremely relevant for the reliability of TMD-based electronics and/or optoelectronics.

Raman spectroscopy is a versatile tool for characterization of 2D materials, especially in terms of quantifying the number of layers, and evaluating the effects of strain, doping and defects. In the case of monolayer TMDs, the most prominent features in the Raman spectra are in-plane (E_{2g}) and out-of- plane (A_{1g}) peaks. Among the recent Raman studies on TMD-metal interfaces, many have reported peak splitting of the A_{1g} and E_{2g} modes. A variety of attempts have been made to explain the peak splitting, usually in terms of strain and charge transfer effects. While these effects could cause splitting of individual peaks in some cases, they are insufficient to explain splitting in both A_{1g} and E_{2g} peaks simultaneously. To better understand the interaction at ML TMD-metal interfaces, which is extremely important for device performance, it is necessary to provide a full explanation of the mechanism causing the Raman peak splitting that occurs in this case.

In this work, we look into the origin of A_{1g} and E_{2g} peak splitting through a systematic measurement and simulation of Raman spectra, along with relevant literature review. We focus on MoS_2/Au as a representative system. We illustrate why strain and charge transfer cannot be the main contribution to the simultaneous splitting of both A_{1g} and E_{2g} Raman peaks. We propose a mechanism based on plasmon-phonon interaction and presence of extrinsic defects at the TMD-metal interface as the main driver leading to peak splitting. We attribute the new peaks to non-Γ phonon modes originating from in-plane (E_{2g}) and out-of-plane (A_{1g}) phonon branches at certain non-zero wave vector. We test the validity of our hypothesis by investigating samples with different interface configurations, including the exchange of Au with Al.

10:30 AM *EQ07.07.02
The Complex Role of Interfaces in Determining Phonon Transport in Two-Dimensional Materials Yan Wang; University of Nevada, Reno, United States

There has been a rising notion of the wave nature of phonons over the past decade. Notably, recent experiments and atomistic modeling have revealed ballistic transport of coherent phonons in superlattices containing dense interfaces. These coherent phonons allegedly arise from the interference of backscattered phonon waves at the densely packed interfaces, which should otherwise greatly hinder the transport of conventional, particle-like phonons. In this invited talk, we will discuss our recent findings of some exotic (and non-exotic) behaviors of coherent phonons in superlattices and phononic crystals, particularly in those made of two-dimensional materials. First, we will demonstrate that randomizing the layer thicknesses of a superlattice, which leads to localization of phonons, can reduce its thermal conductivity to even below the amorphous material limit, which can hardly be achieved by merely scattering phonons. Second, we will discuss the effect of reduced dimensionality on coherent phonon behaviors: can two-dimensional materials demonstrate more prominent coherent phonon transport than three-dimensional ones? what is the effect of anharmonic scattering on coherent phonons? can we find stronger phonon localization in two-dimensional systems than three-dimensional ones? We will explain these behaviors by decomposing thermal transport into coherent phonon and incoherent phonon contributions via the Landauer-Datta-Lundstrom approach. Detailed spectral phonon analysis will further reveal the interplay between coherent and incoherent phonons, as well as their respective effect on thermal transport.

11:00 AM *EQ07.07.03
Tunable Helical Edge States in van der Waals Materials Chun Ning (Jeanie) Lau; The Ohio State University, United States

Helical conductors, systems that have no bulk conduction but support dissipationless conducting states at their edges, may be engineered to realize Majorana statistics for quantum computation. Underlying these remarkable systems are the non-trivial topology of electronic structure in the bulk, arising band inversion in the bulk and crossing of conductance and valence bands at the system boundary. In helical conductors, these counterpropagating states carry different spin quantum numbers, protecting the crossing and preventing a gap from opening in the spectrum of edge states. Traditional helical conductors, such as those achieved in topological insulator systems, are typically not tunable in situ, and helical conduction is only achieved over a narrow range of parameters.
Here we show that helical edge states are achievable and tunable in few-layer van der Waals materials. In Bernal-stacked trilayer and tetralayer graphene, we observe helical edge states at moderate and strong magnetic fields, respectively, arising from the competing effects of inter-layer coherence, electrostatic polarization and exchange interaction. As the interlayer potential and magnetic field varies, we observe a series of quantum transitions among the phases that host 2, 1 and 0 helical edge states on each edge. Our work highlights the complex competing symmetries in few-layer graphene and the rich quantum phases in this seemingly simple system[1, 2]. Lastly, in thin exfoliated Bi4I4 samples, which is a quasi-1D topological insulator and candidate for higher order topological states, we observe gate tunable magneto-transport and Josephson current. Our combined transport, photoemission, and theoretical results indicate that the gate-tunable channels consist of novel gapped side surface states, a 2D TI in the bottommost layer, and helical hinge states of the upper layers[3].

Structural and Electronic Properties of a New 2D Material—Thiophene-Tetrathia-Annulnes (TTA-2D) Raphael M. Tromer[1], Levi C. Felix[1], Cristiano F. Woellner[2] and Douglas S. Galvao[1]; [1]Universidade Estadual de Campinas - Unicamp, Brazil; [2]Universidade Federal do Paraná, Brazil

Since the experimental realization of graphene [1], there is an increasing number of works for new two-dimensional materials (2D) [2]. In this work, we investigated using ab initio methods, the structural, electronic, and mechanical properties of a new 2D semiconductor material, named (TTA-2D) [3], which is topologically based on the molecular structure of Thiophene- Tetrathia-Annulene (TTA), which has been already synthesized. Our results showed TTA-2D has a small indirect bandgap semiconductor of about 0.6 eV with a semiconductor-metal transition when a uniaxial strain is applied. We also carried out molecular dynamics at high temperatures and observed that TTA-2D is thermally stable up to T = 1000 K. From optical analysis, our results also show that TTA-2D absorbs in a large energy range, from infrared to ultraviolet regions. The analysis of refractive and reflectivity index shows that TTA-2D reflects only 10% of the incident light within the visible region. Therefore, these results suggest that TTA-2D is a promising material for solar cell applications.

CO-Induced S Vacancy Formation for Phase Conversion of MoS_2 and WS_2—A DFT Study Deokgi Hong[1], Sungwoo Lee[1,1], Dae-Hyun Nam[2], Gun-Do Lee[1,1] and Young-Chang Joo[1,1,3]; [1]Seoul National University, Korea (the Republic of); [2]Daegu Gyeongbuk Institute of Science & Technology, Korea (the Republic of); [3]Advanced Institute of Convergence Technology, Korea (the Republic of)

Defect engineering in transition metal dichalcogenides (TMDs) is a key approach to controlling the properties of TMDs. Defects in TMDs like chalcogen vacancy can induce the phase conversion of TMDs. Because TMDs have different properties depending on the phase, controlling specific phase of TMDs through defect engineering is crucial to obtain specific properties.
For instance, group VI TMDs such as MoS_2 and WS_2 have thermodynamically stable H phase and unstable T phase. In application of these TMDs in hydrogen evolution reaction (HER), unstable T phase exhibits better performance. However, it is difficult to obtain and maintain the T phase, which causes stability problems. Many research groups have found the ways to tackle this issue. Formation of S vacancies (V_S) on TMD layer is one of the ways for the phase conversion of TMDs.
Recently, our colleagues proposed novel method of forming V_S for phase conversion of MoS_2 from stable H phase to unstable T phase. [1] In this method, S vacancy is formed on MoS_2 by the reaction between CO and S, and the phase conversion of MoS_2 occurs. This method was also applied to WS_2. It was

found that the phase conversion of WS_2 required higher annealing temperature and CO mole fraction than that of MoS_2. To reveal the mechanism of CO-induced phase conversion and elucidate the difference in the phase conversion conditions, we conducted DFT calculations. We calculated the reaction barriers of CO-mediated V_S formation and S diffusion to octahedral site of MoS_2 [2] and WS_2. V_S on the edge sites of MoS_2 and WS_2 were formed. Then, S atoms at the trigonal prismatic site diffused to the octahedral site. The reaction barrier for V_S formation on edge site and S diffusion to octahedral site of WS_2 was higher than that of MoS_2. By DFT calculation, we revealed the mechanism for CO-induced phase conversion of MoS_2 and WS_2. And we identified the cause of the difference in experimental conditions. Consequently, this work provides insights into the defect engineering for phase conversion of several TMD materials using gas-solid reactions.

Creating Quantum Dot Arrays in Two-Dimensional Materials Hui Deng; Univ of Michigan, United States

Large arrays of quantum dots at controlled positions could be pivotal for enabling practical applications of quantum dot systems. While single quantum dots have been widely studied in many material sysetms, creating a large array of quantum dots face different challenges. The engineering flexibility of atomically thin van der Waals crystals have brought about new possibilities to realize localized excitons. Here we explore two ways to create large arrays of quantum dots using transition metal dichalcogenides. First, we demonstrate rapid creation of large, rewritable arrays of localized emitters with high yield through strain engineering. Second, we show that uniform quantum dot arrays are naturally formed via moire potential confinement in twisted bilayers. Both types of quantum dot arrays are compatible with integration with other on-chip photonic structures and large scale fabrication.

Modulating Water Slip Using Vacancy Defects—Towards Realistic Modeling of Hexagonal Boron Nitride Surfaces Aniruddha Seal[1,2] and Ananth Govind Rajan[2]; [1]National Institute of Science Education and Research, India; [2]Indian Institute of Science, India

Vacancy defects, despite being commonly present in nanomaterials, are inadequately understood in terms of their role in modulating interfacial fluid flow. In this work, we study the frictional properties of hexagonal boron nitride (hBN), an up-and-coming 2D material, by considering five different types of "realistic" vacancy defects present in it. In recent years, hBN has gained increasing attention for use in desalination membranes, oil-water separation devices, and osmotic energy harvesting, where hBN-water interfaces are ubiquitous. Thus, understanding solid–liquid friction on real hBN surfaces is important to design and develop such applications. Here, we present a combined quantum-classical approach to achieve this objective. To this end, we use quantum-mechanical density functional theory to obtain point charges to accurately represent the unique electric field produced by each of the five defects considered. Subsequently, using classical molecular dynamics simulations, we study the role of the vacancy composition and concentration in modulating the hBN–water friction coefficient, and the resultant slip length for water flow on hBN. Our findings demonstrate the use of vacancy defects to tune the water flow and slip on hBN, and indicate the promise of defective hBN as an alternative high-slip surface to graphene.

8:45 AM EQ07.08.03
Vacancy-Induced Emission in Proton Beam Irradiated Monolayer Semiconductors Zhepeng Zhang, Haidong Liang, Leyi Loh, Yuan Chen, Yifeng Chen, Su Ying Quek, Bosman Michel, Andrew Bettiol and Goki Eda; National University of Singapore, Singapore

Defect engineering of atomically thin semiconductor crystals is an important approach to tailoring their optical properties for developing single-photon sources and valleytronic devices. Recently, He ion and electron beam irradiation of transition metal dichalcogenide (TMD) monolayers has been shown to induce single-photon emitting defects. Here, we report the generation of robust luminescent defects in chemical vapor deposition (CVD)-grown monolayer MoS_2 and WS_2 via proton beam irradiation with a wide range of ion beam fluences from 10^{11} to 10^{14} cm^{-2}. These defects exhibit subgap photoluminescence peaks that are 100 to 200 meV below the neutral exciton peak. Remarkably, these emissions are robust even at room temperature, unlike the previously reported defect-induced emission. They exhibit sublinear power-dependent emission intensity and long emission lifetime (> 1ns), which are characteristics of localized emitters. Atomic resolution scanning transmission electron microscopy (STEM) images reveal that the areal density of sulfur vacancies is increased by ~10^{13} cm^{-2} after ion beam irradiation, indicating that unpassivated sulfur vacancies are responsible for the observed localized emissions. We conduct DFT and GW-BSE calculations of TMDs with different defect configurations to further discuss the potential role of defect complexes.

Optically Active Selenium Vacancies in $MoSe_2$ Induced by Proton Beam Irradiation Yuan Chen, Haidong Liang, Leyi Loh, Bosman Michel, Andrew Anthony Bettiol and Goki Eda; National University of Singapore, Singapore

Deterministic creation of quantum emitters in transition metal dichalcogenides (TMD) has become a key challenge for their implementation into quantum technology. One of the promising routes to generating quantum emitters is controlled defect engineering by ion beam irradiation. In this study, we investigate the effect of high energy proton beam irradiation on deterministic creation of optically active defects in monolayer $MoSe_2$. We show that proton beam irradiation results in emergence of three narrow sub-gap emission peaks, which are stable up to 160 K. We probe the nature of the defects by studying their valley selectivity and the effect of electrostatic doping. Gate-dependent photoluminescence suggests that the sub-gap emission is suppressed when states near the conduction band edges are depopulated. Our observations are in good agreement with the recent theoretical predictions for selenium-vacancy-induced optical transitions in $MoSe_2$. Our scanning transmission electron microscopy (STEM) imaging reveals that proton beam irradiation results in increase in selenium vacancies but no changes in metal vacancy concentration, which further corroborates that these emissions are related to unpassivated selenium vacancies created by proton beam irradiation. Our work demonstrates that proton beam irradiation can serve as a simple approach to creating optically active defects in TMDs.

9:15 AM EQ07.08.06
Production of Defects in Suspended Graphene with High Density and Low Healing Energy Using Electron Irradiation Ibikunle Ojo, Evan Hathaway, John Femi-Oyetoro, Jingbiao Cui and Jose Perez; University of North Texas, United States

We report the production of defects in suspended graphene that have an extremely high defect density and low activation healing energy using electron irradiation at 20 keV from a scanning electron microscope (SEM). The graphene was suspended over microchambers etched in SiO_2, measuring 5 microns in diameter and 400nm in depth. The graphene completely seals the chamber with air at atmospheric pressure. The samples were then placed in an SEM system and irradiated to a dosage of about 1 x 10^{17} electrons/cm^2. The graphene effectively seals the microchamber so that the air pressure inside does not significantly decrease from atmospheric pressure during the irradiation. This produced an extremely high defect density with a sharp Raman D peak and Raman D peak height to G peak height ratio, I_D/I_G, of over 4.5. Thermal studies showed that the defects almost completely heal after annealing the sample at only 200 ^oC for 5 minutes. In contrast, microchambers in which the graphene does not completely seal the chamber show I_D/I_G ratios of 0.14. The high defect density achieved in the sealed microchambers is attributed to the atmospheric pressure inside and strain induced by the curvature. The low healing temperature rules out damage in the form of lattice defects such as vacancies.The method by which the defects were produced involving SEM, which is compatible with nanolithography, makes it useful for device applications.

9:30 AM EQ07.08.07
Engineering Defect-Related Color Centers in Hexagonal Boron Nitride Using Focused Ion Beams Yue Xu[1], Soumya Sarkar[1], Jing-Yang Chung[1,1], Manohar Lal[1], Sinu Mathew[1,2], T. Venky Venkatesan[1,3] and Silvija Gradečak[1,1]; [1]National University of Singapore, Singapore; [2]Mahatma Gandhi University, India; [3]The University of Oklahoma, United States

Hexagonal boron nitride (hBN), a van der Waals crystal with a honeycomb structure similar to graphene, has been widely investigated as a dielectric substrate for 2D-based devices. More recently, hBN has emerged as a prominent candidate for quantum nanophotonics due to the observation of a tunable single photon emission. These emitters have been associated with mid-gap states in ultra-wide bandgap hBN (~6eV) that originate from atomistic defects in the hBN lattice. Here, we report the observation of near-infrared (~ 800 nm) photoluminescence (PL) emission in hBN at room temperature caused by defects formed *via* focused He-ion beam irradiation. We tune PL intensity of the emitters by tailoring the defect generation in hBN as a function of the irradiation parameters. Raman spectroscopy and high-resolution scanning transmission electron microscopy imaging further confirm that the emerging PL response is correlated with point-defect states in hBN. We also demonstrate that similar results can be obtained by Ga-ion irradiation, confirming the PL emission to be related to intrinsic structural defects in hBN. Our work presents a platform to precisely create and control defect-related color centers in hBN that can serve as building blocks for next-generation nanophotonic and possible quantum devices.

9:35 AM EQ07.08.08
A Comprehensive Study of MoS_2 with Varying Layers Using Correlated Raman, PL, KPFM and TERS Imaging—Implications for Modulating Electronic Properties by Oxygen Plasma Induced Defects Sanju Gupta; University of Central Florida, United States

Modulating physical (electrical, optical, and electrochemical) properties of transition metal dichalcogenides (TMDs) by oxygen plasma treatment has attracted a great deal of attention. However, the effect of exposure time on oxidation and etching process in oxygen plasma treatment and creating lattice defects still lacks systematic structural property investigations at the nanoscale. In this work, we have employed optical microscopy, scanning electron microscopy, micro-and nanoscale Raman (tip-enhanced, TERS) and photoluminescence (TEPL) spectroscopy, and scanning probe microscopy (atomic force and Kelvin Probe) to characterize changes in surface morphology, spectral signatures, electronic structure, oxidation, etching and/or clustering behaviors of atomically thin molybdenum disulfide (MoS_2) nanosheet layers, mechanically exfoliated on gold-coated substrates, treated by oxygen plasma with different times. For oxidation plasma (electron beam), the process is predominantly oxidation from 0 to 20s, while etching becomes the dominant behavior beyond 20s for monolayer (1L) to trilayer (3L) MoS_2 nanosheets under medium power oxygen plasma. By means of TERS, we uncover spectral heterogeneities, strain changes spatially localized to regions as small as 30 nm clustering domains due to sulfur vacancy followed by oxygenation and forming MoO_2/MoO_3, enhancement of certain Raman peaks due to strong electromagnetic confinement between the tip and MoS_2 and appearance of new peaks, often unobserved in confocal Raman spectroscopy. As for excitonic properties measured through photoluminescence spectroscopy, we observed evolution of trion peak and suppression or quenching of neutral exciton A peak with increased oxygen plasma exposure. We also estimated the concentration of sulfur vacancy via correlating the variation in characteristic E' and A' band position (~ 4 cm^{-1}) of MoS_2. We find that regions of maximum local strain correspond to the regions of topographic curvature extracted from AFM measurements. Likewise, we observed nanoscale variation in work function correlated with an alloy of MoS_2/MoO_{3-x}. The TERS study allowed us to determine various chemical compositional phases and built-in strain that arises when 2D materials interact with Au under oxygen plasma. This work is financially supported in parts by NSF and NSF-MRI Grants.

9:40 AM EQ07.08.09
Spatial Inhomogeneity in MoS_2 Monolayer Irradiated by Electron Beam for Different Times—Correlated Study by Raman, PL, AFM, KPFM and TERS Imaging Sanju Gupta; University of Central Florida, United States

Modulating physical-chemical (electrical, optical, and electrochemical) properties of transition metal dichalcogenides (TMDs), particularly MoS_2, has attracted a great deal of attention for diverse technologies. In this work, we exposed exfoliated monolayer MoS_2 under electron beam irradiation with an energy of 15 keV for different times and investigated the possible effects of the structural defects intentionally created by electron-beam on electronic properties at the nanoscale. Among various ways in which an electron beam adversely affects the sample are: local heating, electrostatic charging, displacement damage, sputtering, and hydrocarbon contamination. However, the effects of exposure time on the oxidation and etching process in creating lattice defects by e-beam irradiation still lack systematic investigations. In this work, we have employed scanning electron microscopy, micro-and nanoscale Raman (tip-enhanced, TERS) and photoluminescence (TEPL) spectroscopy, atomic force, and Kelvin Probe microscopy to characterize changes in surface morphology, spectral signatures, oxidation, etching, and/or defect clustering, to obtain high-resolution images and quantitative measurements of the work function heterogeneities. We unravel the evolution of defects formed under electron beam irradiation and observe the formation of metastable defect domains with different work function values. The experiments show that material diffused outward forming ring-like morphologies which become prominent with increasing exposure time while sulfur vacancies formed after exposure to diffuse, coalesce, and migrate molybdenum atoms at the edge of the ring while leaving patches of MoS_2 in the center, suggested by work function variation bringing the system from a metastable to equilibrium ground state. In light of recent experimental evidence, the results provide the importance of defect control and determined that the amount of radiation damage is proportional to the electron dose; and the extent of the damage is proportional to the amount of energy deposited in the sample. The results of this study enhance understanding of the electrical properties of MoS_2 FET devices in terms of defect sites on the MoS_2 surface that work as trap sites, which can deteriorate the carrier mobility and carrier concentration similar to what occurs during oxygen plasma. This work is financially supported in parts by NSF and NSF-MRI Grants.

SESSION EQ07.09: Strain Engineering of vdW Materials II

Wednesday Morning, December 8, 2021
EQ07-Virtual

10:30 AM EQ07.09.01
Boosting Thermoelectric Performance of Ultrathin MoS_2 by Substrate-Induced Non-Uniform Strain Hong Kuan Ng[1,2,1], Kedar Hippalgaonkar[2,3,1], Goki Eda[1,1,1] and Jing Wu[2,1]; [1]National University of Singapore, Singapore; [2]Institute of Materials Research and Engineering, Singapore; [3]Nanyang Technological University, Singapore

Thermoelectric performance in 2D transition metal dichalcogenides (TMDs) are usually optimized through controlling carrier concentration, band engineering, and/or scattering mechanism. Applying uniform strain to TMDs has been demonstrated to increase electrical performance and carrier mobility owing to the alteration of electronic band structure and effective carrier mass. Here, we study the effects of non-uniform strain on the thermoelectric performance of MoS_2 using SiN_x substrates with a crested morphology. The non-uniform strain is demonstrated to suppress phonon-scattering which drastically enhances carrier mobility and thermoelectric power factor in crested MoS_2 by up to 2 orders of magnitude depending on carrier concentration as compared to conventional MoS_2 on flat SiO_2 surfaces. We investigate gate- and temperature-dependent carrier mobility and density to determine the mechanisms responsible for the drastic enhancement in thermoelectric performance. Distinctively, the ultra-high carrier mobility achieved at low carrier concentrations weakens the dependence of thermoelectric parameters on carrier concentration, therefore resulting in a substantial improvement in electrical conductivity without greatly compromising Seebeck coefficient. Our work provides a universal pathway towards engineering carrier mobility and superior thermoelectric performance for a wide range of room-temperature applications.

10:45 AM EQ07.09.02
Site-Controlled and Strain-Tunable Quantum Optical Emission in WSe_2 Monolayers Abel Martinez-Suarez[1,2], Matteo Savaresi[3], Davide Tedeschi[3], Victor M. G. Suarez[1], Johannes Aberl[4], Moritz Brehm[4], Aurelio Hierro-Rodriguez[1,5], Stephen McVitie[5], Pablo Alonso-Gonzalez[1,2], Javier Martin-Sanchez[1,2] and Rinaldo Trotta[3]; [1]University of Oviedo, Spain; [2]Nanomaterials and Nanotechnology Research Center (CINN), Spain; [3]Sapienza University of Rome, Italy; [4]Johannes Kepler Universität Linz, Austria; [5]University of Glasgow, United Kingdom

The development of novel ultra-compact two-dimensional (2D) photonic technologies for application in quantum information processing, relies on our ability to fabricate single photon sources (SPS) in 2D van der Waals materials where we are able to on-demand position them as well as tune their optical emission properties[1]. However, the challenge still remains to fully understand their physical origin in order to be able to efficiently utilize them and how to actively tune their optical properties. One solution is to implement elastic strain engineering through the introduction of a novel class of piezoelectric actuators[2,3].

In this work, we demonstrate site-controlled SPSs with reversible tuning of their emission energy by placing WSe2 monolayers on top of piezoelectric pillars capable of introducing in-plane isotropic strain fields[4]. Our findings prove that it is feasible to have a full control of the emission energy of these SPSs without affecting the single photon emission purity with relatively large energy shifts up to 18mev. The experimental results are further corroborated by finite element simulations along with analytical calculations showing that all SPSs can be energy blue-shifted. Interpretations on the origin of the SPSs will be discussed based on an exciton diffusion model accounting for the variations on the micro-photoluminescence spectra corresponding to individual quantum emitters. Our findings shed light on the understanding of the physical origin of SPSs in 2D monolayers and are of strong relevance for the practical implementation of single photon devices based on 2D materials for future applications in quantum information processing.

Effects of H2O Interaction with Graphene Grain-Boundary Under Strain Julia T. Hatoum, Claire Andreasen and Zubaer M. Hossain; University of Delaware, United States

In recent years, graphene has captured wide attention among engineers and researchers for its unique electronic, thermal, chemical, and mechanical properties, which could revolutionize a number of application areas, including electronics, nanotechnology, drug delivery, sensors, and catalysis. Since discovery, extensive research has been conducted theoretically, experimentally, and computationally to investigate the behavior of pristine graphene under no strain conditions. With the goal of applications in mind, it is critical to develop a fundamental understanding of the properties of defective graphene under deformed or strained conditions. While grain boundary defects within the graphene lattice are known to degrade mechanical properties and decrease both electrical and thermal conductivity, they can serve as an important source for making the graphene layer function as a chemically reactive 2D material, which may be unattainable otherwise. Furthermore, assessing and analyzing defects in the lattice is essential for application because the prevalence of defects (especially grain boundaries) causes graphene's extrinsic effects to have greater influence on the material's behavior than its intrinsic properties. In this work, using density functional theory simulations, we investigated the energetics of an isolated H2O molecule at a linear grain-boundary of pentagonal and heptagonal configurations formed between armchair and zigzag graphene sheets. Using SIESTA, we simulated a water molecule at an initial approach configuration parallel to the graphene lattice at different heights, and we analyzed the results of the relaxed configurations. Because we wanted to observe strain influence on the water molecule, we picked sites where the grain boundary induced tensions and compressions in the graphene lattice. Using these results, we investigated the total groundstate energies of the systems, the net force experienced by the carbon atoms, the orientations of the relaxed water molecules, and the electronic structure of the lattice. Our findings suggest that if the initial placement of the molecule is parallel to the lattice within the van der Waals interaction distance, the molecule undergoes a reorientation and the O atom faces the graphene lattice. On the other hand, if the initial position of the molecule is parallel but closer to the graphene lattice, the H atoms become more reactive and face toward the graphene lattice. We considered five different sites on the grain boundary defect and found similar behaviors throughout. An electronic structure analysis suggests that the electron redistribution at the grain boundary affects the behavior of the molecule; for electronic structure, we analyzed electronic charge and electron density to give us an indication of any polarization at the site and give insight into coulombic interactions at the defect. And through energy and force values that were calculated and plotted, we also found that chemical interactions between the water molecule and graphene lattice is negligible when the molecule is released more than 14.5Å above the sheet. Also, due to separation-distance dependent distinct chemical affinities between the C-O atom pairs vs. C-H atom pairs, the groundstate interaction is strongly affected by the initial position of the molecule. And finally, we looked at the possibilities of reorientation at relaxed states; we calculated the activation energies required to change the configurations of the relaxed water molecules and found that changes in such

configurations is unattainable at room temperature. The results are expected to have important implications to our understanding of strain-chemistry of defective graphene. This talk will present the analysis of these findings as well as their potential applications in catalysis and water purification.

11:15 AM EQ07.09.04
Late News: Probing Excitons in Curved MoTe2 with Monochromated EELS and 4D-STEM Yueming Guo[1], Sergei V. Kalinin[1], Kai Xiao[1], Sergiy Krylyuk[2], Albert Davydov[2] and Andrew R. Lupini[1]; [1]Oak Ridge National Lab, United States; [2]National Institute of Standards and Technology, United States

Bound electron-hole pairs, known as excitons, are critical to the optical and electronic responses of semiconductors. Just as for traditional materials, this principle applies to the newly-emerged Van der Waals semiconductors such as 2H-$MoTe_2$. Distinctinct from conventional bulk semiconductors, the quasi 2D semiconductors are soft and can get buckled spontaneously at micro or nano scale. The mechanism of spontaneous breaking of periodicity in 2D crystals has been proven by David Mermin [1], which means that real 2D crystals either break or buckle [2]. The curvature effect on excitons has been theoretically investigated for various systems [3-5] but few experimental efforts for nanoscaled bucking effect on excitons have been dedicated to Van der Waals semiconductors.
Here, we explore the relationshiop between Gaussian curvature and the excitonic behaviors in multilayer 2H-$MoTe_2$ by acquiring electron energy loss spectroscopy (EELS) and 4D scanning transmission electron microscopy (4D STEM) over a curved area of a 2H-$MoTe_2$ flake. The same types of data have also been acquired from a flat area of the same sample with a similar thickness. We carried out these experiements on a NION monochromated, aberration-corrected STEM, which provides both good energy and spatial resolutions. An energy resolution of 30 meV (with 3meV/pix) and a spatial resolution of 1.5 Å is used here. Each diffraction pattern in the 4D STEM data shows the normal direction of the tagent plane at each spot on the curved surface, and therefore the Gaussian curvature can be computed. Exciton peaks are observed from monochromated EELS with a high exposure for each spot in the scan. Unlike tensile strain effects which show redshift of the exciton peaks [6], the A exciton peaks in the curved area show a blueshift of 20 meV on average. Further results are being analyzed and will be discussed.

Efficiency Roll-Off Free Electroluminescence in Monolayer Semiconductors by Strain Engineering Naoki Higashitarumizu[1,2], Shiekh Zia Uddin[1,2], Hyungjin Kim[1,2] and Ali Javey[1,2]; [1]University of California, United States; [2]Lawrence Berkeley National Laboratory, United States

Two-dimensional transition-metal dichalcogenides (TMDCs) have attracted tremendous attention toward optoelectronic applications. Photoluminescence quantum yield (PL QY) in TMDC monolayer can approach unity at the low exciton generation rate, whereas the PL QY drastically droops at the high generation rate due to a nonradiative exciton-exciton annihilation (EEA), limiting their light-emitting device application. Here, we demonstrate a strain tunable transient-mode electroluminescence (EL) device composed of TMDC and gate oxide. WSe_2 and WS_2 monolayers exhibit near-unity PL QY even at the high exciton density by applying external tensile strain together with gate modulation due to the inhibition of van-Hove singularity resonance, which causes the EEA. With a small strain of 0.5%, notably, the WSe_2 monolayer shows EL enhancement by two order of magnitude and its internal quantum efficiency (QE) reaches 8% at maximum. Furthermore, this concept of EEA suppression by strain modulation is valid even in WSe_2 bilayer. Unstrained WSe_2 bilayer exhibits a low PL QY and EL QE at around 1% and 0.03%, respectively, because of its indirect bandgap nature. By strain modulation, however, we achieve ~50% PL QY and ~1.5% EL QE for a broad range of carrier densities. This improvement is attributed to the indirect-direct bandgap transition and EEA suppression, corroborated by density functional theory calculations. This approach will pave the way for practical optoelectronic device applications based on TMDC monolayer and even multilayers.

11:45 AM EQ07.01.09
Late News: Strain Determined Friction Properties Between MXenes and Other 2D Materials Yanxiao Li; Missouri University of Science and Technology, United States

MXene, as a new type of 2-dimensional (2D) material, can be synthesized by removing A layers from MAX phases by HF etching. MAX phases are ternary carbides or nitrides with the general formula $M_{n+1}AX_n$, where M is an early transition metal, A is an A-group element (mostly group IIIA or IVA), X is either carbon or nitrogen with n value of 1, 2, or 3. During the selective etching process, the outer surfaces of the exfoliated MXene layers are always terminated with F, OH, and/or O groups. Thus, MXenes are referred to as $M_{n+1}X_nT_x$, where T represents the surface groups (F, OH, and/or O) and x is the number of terminations. Since now, about 20 different kinds of MXene have been prepared. More MXene materials are also expected to be exfoliated from more than 70 reported MAX phases in the future. To date, MXenes have shown attractive electronic, optical and magnetic properties, which have great potential in sensing, energy storage, and electromagnetic shielding applications. Their surface frictional properties are critically important to these applications involving layered structures and 2D interfaces. However, there has only been a few experiments conducted on MXenes. The interfacial frictional behaviors between MXenes and other 2D materials are still unknown.
Being a few atoms-thin, 2D materials have unique friction and wear properties that are different from those of their 3D counterparts. Lee et al. conducted the atomic force microscopy (AFM) friction experiments on interfaces between SiO_2 and a group of 2D materials (including graphene, MOS_2, $NbSe_2$ and h-BN). The results have shown that measured coefficient of frictions (COFs defined as the ratio between normal and tangential force) are dependent on both the surface conditions and the contact induced elastic deformations (which is a function of bending flexibility) of the 2D materials. Due to the rich surface chemistry of MXene based on various of possible terminating groups (F, OH, and/or O) and tunable monolayer thickness in terms of atomical structures (i.e., changing n in $M_{n+1}X_nT_x$), it was suspected that the friction between MXene and other 2D materials can be quite different from other 2D materials based on computational investigations. However, there have not been any experiments conducted on the frictional behaviors of MXenes with 2D materials. Most of the experiments conducted so far were limited to MXenes' frictional behaviors with 3D materials.
In this paper, we experimentally investigated the frictional behaviors of $Ti_3C_2T_x$ and Ti_2CT_x MXenes against themselves as well as other 2D materials including graphene and $MoSe_2$. We measured the friction forces using both the bare SiO_2 spherical AFM probes as well as $Ti_3C_2T_x$ and Ti_2CT_x MXenes coated probes on graphene, $MoSe_2$, $Ti_3C_2T_x$ and Ti_2CT_x MXenes sheets with varying number of monolayers (1-25 monolayers), and normal forces (0-2 mN). We have found that the COFs for all the investigated 2D interfaces are below 0.01 indicating the super lubricant frictional behavior of MXenes on themselves and other 2D materials. A less significant number-of-monolayer effect on the friction was also observed for MXenes. The measured COFs were also found to be independent of the applied normal forces at contacts. These results indicate the great potential of MXenes as excellent lubricating materials for 2D homo-/heterostructured materials, also the mechanical vulnerability of 2D homo-/heterstructured materials containing MXenes under shear forces.

SESSION EQ07.10: Twisted vdW Heterostructures II

EQ07-Virtual

1:00 PM *EQ07.10.01
Intrinsic Strain Enables Lattice Reconstructions in Moiré Superlattices Jiamin Quan[1], Lukas Linhart[2], Miao-Ling Lin[3], Daehun Lee[1], Chih-kang Shih[1], Keji Lai[1], Allan H. MacDonald[1], PingHeng Tan[3], Florian Libisch[2] and Xiaoqin E. Li[1]; [1]The University of Texas at Austin, United States; [2]Vienna University of Technology, Austria; [3]Institute of Semiconductors, China

In vertical van der Waals (vdW) homo- or heterobilayers, a finite twist angle between the two layers leads to a moire superlattice that induces periodic modulations of atomic alignments and consequently, a periodic modulation of energy, ground-states, and excited states. While most prior experiments on moire superlattices have been interpreted using a rigid lattice model in which the local atomic stacking is assumed to be determined by rotating pristine two-dimensional lattices, lattice reconstructions can occur in bilayers near a commensurate stacking style, driven by a competition between interlayer coupling and strain.

The lattice reconstructions have been visualized in various scanning probe experiments. Here, we report the signature of lattice reconstruction in phonon spectra in twisted MoS2 bilayers measured by far-field Raman experiments. Over a range of small twist angles (0-6°), the phonon spectra evolve rapidly due to ultra-strong coupling between different phonon modes and atomic reconstructions of the moire pattern. We further develop a new low-energy continuum model for phonons that overcomes the outstanding challenge of calculating properties of large moire supercells and successfully captures essential experimental observations.

Moiré Metrology of Energy Landscapes in van der Waals Heterostructures Dorri Halbertal; Columbia University, United States

The emerging field of twistronics has revolutionized quantum materials research. At the small twist limit, and particularly under strain, as atomic relaxation prevails, the emergent moiré superlattice encodes elusive insights into the local interlayer interaction. In this work we introduce moiré metrology as a combined experiment-theory framework to probe the stacking energy landscape of bilayer structures at the 0.1 meV/atomscale, outperforming the gold-standard of quantum chemistry. Through studying the shapes of moiré domains with numerous nano-imaging techniques, and correlating with multi-scale modelling, we assess and refine first-principle models for the interlayer interaction. We document the prowess of moiré metrology for three representative twisted systems: bilayer graphene, double bilayer graphene and H-stacked $MoSe_2/WSe_2$. Moiré metrology establishes sought after experimental benchmarks for interlayer interaction. Furthermore, in this talk we extend the previously reported framework of moiré metrology[1] to account for multi-layered structures, and demonstrate a few material systems where such a treatment is essential to describe experimental observations.

Topography Induced Plasmon Resonance in Graphene Md Farhadul Haque[1], Chullhee Cho[1] and SungWoo Nam[1,2]; [1]University of Illinois at Urbana-Champaign, United States; [2]University of California, Irvine, United States

Plasmons are collective oscillations of electrons. Plasmon resonance occurs when the collective oscillations of electrons are coupled efficiently with the incident photon through light-matter interactions. Graphene is uniquely advantageous for plasmon resonance when compared to conventional plasmonic materials due to extremely high quantum efficiency for light-matter interactions, low loss of the plasmon, and a wide range of tunability. Graphene plasmon resonance has been reported via nano-patterning, selective doping, or defect engineering. Our previous theoretical study has suggested that inducing surface inhomogeneity via wrinkling or crumpling of graphene thin films may offer increased plasmon resonance tunability over conventional electrical doping methods. Despite this significant potential, there has not yet been experimental evidence of topography-induced plasmon resonance on a semi-infinite atomically thin graphene layer. Here, we report experimental studies of plasmonic resonance tunability of a crumpled graphene using photo-induced force microscopy (PiFM). PiFM is an effective technique for probing light-matter interaction at a sub-20 nm spatial resolution, which is not possible with conventional optics-based technique due to the diffraction limit. By applying uniaxial compressive strain, we created crumpled structures of

graphene with controlled topography features (e.g., wavelength, aspect ratio) on a polymeric substrate. Using PiFM, we observed a wide tunability of plasmon resonance energy (1260-1732 cm^{-1}) which we attributed to both the variation in topography as well as efficient coupling with the incident photon. We further investigated the relationship between the plasmon resonance wavelengths and the topography features by spatially mapping the near-field optical responses. Our observed plasmon resonance followed a redshift trend with an increase in wavelength and aspect ratio of the crumples, which agrees well with our previously established theoretical model. Finally, we demonstrated enhanced chemical imaging of a polymethyl methacrylate (PMMA) film aided by the effective plasmon resonance of the underlying crumpled graphene structure. The coupling between PMMA phonon and graphene plasmon showed a two-fold increase in the obtained near-field optical response. Our results not only are the first experimental demonstration of the coupling between topography and plasmon resonance of semi-infinite atomically thin graphene layer but also suggest widely tunable, plasmonically-enhanced biosensing or spectroscopy in the infrared range.

2:15 PM *EQ07.10.04
Stacking Order Driven Optical and Vibrational Properties in ReS_2 Yongjian Zhou[1], Nikhilesh Maity[2], Abhishek K. Singh[2] and Yaguo Wang[1]; [1]The University of Texas at Austin, United States; [2]Indian Institute of Science, India

Two distinct stacking orders in ReS_2 are identified without ambiguity and their influence on vibrational, optical properties and carrier dynamics are investigated. With atomic resolution scanning transmission electron microscopy (STEM), two stacking orders are determined as AA stacking with negligible displacement across layers, and AB stacking with about a one-unit cell displacement along the *a* axis. First-principle calculations confirm that these two stacking orders correspond to two local energy minima. Raman spectra inform a consistent difference of modes I & III, about 13 cm^{-1} for AA stacking, and 20 cm^{-1} for AB stacking, making a simple tool for determining the stacking orders in ReS_2. Polarized photoluminescence (PL) reveals that AB stacking possesses blue-shifted PL peak positions, and broader peak widths, compared with AA stacking, indicating stronger interlayer interaction. Transient transmission measured with femtosecond pump probe spectroscopy suggests exciton dynamics being more anisotropic in AB stacking, where excited state absorption related to Exc. III mode disappears when probe polarization aligns perpendicular to *b* axis. Our findings underscore the stacking-order driven optical properties and carrier dynamics of ReS_2, mediate many seemingly contradictory results in literature, and open up an opportunity to engineer electronic devices with new functionalities by manipulating the stacking order.

2:45 PM EQ07.10.05
E-Beam Patterning of Dopants in Twisted Bilayer Graphene Ondrej Dyck[1], Andrew R. Lupini[1], Dale Hensley[1], Jacob L. Swett[2] and Stephen Jesse[1]; [1]Oak Ridge National Laboratory, United States; [2]University of Oxford, United Kingdom

E-beams have been suggested to be useful for fabrication on the atomic scale.[1] Here, we leverage techniques that have been developed recently for positioning dopants in single layer graphene[2–5] to pattern arrays of dopants in twisted bilayer graphene (TBG) in a scanning transmission electron microscope. The process is governed by a feedback-controlled algorithm allowing patterning to proceed in an automated fashion. These techniques hold promise for the tailoring of TBG properties by the attachment of foreign atoms to defect sites.[6]

SESSION Tutorial EQ08: Artificial Intelligence in Nanophotonics, Metamaterials and Metasurfaces
Session Chairs: Patrice Genevet and Thomas Zentgraf
Monday Morning, November 29, 2021
Hynes, Level 2, Room 201

10:30 AM
An Overview of On-Demand Design of Metamaterials Enabled by Deep Learning Yongmin Liu; Northeastern University, United States

Over the last years, deep learning has been used for on-demand design of metamaterials by representing and learning the mapping between the topology and composition of metamaterials and their associated optical properties. Prof. Liu will review the recent progress in on-demand design of metamaterials using deep learning, with an emphasis on various model architectures for specific photonic tasks. He will also provide the historical background, key algorithms, fundamentals and applications of deep learning used for design of metamaterials.

12:00 PM BREAK

12:30 PM
An Overview of Numerical Optimization Methods for Metasurfaces Patrice Genevet; Centre de Recherche sur I'Hétéro-Epitaxie et ses Applications, France

Numerical optimizations search for local or global optimal solutions either by evolutionary or gradient-based approaches. The first method search solutions stochastically in an extensive parameter space allowing capture of global optima and the second strategy calculates the derivatives of the cost function and finds local optima. Prof. Genevet will review the recent advanced optimization method to further exploit metasurface capabilities. He will also discuss Bayssian-based optimization techniques which can reduce the computational cost substantially.

2:00 PM BREAK

3:30 PM
An Overview of Machine Learning-Assisted Global Optimization of Photonic Devices Alexandra Boltasseva; Purdue University, United States

Machine learning has shown great promises for generating data by learning important features. By exploiting its versatility and efficiency, machine-learning assisted novel optimization methods have been reported coupled with conventional optimization framework including topology optimization and meta-heuristic optimization. In her tutorial, Prof. Boltasseva will present the recent progress in global optimization assisted by machine learning, with an emphasis on high efficiency and substantial improvement.

SESSION EQ08.02: Metasurfaces and Applications I
Session Chairs: Patrice Genevet and Thomas Zentgraf
Tuesday Morning, November 30, 2021
Hynes, Level 2, Room 201

11:00 AM *EQ08.02.01
Applications and Integration of "Regular" and "Topological" Metasurfaces Patrice Genevet, Qinghua Song, Renato Martins and Samira Khadir; CRHEA, France

Metasurfaces offer complete control of optical wavefront, such as phase, amplitude and polarization at the subwavelength scale, enabling a new class of artificial two-dimensional optics. Metasurfaces hold great potential in on-chip optoelectronic integration applications, which will significantly promote the development of miniaturized optoelectronic systems. In this presentation, i will review our group results on Metasurfaces integration in VCSEL and new results on vectorial holography and LiDARs.

In this presentation, I will discuss basic design and fabrication methods of metasurfaces and summarize various applications for beam steering, polarization control[1,4] and monolithic integration of metasurfaces in opto-electronic systems[2]. As an alternative of conventional bulky, the development of this technology is expected to create a positive disruption in modern optical technologies, in particular in the fields of imaging, holography, 3D dynamic image rendering, AR/VR and LiDAR systems[5], nonlinear optics[6].

11:30 AM EQ08.02.02
Structural Colors with Silicon—Scalable and CMOS-Compatible Nanostructure Fabrication Using Metal Assisted Chemical Etch Akhila Mallavarapu[1,2], Brian Gawlik[2], Paras Ajay[2], Crystal Barrera[2], Mariana Castaneda[2] and S.V. Sreenivasan[2]; [1]University of Pennsylvania, United States; [2]Univ of Texas-Austin, United States

Silicon nanostructures with precisely controlled geometries exhibit vivid structural colors, and enable high-performance optical devices such as metalenses and multispectral filters. The ability to reliably and repeatably control the nanostructure geometries (cross-section, sidewall profile and height) over large areas at low cost is essential for these applications.

High-throughput nanopatterning techniques, such as nanoimprint lithography, can precisely define the nanostructure cross-sections. However, control of sidewall profile and height is limited for traditional pattern transfer using plasma etch due to sidewall roughness, etch taper and loss of feature fidelity for high aspect ratio structures. Metal Assisted Chemical Etch (MACE or MacEtch) has superior etch anisotropy and sidewall profiles. It is an electroless catalyst-based wet etch, and is an inexpensive solution-based alternative to plasma etch. However, MacEtch has largely been demonstrated in literature over small areas, and lacks CMOS-compatibility due to the use of gold as a catalyst.

We present scalable solutions to address these MacEtch challenges, with a focus on adoption in high volume nanomanufacturing [1-3]. Wafer-scale reliable and repeatable fabrication of high aspect ratio silicon nanostructures using nanoimprint lithography and MacEtch is shown. A CMOS-compatible Ruthenium MacEtch process that is comparable in quality to the standard gold MacEtch is presented. Large-area characterization of the process with imaging spectroscopic scatterometry is used for full wafer data on critical dimension control, etch depth uniformity, and yield in silicon nanowire arrays. Varied geometries such as ultrahigh-aspect-ratio silicon nanowires, nanofins, and diamond-shaped cross-section nanopillars demonstrate the resolution and versatility of MacEtch.

The ability to make such large-area high aspect ratio nanostructure arrays with arbitrary geometries enables an extensive design space for optimization of silicon optical devices. Si nanostructure geometry can be tuned to provide a variety of structural colors, as shown by FDTD simulations and experimentally on 4-inch wafers. Thus, the results presented here remove a significant barrier to adoption of MacEtch as a next generation etch technology for scalable fabrication of silicon nanostructures for optical devices.

Spin-Polarized Stimulated Raman Scattering in a High-Q Metasurface for Nanoscale Nonreciprocity Jefferson Dixon, Harsha Reddy, Sahil Dagli and Jennifer A. Dionne; Stanford University, United States

Nonreciprocal devices (i.e. optical isolators, circulators) allow light to pass in one-direction only, which is a critical component of photonic networks. Unfortunately, they remain large (>100um) and are a limiting step in the development of densely-integrated, ubiquitous photonic networks. Here, we fabricate and demonstrate high-Q metasurfaces for submicron nonreciprocal and self-isolated lasing.

Our metasurface is composed of disks 505nm in diameter and 230nm in height, which support ordinary electric (TE) and magnetic (TM) Mie modes. This highly symmetry metasurface geometry also supports antisymmetric counterparts to the ordinary, symmetric TE and TM modes, but these modes are not accessible from free-space radiation, leaving these modes in the dark (i.e. bound in the continuum of free-space radiation). By reducing the symmetry of the metasurface lattice through the introduction of biperiodic diameters (diameter_diskA = 495nm, diameter_diskB = 515nm), the anti-symmetric TE and TM modes become accessible to free-space radiation over a narrow spectral linewidth. As a result, the linewidth of the resonance (and hence its quality-factor) can be controlled by the degree of asymmetry, where smaller asymmetry results in larger quality-factors. Experimentally, we have achieved a quality factors exceeding 15,000, which enables us to observe Stimulated Raman Scattering at lower power thresholds and in this subwavelength formfactor.

In Stimulated Raman Scattering, photons at the pump frequency (omega_p) stimulate emission at the Stokes frequency (omega_s), which results in the amplification of a signal that is injected at the Stokes frequency. We facilitate amplification by aligning the pump and signal frequencies with the high-Q resonances of the metasurface, resulting in a doubly-resonant high-Q metasurface that more efficiently generates Raman amplification. If we consider this process in a spin-polarized basis, wherein the pump is circularly-polarized and the gain medium (i.e. the silicon metasurface) supports such circulating modes, spin-selection rules arise at the Stokes frequency that break Lorentz reciprocity. This nonlinear process enables nonreciprocal gain for a signal at the Stokes frequency and results in one-way, nonreciprocal Raman lasing in a subwavelength (230nm thick) device layer.

12:00 PM EQ08.02.04
Buckling Induced Phase Transition in Nanoelectromechanical Phononic Waveguides Paolo F. Ferrari, SunPhil Kim, Jonathan Bunyan, Ali Kanji, Alexander F. Vakakis, Sameh Tawfick and Arend van der Zande; University of Illinois at Urbana-Champaign, United States

Phononic crystals and metamaterials are an emerging class of engineered structures with applications ranging from vibrations control to heat transfer. Nanoelectromechanical phononic waveguides are 1D metamaterials that allow propagation of elastic waves by coupling several mechanical resonators together. Utilizing these waves as information carriers would allow on-chip mechanical logic and coupling between the optical, radio and mechanical domains. Achieving reconfigurability and tunability to condition and route these mechanical signals is of crucial importance.
In this presentation, we will present a method to effectively switch on and off wave propagation in nanoelectromechanical waveguides. We fabricate phononic waveguides by suspending a 1D array of coupled drumhead resonators made from a silicon nitride film (~60 nm) in a Si/SiO_2 chip. Each resonator consists of a circular plate with a diameter of 10 μm, with a coupling length (overlap) of 1.35 μm. We actuate the waveguide electrostatically at one end, then characterize the band structure of the waveguides using dynamic Fabry-Perot laser interferometry. We relate the band structure to the shape of the corresponding Bloch modes, which are obtained by mapping the dynamic parameters of the waveguide by confocal laser mapping. The waveguides feature bands in the very high frequency range (10-50 MHz). By reducing the temperature from 300 to 80K, a thermally induced compressive stress buckles the waveguide, due to the mismatch in the coefficients of thermal expansion in the silicon nitride and the substrate. At higher temperatures, we observe strong tuning of the band frequencies. Then at a critical temperature corresponding with the buckling transition, transmission along the first pass band is interrupted, while higher bands continue to transmit. We employ finite element analysis to explain the observed behavior. We find that the

explanation of the band disappearance consists of two ingredients. First, through simulations with periodic boundary conditions, we find buckling affects the first pass band by continuously reducing the group velocity, until it reaches zero at the buckling transition, then inverts above the buckling transition. Second, by simulating the entire set of 60 unit cells forming a waveguide and comparing to spatial maps of transmission, we find the global buckling mode of the waveguide above the critical point adds disorder to the system by inducing non-uniform stresses in the unit cells. Because the buckling shape matches the modes of the first pass band, the disorder strongly affects the first pass band but only weakly affects the higher bands. In an analogy with condensed matter physics, this phenomenon resembles a phase transition, where the waveguide switches from a conducting to an insulating phase due to buckling. Our study shows for the first time the use of elastic instabilities to induce transitions in phononic metamaterials at the nanoscale, paving the way for more advanced forms of mechanically-induced reconfiguration in hybrid opto and electro-mechanical circuits.

SESSION EQ08.03: Novel Fabrication and Devices

1:30 PM *EQ08.03.01
Designing Optical Metamaterials from Colloidal Nanocrystal Assemblies Cherie R. Kagan; University of Pennsylvania, United States

Colloidal plasmonic nanocrystals (NCs) are known for their size- and shape-dependent localized surface plasmon resonances and their solution-based printing and imprinting in device fabrication. We use NCs as building blocks of assemblies and exploit their chemical and physical (electrical, optical, mechanical, thermal) tailorability to design and fabricate optical metamaterials. Chemical exchange of the long ligands used in NC synthesis with more compact ligand chemistries brings neighboring NCs into proximity, increasing interparticle coupling and allowing us to tune through a dielectric-to-metal phase transition, seen by a 10^{10} range in DC conductivity and a dielectric permittivity ranging from everywhere positive to everywhere negative across the whole range of optical frequencies [1]. This ligand-controlled coupling is useful in the design of materials that are strong, ultrathin film optical absorbers [2] or strong optical scatterers [3]. Compact ligand exchange and thermal annealing of NC films also drives a large volume shrinkage in NC thin films, allowing a 10X tailorability in their Young's modulus [4-6]. By juxtaposing plasmonic NCs and bulk materials, we exploit their different chemical and mechanical properties to create misfit strain that drives the folding of NC/bulk bilayer heterostructures and the transformation of lithographically-defined two-dimensional structures into three-dimensional structures. We use the three-dimensional structures to demonstrate the scalable fabrication of large-area metamaterials with chiroptical responses of ~40% transmission difference between left-hand and right-hand circularly polarized light and that are suitable broadband circular polarizers [5,6].

Active Epsilon-Near-Zero Photonics Ho Wai (Howard) Lee[1], Aleksei Anopchenko[1], Sudip Gurung[1], Khant Minn[2] and Jingyi Yang[1]; [1]University of California, Irvine, United States; [2]Baylor University, United States

The optical response of epsilon-near-zero (ENZ) materials has been a topic of significant interest in the last few years as the electromagnetic field inside media with near-zero permittivity has been shown to exhibit unique optical properties, including strong electromagnetic wave confinement, non-reciprocal magneto-optical effects, and abnormal nonlinearity.

This talk will review our recent development on conducting oxide and metallic nitride epsilon-near-zero optics. I will present our recent advances on the study of enhanced ultrafast nonlinearity and broadband and field-effect tunable absorption in ultrathin transparent conducting oxide ENZ materials meta-film fabricated by atomic layer deposition technique. In addition, I will discuss the photoluminescence enhancement of 2D materials on epitaxial titanium nitride thin films grown by molecular-beam-epitaxy. These studies enrich the fundamental understanding of emission and nonlinear properties on ENZ thin films that could be important for the development of advanced nanoscale lasers/light sources, optical/bio-sensors, and nano-optoelectronic devices.

2:30 PM EQ08.03.03
Self-Assembly of Gold Nanoparticles Functionalized with Water-Soluble Synthetic Polymers into Two- and Three-Dimensional Superlattices Hyeong Jin Kim[1,2], Wenjie Wang[2], Honghu Zhang[3], Guillaume Freychet[3], Benjamin Ocko[3], Alex Travesset[1,2], David Vaknin[1,2] and Surya Mallapragada[1,2]; [1]Iowa State University, United States; [2]Ames Laboratory, United States; [3]Brookhaven National Laboratory, United States

Here, we report on the self-assembly of gold nanoparticles functionalized with polyethylene glycol (PEG-AuNPs) into two- and three-dimensional superlattices at the liquid surface or in the bulk. Synchrotron-based small-angle X-ray scattering studies including X-ray reflectivity and grazing incidence

small-angle X-ray scattering showed that Gibbs monolayers of PEG-AuNPs were created at the liquid surface with a hexagonal structure by adding salt. Further increases in salt concentration and temperature led to the formation of 3D fcc-like structure in the bulk, which was confirmed by solution small-angle X-ray scattering. Interestingly, the interparticle distance (i.e., lattice constant) decreased with increasing temperature, showing negative thermal expansion. The strong dependence of interparticle distance on functionalized PEG chain lengths was also investigated by theoretical considerations.

2:45 PM EQ08.03.04
Nanocube Epitaxy for the Low-Cost Realisation of High-Quality Nanophotonic Gold Nanostructures Anna Capitaine[1,2,3] and Beniamino Sciacca[1,2,3]; [1]CINaM, France; [2]Centre National de la Recherche Scientifique, France; [3]Aix-Marseille Université, France

High-quality monocrystalline materials and nanostructures are key to high-efficiency optoelectronic devices (Polman et al., Science, 2016), plasmonic materials (Wu et al., Adv Mater, 2014) and metasurfaces (Koenderink et al., Science 2015). However, the techniques used to grow those materials are in most cases time consuming, expensive (high vacuum and temperature) and require lattice-matched substrate, whereas precise control over the nanoscale geometry can only be achieved after further nanofabrication steps, limiting nanostructured monocrysatlline materials to niche applications.

It has been demonstrated that single-crystal silver nanocubes, grown in solution phase, could be used as building blocks for the fabrication of continuous monocrystalline 1D nano-structures through epitaxial welding of adjacent nanocubes (Sciacca et al, Adv Mater., 2017). We demonstrate here that this technique can be used as a general method to fabricate 1D and 2D monocrystalline gold (Au) nanopatterns and macroscopic thin films for the first time, and show that such nanostructures can then be transferred to virtually any kind of substrate, allowing for simple integration in optical and optoelectronic devices.

Monodisperse Au single-crystal nanocubes are first synthesized in solution at room temperature. Next, using capillary forces they are self-assembled in a polydimethylsiloxane (PDMS) mould containing pre-defined 1D and 2D nanoscale patterns, in a closely packed configuration, with individual nanocube subunits lying face-to-face. Then, spontaneous reduction of a gold salt ($HAuCl_4$) on nanocubes surface is performed in soft conditions (40°C, in aqueous environment), enabling for nanocube epitaxy and the formation of a continuous monocrystalline material in the time scale of a few minutes. We use high-resolution transmission electron microscopy, electron diffraction, and x-ray diffraction to provide evidence for epitaxy. The nanocube epitaxy process is thoroughly investigated and a mechanism is proposed, showing that by tuning few key parameters, we can also control the faceting of the resulting continuous monocrystalline nanostructures.
Finally, we show that such complex continuous Au nanostructures of arbitrary shapes can be transferred from PDMS to various substrate by contact printing. As a proof of concept, we show the realization of an optical device composed of monocrystalline Au patch-antenna arrays with tunable optical response, and compare the optical properties to FDTD simulations.

This low-cost solution proves a viable method for the fabrication of complex monocrystalline nanostructures and their use as a high-quality nanophotonic surface, paving the way for integration in more complex devices with unexplored geometries.

SESSION EQ08.04: Metasurfaces and Applications II
Session Chairs: Jason Valentine and Thomas Zentgraf
Tuesday Afternoon, November 30, 2021
Hynes, Level 2, Room 201

4:00 PM EQ08.04.01
Light-Induced Surface Structuring of Azopolymer Films Stefano Luigi Oscurato[1,2], Pasqualino Maddalena[1,2] and Antonio Ambrosio[2]; [1]University of Naples, Italy; [2]Istituto Italiano di Tecnologia, Italy

The light-induced structuration of amorphous azopolymer films is an emerging micro and nano-patterning method for the realization of diffractive optical elements. Sinusoidal surface reliefs, inscribed in a single lithographic step on azopolymer film surface through interference lithography, have been largely used as engineerable diffraction gratings for applications ranging from light couplers and optical filters to structural color and augmented reality devices. Advanced optical functionalities can arise from the additional structural control achievable on the surface geometry by moving beyond simple interference lithography.
The key feature that makes the azopolymers attractive over standard photoresist for photolithographic applications, not limited only to optics, lies in the direct, non-destructive, structuration of film surface, whose final geometry depends on the full electric field of the illuminating light, i.e. on its intensity pattern and its polarization distribution. This peculiar photo-response is the result of a reversible macroscopic material displacement, initiated by a multitude of microscopic light-fueled actuation of the azobenzene molecules under UV/visible illumination.
Controlling the spatio-temporal distribution of the illuminating electric field, together with the possibility of erasing previous surface patterns, allows the tailoring, even dynamically, of the surface topography and its optical functionality with higher degrees of freedom in respect to standard and more sophisticated photolithographic materials and techniques. Advanced structuration approaches range from very simple optical configurations, in which a single collimated light beam is used to generate ordered polarization-dependent microstructures over large scales, to holographic illumination schemes, where both the intensity and the polarization patterns can be engineered independently and used to inscribe high-quality surface reliefs of arbitrary complex geometries, including those of standard diffractive optical elements as gratings and lenses. Additional control on the surface geometry can be achieved with sequential exposures of a previously exposed or pre-patterned film, enabling even a three-dimensional manipulation of the topography in simple and cost-effective fabrication conditions.
Here, I will overview the recent advances in the design and realization of light-induced reliefs on the surface of the azopolymer films obtained in several illumination schemes, mainly focusing the attention on their potentialities in the realization of tunable and reconfigurable diffractive optical elements.

4:15 PM EQ08.04.02
Tuning Microwave Metadevices Using Organic Electrochemical Transistors Giorgio Ernesto Bonacchini[1,2], Siew Ting Melissa Tan[1], Alexander Giovannitti[1], Tyler J. Quill[1] and Alberto Salleo[1]; [1]Stanford University, United States; [2]Istituto Italiano di Tecnologia, Italy

In the past two decades, organic electronic materials have emerged as the key enablers of a large and diverse set of developing technologies. Traditional applications of organic semiconductors include energy harvesting devices, flexible and printed circuitry, optoelectronic and electro-mechanical actuators[1]. New fields continue to bloom, as demonstrated by the recent rise of organic bioelectronics and organic neuromorphic devices[2,3]. Interestingly, despite the extensive research conducted on this class of materials, their use in microwave applications has been comparatively modest, since organic electronics is

generally considered “slow” with respect to other semiconductor technologies – although focused efforts are being dedicated to challenge this view[4,5]. In the past, this preconception has possibly led to underestimating the potential of organic transistors in microwave metadevices, whereas lately they have demonstrated great promise as tuning elements[6].
In a recent work[6], we introduced a new device configuration where organic electrochemical transistors – based on the conductive polymer PEDOT:PSS – actively tuned a set of sub-5GHz microwave metasurfaces and metamaterial-inspired resonant structures. The device structure consisted in individual (or multiple) microwave Split-Ring Resonators in which the split region is bridged by a thin-film conductive polymer, gated through an ionic medium by a lateral gate electrode. By applying a positive bias at the gate electrode, cations are injected within the bulk of the negatively biased organic semiconductor, decreasing the charge carrier density throughout the volume of the polymer[7]. This device configuration enables a fully reversible modulation mechanism that requires very low voltages (<1 V) thanks to the optimal mixed ion-electron transporting ability of PEDOT:PSS. We demonstrated this tuning strategy on a number of different resonant configurations, including magnetic and electric resonators, frequency-tuneable SRRs, dual-band devices, and in a reconfigurable metasurface. All materials were deposited by means of inkjet printing – a mass-scalable and cost-effective fabrication technique – onto plastic and flexible substrates.
The promising results achieved with PEDOT:PSS as the active material encourage a wider exploration of the continuously growing library of organic semiconductors. In this work, we demonstrate a set of tunable microwave devices using different p-type and n-type organic electrochemical transistors. By chemically engineering the organic semiconductors, we are able to operate our devices in selected voltage windows, with fine control over the voltage dependence of the metadevices’ scattering properties. As an example of a possible application, we exploit this strategy within a wireless biosensing platform operating in the 2-2.5 GHz range.
In conclusion, we believe that our tuning strategy based on organic electronic materials presents new exciting opportunities for the field of metadevices, possibly paving the way to a new generation of reconfigurable metasurfaces, fabricated on large-area flexible substrates via high-throughput deposition techniques. Moreover, this class of metadevices could potentially complement other emerging bioelectronic and neuromorphic technologies that are also based on organic electrochemical transistors, expanding the horizon of metamaterials research.

Electrohydrodynamic Jet Printing of Near Infrared All-Dielectric Metasurfaces Brian Iezzi[1], Zahra Afkhami[2], Md Ferdous Alam[3], David Hoelzle[3], Kira Barton[2] and Max Shtein[1]; [1]University of Michigan–Ann Arbor, United States; [2]University of Michigan--Ann Arbor, United States; [3]The Ohio State University, United States

Photonic metasurfaces structured using all-dielectric materials have gained increasing research interest due to low ohmic losses, compared to metals, and the tunability of refractive indices through oxide or semiconductor material selection. Metasurfaces are typically generated using photo- or electron beam-lithographic processes, affording high precision and repeatability, but at the expense of long prototyping cycles and high up-front cost. In this work, high-resolution electrohydrodynamic jet (e-jet) printing and various formulations of high refractive index silicon and germanium nanoparticle colloidal inks are combined to create all-dielectric metasurfaces with tunable response across the near-infrared spectrum (900-3000 nm). Finite-difference time-domain (FDTD) electromagnetic simulations are used to elucidate the relationship between the photonic response and meta-atom geometry and nanoparticle optical constants. These simulations are further guided by a predictive model of the printed spherical meta-atoms based on the ink formulation (e.g., nanoparticle loading percentage, ratio of solvents) and surface energetic properties of the substrate surface. Repeatable printing of metasurface structures with sub-micrometer radii and periodic spacing is demonstrated, and near infrared microspectroscopy measurements are compared to FDTD simulations predicting narrowband (sub-100 nm FWHM) resonant reflectors. The potential implementation of physics-guided reinforcement learning as a tool for optimizing printing parameters, in conjunction with *in-situ* metrology, is discussed as well. Beyond providing a rapid, cost-effective metasurface prototyping platform, e-jet printing enables the incorporation of multiple materials with differing refractive indices into the same structure as well as enabling beneficial, and custom-tuned, spherical meta-atom shapes that cannot be created easily *via* conventional lithographic techniques.

4:45 PM EQ08.04.04
Electro-Optic Modulation of Transmission in a Lithium Niobate Metasurface Helena Weigand, Viola Vogler-Neuling, Marc Reig Escalé, David Pohl, Felix U. Richter, Artemios Karvounis, Flavia Timpu and Rachel Grange; ETH Zurich, Switzerland

The field of active metasurfaces tremendously broadens the application range of planar free-space optics, as it overcomes the restriction of a design defining a fixed functionality. To achieve new flexibility, several approaches have been explored to alter the functionality after fabrication, e.g. changing the refractive index of the metasurface building material itself. This can be realized in a plethora of ways such as thermal tuning, phase change or electric tuning by e.g. free carrier injection. Although the advantage of electric tuning approaches is their fast speed, many of these come with an increased absorption of the material.[1] The electro-optic Pockels effect however, utilizes an electric field without introducing free carriers and is in theory able to tune the refractive index with PHz speed. The crucial parameter, the electro-optic coefficient, is exceptionally strong in lithium niobate (LN), which further combines a high damage threshold with a high refractive index and a low loss, transparent nature in the visible to near-infrared spectrum.
Here, we show transmission intensity modulation in a LN metasurface based on the Pockels effect, which is enhanced by 2 orders of magnitude compared to an unstructured LN film. The effect is observed for voltages as low as 1 V and a bandwidth of 2.5 MHz. We further report on the dispersive properties of this modulation amplitude linked to the metasurface transmission resonance.
We design and fabricate a metasurface from 500 nm LN thin-film on a SiO_2 buffer layer and 500 μm LN as substrate. The unit cells of the metasurface are pillars with a height of 200 nm and a radius of 135 nm, separated by a 500 nm period. The optical resonance of this geometry, dominated by an electrical dipole mode, is experimentally measured at a wavelength of 776.6 nm with a quality factor of 129.
To modulate the transmission, we access the r_{33} electro-optic tensor component of LN using electrodes separated by 25 μm. We utilize the Pockels effect by applying a sinusoidal AC voltage to change the refractive index in the LN pillars and subsequently alter the resonance of the metasurface. A tunable laser probes the transmission between 765 and 780 nm to detect the change in transmitted intensity (modulation) with a photodiode.
We observe modulations already for voltages below 1 V, which allows driving our device with commercial microcontrollers. The modulation bandwidth ranges from 10 Hz to 2.5 MHz and is mainly limited by our electric setup. The modulation amplitude follows the derivative of the transmission, which is confirmed by simulations for our metasurface. As the geometry of the metasurface determines the transmission, we can engineer the electro-optic modulation by different metasurface unit cells and periods. The importance of nanostructuring further manifests in the experimentally observed enhancement by a factor of 80 when comparing the metasurface modulation to the spectrally flat modulation of an unstructured area.

To conclude, we investigate the modulation of transmission in a LN metasurface by the electro-optic Pockels effect. To the best of our knowledge, this is the first time an electro-optically induced transmission intensity modulation is observed in an all-dielectric metasurface. We show an enhancement of the modulation by two orders of magnitude as compared to an unstructured film, which stresses the impact of nanostructuring. Furthermore, we observe a dispersive behavior of the modulation amplitude, which is determined by the derivative of the transmission of the metasurface. Our device is so far the strongest and fastest electro-optic metasurface in LN. This is an important step towards potential future applications such as tunable metalenses, display applications or beam steering applications to further advance free-space data processing.

5:00 PM EQ08.04.06
Late News: Active Angular Tuning and Switching of Brewster Quasi Bound States in the Continuum in Magneto-Optic Metasurfaces Diego R. Abujetas[1], Nuno de Sousa[2], Jose Manuel Llorens[3], Jose A. Sanchez-Gil[1] and Antonio Garcia-Martin[3]; [1]Instituto de Estructura de la Materia (IEM-CSIC), Spain; [2]Donostia International Physics Center (DIPC),, Spain; [3]Instituto de Micro y Nanotecnologia, CSIC, Spain

Bound states in the continuum (BICs) emerge throughout Physics as leaky/resonant modes that remain, however, highly localized[1]. They have attracted much attention in Photonics, and especially in metasurfaces[2,3]. One of their most outstanding features is their divergent Q-factors, indeed arbitrarily large upon approaching the BIC condition (quasi-BICs) [4,5]. Here we investigate how to tune quasi-BICs in magneto-optic (MO) all-dielectric metasurfaces. The impact of the applied magnetic field in the BIC parameter space is revealed for a metasurface consisting of Si spheres with MO response. Through our coupled electric/magnetic dipole formulation, the MO activity is found to manifest itself through the interference of the (MO-induced) out-of-plane electric/magnetic dipole resonances with the in-plane magnetic/electric (directly induced) dipole, leading to a rich, magnetically-tuned quasi-BIC phenomenology, resembling the behavior of Brewster quasi-BICs for tilted vertical-dipole resonant metasurfaces. Such resemblance underlies our proposed design for a fast MO switch of a Brewster quasi-BIC by simply reversing the driving magnetic field. This MO-active BIC behavior is further confirmed in the optical regime for a realistic YIG nanodisk metasurface through numerical calculations. Our results present various mechanisms to magneto-optically manipulate BICs and quasi-BICs, which could be exploited throughout the electromagnetic spectrum with applications in lasing, filtering, and sensing [6].

Reconfigurable 2D Topological Mechanical Metamaterials with Dynamic Covalent Bonds Jason Christopher Jolly[1], Binjie Jin[2], YoungJoo Lee[1], Mohammad Charara[3], Tao Xie[2], Stefano Gonella[3], Xiaoming Mao[4] and Shu Yang[1,1]; [1]University of Pennsylvania, United States; [2]Zhejiang University, China; [3]University of Minnesota, United States; [4]University of Michigan, United States

Topological mechanical metamaterials (TMMs) based on Maxwell lattices exhibit topologically protected states (both static and dynamic behavior), including polarized edge stiffnesses and directional acoustic wave transport, depending on their global conformation. Of particular interest is the 2D generalized kagome lattice (2D GKL) that offers a rich topological phase space and exhibits multiple auxetic, non-polarized and topologically polarized states, respectively. Prior work in TMMs have thus far either been theoretical investigations, toy-model demonstrations, or experimental studies on relatively large models with locked configurations. Here, we aim to explore the topological phase space upon reversible kinematic reconfiguration while being stable in each polarized or un-polarized configuration. To do so, we fabricate monolithic 2D GKL with ligament sizes on the order of 100µm from polycaprolactone diacrylate (PCLDA) and polycaprolactone divinyl (PCLDV) networks with dynamic covalent bonds. Dynamic bonds allow us to spatially program stress relaxation and intrinsic softening, respectively, via the breaking and re-forming of covalent bonds and a photo-catalytically modulated alteration of the network topology. Any elastic stress generated and stored in the hinges of a PCLDA 2D GKL following a soft-twisting kinematic topological reconfiguration can be ‘annealed’ to permanently lock a specific configuration of the lattice. The spatially programmable softening of the hinges in a PCLDV 2D GKL monolith on the other hand has the ability to drastically modulate the topologically protected static and dynamic mechanical behavior of the 2D GKL geometry without any topological alteration in a geometric sense. Our studies allow us to answer fundamental questions such as whether elastic strain energy stored during kinematic transformations affects topologically protected properties and is a big step forward in realizing active, device-like TMMs with potential applications as reconfigurable acoustic waveguides and energy absorbers with controllable depth of penetration.

SESSION EQ08.05: Soft Metamaterials and Bottom-up Approach

Chirality Control in Single Gold Nanoparticle Ki Tae Nam; Seoul National University, Korea (the Republic of)

Chiral structure controlled at nanoscale provides a new route to achieve intriguing optical properties such as polarization control and negative refractive index. However, asymmetric structure control with nanometer precision is difficult to accomplish due to limited resolution and complex processes of conventional methods. Here, we demonstrated novel chiral gold nanostructures exploiting chirality transfer between peptide and high-Miller-index gold surfaces. Enantioselective adsorption of peptides results in unequal development of nanoparticle surface and this asymmetric evolution leads to highly twisted chiral element in single nanoparticle making unprecedented 432 helicoid morphology. The synthesized helicoid nanoparticle showed strong optical activity which was substantiated by distinct transmittance color change of helicoid solution under polarized light.

8:30 AM *EQ08.05.02
Chiroptics with Reconfigurable Metamolecules and Metamaterials Yuebing Zheng; The University of Texas at Austin, United States

We apply directed assembly to realize reconfigurable chiral metamolecules and metamaterials consisted of nanoscale building blocks. New techniques such as opto-thermoelectric tweezers and optothermally gated photon nudging are developed for the reconfigurable directed assembly both in solutions and on solid-state substrates. We further demonstrate applications of the metamolecules and metamaterials in chiroptical spectroscopy for label-free enantiodiscrimination of drug molecules and abnormal metabolites in diabetes.

9:00 AM EQ08.05.04
Foot-Scale Acoustic Self-Limiting Assembly of Particles on Polymer Liang Zhao[1], Bchara Sidnawi[1], Jichao Fan[2], Thomas Scully[1], Weilu Gao[2], Qianhong Wu[1] and Bo Li[1]; [1]Villanova University, United States; [2]University of Utah, United States

Self-limiting assembly of particles, wherein assembly stops automatically once the limiting mechanism is turned on, represents state-of-the-art controllability. Here, we demonstrate a unique Acoustic Self-limiting Assembly of Particles (ASAP) to achieve foot-scale monolayer assembly of both inorganic and organic particles on flexible substrates in aqueous solutions. Unlike the dominating surface self-limiting mechanism, ASAP features a unique synergy of several designs. (1) Hard-to-wet surface energy design of hydrophobic particles and substrate in water ensures the energetic favorability of particle deposition on the substrate. (2) The acoustic field helps maintain the particles dispersion and energize them to collide with the substrate. (3) The viscoelastic behavior of polymer substrates helps absorb the kinetic energy of impacting particles to facilitate the assembly. (4) The assembled rigid particles convert the viscoelastic substrate into an elastic one, thereby preventing further formation of new layers. We have demonstrated the assembly of SiO_2 nanospheres (d = 500 nm-1000 nm, hydrophobic treated) and Poly(Methyl Methacrylate) microsphere (d = 1000-5000 nm) on various micro- and nanopatterned polydimethylsiloxane (PDMS) substrates. Such accurate assembly can be important for many applications. For example, as a proof-of-concept, we demonstrate that the produced films of mono- and bi-layer SiO_2 nanosphere show different colors due to Mie-resonance-induced optical coloration. It is important to note that the unique energy design of ASAP opens the gate toward many desirable but hard-to-assemble systems and thus enables unlimited functionalities. Moreover, ASAP is specially designed for viscoelastic polymer/bio substrates and may enable a wide range of applications in structural coloration, smart textile manufacturing, and drug delivery.

SESSION EQ08.06: Emerging Photonic Materials and Process

EQ08-Virtual

6:30 PM *EQ08.06.01
Nonlinear Metaphotonics and Metasurfaces Yuri Kivshar; Australian National University, Australia

The field of nonlinear optics is a well-established discipline that relies on macroscopic media and employs propagation distances longer than a wavelength of light. Recent progress with electromagnetic metamaterials has allowed for the expansion of this field into new directions of new phenomena and novel functionalities. Nonlinear effects in thin, artificially structured materials such as metasurfaces do not rely on phase-matching conditions and symmetry-related selection rules of natural materials; they may be substantially enhanced by strong local and collective resonances of fields inside the metasurface nanostructures. Consequently, nonlinear processes may extend beyond simple harmonic generation and spectral broadening due to electronic nonlinearities.

For many years, plasmonics was considered as the only available platform for subwavelength optics, but the recently emerged field of Mie-resonant metaphotonics provides more practical alternatives for nanoscale optics by employing resonances in high-index dielectric nanoparticles and their structures such as metasurfaces. This talk aims to discuss recent advances and future emerging directions in the field of nonlinear metaphotonics and optical metasurfaces empowered by Mie resonances. We aim to discuss efficient spatial and temporal control of nonlinear light by employing multipolar Mie resonances and bound states in the continuum, with applications of these concepts to second-, third-, and high harmonic generation, self-action effects, upconversion, and lasing.

We will also discuss our recent results on asymmetric parametric generation of light in nonlinear metasurfaces with bianisotropic meta-atoms to generate images in the visible spectral range when illuminated by infrared radiation. By design, the metasurfaces produce different and completely independent images for the reversed directions of illumination, that is when the positions of the infrared transmitter and the visible light receiver are exchanged. Nonlinearity-enabled asymmetric control of light at a level of individual subwavelength resonators opens an untapped potential for developing novel nanophotonic components via dense integration of large quantities of nonlinear resonators into compact metasurfaces

7:00 PM *EQ08.06.02
The Ultra-Thin Nanophotonic Platform Using Transition Metal Dichalcogenides Layers Su-Hyun Gong and Junghyun Sung; Korea University, Korea (the Republic of)

The emergence of 2D materials stimulated intensive research on both electronic and photonic applications. Especially, transition metal dichalcogenides (TMDs) provided an excellent platform for photonic applications due to their strong light-exciton interaction. Various photonic devices such as a light-emitting device, laser, exciton-polariton device have been successfully demonstrated experimentally using TMD monolayers. However, multilayered TMDs has attracted far less attention than TMD monolayers because they become indirect bandgap materials. Here we show that multilayered TMD itself is a good platform for controlling light-matter interaction without integrating an external photonic structure. A TMD multilayer can be utilized for a passive optical structure because it possesses a high dielectric constant. For example, light guiding is possible along a multilayered TMD, which is very thin compared to the wavelength of the light. Because a high dielectric constant is owing to the exciton resonances, guided light along a TMD layer is referred to an exciton-polariton. The dispersion relation of the exciton-polariton in a TMD layer is very similar to that of surface plasmon polariton. Interestingly, we observed that the polarization of the exciton polaritons in a TMD layer is distinctive to surface plasmon polaritons because it inherits valley-dependent optical response from excitons in TMDs. We will also show that light can be further controlled using a patterned TMD multilayer. First of all, we designed an ultra-thin flat lens using a patterned TMD layer. We will show the optimized thickness and design of a TMD flat lens for efficient light focusing. Lastly, we will present the experimental observation on the lasing action in a bare TMD disk. A 50-nm thick TMD disk exhibits whispering gallery modes with a quality factor of ~400. The disk structure has a very high confinement factor for lasing action because the TMD disk offers both optical modes and optical gains. As a result, we observed the lasing operation under continuous-wave excitation at room temperature. We believe our results show a potential for the TMD-based nanophotonics offering a small mode volume but with a lower loss compared to the surface plasmon polaritons.

7:30 PM EQ08.06.03

Engineering Hyperuniform Phase Plates for Multispectral, Lensless Imaging Systems Yuyao Chen, Wesley Britton and Luca Dal Negro; Boston University, United States

Lensless imaging systems replace the lens of a traditional camera with engineered diffractive optical elements placed in close proximity (~2mm) to the image sensor plane, largely reducing the system volume and enabling on-chip imaging applications. In our recent work, we designed, fabricated, and characterized a novel multispectral lensless imaging system based on the design of hyperuniform phase plates (HPPs). In particular, we demonstrate the imaging capabilities and point-spread-function (PSF) engineering of HPPs based on from scalar random fields that are obtained by solving nonlinear reaction-diffusion equations. In particular, we focus on HPP structures and contour PSFs phase plates derived from the Gary-Scott (GS), Cahn-Hilliard (CH), and Swift-Hohenberg (SH) models that produce highly isotropic modulated transfer functions (MTFs) compared to state-of-the-art lensless imaging systems with contour PSFs based on the Perlin noise. Specifically, we demonstrate the importance of hyperuniform two-component isotropic random fields for the flexible design of novel diffractive phase plates and we introduce an efficient phase retrieval algorithm based on the Rayleigh-Sommerfeld diffraction theory that enables the fabrication of HPPs with desired PSFs. A device HPP structure within a four-level phase discretization approach is fabricated using scalable photolithography and its multispectral imaging behavior is demonstrated at different wavelengths using the high-fidelity (ADMM) optimization algorithm. The scalability of the proposed concepts to infrared spectral regions and their robustness against large photodetection noise will also be discussed.

7:45 PM EQ08.06.05
Focused Ion Beam (FIB) Induced Alignment-Controlled Herringbone Nanostructures on Germanium (100) Surface Bhaveshkumar B. Kamaliya[1,2,3], Mohammed Aslam[1], Jing Fu[2] and Rakesh G. Mote[1]; [1]Indian Institute of Technology Bombay, India; [2]Monash University, Australia; [3]IITB-Monash Research Academy, India

To fabricate nanostructures, direct milling by the focused ion beam (FIB) is deemed as a mask-less and single-step fabrication technique; however, it is a time-consuming process due to pixel-by-pixel dwelling, and the effective beam size of FIB restricts minimum feature size. The self-organized nanostructures have an advantage over directly milled nanostructures owing to the low irradiation dose requirement. Also, self-organization does not possess any limitations on the minimum feature size. Thus, towards achieving miniaturization in the field of nanofabrication, FIB induced self-organization can be an easy and preferred approach. The formation of nanoripples on germanium, with enhanced wideband light absorption, has been reported by reorganization of the surface atoms due to FIB irradiation [1,2]. Systematic control on the topography progression of the germanium surface during FIB irradiation must be studied to attain complicated 3D geometries such as polygonal morphologies [3]. Such polygonal structures are essential as building blocks for photonic integrated circuits; however, superior complexities in morphologies such as corrugated [4] and herringbone patterns can be highly beneficial for hybrid microfluidic and optical sensing devices. The present work demonstrates controlled evolution and realization of complicated morphologies such as alignment-controlled herringbone nanostructures on the Ge surface by FIB induced self-organization. These periodic herringbone nanostructures were found to be evolved from the array of circular nanoholes and are jutting out of the surface, delivering the exclusive capability of FIB to create 3D nanostructures. As revealed by electron microscopy, Raman spectroscopy and molecular dynamics simulations, such complex morphologies were obtained by nanoscale control on the phase transformation of germanium surface during ion irradiation, leading to viscous-fingering process with site-specific self-organization. Moreover, the herringbone structures were manipulated with varying scanning strategies in order to modify their pitch and to orient the structures in a spiral manner. Germanium nanostructures exhibit improved THz emission; thus, such a possibility of easy direction and pitch control in Ge nanostructures can help to create scalable metasurfaces with superior light-matter interactions. The present study fosters the advancement in FIB processes towards manipulating the morphology of individual nanoholes (induced by each FIB-spots), offering a novel capability in the field of FIB-nanofabrication.

9:00 PM EQ08.07.03
Electrically Tunable Varifocal Metalens at Visible Wavelengths Trevon Badloe, Inki Kim, Yeseul Kim, Joohoon Kim and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

Tunable optical devices powered by metasurfaces provide a new path for functional planar optics. In particular, lenses with tunable focal lengths could play a key role in various fields with applications in imaging, displays, and augmented and virtual reality devices. Here, we demonstrate an electrically controllable varifocal metalens at visible wavelengths by incorporating a metasurface designed to focus light at two different focal lengths, with liquid crystals to actively manipulate the focal length of the metalens through the application of an external bias. By utilizing hydrogenated amorphous silicon that is optimized to provide an extremely low extinction coefficient in the visible regime, the metalens is highly efficient with measured focusing efficiencies of around 44%. We numerically design and experimentally realize and characterize tunable focusing and demonstrate electrically tunable active imaging at visible wavelengths using the varifocal metalens combined with liquid crystals. Diffraction limited focusing and imaging is verified through the analysis of the measured optical intensities at the focal points, and the modulation transfer function. The varifocal metalens is used to demonstrate electrically modulated focus switching between the two designed focal planes, to display images of positive and negative target objects.

9:15 PM EQ08.07.04

All-Optical Reconfigurable Metamaterials Jingang Li and Yuebing Zheng; The University of Texas at Austin, United States

Colloidal metamaterials assembled from individual colloidal particles as building blocks exhibit unique collective behaviors beyond single components. Reconfigurable metamaterials with tunable optical properties are of significant interest in understanding the fundamental light-matter interactions at the nanoscale and developing active nanophotonic devices. Optical tweezers can precisely manipulate colloidal particles of variable sizes and materials. However, it has remained challenging for optical tweezers to assemble metamaterials due to the inability to control the interparticle and particle-substrate interactions.

To overcome these limitations, we have developed a series of optical techniques for all-optical reconfigurable metamaterials. Specifically, we invented opto-thermoelectric nanotweezers (*Nature Photonics* **2018**, *12*, 195-201) for versatile manipulation of nanoparticles with ultralow optical power and opto-thermoelectric assembly (*Science Advances* **2017**, *3*, e1700458) for reconfigurable construction of colloidal metamaterials with tunable bonding strength. To tackle the potential photothermal damages to nanoparticles, we further developed opto-refrigerative tweezers (*Science Advances* **2021**, *7*, eabh1101) as a noninvasive tool to trap and assemble metamaterials at the laser-cooling-generated low-temperature region.

In addition to the reconfigurable assembly of optical metamaterials in the liquid media, we developed optothermal nudging (*Nature Communications* **2019**, *10*, 5672) to directly manipulate colloids on a solid substrate. Reconfigurable construction of colloidal metamaterials is achieved with nanoscale accuracy, paving the way for the fabrication of active on-chip functional nanodevices. For instance, we demonstrate the all-solid-phase reconfigurable dielectric metamaterials with tunable optical chirality and their applications in enhanced chiral sensing (*Nano Letters* **2020**, *21*, 973-979; featured as a Front Cover article).

In summary, we have developed versatile optical approaches for bottom-up fabrication of reconfigurable metamaterials, which can operate both in the liquid media or on the solid substrate. Metamaterials with diverse configurations, sizes, and materials can be assembled at single-particle resolution. With highly enriched structures and tunable optical properties, the all-optical reconfigurable metamaterials provide a powerful platform to advance fundamental understandings in colloidal and materials sciences, investigate general design principles for functional metamaterials, and develop active devices for practical applications.

9:30 PM EQ08.07.05
On-Demand Mode Conversion and Wave-Front Shaping via On-Chip Metasurfaces Lin Deng and Yongmin Liu; Northeastern University, United States

To further reduce the overall size and increase the functionalities of integrated photonics, researchers have recently investigated the hybrid system by integrating metasurfaces with photonic waveguides. The wavevector of the guided mode can be modified or the mode coupling coefficient can be optimized with the aid of metasurfaces, ensuring the efficient conversion from the fundamental mode to higher-order modes[1, 2]. On the other hand, 2D phase shaping of the input planar waveguide mode was realized by deliberately controlling the local phase or reflective index with metasurfaces[3, 4]. However, to the best of our knowledge, a general approach for arbitrarily converting TM modes to TE modes or wave-front shaping for the cross-polarized waves is still lacking.
Here, we propose a new design strategy for mode converters and polarization rotators utilizing on-chip C-shaped plasmonic nanostructures, which support pronounced electric and magnetic resonances. Comparing to previous methods that convert the fundamental TE mode to other modes by modifying the wavenumber of guided waves[1, 2], our design can directly generate the required wavefront of the desired TE modes from various TM modes even when the input mode and target mode have the same or very close wavenumbers. Also, the phase tuning range for the co-polarized light using the nano-bar structure in previous work can only cover 0 to π, which would potentially limit its applications. In contrast, the phase change of our C-shape nanoantenna can cover the 2π range, which could be more straightforward and flexible for higher-order cross-polarization modes conversion. In addition to the mode conversion, we demonstrate on-chip lenses that can shrink the spot size while rotating its polarization direction with a footprint of only 9.6 μm along the propagation direction. To the best of our knowledge, it is the first demonstration to achieve polarization rotation and wave-front shaping simultaneously inside the waveguide with the help of on-chip metasurfaces.
In summary, we propose and numerically demonstrate an innovative method for mode conversion and wave-front shaping, when the input guided mode is TM polarized. The rotation of the polarization and tuning of the local phase is achieved through the interaction of the on-chip metasurfaces and evanescent wave components of the waveguide. We envision that our concept may inspire novel applications such as mode division multiplexing, on-chip optical interconnection, optical router, and light detection and ranging.

Near-Infrared Reflection Modulation Through Electrical Tuning of Graphene Metasurfaces Ziqiang Cai and Yongmin Liu; Northeastern University, United States

Metasurfaces made of an array of rationally designed sub-wavelength structures have become one of the most promising frontiers in optics. By combining graphene with a metasurface, the functions of the metasurface can be electrically tuned with high tuning speed, high modulation efficiency, adaptability with silicon fabrication process as well as compactness. However, the tuning wavelengths of the demonstrated metasurfaces are mainly limited in the mid-infrared and terahertz spectra. There are some works that push the tuning wavelength of graphene metasurfaces close to the near-infrared region, but the experiment results either suffer from low tuning range (<5%) [1, 2] or require extremely high applied voltage (150V) to mechanically move graphene flakes [3, 4], imposing considerable limitations for practical applications.
In this presentation, we report a reflective-type tunable graphene metasurface operating in the near-infrared spectrum ($\leq$3.0μm). The device combines metallic plasmonic structures with graphene to enhance graphene's interband transition, so that a decent tunability can be achieved. More specifically, the applied voltage can be rather small due to the 'step-like' change of graphene's conductivity. Moreover, since graphene's interband transition is less sensitive to its carrier mobility, our device can work well with wet-transferred Chemical Vapor Deposition (CVD) graphene that has low mobility. Thus, the device is robust and suitable for large-area fabrication. In addition, by carefully design the structure parameters, our tunable graphene metasurface can work in both near-infrared and mid-infrared spectra under different polarization of light.

Our design has been verified through both simulation and experiment, which agree well with each other. We achieved a reflection modulation ΔR of about 10% and a modulation depth ΔR/Rmax of 17% at 2.42μm, with the applied voltage less than 15V. We have also fabricated another graphene metasurface that can work in both near-infrared and mid-infrared spectra at the same time. The corresponding reflection spectra have a modulation ΔR of about 9.5% and a modulation depth ΔR/Rmax of 18.2% at 2.30μm, and a modulation ΔR of about 7.5% and a modulation depth ΔR/Rmax of 24.7% at 5.67μm. We think that these results provide a new design strategy to advance electrically tunable metasurfaces.

Active and Tunable Dielectric Nanoantennas and Metasurfaces Arseniy Kuznetsov; Institute of Materials Research and Engineering, Singapore

Nanoantennas and metasurfaces based on high-refractive index dielectric and semiconductor materials represent the new branch of resonant low-loss nanophotonics paving the way to real-life applications [1]. They can resonantly enhance light-matter interaction and control the phase and amplitude of scattered, transmitted or reflected light with nanoscale resolution. Recently, the toolkit of dielectric nanoantennas and metasurfaces has been strongly enriched by adding active and tunable functionalities. Active nanoantennas can enhance and emit light in preferred directions, becoming well-controlled nanoscale light sources. Tunable nanoantennas can dynamically switch the phase and amplitude of scattered light providing possibilities for nanoscale dynamic wavefront control. In this presentation, I will review our recent progress in the field of active and tunable dielectric nanoantennas and metasurfaces. I will show our demonstrations of nanoantenna lasers using the concept of bound states in the continuum (BIC) in dielectric nanoantenna structures interfaced with different active media [2-4]. This research paves the way to nanoscale laser devices with wavelengths ranging through the whole visible spectrum. Also, I will present our research on tunable nanoantennas and metasurfaces, demonstrating spatial light modulators with individually controlled micron-scale nanoantenna-based pixels [5]. These devices can provide novel solutions for 3D holographic displays [6] and compact solid-state Light Detection and Ranging (LiDAR) devices for autonomous vehicles.

Topological Guiding of Stress Waves in Bolted Plate Structures Chun-Wei Chen[1], Rajesh Chaunsali[2], Johan Christensen[3], Georgios Theocharis[2] and Jinkyu Yang[1]; [1]University of Washington, United States; [2]LAUM, France; [3]Universidad Carlos III de Madrid, Spain

In the past decades, topological boundary states have been demonstrated in various fields, including photonics, electronics, and acoustics. However, their realization in mechanical systems, particularly in the setting of continuous plate structures, has been relatively unexplored. In this presentation, I will talk about how we can achieve topological guiding of stress waves in a ubiquitous platform of bolted plate structures. I will focus on the realization of three mechanical waveguiding phenomena: (1) 1D edge-state in a Z-shaped domain wall mimicking the quantum spin Hall effect; (2) asymmetric 0D corner localization in the same domain wall; and (3) another type of special non-propagating 0D localized state, so-called a mechanical analog of the Majorana bound states. The first two are realized in an ordered arrangement of embedded bolts in a hexagonal pattern, while the last is achieved using the non-periodic yet ordered mechanical system in the Kekulé distorted pattern. For experimental demonstrations, we adopt a laser Doppler vibrometer to scan the entire plate and create a 2D wavefield, which agrees well with numerical predictions. The topological waveguiding technique investigated in this study has a potential to enhance the degree of freedom in controlling stress waves in plate structures, which can be used for a variety of engineering applications, e.g., energy harvesting, vibration filtering, and structural health monitoring / nondestructive evaluations.

Interference, Scattering and Transmission of Acoustic Phonons in Si Phononic Crystals Yang Li[1], Adrian Diaz[1], Xiang Chen[1], David McDowell[2] and

Youping Chen[1]; [1]University of Florida, United States; [2]Georgia Institute of Technology, United States

In this talk, we report a multiscale study of the phonon transport processes in Si phononic crystals (periodic pore structures) using the concurrent atomistic-continuum method. The transient processes of phonon scattering and transmission in Si phononic crystals are visualized. The nature of phonon transport is demonstrated to be strongly dependent on the relation between the phonon wavelength and the period length, *p*, and the neck width, *n*, of the phononic crystal. Three distinct regimes have been observed: (1) phonons with wavelengths equal to 2.9p or larger propagate predominantly ballistically, which is accompanied by specular reflection of varying extents, depending on the wavelength of the phonons; the properties of these phonons are consistent with the phonon dispersion relations of a homogenous and harmonic system; (2) phonons with wavelengths <n are partly reflected by the pore boundaries and partly propagate ballistically in the solid regions of the necks; two types of vibrational modes are identified: the single crystal Si phonon modes, and the vibrational modes resulting from internal surface scattering; (3) phonons with wavelength close to *p* are most strongly scattered, and the internal surface-related modes dominate the transport; these modes have the slowest group velocities and lowest energy transmission, and the transport is predominantly diffusive even for specimens originally at zero temperature. For phononic crystals that contain a single crystal heater at their center, the interface between the single crystal and the phononic structure provides a strong resistance to short wavelength phonons, leading to predominantly diffusive phonon transport and an average energy flux that is two orders of magnitude lower than a same-sized single crystal specimen.

8:45 AM EQ08.08.04
Late News: Exceptional Light Capturing Metamaterial for Solar Fuel Generation Joel Loh and mahdi Safari; University of Toronto, Canada

Abstract: Metamaterials are a new class of artificial materials that can achieve electromagnetic properties that do not occur naturally, hence they can also be a new class of photocatalytic structures. Harvesting primarily photonic energies to drive catalytic hydrogenation of carbon dioxide to methanol leads to highly sustainable fuel production in a solar refinery. Due to the limited selection of plasmonic metals in the visible, indirect catalysis is commonly performed with a plasmonic material attached to a catalytic material, via charge excitation and transfer. Photo-absorbing catalysts are sometimes achieved with stochiometric bandgap modifications or with light trapping structural support that uses internal reflections, which can lead to catalytic trade-offs in the former and low internal light intensities in the latter. Here we show that metal catalysts can achieve photonic amplification and broadband absorption by decoupling optical properties from material composition as exemplified with a ZnO/Cu metamaterial surface comprising periodically arranged nanocubes. By refractive index engineering towards an index near that of vacuum, and via generalized sheet boundary conditions, it is possible to achieve a virtual perfectly absorbing copper film that absorb 98% of the visible without any modification of stoichiometric composition. The combination of plasmonics and broadband absorption doubles the electric field intensities across the absorption range and within the plasmonic band. This enhances catalytic rates by up to a factor of × 216, in comparison to × 2 to 4 enhancements of ZnO/Cu nanoparticles or films. The metamaterial catalyst shows consistent methanol production even at 50° incidence, which negates the need for solar tracking. These results show that metamaterials can act as a singular light harvesting device that collect and concentrate a broad band of the visible spectrum to substantially enhance photocatalysis of important reactions. We anticipate that achieving perfect absorption and confining electromagnetic fields within a nanoscale layer, through photonic designing of miniscule amounts of catalytic materials, which also circumvents low light penetration into bulk powders or pellets, can be a uniquely valuable and energy-efficient approach to photocatalyst engineering.

Chiral Trabeated Elastic Meta-Beam with a Complete Bandgap Mechanism Jeonghoon Park, Dongwoo Lee, Yeongtae Jang and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

Lots of research have been carried out to utilize elastic metamaterials for vibration reduction. Among them, flexural metamaterials have the advantage of being able to implement a bandgap in the low-frequency region but have a limitation in that it can reduce only the flexural waves. To break the limitation, we propose a novel complete bandgap mechanism created by overlapping a flexural and longitudinal bandgap to attenuate the propagation of all mechanical waves in the low-frequency region. To demonstrate the complete bandgap mechanism, a chiral trabeated elastic meta-beam has been proposed to realize a complete bandgap in periodically arranged beam-shape structures. By utilizing the longitudinal-torsional coupling characteristic of the chiral trabeated meta-beams, which are not found in achiral meta-beams, not only the flexural bandgap but also the longitudinal-torsional bandgap can be implemented in the same frequency region. We introduce an analytic model for the chiral trabeated meta-beam, and the dispersion curve is numerically calculated. We also calculate the dispersion curves from the finite element method, and it is confirmed that numerically and analytically calculated dispersion curves are in good agreement. It allows us to identify the complete bandgap region of the chiral meta-beam. We experimentally observe the complete bandgap in which all mechanical waves were inhibited. The chiral trabeated elastic meta-beam with the complete bandgap mechanism proposed in this study effectively reduces elastic waves and vibrations.

Computational Design of Multifunctional Metamaterials for the Improved Combustion Performance Jose Ceja and Sungwook Hong; California State University, Bakersfield, United States

Aluminum nanoparticles (ANPs) are very promising additives in the combustion applications owing to their high energy density with an increased burning rate.[1] Unfortunately, the ANPs are easily aggregated, leading to an increase in their particle size, and thus lowering the combustion performance. This is primarily because the ANPs have a very high reactivity. As such, recent efforts have been made to synthesize novel metamaterials using ANPs and hydrocarbon precursors. For example, ANPs could be effectively coated by hydrocarbon precursors to lower their reactivity, thus preventing sintering effects of ANPs. However, an effect of precursor types of hydrocarbons on sintering behaviors of ANPs has yet to be understood at the molecular level. Here we perform reactive molecular dynamics (RMD) simulations using on ReaxFF[2] to investigate thermal behaviors of hydrocarbon coated ANPs. In particular, we employed different types of carbon precursors to evaluate the sintering behaviors of ANPs. Our RMD simulations suggest detailed reaction steps for the sintering process of the bare/hydrocarbon coated ANPs. Therefore, our RMD simulations will help provide a valuable input for experimental synthesis of a novel metamaterial for the improved combustion performance.

S.H. and R.E. acknowledge a start-up funding from School of Natural Science, Mathematics and Engineering at California State University, Bakersfield (CSUB).

Optical Response of Spherical Cavity with Temperature Effect in the Presence of Yukawa Potential Varsha Yadav[1], Mohamed Kria[2], L. M. Pérez[3], V. Prasad[1], D. Laroze[3], Gen Long[4] and El Mustapha Feddi[2]; [1]University of Delhi, India; [2]Mohammed V University in Rabat, Morocco; [3]Universidad de Tarapacá, Chile; [4]Saint John's University, United States

In the present study, we have investigated the effect of temperature and geometrical confinement on the behavior of spherical cavities with Yukawa potential presence inside the cavity within effective mass approximation. Using the Finite-element method, we have calculated the energy eigenvalue with the geometric and temperature effects into consideration. The optical transition from the ground to the excited state shows a blue shift in optical absorption coefficient and refractive index changes with an increase in temperature. The increase in the geometric size of the spherical cavity causes the redshift in the optical resonance peaks.

Variable Stiffness Metamaterials to Tune Soft Robot Material Properties Elze Porte, Sreekalyan Patiballa, Nidhi Pashine, Sophia Eristoff, Trevor Buckner and Rebecca Kramer-Bottiglio; Yale University, United States

Mechanical metamaterials can be used to alter the material behavior of soft robots, creating new possibilities to control deformations and enhance their performance. For example, auxetic structures have been embedded in elastomer capacitive sensors to increase the sensor sensitivity through a reduction in the Poisson's ratio. However, the stiffness of the embedded metamaterials needs to be much larger than the stiffness of the soft robots to retain the metamaterial properties. The larger stiffness often limits the range of motion and requires larger actuation forces. In this work, we present a variable stiffness metamaterial that can switch between exhibiting the properties of a metamaterial and soft elastomer. The variable stiffness is achieved by making auxetic structures from a Field's metal-silicone composite. The Field's metal is solid at room temperature and melts around 65°C, giving the composite a stiffness change around the melting temperature. The variable stiffness auxetic structure is embedded into a soft elastomer matrix representative of a soft robot. We investigate the mechanical behavior of auxetic structures with different architectures and Poisson's ratios embedded in different soft elastomers. We measure the Poisson's ratio and stiffness of the embedded structures during tensile tests. The results indicate that the material properties are dominated by the metamaterial in a stiff state (e.g., low Poisson's ratios) and by the elastomer in a soft state (e.g., enabling large strains, Poisson's ratio of 0.5). We show that the mechanical behavior of the embedded structure is both dependent on the rule of mixtures for composites and the architecture of the metamaterials. The Poisson's ratio of the embedded structure was lowest when the stiffness difference between the auxetic and elastomer matrix was highest, which was expected based on the rule of mixtures. We found that the Poisson's ratio of the auxetic structure was not a good indication of the Poisson's ratio when it is embedded into the elastomer. The auxetic structure with the lowest Poisson's ratio did not necessarily result in the lowest Poisson's ratio when embedded into the elastomer. Embedding the auxetic into an elastomer means that all voids in the structure are filled with elastomer, which changes the forces on the structure when strained. This means that for the design of embedded metamaterials both the stiffness of the components and the architecture of the metamaterials should be considered. We showcase the utility of the variable stiffness metamaterials by embedding them into soft capacitive sensors. The sensors show a high sensor sensitivity when measuring small strains (<5%) in the stiff state of the metamaterials (room temperature). When the auxetic structure is softened (>65°C) the sensors can be used to measure large strains (>10%) and require lower forces to be stretched. In conclusion, we developed a variable stiffness mechanical metamaterial that can be embedded in soft robotic structures to switch between favorable properties.

Nonlocal Metasurfaces Andrea Alu; City University of New York, United States

In this talk, we discuss our recent theoretical and experimental progress in the area of metasurfaces, in particular on the role of engineered nonlocality to enable
a new degree of control over spectral and coherent features, in addition to wavefront manipulation.
We demonstrate frequency-selective and wavefront-selective responses based on these principles, of interest for augmented reality and secure communication applications.
We also discuss the impact of these concepts to manipulate thermal emission and photoluminescence and realize efficient, compact and highly flexible optical sources.

7:00 PM *EQ08.09.02
Optical Metasurfaces for Generating Customized Polarization Profiles Xianzhong C. Chen and Yuttana Intaravanne; Heriot-Watt University, United Kingdom

The polarization of light, as a fundamental degree of freedom, has been key to many applications ranging from quantum to classical optics. Light fields with spatially inhomogeneous polarization and intensity distributions play an increasingly important role in photonics due to their peculiar optical features and extra degrees of freedom for carrying information. Optical metasurfaces are ultrathin inhomogeneous media with planar structures of nanopatterns that can manipulate the optical properties of light at the subwavelength scale. The unprecedented capability of optical metasurfaces in the manipulation of the light's polarization at subwavelength resolution has provided an unusual approach for generating various polarization profiles. A compact metasurface platform has been demonstrated to arbitrarily engineer a polarization profile that is very difficult or impossible to realize with conventional optical elements. In this talk, we are going report our recent progress on ultrathin metasurface devices for the realization of customized polarization profiles. The compact metasurface devices with customized polarization profile can greatly expand the range of applications of integrated optics in polarization topology, optical tweezers, nanolithography and photoalignment.

7:30 PM EQ08.09.04
Engineered Hydrogenated Amorphous Silicon for Functional Metasurfaces Working at the Visible Frequencies Younghwan Yang[1], Gwanho Yoon[2] and Junsuk Rho[1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Seoul National University of Science and Technology, Korea (the Republic of)

Dielectric metasurfaces which consist of periodic subwavelength structures have emerged as alternatives to conventional bulk refractive optical elements. Due to the requirement of miniaturization in commercial products such as smartphones, endoscopes, and LiDAR sensors, metasurfaces gain the attentions of industrial engineers. However, they suffer high production costs due to the high deposition cost of visibly transparent dielectrics including titanium dioxide, gallium nitride, and crystalline silicon. Here, we suggest engineered hydrogenated amorphous silicon, which is visibly transparent and exhibits a high-refractive index at the full-visible spectrum. It is deposited with plasma-enhanced chemical vapor deposition, which is commercially used for the deposition of large-area silicon-type films. We manipulate substrate temperature, chamber pressure, gas ratio and plasma power to obtain low-optical losses films at visible and we found that its optical losses are highly suppressed at the temperature of 200 degrees. Also, the chamber pressure is highly related to the complex refractive index and 45 mTorr of it makes the lowest extinction coefficient at the visible frequencies. We conducted X-ray diffraction and Raman spectroscopy and we found that lower extinction coefficient is suppressed as Si-H bonds increase. We also demonstrate beam-steering dielectric metasurfaces which steer the beam at a desired angle. We experimentally measured conversion efficiencies of 75%, 65%, and 42% at the wavelength of 635, 532, and 450 nm. Considering the high CMOS compatibility of hydrogenated amorphous silicon, it will be the dominant material for the commercialization of metasurfaces operating at the visible frequencies.

7:45 PM EQ08.09.05
Dynamically Tuneable Reflective Structural Colouration with Electroactive Conducting Polymer Nanocavities Stefano Rossi and Magnus P. Jonsson; Linköping University, Sweden

Displays form an integral part of modern society while they at the same time are responsible for a significant part of our energy consumption. The limited room for further improvement of emissive displays motivates the development of a complementary energy-effective reflective-based technology. However, it has been challenging to develop a high-performance e-paper in colour, since it is not only sufficient to optimize colour quality (chromaticity) but also to achieve high absolute reflection, having to rely only on ambient light. Recent research has explored various approaches to create highly reflective surfaces based on structural colouration of thin-film cavities, plasmonic or dielectric metasurfaces. These systems have further been combined with functional materials like liquid crystals, phase changing or electrochromic materials to switch such reflective surfaces on/off. However, most of those solutions suffer from low brightness or limited chromatic tunability. In addition, the traditional RGB subpixels division is not efficient for reflective displays, causing the loss of 2/3 of the light to reproduce a primary colour, which adds to the other losses of the optical system. To circumvent this issue, we need to develop reflective pixels with tuneable colours (monopixels) instead of relying on neighbouring subpixels with fixed colours. Recently, the use of materials with electrochromic properties to modulate nanooptical cavities and plasmonic devices has been proposed as a possible solution, but up to date no full tunability in the visible has been obtained yet.
We propose here a tuneable reflective nanooptical cavity that uses an electroactive conducting polymer (thieno[3,4-b]thiophene) as the actuating spacer layer, replacing the dielectric spacer in a conventional metal-insulator-metal (MIM) optical cavity. The cavity was fabricated with a thin semi-transparent layer of gold and chromium and bulk aluminium mirror, and it works combining both a broadband absorber and Fabry-Pérot effect to give a good overall reflectance, while also offering chemical stability. Integrating the nanocavity in an electrochemical cell, the doping and de-doping of the polymer spacer provided reversible tuning of the cavity's structural colour throughout the entire visible range and even beyond. The results indicated that the main working principle for the colour variation is the thickness change associated with the doping state of the polymeric spacer by counter-ions swelling, but a synergistic effect with refractive index change may also be possible. Furthermore, the cavity provided high peak reflectance (50-60%) with a difference within 10% between the reduced and oxidized states of the polymer. Both cyclic voltammetry and chronoamperometric techniques were investigated for the switching and we obtained a maximum wavelength change of 430nm for a nanohole-assisted optical cavity.
Our electroactive cavity concept may find particular use in reflective displays, by opening for tuneable monopixels that eliminate losses in brightness for traditional subpixel-based systems. Future work will preferably address remaining challenges such as long-term stability and improvement of uniformity, for example, by exploring alternative polymers, and strategies for improved polymer-metal adhesion. We believe that the presented concept to place functional polymers inside optical nanocavities may be used for other applications, like other types of tunable metasurfaces, as well as to study the polymers themselves, for example, using colour variations to extract information about spatial and temporal polymer thickness variations.

SESSION EQ08.10: Topological Metamaterials

9:00 PM *EQ08.10.01
High Dimensional Optical Meta-Devices—Classical to Quantum Mu Ku Chen, Xiaoyuan Liu, Jingcheng Zhang, Jiaqi Yuan and Din-Ping Tsai; City University of Hong Kong, Hong Kong

Meta-surface can achieve light manipulation by the artificial nanoantenna array in a compact size. Various meta-devices have been demonstrated according to demands in Optics lately. For applications of full-color imaging and sensing, the correction of chromatic aberration is an important issue. Here, we developed the integrated-resonant unit to incorporate with the geometric phase method to realize achromatic meta-lens. The phase of different wavelengths can be compensated specifically. The full-color imaging is demonstrated by using GaN-based achromatic meta-lens. A 60 by 60 achromatic meta-lens array is used to implement the light field imaging system. The depth and moving speed of dynamic objects are achieved. A new type of high-dimensional quantum entanglement light source is demonstrated by using a meta-lens array which is composed of 10 by 10 meta-lens array. The multi-focusing spots can be delivered to the nonlinear crystal simultaneously and generate the multi entangled photon pairs. We demonstrated 2-, 3- and 4-dimensional two-photon path-entanglement with different phases coded by the meta-lenses. It is significant progress for the quantum light source and quantum applications such as optical quantum computation, quantum communication, and quantum cryptography. We have developed optical meta-devices for beam deflection and reflection, polarization control and analysis, holography, second-harmonic generation, laser, tunability, imaging, color display, focusing of light, multiplex color routing, light-field sensing, and high-dimensional optical quantum source. The meta-devices will come into our real-life very quickly because novel advantages of meta-devices are their novel properties, customizable, small size, lightweight, high efficiency, better performance, broadband operation, lower energy consumption, and Semiconductor process compatibility for mass production.

9:30 PM *EQ08.10.02
Metamaterial Systems Manifesting Non-Abelian Topology Che-Ting Chan; Hong Kong Univ of S&T, Hong Kong

In recent years, topological phases protected by various symmetries have been extensively studied. Most topological systems that have been studied to date, including topological metamaterials, can be described using topological invariants that are integers. Very recently, the notion of non-Abelian topological

charges have been suggested to describe the properties of PT symmetric systems carrying three or more bands. Different from the Abelian topological viewpoint which is focused on a single band or band gap, these non-Abelian charges involve the simultaneous description of two more bulk bands and support non-trivial edge states that inherit the non-Abelian topological features. Furthermore, a system with an even or odd number of bands will exhibit noticable differences in topological charge classifications. We designed parity and time-reversal (PT) symmetric models with 3 or 4 gapped bands as prototypical examples and we used transmission line networks to realize and characterize such systems experimentally. For the 3-band system, the non-Abelian topological charges belong to the quaternion group Q8 that describes the frame rotation of the eigenstate triad. We experimentally observed and characterized the eigenstate-frame rotation for various elements in the quaternion group. In addition, we proposed a non-Abelian quotient relation that predicts the distribution of edge/domain-wall states. For the 4-band system, the non-Abelian charges belong to the generalized quaternion group Q16, in which two new classes of topological charges emerge as well as edge states being special to the even-band systems. These non-Abelian charges are also experimentally observed through the 4D rotations of the eigenstate-frame. The corresponding edge/domain-wall states can also be described using the non-Abelian quotient relation. Being special to the even-band systems, we can obtain the domain-wall charge -1 without the assumption of the basepoint. Our prototypical systems offer a platform for the characterization and manipulation of non-Abelian topological charges, which may lead to interesting observables such as trajectory-dependent Dirac/Weyl node collisions in two-dimensional systems and various admissible nodal line configurations in three dimensions.

10:00 PM *EQ08.10.03
Manipulating Quantum Interference with Lossy Bianisotropic Metasurfaces Hong Liang[1], Tsz Kit Yung[1], Kai Ming Lau[1], Jiawei Xi[1], Wai Chun Wong[1], Shengwang Du[2], Wing Yim Tam[1] and Jensen Li[1]; [1]Hong Kong University of Science and Technology, China; [2]The University of Texas at Dallas, United States

Metasurfaces can lead to promising usage in quantum optics based on their freedom in wavefront control by engineering meta-atom's structures and resonances. Here, we numerically investigate how quantum interference can be controlled by using bianisotropic or inhomogeneous metasurfaces based on the Lindblad master equation formulation. By considering a bianisotropic metasurface with material loss from metal, we numerically demonstrate an asymmetric control of quantum interference with an origin from an exceptional point of the metasurface in the classical regime. We will also discuss possible experimental demonstration on measuring two photon coincidence by focusing the light using the same metasurface on a single photon avalanche diode (SPAD) camera.

Novel Magnetic Nanostructures on Flexible Glass Guinevere Strack[1,2], Yassine AitElAoud[3], Richard M. Osgood[3] and Alkim Akyurtlu[1,2]; [1]Printed Electronics Research Collaborative (PERC), United States; [2]University of Massachusetts Lowell, United States; [3]Optical and Electromagnetic Materials Team, US Army Combat Capabilities Development Command Soldier Center (DEVCOM Soldier Center), United States

Control over nanostructure fabrication on flexible substrates, in particular, 2D arrays and patterns, has been explored using traditional techniques such as e-beam lithography; however, the need for scalable fabrication strategies has resulted in a range of approaches, including nanoimprinting and nanosphere lithography. These techniques involve stamping a pattern into a polymer or assembling micro or nano polymer spheres to serve as a template or mask. In our previous work, we explored a range of approaches to fabricate ordered magnetic nanoparticle arrays on rigid or flexible substrates using nanosphere lithography.[1] One of the aforementioned fabrication methods relies on templating and thermal decomposition. The technique employs self-assembled polystyrene spheres, which serves as the template. A thin layer of metal is deposited onto the spheres and then the metal-coated polymeric pattern is subjected to temperatures high enough to degrade the polymer template and leave behind a metallic nanostructure. The resultant structure depends on several materials properties and process parameters, including the melting temperature and thickness of the metal, the substrate material, the size of the polymer template, and the heating parameters, such as the ramp time and the holding temperature. Using this method, we have fabricated Au, Au–Co, and Co metallic nanoparticle arrays on Si wafer and flexible glass substrates.[2] In addition, novel nanostructured films have been fabricated using thin layers of Ni and Co, including hollow hemispheres, and a structure with nanometric brain-type folding.

For the thermal degradation approach, we also applied intense pulsed light (IPL) to the metal-coated polymeric patterns to induce rapid heating on a millisecond time scale. The high energy density of the applied IPL causes the metal layer to heat enough to degrade or partially degrade the polymer template. The remaining structure is a pattern based on the original shape of the polymer template.[3] The nanostructure shape and pattern depend on materials properties and process parameters, including the substrate material and the thickness and type of the metal film. Given that the application of IPL causes local heating, low temperature substrates—such as thermoplastics, textiles, and paper—can be used.

One of the substrates used in both fabrication approaches is flexible glass. This substrate is suitable for optical characterization using a Vis-NIR spectrometer with integrating sphere. Understanding the unique optical properties of each metasurface can enable novel applications, such as flexible plasmonic materials and reconfigurable magnetic materials.

Accelerating the Design of Photonic Metamaterials by Deep Learning Yongmin Liu; Northeastern University, United States

Over the past decades, we have witnessed tremendous progress and success of photonic metamaterials. By tailoring the geometry of the building blocks of metamaterials and engineering their spatial distribution, we can control the amplitude, polarization state, phase and trajectory of light in an almost arbitrary

manner. However, the conventional physics- or rule-based approaches are insufficient for designing multi-functional and multi-dimensional metamaterials, since the degrees of freedom in the design space become extremely large. Deep learning, a subset of machine learning that learns multilevel abstraction of data using hierarchically structured layers, could potentially accelerate the development of complex metamaterials and other photonic structures with high efficiency, accuracy and fidelity.

In this talk, I will present our recent works that employ advanced deep learning techniques to design and evaluate distinct photonic metamaterials, including 2D and 3D metamaterials that exhibit pronounced chiral or anisotropic responses [**ACS Nano** 12, 6326 (2018); **Advanced Materials** 31, 1901111 (2019)]. Our results show that deep learning, as a data-driven approach, can help to unveil the highly nonintuitive and nonlinear structure-property relationship in metamaterials. The developed deep learning models, after training, can evaluate the optical responses of metamaterials and inversely design them in less than seconds. Moreover, the model capacity can be substantially strengthened in use as we add more information into the database. This feature is fundamentally different from conventional approaches, in which almost every new design has a raw start, without contributions from prior experiences. Deep learning and other artificial intelligence techniques are currently transforming the areas of optical design, integration and measurement. More exciting advancements are anticipated as researchers with different background collectively contribute to this emerging field where photonics and artificial intelligence merge [**Nature Photonics** 15, 77 (2021)].

Inverse Design of Spectrally Sensitive Multiband Absorbers Using Pruned Neural Networks Sunae So and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

Recent advances in deep learning have enabled novel inverse design in the field of nanophotonics [1] by providing a new paradigm for discovering and extracting data representation. These design methods using deep learning have been proven to be particularly efficient in the task of designing multiple structures. Meanwhile, although large deep learning networks are generally known to perform better on a variety of tasks, practical applications require intensive networks that are small in size but perform well. Here, we report an inverse design of spectrally sensitive multiband absorbers using pruned neural networks (NNs) [2]. A five layered metal-insulator-metal structure with top grating structure is proposed and its structural parameters are designed by NNs. To achieve spectrally sensitive designs, additional spectral information of resonant wavelength is provided as well as reflection spectrum. The trained NNs have provided highly robust inverse design results, showing an average spectral error of 0.023. In particular, deep learning design results for several incrementally changing inputs not only demonstrate extremely high design efficiency but also show that deep learning has learned physics from the data. Finally, we discuss a network pruning method that reduces the size of the trained deep learning network with minimal performance degradation. The proposed pruning method leverages the observation of the trained network to guide its pruning, which is expected to significantly reduce the computational cost associated with network reduction.

8:45 AM EQ08.11.03
Embedding Statistical Machine Learning Model in End-to-End Design Loops for Multifunctional Metasurfaces Yihao Xu[1], Wei Ma[2], Bo Xiong[3], Lin Deng[1], Ruwen Peng[3] and Yongmin Liu[1]; [1]Northeastern University, United States; [2]Zhejiang University, China; [3]Nanjing University, China

Supported by precisely designed nanostructures, metasurfaces provide an unprecedented means to control light on a completely planar platform. The advantage lies in their versatility and independent optical responses under varied illumination conditions. Conventional design methods for multifunctional metasurfaces usually follow a two-step, top-down process: First, the design goals are decoupled to obtain the phase requirements for each illumination condition. Then, the metasurfaces are assembled by multiplexing single-responsive meta-atoms or assembling multiple phase-tunning mechanisms such as geometric phase and resonant phase. This empirical intervention in the design process impedes the increase in functional complexity and becomes impractical as the number of design goals increases.

In this work, we propose to apply machine learning algorithms to capture the statistical features in the high-dimensional joint distribution of meta-atom design parameters and the corresponding optical responses, promoting a quantitative estimation of the strength of crosstalk between functions. With the help of the estimation, we improve the design capabilities under certain meta-atom design frameworks. Moreover, the developed machine learning model can be seamlessly embedded in the gradient-based and non-gradient optimization process to form an automatic end-to-end design loop of multifunctional metasurfaces. With the easy-to-manufacture single-layer structure, we have experimentally demonstrated metasurface focusing lenses and holograms working in eight controllable channels in the near-infrared region, where each channel is different combinations of incident frequency and polarization.

Our results show that the data-driven photonic design scheme has superior capabilities compared to traditional physical-guided methods, which will accelerate the development of unprecedented devices and systems for optical display, communication, and computing.

9:00 AM EQ08.11.04
Discovery and Insights into Organized Spontaneous Emulsification via Interfacial Self-Assembly of Amphiphilic Bottlebrush Block Copolymers Xi Chen; Tianjin Key Laboratory of Composite and Functional Materials, China

Since the first discovery of spontaneous emulsification, the process has remained uncontrollable for centuries leading to unstable emulsion droplets with limited uses. Herein, it was found by in-situ observation that uniform water-in-oil (W/O) nano-emulsion droplets can be spontaneously formed and self-organized during solvent evaporation. Amphiphilic bottlebrush block copolymers are strongly adsorbed at the water/oil interface to stabilize the droplets, and their rod-like molecular conformation enables the well-control of droplet spherical curvature. After solvent removal, solidified thin films or microparticles with hexagonal closest packed nanopore arrays are produced in one-step templated by the ordered W/O emulsions. Pore diameter is precisely tunable in a wide range via changing spherical curvature of the water droplets dependent on degree of polymerization of the BBCP. The well-ordered porous structures give rise to full-spectrum structural colors. This work provides a general method for scalable production of well-ordered porous materials with greatly reduced energy consumption.

9:15 AM EQ08.11.05
Disordered Nanoparticle-Based Etalon for Fast Gas-Reactive Structural Colors and Sensor Application Jaehyuck Jang, Junsuk Rho and Chunghwan Jung; Pohang University of Science and Technology, Korea (the Republic of)

Etalon, a cavity made from two parallel reflecting surfaces, allows light at resonant frequencies to pass through. The representative form of the etalon is the geometry of dielectric layers sandwiched by thin upper and lower metal slabs. However, the resonant frequency determined by effective optical path length between two reflecting surfaces is fixed once the device is fabricated. Accordingly, several attempts have been made to tune resonant features by replacing

the dielectric layer with phase change materials, phase transition metals (e.g. magnesium through hydrogenation), and gel-type polymer. Chitosan, one of the biopolymers derived from Chitin, has great capability to absorb water molecules from surroundings. Therefore, the metal-chitosan-metal etalon has shown a tunable resonant feature with respect to humidity environment, and proves the potential toward the humidity sensor [1]. However, the response time is rather slow (~ 1500 s) since the metal upper layer inevitably hinders the penetration of gas molecules into the chitosan polymer network.
In this study, we would like to introduce disordered nanoparticle-based etalon structure for fast change of optical response (*i.e.* spectrum) and its application toward colorimetric sensors [2]. The gas-response time gets dramatically faster (~ 0.1s) because the disordered metal nanoparticles (MNP) forms membrane pores smaller than the mean free path of penetrating gas, known as Knudsen diffusion. The distance between adjacent MNPs acting as pores is an important factor to determine the response time of the device. Since the inter-distance is determined by the type of ligands attached to the MNP, we compare three types of samples in terms of temporal and spectral features: MNPs with Oleylamine ligand, MNPs with Thiocyanate ligand, and metallic film as the top layer on chitosan-(bottom reflector)-substrate. The entire geometry such as the radius of MNPs, type of ligand, and thickness of each layer is further optimized for the faster response time and sharper resonance features. This disordered nanoparticle-based etalon is next applied to reflective type tunable structural colors. In addition, we demonstrated an image sticker that changes the displayed image in response to external humidity, thus successfully showing the potential toward sensor and anti-counterfeiting application.

Late News: Bound State in the Continuum in Slab Waveguide Enables Low-Threshold Quantum-Dot Lasing Mengfei Wu[1,2], Lu Ding[1], Randy Sabatini[2], Laxmi Kishore Sagar[2], Golam Bappi[2], Ramon Paniagua Dominguez[1], Edward H. Sargent[2] and Arseniy Kuznetsov[1]; [1]Institute of Materials Research and Engineering, A*STAR, Singapore; [2]University of Toronto, Canada

Colloidal quantum dots (CQDs) are a promising gain material for solution-processed, wavelength-tunable lasers, with potential application in displays, communications, and biomedical devices. In this work, a ~ 300 nm-thick film of CQDs engineered for high optical gain is coated over an array of titanium dioxide (TiO_2) cylinders. The structure supports slab waveguide modes which, when coupled to the periodic array, give rise to symmetry-protected bound states in the continuum (BICs). The BICs have minimal radiation loss in the normal direction and thus possess extremely high quality factors. In particular, the BIC arising from a 2nd-order TE-polarized waveguide mode has a good spatial overlap with the gain medium, allowing us to achieve room-temperature CQD lasing with a low threshold of approximately 11 kW/cm^2 (peak intensity) under nanosecond optical pumping. Our work highlights that BICs are effective, surface-emitting lasing modes that allow versatile device structures to achieve low lasing thresholds.

Ultrasensitive and Selective Gas Molecule Detection Using Vertically Oriented Metamaterial Absorber Takuo Tanaka[1,1,2]; [1]RIKEN, Japan; [2]Tokushima University, Japan

High-sensitive measuring or detecting techniques for biological and chemical components becomes imperative in our daily lives. Among the wide range of techniques, vibration spectroscopy, including infrared (IR) absorption spectroscopy and Raman scattering spectroscopy, is one of the most promising analysis methods due to its intrinsic label-free and noninvasive detection characteristics. But the weak signals caused by the inherently low absorption or scattering of the natural substance severely limits its practical applications. Recently, localized surface plasmon resonance in nanometer-scale metal structures has been shown to produce an enhanced electromagnetic field, and metamaterial-based plasmonic nanostructure using plasmonic−molecular coupling was proposed and high molecular sensitivity was realized [1-4]. However, this high sensitivity was realized only when analyte molecules are located in the vicinity of the localized plasmonic enhanced field (hot spot region); thus, introducing target molecules into the hot spot region to maximize plasmonic−molecular coupling is crucial to developing the sensing technology. To answer this requirement, we designed a metamaterial consisting of a vertically oriented metal-insulator-metal (MIM) structure with a 25 nm channel sandwiched between two metal films, which enables the delivery of molecules into the hot spot regions, offering an ultrasensitive platform for molecular sensing [5]. This metamaterial was applied to carbon dioxide and butane detection. We designed the structure to exhibit resonances at 4033 and 2945 cm^{-1}, which overlap with the C=O and −CH_2 vibration modes, respectively. The mutual coupling of these two resonant modes creates a Fano resonance, and their distinct peaks are clearly observed in the corresponding transmission dips. In addition, owing to its small footprint, such a vertically-oriented MIM structure enables us to increase the integration density and allows the detection of a 20 ppm concentration with suppressed background and high selectivity in the mid-infrared region.

Metamaterial Absorber for Intensifying Thermal Gradient Across Thermoelectric Device Wakana Kubo; Tokyo University of Agriculture and Technology, Japan

Thermoelectric conversion is a technology based on direct conversion of heat energy into electricity; it is expected to be a promising tool for recovering waste heat for energy saving and more efficient fuel usage [1]. Since a thermal gradient across a thermoelectric device induces a potential difference between the hot and cold sides of the device, technology that increases the thermal gradients is the key for efficient power generation. Several attempts have been made to expand the thermal gradient across thermoelectric devices. Vertical geometric configuration of the thermoelectric bismuth telluride (Bi_2Te_3) device to the surface of a heater is a promising technology to enlarge the thermal gradient across the device. Nevertheless, power generation efficiencies of Bi_2Te_3 based thermoelectric devices remain at ~10%, indicating that further improvements in power generation efficiency are required. Hence, development of novel thermoelectric materials and concepts for improving the thermal gradient are necessary for extending the practical

applications of thermoelectric devices.

To increase the thermal gradient across a thermoelectric device, we utilized the localized surface plasmon resonance as the heat source [2, 3], and proposed the attachment of a metamaterial perfect absorber (MPA) on the surface of a Bi_2Te_3thermoelectric device to realize a thermoelectric device than can generate electricity under homogeneous temperature environment [4].

In this report, we demonstrated a metamateria-Bi_2Te_3 thermoelectric genearation that can enlarge thermal gradient across a thermoelectric device. We observed an enhancement in output voltages triggered by MPA thermal radiation absorption.

Directed Self-Assembly of Polymer Grafted Nanocrystal for Ordered 2D Superlattices Boyce Chang[1], Priscilla Pieters[2], Eric Dailing[1], A. Paul Alivisatos[2], Yi Liu[1] and Ricardo Ruiz[1]; [1]Lawrence Berkeley National Lab, United States; [2]University of California, Berkeley, United States

Nanocrystals have received tremendous attention arising from potential applications as metamaterials, plasmonics and semiconductor devices. A key factor in the development of nanocrystal-based devices is the ability to control assembly in a scalable manner. Despite impressive progress in this area, the majority of work have focused on kinetically driven processes such as solvent drying and liquid interfaces, which are undesirable for large scale fabrication. Replacing small molecule ligands with polymer grafts significantly improves processibility, creating particles that resemble star polymers. This allows access to thermodynamically stable structures and create a larger variety of design handles including molecular weight, chain architecture and grafting density. More importantly, the polymeric behavior opens the opportunity for techniques such as solvent vapor annealing and directed self-assembly to induce thermodynamically stable superlattice configurations of polymer grafted nanocrystals (PGNC), dramatically improving their development into potentially scalable devices. Herein, we explore methods to direct the assembly of PGNC 2D superlattices using pre-patterned substrates. A similar process flow utilized in directed self-assembly of block copolymers was implemented to generate lithographically defined patterns. We successfully demonstrate long-range orientational order of PGNCs using periodic stripes. The effects of surface topography, chemistry and PGNC architecture on the quality of the superlattice were investigated. This work serves as a guide to achieving 2D orientational order in PGNCs.

7:30 PM EQ08.04.05
VO_2 Based Dielectric Metasurfaces and Metamaterials for Reconfigurable Optical Systems Applications Jimmy John[1], Aditya Tripathi[2], Sergey Kruk[2], Yael Gutierrez[3], Helmut Karl[4], Fernando Moreno[5], Yuri Kivshar[2], Shriram Ramanathan[6], Zhen Zhang[6], Hai Son Nguyen[1], Lotfi Berguiga[1], Pedro Rojo-romeo[1], Régis Orobtchouk[1] and Sébastien Cueff[1]; [1]Université de Lyon, France; [2]The Australian National University, Australia; [3]University Campus Ecotekne, Italy; [4]Universität Augsburg, Germany; [5]Universidad de Cantabria, Spain; [6]Purdue University, United States

Metasurfaces and metamaterials have been at the forefront of optical progress in terms of applications over the past decades. With the growth of the telecommunications sector and quantum advances have propelled the requirement for compact, energy efficient and reconfigurable nanophotonic components in an optical system. All-dielectric meta-photonics research, in search for these ideal characteristics is reaching maturity, as optical devices based on dielectric metasurfaces are currently outperforming their conventional counterparts[1]. However, the design and fabrication of efficient, switchable, and reconfigurable metamaterial-based components or meta-devices for practical applications[2] are still in their infancy and remain largely unexplored.

Since most metamaterial-based devices are functionally locked once fabricated, subsequent progress in the search for reconfigurable and switchable nanophotonic components has seen the increasing use of phase change materials, thanks to their stable switchable phases with different refractive indices. This makes them an attractive choice for various applications such as beam steering[3], memory devices[4,5], electro-optical modulation[6], neuromorphic computing[7], metasurfaces and metamaterials[8, 9].
Among all PCMs, vanadium dioxide (VO_2) is a prototypical example of functional materials exhibiting large changes in physical properties upon specific external excitation. Its easily controllable transition (optically, electrically or thermally at near-room temperatures) and the exceptionally large change in optical properties upon its insulator-to-metal transition (IMT) open interesting possibilities for dynamically tunable optical systems. Above all, change of its atomic structure during IMT is crystalline to crystalline in nature allowing the possibility of repeatability in the design of nanophotonic devices without the creation of defects.
Here, we demonstrate two different platforms and strategies to create highly tunable VO_2-based building blocks for a multi-application metamaterial based optical system.

Our first strategy is based on VO_2 nanocrystals (NCs) embedded in SiO_2, in which we show that the multipolar resonances supported by VO_2 NCs can be actively tuned through its insulator-to-metal transition (IMT) and tailored based on its size. By combining Mie theory and Maxwell-Garnett effective medium theory we retrieve the complex refractive index of the effective medium containing VO_2 NCs in SiO_2. Through this, we show that the resulting NC metamaterial exhibits distinct tunability compared to the unstructured VO_2 thin film. In addition, we also show the possibility of designing these composite NCs in order to achieve refractive index variation with almost no variation in its extinction coefficient during its transition, in other words zero induced extinction value. This property is predominantly important for designing reconfigurable optical system with minimal losses.

Our second strategy is based on embedding a layer of VO_2 coupled to a dielectric metasurface consisting of silicon resonators. We demonstrate designing and fabrication strategy and characterize the resulting metasurface that is designed to support both electrical and magnetic Mie resonances. The interaction between these resonances and the incident light can be tuned depending upon the transition state of the VO_2, and we show, first, 2 orders of magnitude modulation in metasurface transmission and second, a spectral modulation of near-perfect absorption. These spectral and magnitude modulations are accompanied by hysteresis-like behaviour that can be exploited for versatile memory effects and can find their application in optical communication, memory devices, detectors and sensors.

Surface Modification and Functionalization of Biomaterials by Plasma and Related Technology Paul K. Chu; City University of Hong Kong, Hong Kong

The interactions between biomaterials and biological tissues and body fluids depend on the surface properties of the biomaterials and biological interactions and response. However, many types of current biomaterials with favorable bulk characteristics cannot produce the desirable biological and biochemical effects and surface modification is one of the effective ways to alter selectively the surface properties of biomaterials and biomedical implants. By means of plasma surface modification, predesigned surface properties such as biocompatibility and bacterial resistance can be endowed and at the same time, the inherent bulk properties such as mechanical strength can be maintained. Our research group has been conducting research on plasma immersion ion implantation and deposition (PIII&D) for more than 20 years. It is a non-line-of-sight technique and especially suitable for biomaterials and biomedical implants with a complex shape. Moreover, since the interface between biodegradable biomaterials and tissues and body fluids is dynamic, PIII&D offers the unique capability to optimize the interfacial physics and chemistry to achieve controlled and timely degradation and drug release. In this invited presentation, recent research activities in the Plasma Laboratory of City University of Hong Kong pertaining to surface treatment of biomaterials and biomedical devices, especially biodegradable and antibacterial materials, will be described.

Surface Functionalization of Polymeric Surgical Meshes with Antibacterial Properties by Atmospherics Plasma Surface Modification and Silver Nanoparticles Immobilization Amin Zareei, Allison Thornton, Ulisses Heredia, Venkat Kasi and Rahim Rahimi; Purdue University, United States

Inguinal hernia occurs when an intestinal abdominal organ mostly part of small intestine protrudes into the inguinal canal through a weak spot in the abdominal muscles. Such weak spot results in the inner lining of the abdomen to pushes through the weakened area to form a balloon like sac. Up to date identified associated causes for inguinal hernia include increased pressure on the abdomen, pregnancy, obesity, heavy lifting and continuous coughing and sneezing. Recent data has shown that in the US, at least 10% of the population experiences some type of hernia that requires at least one million of abdominal hernia repair surgery each year. The hernia is repaired by an incision through the skin and then covered with a piece of surgical mesh. The most common material for such surgical meshes used in the US is polypropylene due to inert chemical property, light weight and mechanical strength that could withstand up to 170 mmHg of abdominal pressure. However, the main drawback with such polypropylene meshes (PoM) is bacteria growth induced infection after implanting the mesh in the body within the textile woven structure of the PoM. Such infection is mainly due to uneven topography of the mesh structure and is responsible for up to seven percent of post-operational complications that result in significant health risks and costs for prolonged patient treatment. Therefore, to address this issue, we have developed an innovative two-step process for fabrication of an antibacterial PoM via atmospheric plasma surface modification and functionalization and laser immobilization. First, the surface of the mesh was coated with 50 nm thick organosilicon by atmospheric plasma deposition system to enhance the hydrophilicity of the mesh surface and as a receptor layer for silver nanoparticles (AgNPs). Next, a thin layer of < 1µm AgNPs in the form of low viscosity ink was printed on the plasma deposited mesh via inkjet printing as an antibacterial agent. And then, non-destructive laser treatment technique was employed to selectively immobilize the deposited AgNPs onto the mesh. Such technique enables selective delivery of the laser thermal energy to the printed AgNP ink and fuse the particles together whereas the PoM is transparent to

the laser wavelength and would not get damaged under laser beam irradiation. In addition, such fusion enhances sustained antibacterial properties of the mesh by delaying the release of the AgNPs immobilized layer from the PoM when implanted. A systematic study was performed against *Staphylococcus aureus* and *Escherichia coli* to assess the antimicrobial properties of the AgNPs immobilized PoM. Moreover, thermal, optical and mechanical characterizations evidenced no significant effect of plasma surface modification and functionalization and laser AgNPs immobilization on microstructure of the PoM.

Combact Corona Virus with with Corona Discharge—Mask and Surface Disinfection Ying Zhong, Sriram Sundar Shankara Narayanan, Libin Ye and Zijian Weng; University of South Florida, United States

Because of the COVID-19 pandemic, there is need to urgently advance a safe, sustainable, and highly efficient disinfection technologies to treat face masks and various surfaces that are regularly exposed to public use. The demand of masks is challenging especially for the societies in less-developed areas across the world. Billions of used masks are threatening the environment as a new source of plastic pollution. Creating a safe and reliable method for mask reuse would help alleviate the situation. To this extent we developed a corona discharge (CD) based disinfection method to efficiently disinfect and recharge face masks simultaneously. Electric field, ions and reactive species generated by CD are the key components causing DNA damage and protein denaturation to effectively disinfect the 1.8 mm thick, dielectric, porous N95 masks. Up to 99.99% reduction in E. coli can be easily achieved under 10 mins, consuming only 1.25 W of power. This makes it ideal for affordable and portable disinfection and reuse applications. Further, up to 99.99999% reduction can be achieved after 3 cycles of treatment with optimized parameters. Most importantly, CD can simultaneously restore electrostatic charges on the mask surface to prevent filtration efficiency deterioration. It also provides an efficient disinfection solution for shared surfaces, confined spaces, and possibly open air reduce application of disinfectants and to mitigate the spread of COVID-19. We are also developing a corona discharge (CD) based disinfection robot with for the purpose of automatic and non-contact disinfection. The advance of CD disinfection will help us get better prepared for future pandemics.

SESSION EQ09.02: Plasmas for Catalysis and Energy

Non Thermal Plasma Catalysis for Emission Control and Clean Hydrogen Production Chris Hardacre; University of Manchester, United Kingdom

Hybrid non-thermal plasma catalysis has a significant potential to provide a low energy pathway to activate molecules and catalysts to enable processes to operate at lower temperatures than would occur if activated thermally. This talk will show how plasma activation can be utilised to promote the gas phase reactions for emsission control and clean hydrogen production. The mechanism of the reactions determined by kinetic analysis and in-situ diffuse reflectance infra-red Fourier transform spectroscopy (DRIFTS) will be shown and how this differs from the thermally activated reactions. A new cell was developed to enable the DRIFTS measurements to be performed in the presence of the plasma. A range of catalysts have been examined including the use of metal organic frameworks which show high levels of stability under plasma activation which opens up the possibility of using them as heterogeneous catalysts in the gas phase which is challenging under normal operating conditions in many cases.

Cold Atmospheric Plasma Deposition of Functional Conductive Polymers Ulisses Heredia, Venkat Kasi and Rahim Rahimi; Purdue University, United States

Conductive polymers such as polypyrrole (PPy), polyaniline (PANI) and poly(3,4-ethylenedioxythiophene) (PEDOT) are extensively used as sensing materials and conductive electrodes in printed and flexible sensors. As sensing materials, conductive polymers provide an electrical response to changes in temperature, gas concentration, humidity and/or radiation exposure that easily couple to simple electronics to achieve real-time detection and wireless readings. Typical synthetic methods for the fabrication of conductive polymer films are complex chemical processes that involve several steps of processing and the use of toxic solvents such as sulfuric acid, N-methylpyrrolidinone, and acetonitrile. Conductive polymers prepared via these methods are required to be in the form of suspended solutions which eventually need to be deposited onto desired substrates through either printing or additive manufacturing process. In addition, the films produced by these methods often exhibit inferior properties due to challenges associated with solvent-substrate incompatibility, poor film adhesion, remnant of toxic solvents in the films and long drying times. In order to address such drawbacks an effective approach is to deposit such functional conductive polymers directly onto the targeted substrates of interest.

Recently, cold atmospheric plasma chemical vapor deposition (CAP-CVD) has become an attractive approach to synthesize and deposit different organic and inorganic functional materials directly onto the desired substrate in atmospheric conditions. In CAP-CVD, conductive polymers are synthesized by plasma polymerization where the precursor of interest is introduced into the plasma stream and polymerized on the substrate by the action of the reactive species present in the plasma glow. Thus, post processing operations like solvent drying or sintering are eliminated. The resultant conductive polymer films can act as active layers to produce printed gas and radiation sensors with high quality, good adhesion, and intrinsic conductivity. Moreover, since this process deposits high quality films at high production rates, it is highly compatible with roll-to-roll manufacturing techniques to produce low cost printed sensors.

As proof of concept, a systematic study on different plasma processing conditions including power, an ionizing gas mix composed of oxygen and argon, and introduction of oxidants such as bromine was carried out on the CAP-CVD polymerization of PANI, PPy and PEDOT. In this work we present our investigation on the optimum processing conditions to deposit high quality conductive polymer films by CAP-CVD as well as the characterization of plasma conductive polymers by using Raman Spectroscopy, ATR-FTIR, TGA and SEM techniques.

Pulsing as an Effective Strategy for the Reduction of the Energy Cost for the Non-Thermal Plasma Synthesis of Ammonia Minseok Kim, Giorgio Nava, Sharma S. Yamijala, Bryan Wong and Lorenzo Mangolini; University of California, Riverside, United States

Ammonia synthesis from N_2 and H_2 through non-thermal plasmas has recently attracted great attention as an alternative to standard ammonia production methods, such as the Haber-Bosch process (HB process). Production of ammonia through the HB process has made a significant positive contribution via

production of fertilizers directly linked to the high crop yields. However, the environmental problems associated with the HB process threatens the sustainable future of mankind with massive anthropogenic emissions, estimated at over 300 million metric tons of CO_2 annually [1]. Non-thermal plasmas could significantly reduce ammonia production associated greenhouse gas emissions as plasma-based reactors can be operated entirely by renewable energy resources. The synergistic effects between catalytic materials and plasmas in particular are being widely investigated to improve the yield and energy cost in plasma-driven ammonia production. One bottleneck in this effort is the lack of a microscopic-level understanding of the interaction between the low-temperature plasma and various materials. In this work, a non-thermal plasma was pulsed with different frequencies, respective to plasma residence time, in order to investigate effects on ammonia yield and related energy costs. The measurements were performed on an RF-driven plasma system including a quartz cylindrical plasma reactor whose diameter was 1", power supply, and matching network. The reaction products were sampled downstream of the reaction zone through a 50 μm orifice into a Residual Gas Analyzer (RGA). We observed a weak dependence of ammonia yield on various metallic catalysts [2]. This is consistent with a reaction mechanism that is initiated by the interaction between plasma-produced atomic nitrogen and the hydrogen terminated surface, via an abstraction mechanism. This pathway is consistent with the results from Born-Oppenheimer Molecular Dynamics (BOMD) simulation, which suggest that the direct surface abstraction pathway is fast and proceeds with near 100% probability. We have also investigated approaches to reduce the energy cost of this process and found that plasma pulsing is an effective strategy to achieve that. Measurements on energy cost was conducted at 60 W with various fraction of nitrogen flow rate per total flow rate (5%~90%). Based on the geometry of stainless-steel cone mesh utilized as a catalytic material, the residence time in the plasma reaction zone is around 40 msec. By decreasing the plasma on-time to 2 msec, it was possible to decrease the energy cost by roughly a factor of four, compared to the continuous plasma-on case. We interpret this measurement according to the following mechanism: plasma-produced atomic nitrogen diffuses to the catalyst surface on a time scale of one millisecond and it is quickly converted to ammonia, but the plasma is then rapidly extinguished to prevent it from dissociating the ammonia as it diffuses back into the reactor volume. In other words, pulsing utilized the electrical power input more efficiently as it is not used to re-dissociate the desired reaction product.

Understanding the Cold Plasma Synthesis of Ammonia with Model Catalysts Sophia Gershman[1], Henry Fetsch[1], Fnu Gorky[2] and Maria Carreon[3]; [1]Princeton Plasma Physics Laboratory, United States; [2]South Dakota School of Mines & Technology, United States; [3]University of Massachusetts Lowell, United States

Ammonia is essential for food security due to its use in fertilizers. Currently, ammonia synthesis at industrial scale proceeds via Haber-Bosch (HB) process typically at ~500 C and 500 bar, which is the most energy-consuming process in the chemical industry. Global ammonia production (~249.4 million tons) consumes ~1-2% of the world's energy, 2-3% of the world's natural gas output, and emits over 300 million metric tons of CO_2. With such energy requirements, the HB process is only economically viable at large-scale plants running continuously. Consequently, ammonia synthesis is currently centralized, hampering the access to affordable fertilizers in remote areas . The development of simplified alternatives to HB at milder conditions and compatible with intermittent electric power (e.g. from renewable energy sources) is a critical step toward small-scale, decentralized ammonia production. During the past decade plasma catalytic ammonia synthesis has been driven by the cost-effective implementation of solar and wind sources, that would also reduce the carbon footprint of the process. The possible implementation of non-thermal plasma technology will be only feasible if there is an effective plasma catalytic system in terms of material selection and reactor design. However, to-date there is no fundamental basis for the rational selection of catalytic materials suitable for plasma systems. Selection of catalysts based on fundamental principles would help in developing new materials and further understanding the synergies in plasma catalytic processes.
One of our central hypotheses is that an optimal catalyst for plasma-assisted ammonia synthesis is one that delays the recombination of *adsorbed* hydrogen radicals (H*) into molecular hydrogen (H_2), allowing them to bind instead to the *adsorbed* nitrogen plasma activated species ($N^{activated}$) to form NH*. We postulated that a delay in recombination of hydrogen radicals can be achieved with catalysts that dissolve hydrogen more easily. Therefore, our interest in oxides stems from the possibility of facilitating hydrogen dissolution at mild reaction conditions. Moreover, oxides may promote NH* formation (an essential step in ammonia synthesis) by not binding strongly with nitrogen. An illustrative example is silica, where the N_2 adsorption obeys a peculiar mechanism governed by short-ranged forces.
Oxides, such as silica, are appealing materials for ammonia synthesis due to their: 1) lower electrical resistivity that can lead to more stable and uniform plasma discharges, a challenge in atmospheric plasmas; 2) readiness to dissolve hydrogen; 3) weakly bonding with nitrogen; 4) high chemical stability in the presence of water and some hydrocarbons, which are typical impurities in natural gas wells (hydrogen for ammonia production is typically obtained from steam reforming of methane), and 5) the presence of a porous structure with accessible pores for guest molecules diffusion. Herein we employ mesoporous silica SBA-15 with unimodal pore size of ~ 7 nm to assess the effect of ordered mesopores with and without being Ag impregnated. Interestingly, our data confirms the dominant presence of N_2 vibrational bands and a marginal benefit in the catalytic performance when using a metal i.e., Ag in this case. At specific discharge conditions SBA-15 performs better than the Ag impregnated mesoporous silica leading to the highest ammonia production of 11,000 ppm. Plasma on/off cycles demonstrate the desorption of ammonia when the plasma was turned off. Which can lead to future optimal reaction conditions for this reactor when adapted to intermittent renewable sources. We were able to measure a vibrational excitation temperature using the optical emission of the second positive N_2 vibrational band of 0.2±0.05 eV for SBA-15 and SBA-15-Ag.

Plasma Synthesis of Nanoparticles for Applications in Plasmonics and Energetics Chris Rudnicki, Carla Berrospe Rodríguez, Giorgio Nava, Feiyu Xu, Michael R. Zachariah and Lorenzo Mangolini; University of California, Riverside, United States

The nucleation and growth of nanoparticles in low-temperature plasmas is recognized as a desirable powder synthesis technique. These systems impart a unipolar charge distribution onto particles dispersed within the ionized gas, slowing down growth via agglomeration and typically keeping the particle size well below 10 nm.[1] In addition, plasma-induced heating allows producing high quality single-crystal nanoparticles. While these properties are unique to these gas-phase processing technique, it can be argued that the full potential of low-temperature plasmas for nanoparticle synthesis and processing is still

severely underexplored. This talk will present two applications of low-temperature plasmas for nanoparticle growth that in our opinion suggest that there is significant room for growth in this field.
The first study involves the plasma synthesis of alternative plasmonic materials. Our group has recently shown that titanium and zirconium nitride nanoparticles can be obtained from low-temperature plasma reactors using the corresponding metal chlorides and ammonia as precursor couple.[2, 3] These ceramic materials have high free charge carrier density, showing plasmonic response in the visible part of the spectrum. Compared to standard plasmonic materials such as gold and silver, they are abundant, inexpensive and possess a high melting point, enabling application in high temperature environments. Example of the application of plasma-produce nitride particle for photochemistry and for wavelength-selective thermal emitters will be discussed in details.[4, 5]
The second case to be discussed is centered on the use of low-temperature plasma not to produce high-quality crystalline particles, but rather for the production of amorphous nanoparticles. Simple tuning of process parameters such as plasma power allows producing silicon particles with an amorphous structure. In addition, for the case of silicon particle produced using silane as precursor, we have found that these particle are rich in hydrogen. The hydrogenated amorphous silicon particles are highly desirable for application in nanoenergetics, where they show superior performance compared to their crystalline counterpart in terms of reaction kinetics because of the rapid release of hydrogen from the nanomaterial upon ignition.

4:30 PM EQ09.03.02
Nonthermal Plasma Synthesis of Indium Nitride Nanoparticles Alexander Ho and Rebecca J. Anthony; Michigan State University, United States

Indium nitride is a direct bandgap semiconductor with a small bandgap of 0.7 eV. Properties such as high electron mobility and low electron effective mass make this material suitable for a variety of optoelectronic and electronic devices. Indium nitride can also be alloyed with gallium nitride to form a ternary compound whose bandgap can take a value from 0.7 to 3.4 eV allowing for use in applications that span from the infrared to the ultraviolet range of the spectrum. Here we present on our work to synthesize indium nitride nanoparticles. A low-pressure plasma reactor made from a glass tube was supplied with precursor gases of trimethylindium and ammonia along with a background gas of argon. A 13.56 MHz RF power supply was used to generate a nonthermal plasma in the reactor between three external cylindrical electrodes. During synthesis conditions were controlled to obtain nanoparticles with specific characteristics and properties. From image analysis of TEM data, we have been able to obtain indium nitride nanoparticles with a diameter smaller than the Bohr-exciton radius of this material. Average nanoparticle size as small as 3.6 nm with a standard deviation of 0.5 nm have been synthesized. XRD was used to characterize the crystallinity of nanoparticles, by controlling the power delivery to the plasma particle crystallinity was controlled. Primarily crystalline nanoparticles were synthesized at 75 W of forward power with a diffraction pattern consistent with hexagonal indium nitride. Surface analysis of the particles was conducted using FTIR which showed characteristic absorptions from bonds containing indium, nitrogen, oxygen, carbon, and hydrogen. Optical properties of the nanoparticles were probed with photoluminescence measurements and absorption spectroscopy.

Plasma-Enhanced Chemical Vapor Deposition to Produce Highly Energetic Core/Shell Nanostructures of Aluminum Prawal P. Agarwal and Themis Matsoukas; The Pennsylvania State University, United States

Aluminum (Al)-based nanoenergetic materials have emerged as promising propellants and fuel additives in civilian and defense-related applications due to their superior gravimetric energy density, green combustion, and abundance on the earth. The native oxide layer on the surface of Al particles provides stability during storage, but adds weight, contributes no energy, and acts as a barrier to oxidation under combustion. For particles in the nanometer range, these limitations are serious because the oxide represents a significant fraction of the total mass. Hence, there is a need to eliminate the adverse effects of oxide on the energetic performance of Al nanoparticles. In this work, we demonstrate a nonthermal plasma-enhanced chemical vapor deposition (PECVD) to prepare core/shell nanostructures of Al with significantly improved energy release. We deposit thin fluorocarbon films (CF_x) onto the surface of Al nanoparticles and study their energy release under thermochemical analysis. We suggest that the perfluoro-based plasma films can improve the overall energy released from Al nanoparticles by providing F for the reduction of Al_2O_3 via an exothermic reaction to produce AlF_3, thereby utilizing the oxide to produce energy. We accomplish this by coating Al nanoparticles with F containing film via plasma deposition of a perfluorocarbon precursor. By depositing the right amount of coating, we aim to reduce the oxide in situ. As a result of the removal of the oxide barrier, we can derive maximum chemical energy due to improved contact between oxygen and metallic Al. We prepare the Al/CF_x core/shell nanoparticles using perfluorodecalin ($C_{10}F_{18}$) as a coating precursor in PECVD for different periods ranging from 30-165 min, corresponding to film thickness from 5 to 22 nm, as measured using high-resolution transmission electron microscopy (HRTEM). The thickness of the deposited films shows a linear relationship with deposition time with a rate of 0.15 nm/min. This allows for nanometer-level control of the film thickness and precise control of the amount of F on the surface of Al. The coated samples and the uncoated control were studied by thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC) to determine the effects of plasma films on their oxidation and energy release. All coated samples show increased weight gain, directly attributable to the conversion of Al into its oxide, and higher energy release relative to the uncoated control. In particular, at 55 min of plasma deposition, we obtain ~50% increase in the amount of energy released relative to the untreated sample. The composition of the plasma films was studied using high-angle annular dark-field (HAADF)-scanning transmission electron microscopy-(STEM)-energy dispersive spectroscopy (EDS), X-ray diffraction (XRD) analysis, and X-ray photoelectron spectroscopy (XPS). The results show the uniform distribution of F on Al nanoparticles and the presence of CF3, CF2, CF, and C-C bonds on the surface. The systematic increase of the energy released with deposition time is attributed to the increased amount of F in the coating. Optimum conditions are met when the amount of F matches the amount needed to react with the oxide on the particle surface. Above the optimum thickness, the gravimetric energy decreases because the coating adds more weight than the energy it extracts. In all cases, the energy of the treated particles is higher than that of the untreated control. This increase is further explained by the mechanism of interfacial reactions triggered due to the presence of perfluoro-based plasma films on the surface. XRD analysis along with SEM and TEM micrographs are used to support the claims in the explained mechanism. Thus, we conclude that the nonthermal plasma process has great potential in improving the performance of nanoenergetic materials by converting their native surface oxide into fuel.

5:00 PM EQ09.03.04
Surface Tailored Core-Shell Aluminum Nanoparticles via Two-Step Atmospheric Plasma Surface Modification and Coating Chi-Chin Wu[1], Scott D. Walck[2], Jianguo Wen[3], Dinesh Thapa[4] and Rose Pesce-Rodriguez[1]; [1]U.S. Army Research Laboratory, United States; [2]Survice Engineering, United

States; [3]Argonne National Laboratory, United States; [4]Oak Ridge Associated Universities, United States

Core-shell metallic nanoparticles such as nano-aluminum (nAl) are sought-after potential energetic additives due to the high heat of combustion of Al and potentially faster burning rate enabled by the high surface area to volume ratio. This work describes a recent effort conducted at US Army Combat Capabilities Development Command-Army Research Laboratory to increase the reactivity of commercial nAl by a two-step atmospheric pressure plasma surface treatment and coating using custom-made dielectric barrier discharge plasma reactors. The commercial nAl particles of nominal 40-60 nm average size were first treated with a helium (He) plasma for 30 min, followed by a subsequent coating of carbonaceous materials by diluting carbon monoxide (CO) in the He plasma for different durations. The He-plasma treated nAl has thin roughened alumina shell with its thickness more than 40% less than the as-received nAl with an intact single crystalline Al core. High resolution transmission electron micrographs (HRTEM) revealed sporadic crystalline deposits on nAl surfaces and in gaps among particles and short-ordered structure in the amorphous alumina shell for all plasma-treated samples, confirmed to be γ-alumina via electron energy loss spectroscopy (EELS) at the scanning TEM (STEM) mode. All plasma-coated samples after the second step possessed dispersive thin layers of carbonaceous coating, as evident by nanoscale chemical analyses with elemental mapping and X-ray energy dispersive spectra (XEDS) at STEM mode. The coating was determined as aluminum carboxylate via Fourier transform IR spectroscopy, a product from chemical reactions of Al and carboxylic acid functional groups coated on the He-plasma modified alumina surface. This work demonstrates the preliminary success of exploiting a new approach for mitigating the inactive alumina shell and further tailoring the superficial morphology and chemical properties of core-shell commercial nAl via a two-step atmospheric pressure plasma process. The efforts also emphasizes the significance of exploiting advanced materials characterization for a deeper understanding of the resultant nanoscale surface properties for ultimate optimization of plasma conditions.

5:15 PM EQ09.03.05
Plasma Assisted Growth of Hydrophobic Silicon Nanoparticles for Oil-Water Separation Sankhadeep Basu, Gabriel Ceriotti and Rebecca J. Anthony; Michigan State University, United States

Hydrophobic nanomaterials have drawn significant attention due to their applications in coatings, protein adsorption, nanomedicines, etc. For silicon nanomaterials, researchers have generally used external agents which react with the surface terminated Si-H bonds and render the surface hydrophobic. In the present work we investigate the hydrophobic nature of as-prepared silicon nanoparticles (SiNPs) produced in a nonthermal plasma reactor. SiNPs were synthesized in a flow-through reactor using silane with argon as the background gas. The total gas flowrate was 20 standard cubic centimeters per minute (sccm) and with a reactor pressure of 1.4 Torr. The plasma as generated using radiofrequency (rf) power of 10W at 13.56MHz is delivered via ring electrodes encircling the reactor. SiNPs formed in the plasma were collected on a stainless-steel mesh filter at the reactor exhaust. Further examination under Scanning Electron Microscopy (SEM) revealed the formation of flow-through aggregated wires of around 12 microns in length and 7-8 microns in diameter, comprised of primary SiNPs. Transmission electron microscopy showed the primary particle size to be in range of 5-7 nm, but no electron diffraction rings were detected, indicating that the Si NPs were amorphous.
Contact angle measurements were performed to test the hydrophobicity of the as-prepared SiNPs. A water contact angle of 146° was observed demonstrating the near-superhydrophobic (> 150°) nature of the aggregated SiNPs. The hydrophobic material was also successful in separating both vegetable cooking oil as well as heavy-duty pump oil from oil-water mixtures. Thermal experiments were also performed to illustrate the thermal stability of the hydrophobic nature. The nanomaterial was able to retain its hydrophobicity even at 450°C after 2h of heating showing robust stability. The material was also found to be stable under ambient air conditions as water contact angle did not change significantly even after a week of synthesis. These exciting properties signify the future prospects in coatings, biotechnology and more.

SESSION EQ09.04: Poster Session

EQ09.04.01
Plasma Synthesis and Processing of Epitaxial β-FeSe/$SrTiO_3$ Heterostructures Kamron L. Kopecky[1], Adam D. Smith[1], Mphande N. Phiri[2], Sumner B. Harris[1] and Renato P. Camata[1]; [1]The University of Alabama at Birmingham, United States; [2]Alabama A&M University, United States

The combination of different materials in heterostructures often enables phenomena that are impossible to achieve in a single compound. A now-classic example is the interface-enhanced superconductivity of monolayer β-FeSe on (001)-oriented $SrTiO_3$ (STO). The observed superconducting gap in this system is substantially larger than in bulk β-FeSe due to a combination of electron doping and electron-phonon interactions at the FeSe/STO interface. Heterostructures derived from this FeSe/STO system are useful for the creation of layered quantum materials arrangements to study interface-enhanced processes, magnetic/superconducting proximity effects, and control of quantum properties via electrostatic gating. The plasma environment of pulsed laser deposition (PLD) is particularly suited for growing such heterostructures, either as stand-alone thin films on a variety of substrates or as designed multilayered and superlattice configurations. While characterizing the vacuum PLD environment in terms of the flux of depositing species, their kinetic energy, and the substrate temperature is generally considered sufficient for controlling film growth, in this work we explore how tuning more fundamental laser plasma parameters, such as the electron density and temperature, may alter the structure and interface of β-FeSe/STO heterostructures. We correlate measurements from Langmuir probe plasma diagnostics during FeSe growth with x-ray diffraction and x-ray reflectivity data from the epitaxial heterostructures obtained. Laser plasmas with electron density (n_e) below $\sim 5\times10^{19}$ m^{-3} and electron temperatures (T_e) of 0.1-0.2 eV lead to epitaxial *c*-axis oriented β-FeSe/STO with clear thickness fringes in dynamical x-ray diffraction (Pendellösung oscillations), indicating high crystal quality and sharp interface. On the other hand, plasmas with $n_e \sim 10^{20}$ m^{-3} and $T_e \approx$ 0.5-0.6 eV result in β-FeSe with a mixture of two epitaxial orientations, less defined interface, and a greater degree of mosaicity or defects. We will discuss how adjusting the laser plasma parameters may allow further control in plasma-mediated growth of β-FeSe/STO such as spatial modulation of nucleation sites, modification of island growth patterns, and activation of plasma-enhanced surface reactivity.

EQ09.04.02
The Angular Distribution of Species in Single- and Multi-Component Laser Plasmas for Materials Processing Audrey M. Collins[1], Jacob H. Paiste[1], Robert R. Arslanbekov[2] and Renato P. Camata[1]; [1]The University of Alabama at Birmingham, United States; [2]CFD Research Corporation, United States

The forward peaking of the angular distribution of plasma species is one of the most distinctive characteristics of plasmas produced by pulsed nanosecond UV laser ablation of solids. It is the result of gas dynamics effects and it depends strongly on the photo-physics of the laser-plasma interaction. In pulsed laser deposition, where the plasma may comprise a variety of chemical species and ionization states, chemical heterogeneity in the angular distribution may

affect the quality and properties of the resulting thin films. In processing applications, lack of control of the angular distribution may result in dissimilar effects in different locations of a single sample. In this work, we use a laser ablation/fluid plasma expansion model to simulate the angular distribution of single- and multi-species laser plasma expansions. We implement the model for plasmas produced by the ablation of elemental and compound metallic targets. The fluid simulation accounts for singly and doubly charged ions, as well as electrons and neutrals. The simulation is carried out over the centimeter distances required for proper evaluation of the angular distributions in a multidimensional setting using a state-of-the-art, open-source adaptive Cartesian mesh framework. The compressible solvers available in this framework (Riemann and all-Mach solvers) were adapted to include the equations of state of the plasma, which link local Saha equilibrium with augmented ideal gas expressions that include the internal degrees of freedom of the atomic species. Our implementation allows broad and detailed studies of the time-dependent angular behavior of all plasma constituents. This includes distributions of neutrals, ions, and electrons, as well as temperature and flow velocity profiles. As an example, the ablation of FeSe by the focused beam of a single KrF excimer laser pulse (248 nm, 25 ns, 10 mm^2 spot area), leads to a predicted angular distribution for peak number density of Fe^0 with FWHM of ~80° at a fluence of 2.0 J/cm^2. The FWHM decreases to ~71° for 3.2 J/cm^2, in qualitative agreement with typical angular distributions observed in film growth. For the same conditions, the angular distribution for peak number density of Fe^+ (i.e., singly charged ions) has FWHM of ~40° and ~22°, respectively. These results allow creation of spatially resolved maps of the degree of ionization during plasma irradiation of materials, enabling new types of gradients to induce materials transformations. We will discuss differences in elemental vs. compound metallic plumes and subtle variations in predicted angular distributions of different chemical species in compound plumes, which are critical for reproducible film synthesis and processing.

EQ09.04.03

Measurement and Simulation of the Plasma Parameters of a Bimetallic Laser-Produced Plasma Mphande N. Phiri[1], Braden L. Spiller[2], Adam D. Smith[2], Jacob H. Paiste[2], Robert R. Arslanbekov[3] and Renato P. Camata[2]; [1]Alabama A&M University, United States; [2]The University of Alabama at Birmingham, United States; [3]CRD Research Corporation, United States

Pulsed laser deposition (PLD) is a versatile plasma-based technique for nonequilibrium growth of materials of complex stoichiometry. Kinetic manipulation of materials processing in PLD requires controlling the plasma parameters of its chemically intricate and transient plasma flows. In this research we compare trends in the plasma parameters measured for a laser plasma with predictions from a laser ablation/plasma fluid expansion simulation. Planar and cylindrical Langmuir probes were used to measure the ion and electron densities, as well as the electron temperature and Mach number of the plasma expansion. The laser plasma simulation couples laser-induced surface evaporation with fluid plasma expansion and is implemented in 2D-axisymmetric coordinates, effectively delivering predictions for the 3D temporal evolution of the corresponding plasma parameters. The simulation accounts for singly and doubly charged ions, as well as electrons and neutrals, and is performed in a multidimensional setting using a state-of-the-art, open-source adaptive Cartesian mesh (ACM) framework. The use of the dynamic ACM approach is essential for reliable evaluation of plasma parameters. This is because the initial ($t < 30$ ns) spatial resolution required near the target is tenths of microns, while the simulation domain is larger by multiple orders of magnitude. As the plasma plume expands ($t > 30$-60 ns), the fine near-target resolution is no longer required for most of the simulation domain which allows the grid to be coarsened. However, proper resolution of the moving plasma front is still necessary throughout the entire plasma dynamics until the front reaches the anticipated substrate location. Only the very narrow plasma front region needs to be resolved for this purpose, while the remainder of the computational mesh can stay coarse. In this combined experimental and computational investigation, we analyzed a bimetallic plasma containing iron (Fe) and selenium (Se), obtained by ablating a solid pellet of FeSe with the 25 ns pulse of a KrF excimer laser (248 nm). For laser spot areas below 4.5 mm^2, the peak values of the experimental electron density, electron temperature, and Mach number of the expansion all increase gradually when laser fluence is in the 0.5-4.0 J/cm^2 range. The same trend is reproduced in the simulation. We will discuss how the measured time dependence of the plasma parameters can be used to constrain the simulation and test mechanisms of laser plasma formation that need to be invoked for accurate predictions of PLD plasmas containing multiple chemical species.

EQ09.04.04

Functionalization of Titanium by an Ionic Implantation Process by Plasma Oxygen Immersion Michaël Redolfi[1], Brigitte Bacroix[1], Danièle Chaubet[1] and Laurent Berthe[2]; [1]LSPM CNRS (UPR 3407), France; [2]PIMM (UMR 8006), France

Titanium alloys are used in many industrial sectors including aeronautics and biomedical sectors, due to their low density combined with excellent mechanical properties (high strength and Young's modulus, corrosion resistance, etc.). Surface properties are also of paramount importance, for example to ensure good resistance to wear or to increase biocompatibility, main properties sought after in the biomedical field. Thus, many surface treatments are carried out, among which oxidation treatments, which in addition to the properties mentioned above, affect to varying degrees the fatigue resistance of the part treated depending on the degree of roughness, porosity and density adhesion of the formed layers. In the present work, we presents an original oxidation treatment based on the coupled use of laser shock and microwave plasma oxygen implantation (MWPO) in order to improve in the first place the adhesion of the oxide layers, while inducing new functionalities. The process is versatile enough allowing (i) to obtain adherent oxide layers without adversely modifying the substrate, and (ii) to provide additional functions to the material treated, we propose here to explore a new combination of the two MWPO and ceramic conversion (CC) treatments, completed by preliminary mechanical hardening by laser shock. Here, the CC treatment consists of 2 successive stages of high temperature thermal treatment of oxidation then diffusion. The implementation of this process has been carried out initially on single-phase pure titanium. The treatment made up of 3 stages: (i) a preliminary surface treatment by laser shock, in order to create special grain boundaries on the surface making it possible to improve the diffusion of oxygen during the following two stages, (ii) an oxygen implantation step by MWPO process to produce more or less thick oxide layers, depending on the process parameters without modifying the substrate and (iii) a thermal step (of CC type) to allow more partial diffusion of oxygen and thus improve the adhesion of the layer. In order to keep the benefit of the previous steps and to simplify the process, this 3rd step has been carried in the plasma reactor at a lower temperature than the standard CC treatment. The characterization of the thickness and adhesion of the layers, the observation of the substrate microstructure by SEM/EBSD, the characterization of roughness and microhardness and the characterization of fatigue behavior have been performed.

SESSION EQ09.05: NP Synthesis and Processing II

Nanoparticle Growth Mechanics from Pulsed Plasma Exposure Brandon A. Wagner, Joseph Schwan, Minseok Kim and Lorenzo Mangolini; University of California, Riverside, United States

Applications of pure nanoscale materials have rapidly expanded in recent years and with the development of non-thermal plasma as a synthesis method, these materials can be produced with high purity and narrow size distribution compared to standard thermal or wet production methods. Unfortunately, non-thermal plasma synthesis has been limited to structures below 10 nm in diameter due to unipolar charging effects inhibiting particle growth, thus restricting potential applications [1]. For instance, current efforts in lithium-ion battery development are focused on integrating nanoscale silicon into the anode with a theoretically optimal size near 100 nm in diameter [2]. The relaxation of particle net charge outside of a plasma and re-initiation of the plasma-instigated growth process merits investigation as the reduction of net charge may allow further particle growth through increased particle collision.

To perform this investigation, an RF capacitive plasma was simply pulsed at different frequencies with respect to a particle's residence time within the plasma reactor. Silicon particles were produced through the decomposition of silane gas in the plasma flowing through a cylindrical region top to bottom and collected onto a stainless steel mesh. Ex-situ characterization was performed via Transmission Electron Microscopy (TEM) and Scherrer's Analysis through X-Ray Diffraction (XRD). Effects of reactor pressure and length were tested and accounted for in the produced materials, showing generally understood trends. Additionally, pulsing frequency with respect to particle residence time, plasma exposure time (different pulsed frequencies with identical amounts of time in plasma), and duty cycle effects were tested. These pulsing trails enabled production of larger particle diameters in comparison to their non-pulsed counterparts. A constant plasma condition with a reactor pressure at 8 Torr produces nanopowder with average particle size of 8.0 nm; however, pulsing conditions were able to achieve an average particle size of 22.6 nm. Trends relating to crystallinity and new particle size limitations were also observed.

Materials produced at varying pulse rates were coated with graphitic carbon and tested in lithium-ion batteries to observe cycling stability and associated charge capacity. Finally, numerical simulations were performed to explain the altered charging and growth mechanics of particles repeatedly exposed to non-thermal plasma conditions.

Nonthermal Plasma Synthesis of Carbon Nanodots Sankhadeep Basu, Cameron Papson, Tanvi Nikhar, Sergey Baryshev and Rebecca J. Anthony; Michigan State University, United States

In recent years, carbon nanodots (CDs) have been of great interest for their applicability in areas such as solar energy harvesting, nano-sensing, photocatalysis, etc. Traditional routes for synthesis for CDs involve both top-down methods like laser ablation, electrochemical synthesis, and chemical oxidation, as well as bottom-up techniques like hydrothermal synthesis, microwave pyrolysis and others. In this work we report the synthesis of CDs in a nonthermal radiofrequency plasma reactor using methane as the carbon precursor. Nonthermal plasma synthesis offers several advantages over traditional routes in terms of simplicity, solvent free synthesis and near room temperature growth of nanoparticles. Radiofrequency power at 13.56 MHz was supplied through ring electrodes to a flow-through reactor. The methane precursor was diluted with argon and hydrogen (H_2), in varying concentrations, for a total flowrate of ~100 sccm. The reactor pressure was kept at 2.9 Torr. The CDs formed in the plasma were deposited onto arbitrary substrates via inertial impaction. The synthesized material was characterized using Transmission Electron Microscopy (TEM), Scanning Electron Microscopy (SEM), Raman spectroscopy, and UV-Vis optical absorption. Raman spectroscopy exhibited two significant features: the D band around 1330 cm^{-1} and the G band around 1590 cm^{-1}. While Raman spectroscopy did not reveal significant modifications in the bonding configuration upon changing synthesis parameters, by controlling the hydrogen content in the plasma via introduction of H_2 gas, there arose a dramatic shift in the visual appearance, nanostructure, and UV-Vis optical absorption. Under hydrogen-poor conditions, the CDs were black and accompanied by optical absorption across the visible range, while hydrogen-rich conditions led to white-appearing CD powders with an onset of optical absorption in the UV. TEM image analysis indicated that the average particle size was around 6nm under hydrogen-poor conditions, and much larger at >40nm for hydrogen-rich conditions. Additionally, the black CDs appeared to be in nano-onion-like morphologies, as evidenced with TEM imaging, while the white CDs appeared entirely amorphous with no layered structure within the primary particles, consistent with highly diversified sp^2 and sp^3 bonding within the CDs. Our future work will quantify the degree of sp^3 hybridization for CDs of both varieties, as well as measuring the effect of hydrogen during synthesis on the electrical conductivity of CD films created by inertial impaction directly from the reactor.

11:00 AM EQ09.05.03
Synthesis of 3D Films of Resonant Si Particle Absorbers by Filamentary Plasmas Mohammadali Eslamisaray[1], Gunnar Nelson[1], Parker Wray[2], Harry A. Atwater[2] and Uwe Kortshagen[1]; [1]University of Minnesota, United States; [2]California Institute of Technology, United States

Nonthermal plasmas have attracted increasing attention for the synthesis of groups IV and III-V semiconducting nanocrystals owing to their nonequilibrium environment which enables the nucleation, growth, and crystallization of materials with high melting point from gas phase precursors at room temperature. The resulting negatively charged nanocrystals with a narrow size distribution can be accelerated to a high velocity through a nozzle to form thin films via impaction onto a substrate. The scalability of this single step, ligand-free, amenable to doping, and high yield deposition technique has recently been demonstrated by depositing uniform nanoparticle films of tunable thickness and porosity on 125 mm-diameter silicon wafers. Despite impressive applications in electronic and light-emitting devices, plasma-synthesized thin films have come short in supporting optically-induced magnetic resonances (OMR) due to the small size of their constituent nanoparticles. This is mainly because of the short nanoparticle residence time in dusty plasma reactors with a uniform diffuse discharge resulting in particle sizes in the range of 2 to 10 nm. Synthesis attempts aimed for larger nanocrystals in diffuse discharges via changing the operating conditions, including the flow rates, operating pressure, tube size, and plasma power usually lead to either polycrystalline or amorphous nanoparticles, or nanocrystals with a wide size distribution. Here, we report the synthesis of monodisperse Si nanocrystals of over 80 nm with a standard deviation of 1.0 nm by intentionally operating the plasma in a regime where the discharge is constricted. In this regime, the plasma consists of two regions: a diffuse region that extends a few centimeters upstream of the RF electrode, and a striated high-luminosity plasma filament that rotates close to the wall of the tube between the RF electrode and the lower flange. Previous laser scattering studies have shown that the particle growth begins in the diffuse plasma and particles are trapped in a region upstream of the electrode. The filamentary plasma then most likely sinters the particles by annealing them to temperatures much higher than the gas temperature resulting in formation of single crystals. Using this method, we deposited a 550 nm thick fractal-like random film of resonant Si nanocrystals in an air host matrix with a 23% volume fill fraction on a glass substrate. Angle, polarization, and wavelength resolved reflection and transmission measurements of the film were performed. The film shows an absorption peak of close to an ideal blackbody at the particles' OMR with a broadened absorption tail emanating from the OMR and progressing out to longer wavelengths. Overall, the particle film is over 38% more absorbing compared to an antireflective-coated crystalline silicon slab of the same thickness using 77% less material. The particle film has antireflective properties regardless of the form of the incident excitation as evident by the fact that transmission $\approx 1-$ absorption. Similar to a blackbody, there is a strong angle insensitivity of absorption up to angles of incidence as steep as 70 degrees at the OMR spectral

location. The film's optical response also shows significant polarization independence. This study paves the way for synthesis of resonant Si nanoparticles using nonthermal plasmas and displays the unique optical properties of 3D films fabricated by this single-step technique.

Tailoring the Properties of 2D Transition Metal Chalcogenides Using Plasma-Enhanced Atomic Layer Deposition Ageeth A. Bol; Eindhoven University of Technology, Netherlands

2D materials have been the focus of intense research in the last decade due to their unique physical and chemical properties. This presentation will highlight our recent progress on the synthesis of two-dimensional transition metal di- and tri-chalcogenides (2DTMCs) for nanoelectronics and catalysis applications using atomic layer deposition (ALD). ALD-grown 2DTMC films typically exhibit a high density of out-of-plane 3D structures in addition to 2D horizontal layers. While the out-of-plane 3D structures are ideal for catalysis applications, the presence of such 3D structures can hinder charge transport, which hampers device applications. In this presentation I will show how we used mechanistic insight obtained by HRTEM and DFT simulations to tune the shape and density of the 3D structures during plasma-enhanced ALD. The obtained morphology control was further confirmed by electrocatalysis and electrical measurements.
In the second part of my talk I will demonstrate that we also can modulate the crystal phase of transition metal chalcogenides through plasma-enhanced ALD. Phase-control between the metallic TiS_2 and semiconducting TiS_3 phases was achieved by carefully tuning the co-reactant (H_2S gas vs plasma) and deposition temperature during ALD. These two material phases were differentiated using a variety of characterization techniques.
This work sets the foundation for achieving electrical and catalytic property modulation through phase and morphology control in low-dimensional materials using plasma-enhanced ALD.

2:00 PM EQ09.06.02
Laser-Produced Plasmas in the Synthesis and Processing of 2D Materials Renato P. Camata; The University of Alabama at Birmingham, United States

Low-temperature plasmas (LTPs) have long been recognized as effective in enhancing physical and chemical processes during materials synthesis. The emergence of two-dimensional (2D) materials has renewed the interest in using LTPs for engineering these systems at the atomic scale. LTPs generated by laser ablation are of particular interest because of their rich chemistry and spatiotemporal phenomena. These plasmas can produce reactivity, temperature, and stress profiles to induce chemo-thermo-mechanical materials transformations that are not accessible by other approaches. The kinetic energy of ions can be tuned in the ~1-400 eV range and ion densities controlled between 10^9 and 10^{15} cm^{-3}. Compressive stress ranging from kPa to tens of GPa, due to energetic bombardment, and temperature pulses between hundreds and thousands of kelvin can be delivered by the leading edge of the plasma expansion. The sequence and timing of these conditions are adjustable, allowing new types of nonequilibrium processing. Despite their use in solid state physics for decades, there is a vast domain of unexplored plasma regimes with potential for breakthroughs in 2D materials research. In this talk, I will review the state of the art in plasma synthesis and processing of 2D materials, such as graphene, transition metal dichalcogenides, and atomic-monolayer epitaxial quantum materials. In particular, I will show how Langmuir probe, optical emission spectroscopy, gated-intensified CCD imaging, and laser-induced fluorescence spectroscopy diagnostics are being used in conjunction with particle-in-a-cell and fluid simulations to control plasma parameters and effect materials transformation in 2D and quantum materials.

2:15 PM EQ09.06.03
Non-Thermal Plasma Synthesis of Structural Materials Steven Herzberg, Lorenzo Mangolini and Suveen N. Mathaudhu; University of California, Riverside, United States

The low-temperature plasma synthesis of nanoparticles has many benefits over conventional powder production methods. Some of these include the ability to produce high purity semiconductor and ceramic nanoparticles with narrow size distributions[1]. By varying the ratio of precursors, the final composition of the materials can be finely controlled. In addition, the relatively low temperatures of non-thermal plasmas enable the production of amorphous nanoparticles, providing opportunities and potential applications that are still severely underexplored by the plasma community. This study focuses on the plasma processing of structural materials, with particular attention to amorphous ceramics. For this work, the silicon-carbo-nitride system (SiCN) was chosen because of its high temperature structural properties. SiCN has been shown to have good creep resistance and oxidation resistance[2] as well as high hardness[3] at temperatures past 1000°C. However, SiCN is primarily produced polymer pyrolysis and ceramisation of organosilicon precursors, which can make it difficult to control the final composition of the material and typically crystallizes durring sintering. We have successfully produced bulk amorphous SiCN samples by sintering plasma-produced nanoparticles. The resulting hardness, fracture toughness, and microstructure of the samples will be discussed in detail.

Atmospheric Plasma Surface Modification to Enhance Performance of Printed All-Solid-State Ion Selective Electrode Sotoudeh Sedaghat, Venkat Kasi and Rahim Rahimi; Purdue University, United States

All-solid-state potentiometric sensors based on printed solid-contact ion-selective electrodes have shown great potential for point of care and portable diagnostic systems due to their simple integration, cost-effectiveness, and scalability. Despite the low cost such printed electrochemical sensors, they are often unsuitable for long-term monitoring application due to the sensor drift. One of the main causes of drift in printed ISEs is the water-layer-formation

between the ion selective membrane (ISM) and the electrode resulting in an interfacial potential change overtime. To date, significant efforts have been undertaken to improve the electrochemical performance and stability of the solid contact- ISM in order to modify the interfacial properties of ISM and electrode. However, their added fabrication steps, increased cost, and need of various chemical agents have restricted their wide application. In this study, we have attempted to address the current challenges by employing a simple, scalable, and novel atmospheric plasma surface treatment to modify the screen-printed carbon electrode surface and improve interfacial boding between ISM and carbon electrode. As a proof of concept, the plasma surface modification effect was assessed with nitrate ISEs. Our results showed that plasma-treated electrodes had a significantly lower potential drift as compared to ISEs that were not surface treated with plasma. In addition, plasma treated ISEs demonstrated an improved reproducibility with less potential variation between fabricated sensors as compared to untreated electrodes. The enhanced electrochemical performance of plasma-treated ISE can be explained by the improved interfacial bonding and reduced water-layer, which was also confirmed by standard mechanical peel tests. Raman spectroscopy analysis of the carbon surfaces revealed a highly organized graphenic structure on the printed carbon surface originated by atmospheric plasma treatment. Effect of plasma treatment on reduced water uptake and generated graphene structure were further confirmed by electrochemical impedance spectroscopy with decreased charge transfer resistance for the plasma treated ISEs. Delamination of ISM for the untreated electrodes, as characterized by scanning electron microscopy (SEM), indicated the ingression of water at the interface for sensors with the untreated electrode while the plasma-treated electrodes showed a firmly packed configuration.

2:45 PM EQ09.06.05
Nonthermal Plasma Synthesis of Aluminum Nanoparticles from Aluminum Trichloride Uwe R. Kortshagen[1], Chad Beaudette[1], Himashi P. Andaraarachchi[1] and Chi-Chin Wu[2]; [1]University of Minnesota, United States; [2]U.S. Army Combat Capabilities Development Command—Army Research Laboratory, United States

The synthesis of pure metal particles is of great interest for many applications including catalysis and metal additive manufacturing. For metal particle synthesis with nonthermal plasmas, metalorganic precursors with suitable vapor pressures are widely available. However, with many of these precursors it is difficult to avoid the incorporation of carbon contaminations into the metal particles. Metal chlorides are another group of attractive precursors. For many metals, chlorides are often produced as intermediates early in the extraction process or they are easily derived from other low-refined metal compounds. Most metal chlorides are liquid or solid at room temperature but many have attractive vapor pressures for low pressure synthesis. Here, we demonstrate the synthesis of aluminum (Al) nanoparticles from aluminum trichloride ($AlCl_3$). A vapor of $AlCl_3$ carried by an excess flow of argon is fed into a tubular low pressure nonthermal plasma reactor with one inch outer diameter operating at pressures around 5 Torr. Radiofrequency power between 80-200 W (nominal) is applied through inductive coupling. Hydrogen is added as a scavenger for chlorine. Aluminum nanoparticles with average diameters between 10-20 nm are produced with minimal chlorine contamination. While the nanoparticles oxidize rapidly when removed from the synthesis reactor, X-ray diffraction and transmission electron microscopy provide clear evidence for the presence of Al nanoparticles.

This work was primarily supported through the US Army Combat Capabilities Development Command-Army Research Laboratory under Cooperative Agreement W911NF-19-2-0283.

4:00 PM *EQ09.07.01
***In Situ* Optical Diagnostics of Plasma-Water Interfaces for Applications in Graphene Synthesis** David Pai[1,2], Thomas Orriere[2], Francesca Caeilli[2], Karthik Thyagarajan[2], Darwin Kurniawan[3], Yi-Chen Chang[3], Jhih-Siang Yang[3] and Wei-Hung Chiang[3]; [1]LPP CNRS Ecole Polytechnique, France; [2]Institut Pprime CNRS Université de Poitiers ISAE-ENSMA, France; [3]National Taiwan University of Science and Technology, Taiwan

Many approaches to graphene synthesis can require high temperature, strong/toxic reducing agents, or are expensive. The microplasma-electrochemical reactor (MEC), composed of an atmospheric-pressure microplasma with an aqueous solution as an electrode, may overcome these difficulties by providing physico-chemical conditions that are difficult to achieve otherwise. They can initiate non-equilibrium electrochemistry and nucleation in solution without additional heating or reducing agents, improving the efficiency of synthesis. In addition, the technological barrier to implementing MECs is low. MECs have successfully synthesized graphene quantum dot (GQD) synthesis in aqueous solution [1,2].

One of the main challenges going forward is to develop a detailed mechanism of GQD growth, which is a general difficulty in plasma-based nanomaterials synthesis due to the complexity of non-equilibrium plasma chemistry and interactions with surfaces. So far the relevant species and reactions have mainly been inferred from ex situ or macroscopic effects, with a limited degree of detail and certainty. The liquid-phase diagnostics of the plasma-water interfacial region can provide new insight into how the MEC transforms the precursor into GQDs. Current experimental techniques used for the analysis of liquid chemistry suffer from a lack of selectivity and/or degradation of dyes, chemical probes, or spin traps/probes introduced into the liquid. The spatial distribution of species is not often accessible. Most importantly, the majority of the diagnostics must be performed ex situ, removed from the plasma reactor and after treatment.

To address this challenge, we have developed an *in situ* multi-diagnostics approach to encompass a wide range of physical and chemical properties at the plasma-water interface. The centerpiece of this platform is *in situ* spontaneous Raman microspectroscopy, which offers several important advantages over the aforementioned diagnostic tools: non-intrusiveness, selectivity, versatility, and straightforward calibration. By developing a light-sheet technique, we have experimentally investigated the interfacial region with a spatial resolution as high as several tens of microns. To gain insight into the physical state of the solvent, we tracked the Raman spectrum of water. In particular, changes to the –OH stretch band shape indicate a weakening of the hydrogen bonding network of water with. These changes to the Raman spectra over the course of plasma treatment occur at both fast and slow time scales and become more pronounced as the detection volume approaches the interface. We also tracked the aqueous species H_2O_2 and NO_3^-, whose concentrations both increase when approaching the interface to within several tens of µm [3]. An interfacial layer of excess NO_3^- concentration was found to extend 28 µm in depth. Similar interfacial layers have been modeled for transient species such as OH radicals but not for NO_3^-, a stable product of plasma-activated water.

Raman spectroscopy of the liquid environment was complemented by *in situ* photoluminescence (PL) spectroscopy to track the appearance of GQDs in real

time. The PL spectrum evolves differently according to the depth of detection in the liquid, and so particle image velocimetry of the liquid flow field was performed to gain an understanding of possible transport mechanisms. These measurements of the liquid phase were complemented by optical emission spectroscopy of plasma properties such as the electron number density and presence of excited species as a function of the distance from the interface. Together, these experimental results represent the fullest description to date of the physico-chemical environment enabling GQD synthesis and mark an important step towards the discovery of the reaction mechanism.

4:30 PM EQ09.07.02
Time Resolved Ion and Electron Energy Distribution Functions During a HiPIMS Discharge David E. Barlaz[1], Zach Jeckell[1], Wolfgang Huber[2], Tom Houlahan[2], Ian Haehnlein[2], Brian Jurczyk[2] and David Ruzic[1]; [1]Univ of Illinois, United States; [2]Starfire Industries, United States

The expansion of HiPIMS as both a research and production technique has demonstrated the need to better understand transient events inherent to the discharge, specifically the Positive Kick™ pulse, first commercialized by Starfire Industries, responsible for imparting ion energy to the workpiece at low gas temperatures. Previous research has shown that sputtered metal ions arrive at the workpiece with tunable ion energies depending on the conditions of the discharge, while limiting ion energies of working gases. Much remains to be understood about the nature of the plasma responsible for this.

In the current work, a Starfire Industries 2-2 Impulse® with Positive Kick™ was utilized in conjunction with an Impedans Semion gridded energy analyzer to determine the transient nature of the ion energy distribution function (IEDF) during the positive kick pulse. Simultaneously, time resolved Langmuir probe data allowed for the plasma potential, electron energy-distribution function (EEDF), and normalized plasma density to all be resolved with μs-resolution. An unbalanced magnetron was characterized for a variety of gas pressures, pulse lengths, kick pulse lengths and amplitudes.

Ion energies within 5% of the kick pulse bias voltage are consistently observed at the detector within several μs of the beginning of the kick pulse indicating rapid transit times for the plasma across the chamber. Plasma transit times were mild functions of pressure, but not of pulse lengths or amplitudes, as measured both by the IEDF and plasma potential. Shifts in the IEDF early in the kick pulse suggest a transition between mechanisms for ion transport as the plasma sheath forms. Additionally, decay times for ion energy distributions occurred on similar time scales suggesting the plasma expansion enabled by the kick pulse is short lived. Ion energies above the kick pulse bias voltage are consistently absent over the conditions tested (Semion detection maximum for this configuration is 150 eV) indicating that the pulse conditions may be suitable for the minimization of instabilities that may be deleterious to both film quality and uniformity of deposition. These and other results will be discussed in conjunction with time resolved electron energy distribution measurements to provide an understanding of plasma dynamics and the effect of the magnetron's magnetic trap.

4:45 PM EQ09.07.03
Multidimensional Simulation of Laser-Generated Chalcogen Ion Plasmas in Length Scales Relevant for Materials Processing Jacob H. Paiste[1], Sumner B. Harris[1], Joseph Edoki[2], Robert R. Arslanbekov[3] and Renato P. Camata[1]; [1]The University of Alabama at Birmingham, United States; [2]Alabama A&M University, United States; [3]CFD Research Corporation, United States

Plasmas generated by laser ablation are of interest for materials processing because of their rich chemistry and spatiotemporal phenomena. The chemical diversity, variety of gas backgrounds, and shock wave characteristics of laser-produced plasmas are particularly conducive to kinetic control of materials synthesis. Measurements of laser plasma parameters using Langmuir probes, TOF mass spectroscopy, optical emission spectroscopy, laser-induced fluorescence, as well as photography and imaging techniques have established numerous correlations between plasma parameters and processing outcomes. These correlations represent a substantial body of knowledge, but do not provide an exhaustive picture of the laser plasma processing environment. This is due in part to the difficulty in gathering direct experimental information on the strongly time and space dependent plasma parameters at the plasma-surface boundary. Moreover, processing of 2D materials has raised new questions about the ion densities, kinetic energies, and plasma temperatures that are useful for manipulation of these atomically thin systems. In this context, laser plasma simulations may offer insights into the plasma characteristics in the vicinity of the processing area which, in conjunction with experiments, could reveal plasma conditions for controlling processes such as doping, defect annealing, and kinetically-driven phase transformations. The complexity and broad technical applications of laser-generated plasmas have for decades been motivators for their study via numerical simulations. Modern studies based on a variety of fluid, kinetic, and hybrid models are well described in the literature. The majority of investigations have focused on one-dimensional (1D) descriptions of single-element plumes, very close to the ablation target surface (<1 mm) and over short timescales (<1 μs). Detailed analysis of this domain is valuable in applications dominated by near-target processes, such as micromachining, laser-induced breakdown spectroscopy, and laser sintering/additive manufacturing. Simulations up to several centimeters in length and times >10 μs, have received much less attention but are needed to guide materials synthesis and modification approaches, where substrates are placed several centimeters away from ablation targets. Simulations over long distances are computationally costly and must include three-dimensional (3D) effects. They also need to account for the thermo-physical properties of specific chemical species. While embedding detailed mechanisms is desirable, simulations of practical utility need to be fast and meet predictive benchmarks. In this work we balance these demands using an effective model that incorporates standard features of UV nanosecond laser ablation plasmas: thermal evaporation, bremsstrahlung emission from plasma electrons, as well as photoionization and free-free laser absorption by the plasma. An additional effective plasma absorption coefficient is introduced as a stand-in term for other mechanisms that are impractical to account for directly—due to computational cost or unavailability of physical parameters. The effective model is constrained by Langmuir probe experimental data. The simulations are set up in a 2D-axisymmetric geometry using a solver with an adaptive Cartesian mesh. We simulate plasmas of selenium (Se) and tellurium (Te), which are of current interest in synthesis of transition metal chalcogenide materials. Predictions of Se and Te plasmas produced by 248-nm, pulsed nanosecond ablation of metal targets (4 J/cm^2 laser fluence and 1.8 mm^2 laser spot area) show chalcogen plumes with spatial gradients of plasma density that are steeper than those for more commonly studied copper (Cu) plumes by up to three orders of magnitude. Their spatial ion distributions have central bulges, in contrast to the edge-only ionization of Cu. The range of plasma temperatures for Se and Te is higher than for Cu by more than 0.5 eV.

5:00 PM EQ09.07.04
Plasma Enhanced Low Temperature Processing for Dopants Activation in CMOS Devices Yuanning Chen[1], Orlando Auciello[2] and Israel Mejia[3]; [1]MicorSol Technologies Inc., United States; [2]The University of Texas at Dallas, United States; [3]Center for Engineering and Industrial Development, Mexico

A novel plasma enhanced low temperature (around 400°C) process was developed for CMOS device dopant activation, post integrated circuits (ICs) fabrication processing, and for low temperature processing of organic and other materials needing low temperature conditioning. The main challenge for CMOS device processing is to maintain low thermal budget for source/drain's dopant activation while limiting dopant diffusion within the source/drain thickness layers, to produce optimal transistor performance. Low temperature processing of ICs is critical to eliminate undesirable materials alloying and structural changes in metals used in ICs' interconnect layers, and to limit diffusion-based doping profile changes in the CMOS source/drain regions, which degrade transistor performance and reliability.

Most frequently used annealing processes are furnace annealing, rapid thermal processing (RTP), arc flash annealing, laser annealing, and microwave

annealing (MWA). Recent publications show that MWA produce dopant activation at temperatures of 500-600°C, which are low compared to other processes, but still higher than the post IC processing target of 400°C.

An innovative plasma-based low temperature annealing process will be discussed, with plasma energy providing enhanced dopant activation at relatively low temperature with controlled nanoscale depth dopant diffusion. Preliminary experiments demonstrated good activation of phosphorus (P) dopant at 416 °C while maintaining a relatively uniform junction depth of ~ 20 nm.

Experiments involved using Si wafers implanted with 60 keV P ions with a dose of $5x10^{15}$ ions/cm^2. The Si surface temperature, read by a pyrometer, was around 416 °C during the annealing process. Four-point probe measurement revealed sheet resistance of the Si surface wafer before (77-163 KW/sq) and after (42-46 KW/sq) annealing, indicating very good activation of the P atoms at 416 °C.

Following annealing, the P-doped Si wafer was analyzed using X-ray photoelectron spectroscopy (XPS) depth profiling, to explore the distribution of P atoms from the surface into the bulk of the activated Si wafer. Prior to depth profiling, the sample was cleaned with low energy (1 kV) Ar ions bombardment for 2 minutes to remove adventitious carbon and oxygen atoms adsorbed on the surface of materials exposed to atmospheric conditions. The P-activated Si wafer surface cleaning was confirmed by the disappearance of the XPS C / O peaks. P atoms-depth profiling was performed by bombarding the Si surface with 5 keV Ar^+ ions at 5 minutes interval plus XPS analysis, which revealed that the P 2p and Si 2p XPS peaks remain stable in intensity until full 40 minutes bombardment time. Measurement of the step between the original and etched Si surface, across the etched Si surface edge, revealed 20 nm depth. This value, together with the stable intensity of the XPS P 2p peak after etching indicates that the P dopant concentration is fairly uniform in the first 20 nm of the plasma-enhanced annealing activated Si wafer. Further longer time analysis will determine the P-atoms distribution throughout the entire junction depth.

The preliminary results reported here show that plasma enhanced low temperature processing can induce dopant activation at ~ 400 °C while maintaining shallow junction around 20 nm for fabrication of high-performance Si-based CMOS devices, as well as post IC processing. The process can also be used to condition organic and other materials requiring low temperature conditioning.

SESSION EQ09.08: Synthesis and Processing II

Atmospheric Pressure Plasma Surface Modification of Materials for Environmental Protection and Remediation Antonella Uricchio[1], Teresa Lasalandra[1], Francoise Massines[2], Gael Plantard[2,3] and Fiorenza Fanelli[4]; [1]University of Bari "Aldo Moro", Italy; [2]Laboratoire Procédés Matériaux et Energie Solaire, PROMES-CNRS, UPR 8521, France; [3]University of Perpignan Via Domitia, France; [4]National Research Council (CNR), Institute of Nanotechnology (NANOTEC), Italy

Atmospheric pressure non-equilibrium plasmas continue to attract considerable attention in surface engineering [1,2]. By providing unique reactive environments at moderate gas temperatures and atmospheric pressure, they have opened new opportunities to tailor the surface properties of materials as well as to prepare a variety of thin films with different chemical compositions, structures and morphologies. In this context, dielectric barrier discharges (DBDs) have played a major role due to their simple design and versatility. A plethora of DBD-based apparatuses and processes has been therefore devised to meet the ever-increasing demand for atmospheric pressure plasma technologies in various surface engineering applications. In this contribution we will present our recent advances in surface modification by DBDs with a special focus on the development of materials for environmental protection and remediation. The presented examples will include the design of surfaces for enhanced water condensation and recovery [3,4], the preparation of recyclable sorbents for the separation of hydrocarbon liquids from water [5], the deposition of photocatalytic thin films on macroporous supports for wastewater treatment [6], the plasma-assisted exsolution of nanoparticles on the surface of perovskite oxides as a promising approach towards the preparation of nanocatalysts for sustainable chemical production.

Toward a Single-Step Process to Produce a Zn-CNT Hybrid Material Ruairi McGlynn, Paul Brunet, Abhijit Ganguly, Hussein S. Moghaieb, Supriya Chakrabarti, Paul Maguire and Davide Mariotti; Ulster University, United Kingdom

New devices and applications are increasingly requiring tailored material properties which necessitates the development of advanced materials and novel nanocomposites to drive these new technologies. In addition to the material-specific properties there are two other key requirements to the success of new technologies, low-cost to performance ratio and a relative abundance of the materials. Two materials that can satisfy these requirements are carbon and zinc, with their derivative forms such as oxides or sulfides as well as micro- or nano-geometries widening the research impact to a myriad of applications. Blending these materials can lead to composite materials that greatly outperform each individual component material in energy storage applications. ZnO sites can act as pseudocapacitors to enhance the total capacitance, which when combined with a supportive carbon matrix leads to a highly reversible supercapacitor device.[1] Additionally, both ZnO and ZnS have high theoretical capacities in the application of lithium-ion battery anodes, and are relatively abundant, non-toxic, low-cost and environmentally friendly.[2,3] Mechanical failure due to volume expansion and contraction during the charge and discharge can be alleviated by the usage of highly conductive, flexible and strong carbon-based supports can lead to a range of devices with enhanced performance.[4]
It is obvious that a wide range of applications and benefits are available from the combination of zinc oxides and sulfides with nanocarbons, though the question remains; how can this be achieved simply, at minimum cost and on a larger scale? Significant progress has been made in forming macroscopic

assemblies of CNTs by direct spinning CNT aerogels in a floating-catalyst chemical vapour deposition (FC-CVD) into a fibre or mat,[5,6] which would represent a strong candidate for the supportive and conductive base. To create a composite material with the FC-CVD system as-is, these fibres and mats would have to be post-treated, diminishing the overall production rate. In this work, we detail the integration of an atmospheric-pressure plasma system with a FC-CVD system where we can successfully obtain a CNT-Zn composite material in a single step. XPS depth profiling measurements demonstrate that the zinc materials penetrate further into the composite when treated in-line compared with an off-line post-treatment. Application-related measurements are reported utilising the in-line produced composite material.

On the Early Stages of Si Nanoparticles Growth in Non-Thermal Plasma Paolo Elvati, Xuetao Shi and Angela Violi; Univ of Michigan, United States

The synthesis of nanoparticles (NPs) and films with non-thermal plasma assisted methods offers unique opportunities in the fields of bio-imaging, drug delivery, photovoltaics, microelectronics manufacturing, as well as in renewable energy efforts. The unique conditions of non-thermal plasma systems make them suitable for the synthesis of nanoparticles of materials with high melting points or with properties that are highly dependent on the NPs size distribution (luminescence, hardness). Plasmas also enable synthesis of compound nanoparticles such as group III-V semiconducting materials and metal oxides that require covalent bonding rather than the ionic bonding promoted by liquid phase synthesis.
Understanding the relationship between plasma operating parameters and particle growth, morphology, and composition can lead to the development of tailored nanomaterials and optimization of the conditions for the production of new and novel NPs. These relationships, however, are complicated by the variety of phenomena that occur in plasma and that dominate different stages of the particle growth. One of the key phenomena that controls the early stages of NP growth is the deposition of small species on the surface of incipient nanoparticles. This process is highly dependent on the shape and chemistry of both the small fragments and the surface of clusters, which makes its understanding and modelling still quite difficult.
In this work, we report on results from a computational investigation of silicon NPs with the goals of clarifying how operating conditions (temperature), size and surface of clusters influence the collision events and the dynamics of the surface growth mechanism. Specifically, we focus on the probability to form a bond between small silane fragments (SiH_x, x = 1-4) and large silanes Si4, Si2H6, and Si29H36 molecules after a collision has taken place (sticking probability). To reduce the parameter space, we investigate the effect of temperature, size, and hydrogen surface coverage.
The results, obtained by using classical reactive molecular dynamics simulations, show that the sticking probability is the result of the interplay between two phenomena: physi- and chemi-sorption. While some general trends are common to all types of collisions, like a decrease in the sticking probability with increasing temperature and hydrogen coverage, it is possible to observe a complicated dependence on the colliding species characteristics especially for temperatures below 400 K. This effect is the results of the different reaction pathways and the corresponding surface embedding that are possible for the small fragments, as well as the competing effect between desorption and physisorption to chemisorption conversion. Although the resulting sticking coefficients are not easily expressed in terms of the numerous factors that affect them, they constitute a good dataset for supervised learning models, which we used to quantify both the amount of potential computational effort that can be saved when analyzing similar systems, and to perform a regression of the sticking coefficients, when species that were not directly modelled are required.

Surfactant-Free Copper Oxide Nanoparticles Synthesized by Plasma-Induced Non-Equilibrium Electrochemistry for Solar-Thermal Energy Conversion Hussein S. Moghaieb[1], Chiranjeevi Maddi[1], Praveen Kumar[2], Miryam Arredondo[2], Attaul Haq[1], Ruairi McGlynn[1], Harjit Singh[3], Paul Maguire[1] and Davide Mariotti[1]; [1]Ulster University, United Kingdom; [2]Queen's University Belfast, United Kingdom; [3]Brunel University, United Kingdom

Solar thermal collectors are one of the technologies used for harnessing and utilizing solar energy, in which the incident radiation is absorbed and converted into thermal energy for use in a wide variety of applications [1]. However, conventional collectors, which rely on solid surface absorbers and use traditional heat transfer fluids, exhibit deficiencies due to large heat losses[2] and poor solar-thermal conversion (STC) performance.[3] Direct absorption solar collectors (DASCs), therefore, were introduced to volumetrically absorb and convert solar radiation into heat,[4] in which nanofluids (NFs) with their exceptional optical and thermal properties can significantly improve the STC efficiency.[5,6]
In this work, copper oxides (CuO_x) were chosen due to their high thermal conductivity,[7] broad absorption,[8] high physical and thermal stability [9], abundancy at low cost and limited environmental impact with low toxicity.[10] The synthesis of our surfactant-free CuO_x nanoparticles (sf-CuO_x NPs) was carried out with a custom-built system based on plasma-induced non-equilibrium electrochemistry (PiNE) which has recently demonstrated exceptional versatility for the production of a wide range of sf-NPs including oxides.[11] Furthermore, post-synthesis heat treatment was performed to determine the impacts on the size, morphology, surface structure, and chemical composition of the NPs.
Following, we re-dispersed sf-CuO_x NPs in ethylene glycol (EG) as a base fluid at different volume fractions up to 0.01%. After determining the solar absorption and scattering behaviours of the NFs using measurements from ultraviolet/visible/near-infrared spectroscopy over the wavelength range 280-2500 nm, the NFs were then exposed to simulated solar radiation of one sun (~1000 W/m^2) and the temperature change was recorded. Temperature measurements were then used to validate a 3-D numerical model employed in Ansys Fluent. The model results revealed that the STC efficiency reached a remarkable value of 81.92% at a volume fraction of as low as 0.01%, indicating that our sf-CuO_x NPs prepared by plasma-liquid interactions represent a promising candidate for NF-based DASCs.

Plamsa-Asssisted Structural Design of Multifunctional Nanocarbon Materials for Extreme-Environmental Applications Ming Xu; Huazhong University of Science and Technology, China

Structural design has always been considered as one of the approaches to obtain and optimize material properties, realizing their value in applications. The same material will display different macro performances through the construction of different structures. One-dimensional and two-dimensional nanomaterials, such as carbon nanotubes, graphene, etc., have a series of excellent physical properties that other traditional materials cannot reach, and have become the preferred research materials in many application fields. Taking them as the "Building Blocks", the final performance of their assembly also depends on the structural design and construction. This time, we will show how to apply the concept of structural design to these nanostructured "building blocks" such as carbon nanotubes and graphene to achieve new breakthroughs in adhesion, sensing, energy storage in extreme environments [1-5].

Bringing Plasmas to the Gas-Liquid Interface at the Surface of a Liquid Microdroplet Paul Maguire; Ulster University, Ireland

Microscopic liquid droplets are gaining attention as efficient microreactors for new chemical and nanomaterials processing techniques. Typically, aqueous droplets are introduced into a carrier fluid in a microfluidic channel. However, charged microdroplets, especially in the gas phase e.g. from electrospray, have exhibited interesting effects with regard to enhanced nanomaterials synthesis or accelerated reactions and, as yet, the mechanisms involved are unclear. When a low temperature plasma is added to the gas – liquid interface at a droplet surface, the plasma provides a much greater source of charge flux than other techniques. When the droplets travel through a low temperature plasma at atmospheric pressure a number of remarkable and unexpected effects have been observed. For flight times less than 1 millisecond, certain plasma-induced chemical reactions proceed significantly faster than in plasma – bulk liquid configurations and many orders of magnitude faster than in standard bulk chemistry. The plasma also delivers chemical radicals, photons and ions to the surface and the complex interplay between arriving flux, droplet surface charge, internal and external electric fields as well as the restricted volume and high surface to volume ratio, offers new avenues for microreactor development.

There is a large potential for new plasma-liquid processes in medical, chemical, biological, environmental and materials applications, and the plasma – microdroplet system has unique features that provide opportunities for exploitation, including a controlled gas environment, a large surface area to volume ratio for surface reactions, small volume for rapid mixing, and low droplet temperature which allows for a wide range of liquids, additives and precursors. Chemical synthesis and encapsulation in flight enables on-demand supply of materials and chemicals and also remote delivery, without intermediate filtration or purification stages. However synthesis rates need to be rapid i.e. closer to microseconds than minutes. Applications requiring instantaneous and remote chemical species and/or nanoparticles include, for example, plasma-medicine, agriculture and microreaction.

We have demonstrated the use of droplet streams where each individual droplet acts as a chemical microreactors to produce nanoparticles in flight, many orders of magnitude faster than reported by high energy radiolysis or chemical synthesis. The nature of the charge flux and the formation of a charged surface layer composed of solvated electrons is a critical aspect of this system but little explored or understood. Current theories of microparticle charging in a collisional plasma environment are very limited. While inflight charge measurements represent a significant challenge, in the high noise environment of a plasma, the relatively large size of the droplet (10 – 20 μm diameter) and the limited evaporation over the flight time, offer the prospect of using droplets as a spherical probe to develop enhanced collisional probe theories. We have measured the average charge of microdroplets of ~1E6 electrons, close to the Rayleigh limit and considerably higher than that obtained by other charging methods. Analytical – numerical and finite element simulations, in tandem with charge measurements, are being developed to better understand the droplet electrical environment and ultimately to link chemistry and charge in a consistent framework.

11:00 AM EQ09.09.02
Room Temperature and Time-Efficient Plasma-Induced Exsolution in Perovskites Oxides at Atmospheric Pressure Attaul Haq[1], Fiorenza Fanelli[2], Hessan Khalid[1], Bruno Alessi[1], Evangelos I. Papaioannou[3], Kalliopi Kousi[3], Ian S. Metcalfe[3], Cristian Savaniu[4], John T. Irvine[4] and Davide Mariotti[1]; [1]Ulster University, United Kingdom; [2]National Research Council (CNR), Institute of Nanotechnology (NANOTEC), Italy; [3]Newcastle University, United Kingdom; [4]University of St Andrews, United Kingdom

Plasmas are widely used industrially for a wide range of processes including for surface cleaning, inducing functionality to the surfaces, chemical reduction of metal oxides and polymerization etc. Here we report the use of an atmospheric pressure plasma in a dielectric-barrier discharge (DBD) configuration for exsolving nanoparticles (NPs) from within the oxide matrix. Usually, the exsolution of NPs in perovskites oxides follows a thermal-reduction process in the presence of hydrogen at temperatures higher than 800 ºC for more than 12 h. Surprisingly, DBD treatments of perovskites oxides ($La_{0.43}Ca_{0.37}Ni_{0.06}Ti_{0.94}O_{2.955}$, $LCTN_{A\text{-}site\ deficient}$) resulted in the exsolution of NPs within few minutes at ambient-temperature even without the need for hydrogen. The changes in the size and distribution of NPs in He-fed DBD at 1.2 kV and at 1 kV are compared. Furthermore, the role of hydrogen-containing DBD on the nature of exsolution has also been studied and compared with pure He DBD. The DBD not only induces oxygen vacancies but also provides free electrons that are sufficient for driving the exsolution of NPs from an estimated exsolution depth ranging from 15-45 nm. Such exsolved NPs are firmly socketed within the oxide surface and hence induced excellent catalytic activities as discussed in this contribution. The concept of exsolution on a variety of perovskites oxides can be demonstrated with our DBD system that can even directly be applied for an in-situ energy application [1-8].

11:15 AM EQ09.09.03
Defluorination of the Fluoropolymer Surfaces for Composite Materials in the Industrial Market Faegheh Fotouhi[1,2,3], Jacopo Profili[2,3], Morgane Laurent[4], Sethumadhavan Ravichandran[4], Gowri Dorairaju[4] and Gaétan Laroche[1,2,3]; [1]Université Laval, Canada; [2]Département de génie des mines, de la métallurgie et des matériaux, Centre de Recherche sur les Matériaux Avancés, Université Laval, Canada; [3]Hôpital St. François d'Assise, Canada; [4]Saint-Gobain Research North America, United States

Fluoropolymers are suitable for many applications, including textile, building, and biomedical materials. They are mainly used for their chemical inertness and low friction coefficient. However, for many applications, their low surface energy leads to poor adhesion during the assembly with other materials. Among the different techniques used to enhance the adhesion of polymers, atmospheric pressure discharges (APD) remain fast and cheap methods that are suitable for industrial applications. The highly energetic species present in the ionized gas allow the breaking of molecular bonds at the film surface and favor the recombination with polar free radicals from the discharge. Although this approach has been proven to be efficient, the understanding of the chemical and physical processes leading to these results remains not yet fully understood. In this study, we performed the modification of fluoropolymer surfaces at atmospheric pressure by using an inert plasma treatment equipped with a roll-to-roll system. The effect of the discharge on different fluoropolymers was studied through a detailed surface analysis before and after each treatment. The characterization of the extreme surface was carried out by X-ray photoelectron spectroscopy (XPS) in both survey and C1s high resolution. In addition, infrared spectroscopy in the attenuated total reflectance mode (IR-ATR) was used to evaluate the modifications observed on the first top micrometers of the samples. All results were correlated with the modification of the surface energy obtained from the static contact angle analysis measured using both water and diiodomethane. The dynamic contact angle was used to evaluate the affinity of the different functional groups deposited with water. The obtained results highlight the possibility to create new hydrophilic functionalities bonded on the fluoropolymer that is likely to improve the adhesion of these polymers in composite assemblies. These promising results constitute the first step toward a better understanding of the fundamental chemical modifications induced by using this relatively new approach.

Water-Soluble Luminescent Si Nanocrystals Through Colloidal PEGylation and Plasma Induced Acrylic acid Grafting Himashi P. Andaraarachchi, Zhaohan Li and Uwe R. Kortshagen; University of Minnesota Twin Cities, United States

Luminescent silicon (Si) nanocrystals are intriguing nanomaterials for biomedical application due to their unique optical properties and biocompatibility. Compared with cadmium containing fluorophores, Si nanocrystals are relatively non-toxic, abundant, and biocompatible. Synthesis of water-soluble Si nanocrystals is challenging as they are hydrophobic and mainly dispersible in non-polar organic solvents through hydrosilylation with non-polar alkyl ligands. A variety of approaches have been used to synthesize water-soluble Si nanocrystals through post synthetic surface modification with hydrophilic ligands including carboxylic acids, amines, hydroxyl groups, and hydrophilic polymers. Here, we demonstrate two approaches to synthesize water-soluble Si nanocrystals: A single ligand colloidal surface modification with polyethylene glycol (PEG) ligands and a two-step method of mixed-ligand surface modification through inflight surface functionalization with acrylic acid ligands coupled with colloidal PEGylation. Silicon nanocrystals were synthesized in a continuous-flow, low pressure capacitively coupled plasma reactor operating at pressure around 2 torr. In contrast to pristine hydrophobic Si particles, surface functionalized Si nanocrystals were dispersible in both water and biological buffer solutions and colloidally stable for about 24 h. Their surface properties were evaluated using X-ray photon spectroscopy and Fourier transform infrared spectroscopy. Transmission electron microscopy images provided evidence for both individual passivation and encapsulation of multiple nanoparticles together. The acrylic acid grafted-PEGylated Si nanocrystals were evaluated with MDA-MB-231 cell line and found that the cells are tolerant to these nanocrystals up to 30 μg/mL for 72 hours.

This work was primarily supported through the National Institute of Health under award R01DA045549.

Microplasma-Based Synthesis of Metal-Oxide Transport Layers for Perovskite Solar Cell Subha Sadhu, Dilli Babu Padmanaban, Chiranjeevi Maddi,

Slavia D. Dsouza, Paul Maguire and Davide Mariotti; Ulster University, United Kingdom

Perovskite solar cells are considered as “The Next Big Thing” in photovoltaics research as within only ten years the power conversion efficiency (PCE) has reached from 3.8% to 23%.[1] Researchers worldwide are developing various procedures for mass scale fabrication of perovskite devices. The three main components of fabricating any types of solar cell devices are: absorbing layer to absorb photons followed by exciton formation, transport layers to conduct the charge carriers and metal contacts to transfer the carriers to the circuit. Transport layers are divided in two main categories electron transport layer (ETL) and hole transport layer (HTL) and metal oxides are largely favoured for both types of transport layers. Microplasma-based synthesis of metal-oxide transport layer is an emerging technology and a potential alternative to other chemical and physical synthesis methods.[2] The one-step synthesis procedure is simple, less time consuming than other chemical method, can be performed in atmospheric condition and does not require any harsh or toxic chemicals. The transport layers can also be deposited easily with flexible substrates and do not need high temperature annealing which reduce the conductivity of the transparent conducting oxide substrates. In this contribution, we have synthesized HTL (NiO, CuO) and ETL (ZnO) through microplasma methods and directly deposited onto the device structure. From in-depth characterization techniques we observed that the as-synthesized metal-oxides are highly pure, stable and do not require any purification or annealing after the deposition. The absolute position of the band-edges can be tailored to match, for instance, with that of methyl ammonium lead iodide (MAPI) perovskite and the metal-oxides. The as-fabricated perovskite devices show promising photon to electron conversion efficiency.

Plasma-Driven Solution Electrochemistry—Synthesizing Materials at the Plasma-Liquid Interface Peter Bruggeman; University of Minnesota, United States

Plasma-induced solution chemistry can be driven by electrons, ions, photons and radicals. In thermal catalytic, electrocatalytic, conventional electrolysis and plasmon-driven chemical transformations, metal surfaces play key roles. In contrast, in plasma-driven processes, electrons are produced in a gas phase plasma and injected into the interfacing liquid without the need for a solid electrode. The high-power density in plasmas enables exceptionally large yields of electrons, some having high energies up to 10 eV or more, leading to a high concentration of electrons in a near plasma-liquid interfacial region with a thickness up to a few tens of nm. These conditions enable unique chemical transformations including the synthesis of metallic nanomaterials enabled by the reduction of salt ion precursors. This presentation will provide an overview of our current understanding of the processes underpinning material synthesis at the plasma liquid interface and an outlook on opportunities to control such processes.

Flexible Glass-Based pH Sensor Using Cold Atmospheric Plasma Deposition Venkat Kasi, Ulisses Heredia, Sotoudeh Sedaghat and Rahim Rahimi; Purdue University, United States

pH is an essential parameter most commonly used to evaluate and control the conditions of various chemical and biological processes as well as to maintain the quality of products in many industries ranging from health care, food, environmental, chemical, and pharmaceutical industries. Different techniques including potentiometric, chemiresistive, capacitive, and optical methods have been developed for measuring pH. Among these methods, potentiometric sensing technique has gained considerable interest because of simple and low-cost fabrication process. Various functional materials including glass, metal oxides, and conductive polymers have been investigated for the fabrication of potentiometric based pH sensors. Generally, sensing performance of a pH sensor is evaluated in terms of its sensitivity, selectivity, working range, and repeatability. Most of the commercially available pH sensors consist of glass membrane as the sensing component because of several advantages of glass-based electrodes such as long service life, high accuracy, and excellent stability in various solutions. However, due to their bulkiness and poor mechanical properties, conventional glass-based sensors are not ideally suitable for wearable or flexible applications.

In recent years, cold atmospheric plasma (CAP) assisted deposition technique has gained much attention because of its feasibility in producing thin films with high quality and consistent properties in large scale onto desired substrates in atmospheric conditions. The CAP deposition technique eliminates the requirement of conventional slow vacuum deposition processes (e.g., CVD and PVD) while producing superior thin film deposition results compared to the conventional thermal spray coating technologies. In this work, we have demonstrated the use of CAP thin film glass deposition to fabricate flexible solid-state glass-based pH sensor using siloxane precursors in a simple and facile approach. Our sensitivity test results indicated that these sensors exhibit excellent sensitivity and selectivity over a wide physiologically relevant pH range. Additionally, in this study we investigated the morphology and chemical composition using SEM and FTIR and correlated with the sensing properties of the demonstrated all solid-state pH sensor.

4:45 PM EQ09.10.03
Plasma Induced Rapid Exsolution of Nanoparticles in Non-Stoichiometric Perovskite Oxides Hessan Khalid[1], Attaul Haq[1], Bruno Alessi[1], Evangelos I. Papaioannou[2], Kelly Kousi[2], Ian S. Metcalfe[2], Cristian Savaniu[3], John T. Irvine[3], Paul Maguire[1] and Davide Mariotti[1]; [1]Ulster University, United Kingdom; [2]Newcastle University, United Kingdom; [3]University of St Andrews, United Kingdom

Exsolution of nanoparticles (NPs) for oxide support is considered as highly effective and efficient process for the synthesis of functional nanomaterial to be applied in catalysis and energy conversion applications. Unlike other nanoparticles decoration techniques (for instance deposition or impregnation), exsolution offers great control on the size and distribution of the particles and offers anchorage with the host matrix making them resilient to agglomeration. Conventionally, exsolution is performed in mild reducing atmosphere at elevated temperature, making them a relatively lengthy (10-30 hours) and energy demanding process. Herein a new dimension in exsolution is explored and NPs exsolution is demonstrated using low pressure plasmas, making exsolution to occur in minutes rather than hours. A non-stoichiometric (A-site deficient) perovskite oxide (POx) having a composition of $La_{0.43}Ca_{0.37}Ti_{0.94}Ni_{0.06}O_{2.955}$(LCTN) treated in low pressure plasma in argon atmosphere results in the exsolution of nanoparticles. Particle size and density of the exsolved nanoparticles were optimized by tuning the treatment time and plasma power, which also helps in understanding the mechanism involved

in plasma enhanced exsolution. The average particle size does not change drastically and lies within the range of 19-22 nm for different plasma treatment times. However, the plasma density changes from 60 particles/μm^2 to ~500 particles/μm^2 when process time is increased from 10 minutes to 15 minutes. The creation of oxygen vacancies and a negative surface charge density are considered the main driving forces for plasma-induced exsolution. The effect of exsolved nanoparticles was analysed by employing CO catalytic testing to access CO_2 production rate. The catalytic reactivity of the plasma exsolved LCTN samples have been tested and present encouraging results. This makes plasma exsolution an interesting approach which will open new dimension in the field exsolution and provides future solutions in catalysis and energy conversion.

5:00 PM EQ09.10.04
Late News: Optical Emission Spectroscopy of an Atmospheric Pressure Dielectric Barrier Discharge for Surface Modification Alex Destrieux[1,2,3], Jacopo Profili[2,3], Morgane Laurent[4] and Gaétan Laroche[1,2,3]; [1]Université Laval, Canada; [2]Département de génie des mines, des matériaux et de la métallurgie, Centre de Recherche sur les Matériaux Avancés, Université Laval, Canada; [3]Hôpital Saint François d'Assise, Canada; [4]Saint-Gobain, United States

Today, atmospheric pressure dielectric barrier discharges (DBD) have the potential to make the difference for the transition toward a cleaner and prosperous manufacturing processes. Compared to low pressure plasma, atmospheric pressure plasma does not require expensive pumping systems or closed reactors. For this reason, DBD processes are more suitable for industrial applications where large surfaces must be treated. Also, the possibility to operate surface modifications at room temperature makes DBDs particularly suitable for the modification of thermosensitive materials such as composite polymers.
In the last years, researchers have demonstrated that discharges at atmospheric pressure are very sensitive to the gas composition, the electrodes geometry, or the electrical excitation used. As an example, in nitrogen operating plasma, few tenth of ppm added can stabilize the discharge in a homogenous physical regime, while few hundreds of ppm can create a filamentary mode. These different physical regimes can differently affect the surface, provoke a change in the chemical reactions and finally lead to different surface proprieties. One can easily imagine that a small modification of the physical regime during an industrial process could provoke a strong modification of the performance of the final products.

Through this work, we aim to highlight the current understanding of the chemical reactions involved in a DBD process during the modification of a large polymer area. The remaining scientific challenges to control the physical regimes in an industrial reactor will also be presented. To gain insight into the physics of the discharge, optical emission spectroscopy (OES) and electrical characterization have been performed in real time. Measurements were performed at atmospheric pressure in flowing N_2. N_2O was also admixed to understand the influence of impurities on the behavior and the species present in the discharge. Results show that in pure N_2, the main feature of the spectra corresponds to transition of the N_2 second positive system (C-B). Several peaks of the NO (A-X) transition, as well as the CN (B-X) have been also observed. When a small amount of N_2O is added to the discharge, a complete disappearance of the CN and NO is denoted. The N_2 level and NO being excited mainly by direct electron impact, the absence of NO and the slight decrease of N_2 intensities have been related to the reduction of the electron temperature. In comparison, a decrease of CN emissions with the increase of N_2O has been related to lowered production of C or CN from the etching of fluoropolymer during the process. To confirm this, different electrical conditions have been compared. A modulated voltage has been created to control the ON time of the discharge. The results suggest that, by changing the duty cycle while maintaining the same mean power, optical emissions of the CN were less intense at lower voltage and higher duty cycle.

These results were correlated with XPS analysis of the surface. The analysis indicates that the lower the voltage, the higher the amount of CN present on the surface, which was correlated to the lesser CN concentration measured in the gas phase. This means that impurities and/or the electrical excitation of the discharge play an important role in the amount of CN on the surface, and hence on the adhesion improvements of the polymer. In conclusion, the real-time analysis of the CN emissions by OES seems a very promising method to control the process and ensure the good reproducibility of the surface properties.

Atmospheric Pressure Plasma Synthesis of Bismuth Quantum Dots Ankur U. Kambley, Bruno Alessi, Paul Maguire and Davide Mariotti; Ulster University, United Kingdom

Plasma processes operated at atmospheric pressure have been shown to be reliable and cost efficient methods[1] for material synthesis and surface engineering for micro/nanoscale fabrication. More specifically, atmospheric pressure microplasmas are of great interest for metal nanoparticle synthesis from bulk solid materials, by-passing conventional processes that require hazardous chemicals, numerous processing steps and/or expensive vacuum equipment.[2] Metal nanoparticles have shown interesting optical and electronic properties. At the nanoscale, metal nanoparticles exhibit a transition into a semiconductor behaviour and bandgap widening due to quantum confinement.[3,4] Especially bismuth metal, owing to its large exciton Bohr's radius, starts exhibiting quantum confinement at diameter of ~50nm.[4] This bismuth semimetal behaviour is highly desirable for optoelectronics, energy storage and thermoelectric applications.
Here we present work on the synthesis of bismuth quantum dots (Bi-QDs) by a one-step atmospheric pressure plasma process from a bismuth wire, either for direct deposition in the form of films or directly dispersed in liquid. Various plasma reactor architectures are examined to study the possible deposition conditions. The synthesised Bi-QDs are studied for their morphological, chemical, optical and electronic properties. The mean diameter of these QDs is in the range of 2-3 nm depending on the gas flow. XPS analysis shows the presence of oxidation peaks however XRD analysis show metallic peaks only which indicates the presence of surface oxidation which may have been caused by atmospheric interactions following the synthesis process.

Rapid and One-Step Synthesis of Nickel Oxide Nanoparticle Thin Films Using Gas Phase Microplasma in Ambient Air Dilli Babu Padmanaban, Slavia D. Dsouza, Paul Maguire and Davide Mariotti; Ulster University, United Kingdom

Microplasma techniques in recent times achieved attractive performance in nanomaterial processing. Microplasmas are special kind of sub-millimetre plasmas that are simple and easy to establish for different applications.[1,2] With this technique several kinds of nanomaterials such as metal, transition metal oxides etc. were demonstrated with flexibility over the choice of precursors.[3] Nickel oxide (NiO) is an excellent p-type semiconductor, which is widely employed as electrode material in many applications like supercapacitors, batteries, solar cells.[4,5,6] NiO can be produced through chemical and physical deposition methods, however, most of current methods rely on toxic precursors and time consuming post-process steps.
In this work, we demonstrate the synthesis of nickel oxide nanoparticle thin film using a gas phase microplasma technique. The characteristics of the films

were studied for different oxygen precursor along with He carrier gas and film deposition conditions. It was observed that at a given He/O_2 gas mixture, the films appear with different macroscopic morphologies including columnar or planar features depending on the deposition condition. The nanoparticles deposited however exhibit diameters well below 10 nm. Surface chemical analysis and the investigation of the crystal structure show that the nanoparticle are composed of cubic NiO phase. We present the initial application of this process for transport layer in solar cell devices.

Plasma Materials Processing with Controlled Microdroplets—Printing and Particles Synthesis Tsuyohito Ito[1,2], Kaishu Nitta[1], Yoshiki Shimizu[2] and Kazuo Terashima[1,2]; [1]The University of Tokyo, Japan; [2]National Institute of Advanced Industrial Science and Technology (AIST), Japan

With recent development of atmospheric-pressure technologies, various plasma applications with liquid/solution have been extensively studied. In this presentation, we are demonstrating pattern drawing as well as monodispersed spherical particle synthesis via atmospheric-pressure plasma using controlled microdroplets. Such microdroplets were ejected from an inkjet device with high reproducibility in place and size.
The first part of the presentation is about development of plasma-assisted inkjet printing, where inks during flight and after landing on a substrate are irradiated by atmospheric-pressure nonequilibrium plasma. Nanosecond pulsed discharge plasmas were applied here. When the ejected ink was exposed to plasma, reactive species from the plasma as well as rapid and local heating are expected to promote various reactions. Thus plasma-assisted inkjet printing could provide various advantages to inkjet printing, such as less pre- or post-treatments, low-temperature and rapid sintering/reduction, narrower pattern width, and/or on-site polymerization. Such advantages will be demonstrated with silver patterning using silver-nanoparticle-dispersed ink [1], poly(3,4-ethylenedioxythiophene) (PEDOT) pattern fabrication using 3,4-ethylenedioxythiophene (EDOT) monomer stock solution ink [2], and gold patterning using particle-free aqueous chloroauric acid solution ink [3].
The later part will be about monodispersed sub-micrometer spherical gold particles synthesis from chloroauric acid ($HAuCl_4$) solution [4]. While our previous study demonstrated that size-controlled particle synthesis with microdroplets generated by a mist atomizer, the particle sizes were distributed widely, originating from wide size distribution of the mist [5]. Here, by using an inkjet device, microdroplets were generated with high reproducibility. The plasma applied here was radio-frequency argon plasma. The synthesized sub-micrometer gold particles have a narrow size distribution (3%–9% standard deviation), and their diameters can be controlled at least in the 0.3–0.6 μm range by adjusting the concentration of the solution. Further details will be presented in the symposium.

Sputtering Deposition with Impurities—Another Key Parameter to Control Film Structures Naho Itagaki; Kyushu Univ, Japan

Structures of sputter-deposited films have been mostly determined in a way shown in the Thornton diagram, in which there are two key parameters: substrate temperature and sputtering pressure. Here we add another parameter, *impurity*, that adsorbs on, migrates on, and eventually desorb from the surfaces, and thus modify the film structures.
The first example is sputter deposition of single crystalline ZnO films on 18%-lattice mismatched sapphire substrates using N atoms as impurities. Generally, growth of single crystalline films on such large lattice mismatched substrates is impossible because the crystal growth ends up in the formation of relatively large three-dimensional (3D) islands (~100 nm in diameter) with large number of dislocations. Interestingly, however, we have observed that control of adsorption/desorption behavior of N atoms during deposition enables us to grow single crystalline ZnO films even on the sapphire substrates [1]. Here, buffer layers consisting of nano-sized 3D islands are initially grown by making N atoms adsorb on the surfaces. Next, ZnO films are fabricated on the 10-nm-thick buffer layers without N atoms. The crystal grains start to grow originating from the 3D islands, but in a short time, they coalesce to form two-dimensional (2D) layers. Eventually, the films grow in 2D mode having atomically flat surfaces. We consider that the desorption/adsorption behaviour of N atoms influences the surface energy and brings this interesting growth mode. During the buffer layer deposition, adsorbed N atoms lower the surface energy and lead to the formation of nano-sized grains. Such grans with high surface-to-volume ratio relieve the strain efficiently at the surface, resulting in the low dislocation density. On the other hand, N-atom desorption after the buffer layer deposition causes a drastic increase in the surface energy, which provides a driving force for coalescence of crystal grains and 2D-layer formation. In fact, we observed from vacuum ultraviolet absorption spectroscopy (VUVAS) and secondary ion mass spectroscopy that N solubility in ZnO is low of a few atomic ppm. This property makes N atoms segregate to the surface as well as to the grain boundaries, and thus reduces the surface free energy.
The next example is sputter deposition of amorphous In_2O_3:Sn (a-ITO) films on glass substrates. ITO films are essential for transparent electrodes, and a-ITO films have recently attracted attention due to the advantages such as surface smoothness, good short-range uniformity, low internal stress, and high etching rate. However, the mobility of conventional a-ITO films, fabricated below crystallization temperature, is quite low of 20–30 cm^2/Vs. Furthermore, the amorphous phases are unstable and easily crystallized around 150°C, limiting the use of a-ITO films in practical devices. Here we show that impurities

can solve the problems again. We have succeeded in fabrication of a-ITO films at high temperature of 150°C using N atoms, where the films maintain the amorphous structures even after annealing at 300°C . Both VUVAS and x-ray fluorescence results indicate that the amorphization is caused not only by the incorporated N atoms into the films that disorder the bixbyite In_2O_3 structure, but by the adsorbed N atoms inhibiting the crystal nucleation, which are eventually desorbed from the surfaces. The most remarkable feature of the a-ITO films is the high carrier mobility over 50 cm^2/Vs, attributed to the high-temperature deposition leading both to increased film density and to enhanced short- and mid-range ordering in the amorphous structures.
We believe that sputtering deposition with "impurities" offer new opportunities for designing materials with unprecedented structures.

Boron Nitride Modified via Plasma Processing in Hydroquinone Solution for Preparation of Polyrotaxane Composite Kenichi Inoue[1,2], Taku Goto[1,2], Tsuyohito Ito[1,2], Yoshiki Shimizu[2], Yukiya Hakuta[2], Kohzo Ito[1] and Kazuo Terashima[1,2]; [1]The University of Tokyo, Japan; [2]National Institute of Advanced Industrial Science and Technology (AIST), Japan

Plasmas in solution provide attractive processing environments for surface modification of materials. The chemical species such as oxygen and hydroxyl radicals in plasma introduce functional groups on surface of materials [1,2], and such surface modifications on carbon nanotube or hexagonal boron nitride (hBN) were reported to help their dispersion in polymers for developments of composite materials [3,4]. Our group revealed that surface modification via plasmas in solution was effective to achieve tough composites with high filler contents [4]. However, the mechanism of dispersion via such plasma modification is not fully understood and the methods to evaluate the surface modification is still insufficient.
In this study, zeta potential was used as the indicator of surface modification of hBN particles for developing its composite elastomers with polyrotaxane. Our previous study demonstrated that a plasma in solution with hydroquinone additive could produce water-dispersible hBN with higher zeta potential than hBN modified by a plasma in solution without additives [5]. Here, such water-dispersible hBN was dispersed into polyrotaxane as composite materials. Polyrotaxane is a unique polymer with movable crosslinking points allowing homogeneous deformation which agrees with ideal rubber elasticity [6]. The prepared hBN/polyrotaxane composites were observed with X-ray computed tomography (X-CT), and their tensile properties were measured.
In this experiment, plasmas were generated in flowing solution with cavitation bubbles dispersing hBN particles having a diameter of 0.2 μm by applying a bi-polar pulsed voltage [7]. Plasma processing in hydroquinone solution could produce water-dispersible hBN particles named as "HQpBN", and hBN particles modified via plasma processing in pure water were named as "pBN". The zeta potential measurement (ZetaView PMX 110, Particle-Metrix) confirmed that HQpBN had zeta potential of -43 mV at pH 7, slightly higher than -37 mV of pBN. Polyrotaxane composites with hBN concentration of 30 wt% were prepared with the pBN and HQpBN. X-CT (SkyScan1278, Bruker Inc.) observation revealed that pBN/polyrotaxane composite had pBN aggregate with size of 1–10 μm inside the composite, whereas HQpBN/polyrotaxane composite had no observable aggregates with a resolution of 0.5 μm/pixel. The pBN/polyrotaxane composite had tensile strength of 3.7 MPa and extension ratio at break of 1.6, whereas the HQpBN/polyrotaxane composite achieved tensile strength of 6.5 MPa and extension ratio at break of 2.0.
It was demonstrated that hBN with enlarged zeta potential showed uniform dispersion in composite and achieved high tensile properties of composite. These results suggest that the zeta potential can be an indicator of surface modification via plasma in solution with the purpose for preparing uniformly dispersed composites.

Three–Dimensional Porous Au/Ag Nanostrutures Microplasma-Engineered Nanoassemblies on Cellulose for Surface Enhanced Raman Scattering Properties Jui-Yi Yeh; National Taiwan University, Taiwan

Assembly of functional nanostructures on substrates are useful for chemical and biomolecular sensing,optoelectronics, catalysis, and energy conversion and generation. However, conventional methods to produce assembly of nanostructures on substrates are usually time-consuming, complicated, and involving toxic and expensive chemicals. Here we report the fabrication method of microplasma-engineered nanoassembly (MEN) of plasmonic Au-Ag core-shell nanoparticle for ultrasensitive flexible surface-enhanced Raman scattering (SERS) substrates. Plasmonic Au- Ag core-shell NPs with tuned LSPR properties can be synthesized
and deposited on cellulose papers in one step with ambient condition using microplasmas[1]. The synthesized Au-Ag core-shell NPs are composed with crystalline-twinned Au cores coated by Ag shells via epitaxial growth under microplsamas, providing enhanced charge transportation during Raman scattering. 3D confocal microRaman scattering study shows that a large SERS volume was formed in the as- fabricated MEN substrates, leading significant SERS properties of 1 fM LoD and ~10^{12} enhanced factor (EF) with the Rhodamine 6G (R6G) as the Raman probe. However, However, we also demonstrated the different kinds of Raman probe including Ketoprofen (KP), folic acid (FA), and Salicylic acid (SA). They are one of the important molecules of the human body. The limit of detection (LOD) of KP , FA and SA by Au@Ag SERS paper-based substrate can be low to 10^{-10}M,10^{-12}M and 10^{-8}M. To sum up, Au@Ag material on paper-based substrate could provide SERS performance as sensitivities technique for the detection of human body molecular. In the future, our work demonstrates a scalable method to synthesize plasmonic nanoassenblies under ambient condition for emerging applications including nanocataysis, sustainable energy, and biomedical imaging.

8:00 PM EQ09.11.05
Microplasma Nanoengineering of Emission-Tunable Colloidal Nitrogen-Doped Graphene Quantum Dots for Broad-Range Fluorescent pH Sensors Darwin Kurniawan[1], Kostya (. Ostrikov[2] and Wei-Hung Chiang[1]; [1]National Taiwan University of Science and Technology, Taiwan; [2]Queensland University of Technology, Australia

Graphene quantum dots (GQDs), one of the newest types of carbon nanoparticles (CNPs) with size <20 nm, have attracted many research attentions due to the highly tunable photoluminescence (PL) properties, biocompatibility, chemical and photo stability, and low toxicity. Doping GQDs with heteroatoms, such as nitrogen, can increase the PL quantum yield and has strong electron withdrawing ability. Therefore, nitrogen-doped GQDs as fluorescent pH monitor excels in sensitivity, selectivity, rapidity, and applicability comparing with the conventional electrochemical method, especially for bio-related and

medical applications. Good biocompatibility and low toxicity also make NGQDs more preferable to semiconductor quantum dots, organic fluorescent dyes, and noble-metal nanoparticles. As a matter of fact, pH value plays a very important and crucial role in all life forms. A small variation in pH not only endangers the lives of plants and animal but also human beings as it will mainly pollute our drinking water, which may cause some health issues, like physiological dysfunction or diseases. Moreover, with the fact the extracellular pH value of cancerous cell is lower than the intracellular pH value, early cancer diagnostic can be achieved.

Most of the approaches for synthesizing NGQDs are complex, time-consuming, in need of harsh reaction condition, and costly. Hereby, microplasma emerges as one of the most promising approaches for nanomaterials processing due to its facile, stable, efficient, and relatively low cost. The high electron density provided are very energetic (~10eV), which allows non-thermal dissociation of molecular gases to form high concentrations of reactive radical species, *e.g.* $OH^{\bullet}$, $O^{\bullet}$, $O_2^{-\bullet}$, and $NO^{\bullet}$. These reactive radical species along with electrons are brought into the precursor solutions and will interact with the solution chemical species to form GQDs in a cascaded chemical reactions.

Here we report a novel and effective synthesis of the emission-tuneable NGQDs by nanoengineering the N dopant configuration and surface functionalities of GQD surfaces under ambient conditions using microplasmas. The emission-tuneable NGQDs was explored by precisely controlling the chemistry conditions of the reactions during the synthesis This synthetic method leads to highly crystalline particles with easily tunable properties in high reproducibility from a simple chitosan biomass treated in different dilute acid solutions. Based on protonation and deprotonation of NGQDs surface functional groups, it is believed that the distinct proportions of surface functionalities can greatly influence the pH sensing performance. An optimum PL based pH probe with broad linear range of 1.78-13.56 and high accuracy can be obtained from acetic acid treated chitosan with high quantum yield up to ~30%. Moreover, the linear relationship between the UV absorption and the pH values are also obtained, covering from pH 1.25-10.17 and pH 10.17-13.24. The dual optical sensing characteristics allow for almost covering the entire pH range and better accuracy. Our work offers a promising strategy to engineer the functionalities of NGQDs applicable not only for optimal pH sensors but also for other applications with great potential.

Applications of Atmospheric Pressure Plasmas in Interfacial Treatments for Perovskite Solar Cells I-Chun Cheng, Cheng-Che Hsu and Jian-Zhang Chen; National Taiwan University, Taiwan

Atmospheric pressure plasmas have drawn great attention in a wide variety of fields, such as surface engineering, material processing, biomedicine and agriculture. Possessing potential economic benefits in comparison with low-pressure plasmas, atmospheric pressure plasmas, without the requirement of vacuum technologies, are particularly attractive for processing large-area low-cost photovoltaic devices. Here we demonstrate examples of performance enhancement of n-i-p lead halide perovskite solar cells with the assistance of atmospheric pressure plasma treatments. In the first case, a nitrogen DC-pulse atmospheric-pressure plasma jet (APPJ) was applied to pre-treat the fluorine-doped tin oxide (FTO) glass substrates for perovskite solar cells. In comparison with a conventional 15-min UV-ozone treatment, a 10-s APPJ treatment can effectively decontaminate and enhance the wettability of FTO substrates and thus improve the cell efficiency by 27%. In the second case, a planar-type dielectric barrier discharge apparatus (DBD) was used to treat the absorber layers of perovskite solar cells. The perovskite absorber layer was formed by spin-coating a dimethylformamide solution containing CH_3NH_3I and PbI_2, followed by a soft-bake. Prior to the deposition of the spiro-OMeTAD hole transport layer, the DBD treatment was carried out in the nitrogen ambient. The result shows that a 20-s treatment can introduce the proper surface modification and grain growth of the perovskite absorber and thus improve the cell efficiency by 38%. In the third case, a low-temperature atmospheric-pressure dielectric-barrier-discharge-jet (DBDjet) was applied to post-treat the jet-sprayed silver nanowires (AgNWs) counter electrodes for fully solution-processed perovskite solar cells. The DBDjet treatment can remove the polyvinylpyrrolidone on the surface of AgNWs and thus improve the interfacial contacts among AgNWs and between the AgNWs layer and hole transport layer. A 33% enhancement in the cell efficiency was achieved when the AgNWs electrode was treated by the DBDjet for 10 times at a scan rate of 0.5 cm/s.

9:30 PM EQ09.12.02
Synthesis of Cuboid $Cu(HBTC)(H_2O)_3$ Using Plasma-in-Solution Treatment to Organic Ligands Moriyuki Kanno[1], Tsuyohito Ito[1], Yoshiki Shimizu[2] and Kazuo Terashima[1]; [1]The University of Tokyo, Japan; [2]National Institute of Advanced Industrial Science and Technology (AIST), Japan

Metal-organic frameworks (MOFs) or supramolecular coordination polymers are porous materials composed of metal ions and organic ligands. Due to their high surface area and designability, they are expected to be applied to catalyst, gas storage, and drug delivery. Moreover, they also serve as solid precursors for metals and metal oxide. Many porous transition metal oxides, such as CuO and Cu_2O, have been obtained by pyrolysis of MOFs under controlled atmospheres. Therefore, the control of the morphology of MOFs has recently attracted much attention in terms of both direct applications of MOFs and their application to intermediate materials for various metal or metal oxide materials synthesis. Here, we focused on $Cu(HBTC)(H_2O)$, a MOF with Cu^{2+} ions and organic ligands, 1,3,5-tricarboxylbenzene (H_3BTC, trimesic acid), as raw materials. $Cu(HBTC)(H_2O)_3$ has been studied as an antibacterial material, a support agent for catalysts with metal nanoparticles, and intermediate material for Fe-BTC, which is a highly efficient nanozyme. $Cu(HBTC)(H_2O)_3$ is known as a one-dimensional material, but in recent years, the synthesis of two-dimensional nanosheets has been reported. In this study, using plasma-in-water treatment solution of H_3BTC, three-dimensional cuboid $Cu(HBTC)(H_2O)_3$ was synthesized [1]. It was also observed that the morphology changed with plasma treatment time. Plasma in liquid has been studied for applications in materials synthesis and surface modification, including the synthesis of MOFs [2]. However, the effect of plasma in liquid on organic ligands has not yet been clarified, and in this study, we observed the effect by treating only organic ligands with plasma in water. The plasma-treated solution of H_3BTC was also analyzed to study the effect of plasma-in-water treatment on the organic ligands by liquid chromatography, fluorescent emission spectra, and UV-Vis spectra. These results suggest that hydroxy groups are functionalized on the organic ligands by plasma-in-water treatment. Partial plasma treatment of raw materials, demonstrated here, could be useful in future studies on complex synthesis.

Microplasma-Reinforced Fabrication of Crosslinked Nitrogen-Doped Graphene Quantum Dot Sponges for Environmental Water Purification Applications Darwin Kurniawan[1], Kostya (. Ostrikov[2] and Wei-Hung Chiang[1]; [1]National Taiwan University of Science and Technology, Taiwan; [2]Queensland University of Technology, Australia

Quantum confinement of graphene quantum dots (GQDs) yields a unique photoluminescence (PL) properties which has been widely used for many applications including bioimaging, chemical and biological sensing, LED, optoelectronic devices, and energy related applications. This performance can be further enhanced by introducing heteroatom, such as nitrogen (N) into the sp^2 carbon core. The high electronegativity of N atom has been proven to provide better electron transfer for improving both sensing and catalytic performances. Despite the promising facts, the applicability of NGQDs have been hampered by their synthesis methods. Postgrowth N doping has been regarded as time consuming and requiring harsh reaction conditions, while the direct synthesis via top-down or bottom-up approach also suffers from uncontrolled NGQDs properties, long reaction time, laborious synthetic procedures, harsh reaction conditions, and scalability.

Moreover, the practicality of NGQDs can be further enhanced by incorporating the NGQDs in appropriate 3D matrices. Materials with 3D architectures like hydrogels and sponges have shown great potential in relevant applications due to their own merits. With regards to the presence of surface functional groups, the NGQDs not only able to act as stimuli response probe to the matrices, but also as nanoscale crosslinker via covalent or non-covalent interaction. As a result, the resulting composites exhibit better mechanical properties than the control groups. It is also envisaged that this nanoscale crosslinker is capable of replacing the conventional toxic crosslinker (*e.g.* EDC-NHS, glutaraldehyde, etc.), which further boosts the applicability either in biomedical or environmental field.
Water contamination has undoubtedly been one of the most concerning problem faced by many people. The contamination generally involves heavy metal ions (Hg^{2+}, As^{3+}, Cd^{2+}, etc.), organic dyes (remazol brilliant blue R (RBBR), rhodamine B, congo red, etc.), and organic pollutants (nitroarenes family) which are highly toxic and dangerous to human being. Among other available methods, adsorption has been one of the most promising method to remove those contaminations from water owing to its effectiveness, efficiency, low cost, and simplicity.

Microplasma as gaseous discharge with one dimension geometrically confined to <1 mm emerges as an alternative way to promote crosslinking and polymerization process with the absence of toxic chemical crosslinker at ambient conditions. Besides, microplasma is also capable of cleaving polymeric chain to generate porous structures in the resulting 3D materials, resulting in enhanced pore size, surface area, hydrophilicity, and wettability. Herein, we utilized a microplasma system to synthesize NGQDs from chitosan at ambient conditions. The post-plasma solution was converted into NGQDs gel by neutralizing the unreacted chitosan with sodium hydroxide (NaOH) and subjected to another microplasma treatment for crosslinking process to generate NGQDs hydrogel. The fabricated NGQDs hydrogel can be further converted to NGQDs sponge by subsequent freeze-thawing method, showing remarkable water uptake and dye adsorption ability for RBBR. Our work provides an insight into the green and sustainable development of NGQDs sponge applicable for water environmental application.

Microplasma-Assisted and One-Step Fabricated Silver/N-GQD Nanohybrids for Improve Raman Detection and PL Detection for Arsenic Species Jui-Yi Yeh[1] and Wei-Hung Chiang[2]; [1]National Taiwan University, Taiwan; [2]National Taiwan University of Science and Technology, Taiwan

Recently experimental and theoretical works have reported that graphene quantum dots (GQDs), a unique form of zero dimensional nanostructure, and their exceptional properties make them promising in biosensing applications. Surface-enhanced Raman scattering(SERS) is an ultra-sensitive analytical technique for bio-molecules detection. While the potential of surface plasmon resonance(SPR) metals (e.g. Au and Ag) and graphene for SERS has been demonstrated, but the work of GQDs applied as SERS substrates is still lacking. Here we reported the rational design to develop GQD-based SERS active substrate.
Furthermore, modified GQD with metal nanostructures will lead to important advance for SERS-based detection. Here we demonstrate a facile synthesis of NGQD/AgNP nanohybrids by the atmospheric-pressure microplasma-assisted electrochemistry. Detailed nanomaterial characterizations including transmission electron microscopy, UV/Vis spectroscopy show that the microplasma-assisted electrochemical reaction can successfully grow Ag nanoparticles (AgNP) onto the NGQD surfaces to form the Ag@NGQD NP nanohybrids with heterodimeric nanostructures within minute scale. Besides, the photoluminescence (PL) optical study of NGQDs and AgNP@NGQD indicated that the non-radiative fluorescence resonance energy transfer(FRET) involved in the AgNP@NGQD nanohybrids.In the systematic Raman study, Rhodamine 6G(R6G) and B-carotene are selected as the Raman probe molecules. First we compare the SERS property of four kinds of Ag@NGQDs with different photoluminescence property (e.g. different emission wavelength), Raman results show that SERS performance of Ag@NGQD0.02 is highly influenced by overlap area in PL-UV image. The as-produced AgNP@NGQD nanohybrids shows superior SERS performance with high enhancement factor (EF) around $1x10^8$. We further studied the NGQD-AgNP nanohybrids with different FRET efficiency. The results revealed that FRET of the as-produced AgNP@NGQD nanohybrids is the dominant factor to SERS properties in our
study.
On the other hand , the asprepared Ag@NGQD exhibited excitation-independent behavior and high optical stability. Furthermore, based on the complexation between As3+ and Ag@NGQD, the fluorescence intensity of the Ag@NGQD could be greatly quenched by the addition of a small amount of As 3+ ions. The linearity range is 0.1–1000 μM with a detection limit of 0.7 nM. For this reason, the proposed method was demonstrated to be selective and suitable for As 3+ analysis in natural water samples. And, Ag@NGQD with the biosafety have the potentials for intracellular As3+ detection.

Plasma Fabrication of Graphene Nanostructures for Solar-Thermal Conversion Zheng Bo; Zhejiang University, China

Plasma technology plays a vital role in the manufacturing of materials for a wide range of industries. This talk presents a plasma-fabricated graphene nanostructure and its applications for solar-thermal conversion. In the plasma-enhanced chemical vapor deposition process, an electric field is produced by gas discharge and the graphene planes are grown along the electric field lines that converge normally onto the surface of substrates, forming vertically-arranged graphene nanosheets (VGs). With vertical orientation and open channels, VGs show the potential of constructing light traps that enable a high absorptance of 98% towards solar irradiation. Besides, plasma-enabled in-situ nitrogen doping during the graphene growth can mediate the surface wettability of the VGs from hydrophobic to hydrophilic. In particular, the hydrophilic N-doped VGs can serve as capillary pumps to provide sufficient water supply for solar-driven interfacial evaporation, and thus establish a high evaporation rate and high energy conversion efficiency in solar desalination applications.

Inverted Stranski-Krastanov Growth of Single-Crystalline $Zn_{1-x}Mg_xO$ Films on Sapphire Substrates Using Magnetron Sputtering Daichi Takahashi, Daisuke Yamashita, Takamasa Okumura, Kunihiro Kamataki, Kazunori Koga, Masaharu Shiratani and Naho Itagaki; Kyushu University, Japan

$Zn_{1-x}Mg_xO$ are promising materials for optoelectronic/excitonic devices because of the large exciton binding energy (60 meV) and the potentially tunable band gaps [1]. Ohtomo *et. al.* have recently demonstrated the bandgap tuning of wurtzite $Zn_{1-x}Mg_xO$ films in the range 3.4–4.15 eV [2], where the films have been grown by pulsed laser deposition (PLD). However, the large lattice mismatch between $Zn_{1-x}Mg_xO$ films and commonly used substrates, such as sapphire, often results in poor crystal quality. Aiming to overcome this challenge, we here perform epitaxial growth of $Zn_{1-x}Mg_xO$ films on sapphire substrates using *inverted* Stranski-Krastanov (inverted SK) mode [3]. In this mode, strain-relaxed nano-sized 3D islands (buffer layers) are initially grown by using impurities to control the surface energy. Then the islands coalesce to form 2D layer after the desorption of impurities, and eventually, films grow in 2D mode and form single crystals. This mode has enabled us to grow single crystalline films on large lattice mismatched substrates [3]. Here we demonstrate inverted SK growth of $Zn_{1-x}Mg_xO$ films using N atoms as impurities, where sputtering method is employed for film deposition taking the advantages of the high dissociation degree of N_2.
All the films were fabricated by radio frequency magnetron sputtering. First, 10-nm thick buffer layers consisting of 3D islands were deposited on sapphire substrates at 780°C using N_2/Ar gas. Next, wurtzite $Zn_{1-x}Mg_xO$ films were fabricated on the buffer layers at 800°C using O_2/Ar gas, and the films were post annealed in O_2 atmosphere at 880°C for 10 hours.
We have observed inverted SK growth and thus obtained high-quality single-crystalline $Zn_{1-x}Mg_xO$ films of x = 0.05–0.33. Atomic force microscopy measurement revealed that the films have atomically flat surfaces with root mean square roughness of 0.41–0.75 nm. The high crystal qualities of the films even with large Mg contents were also proved by x-ray diffraction analysis.The full widths at half maximum of the (0002) rocking curves are in the range between 0.05° (x = 0.33) and 0.07° (x = 0.14). These values are comparable to that of bulk single-crystal ZnO. Furthermore, we observed that the optical absorption edge shifts continuously toward the shorter wavelength with increasing x, and the band gap has been tuned in the range 3.37–4.03 eV. These results allow us to conclude that the combination of inverted SK growth and magnetron sputtering is a powerful method of growth of high-quality single-crystalline $Zn_{1-x}Mg_xO$ films on lattice mismatched substrates.

Epitaxial Growth of $(ZnO)_x(InN)_{1-x}$ Films on ZnO Substrate by Magnetron Sputtering—Impact of Substrate Surface Polarity Ryota Narishige, Daisuke Yamashita, Kunihiro Kamataki, Takamasa Okumura, Kazunori Koga, Masaharu Shiratani and Naho Itagaki; Kyushu University, Japan

We have developed novel semiconductors, $(ZnO)_x(InN)_{1-x}$ (called "ZION" hereinafter), which are pseudo-binary alloys of ZnO and InN. ZION have tunable band gaps across the entire visible spectrum, high exciton binding energy of 30–60 meV, and high optical absorption coefficients of 10^5 cm^{-1}, making ZION promising materials for optoelectronic and excitonic devices [1, 2]. Recently, we have succeeded in the heteroepitaxial growth of ZION films on sapphire, ZnO and GaN substrates by radio-frequency (rf) magnetron sputtering, where the temperature has been kept below 550°C so that the thermal dissociation of In–N bond is reduced. Furthermore, we found that under such conditions, "skewness", the third moment of the surface height distribution of the substrates, is a key parameter for enhancement of adatom migration on the surface and thus for growth of high quality ZION films [3]. Beside the morphology, the surface polarity of the substrates might also play an important role in adatom migration since it affects the sticking coefficient of adatoms [4]. We here demonstrate epitaxial growth of ZION films on both O-polar and Zn-polar ZnO substrates and discuss the impacts on the migration as well as the crystal growth of ZION films.
ZION films were deposited on ZnO substrates by rf magnetron sputtering where the lattice mismatch between the film and the substrate is 1.6%. O_2, N_2 and Ar gases were used, and the gas flow rates were 1.8, 24.0, and 30.2 sccm, respectively. The total pressure was 0.50 Pa. ZnO and In targets with purity of 99.99% were used. The substrate temperature was 450°C. The deposition time was 220 seconds, and the film thickness on the O-polar and Zn-polar substrates were 25 and 35 nm, respectively. The chemical composition ratio was $(ZnO)_{0.85}(InN)_{0.15}$, confirmed by x-ray fluorescence spectrometry. The heteroepitaxial growth of ZION films on both surfaces were confirmed by high-resolution transmission electron microscopy (HRTEM), where all the films have atomically sharp interfaces with the substrates. Interestingly, however, the HRTEM images show a significant difference in the lattice relaxation process between the films. On Zn-polar ZnO surfaces, relaxation occurs at the beginning of the film growth, whereas on O-polar surfaces, ZION films are fully coherent with the 1.6%-lattice-mismatched ZnO substrates at least for 15 mono layers. We also found that the difference in the depth profile of the chemical composition. Rutherford back-scattering spectra show that on Zn-polar surfaces, there is no compositional change in the depth direction, indicating the particle flux toward the substrate mainly governs the film growth. While on O-polar surfaces, In and N contents decrease toward the surfaces, where adatoms tend to be incorporated into thermodynamically favored lattice positions. We consider that these differences are brought by the differences in the adatom migration, that is, O-polar surfaces provide smaller sticking coefficients and thus longer migration length of Zn/In atoms due to the smaller number of back bonds of Zn/In atoms on the surfaces [4]. This hypothesis is consistent with the facts that O-polar surfaces lead to lower deposition rate and to higher crystal quality of ZION films where the full-width at half maximum of (002) x-ray rocking curves is about 0.2°.

High-Temperature Growth of Amorphous In_2O_3:Sn Films by Magnetron Sputtering Using Nitrogen Yuta Mido[1], Keigo Takeda[2], Daisuke Yamashita[1], Takamasa Okumura[1], Kunihiro Kamataki[1], Kazunori Koga[1], Masaharu Shiratani[1], Masaru Hori[3] and Naho Itagaki[1]; [1]Kyushu University, Japan; [2]Meijo University, Japan; [3]Nagoya University, Japan

In_2O_3:Sn (ITO) films are essential for transparent electrodes in flat panel displays, touch screens, and so on. Recently, amorphous ITO(a-ITO) has attracted

attention as an alternative to polycrystalline ITO due to the advantages such as surface smoothness, high etching rate and low internal stress. However, the mobility of conventional a-ITO films, deposited by sputtering below crystallization temperature of In2O3 (~150°C) is quite low of 20–30 cm^2/Vs. Furthermore, the amorphous phases are unstable and they easily crystallize around 150°C, limiting the use of a-ITO films in practical devices. We have recently clarified that beside the substrate temperature, *impurity behavior* on the surfaces during the growth affects the film structures [1], and have succeeded in fabricating a-ITO films at 150°C using nitrogen as impurity, where the mobility is high of 50 cm^2/Vs [2]. Here we demonstrate sputtering synthesis of a-ITO films at 350°C using nitrogen and see what happens if we increase the temperature far above the crystallization temperature of In_2O_3.
ITO films were deposited by radio-frequency magnetron sputtering on quartz grass substrate at 350°C. Ar and N_2 gases were used and the total pressure was 0.9 Pa. The gas flow rate ratios of N_2 was 0–20%. In_2O_3:Sn (10wt.%) targets were used. The film thickness was 50 nm. N content in the films and the absolute N atom density in the plasma were measured by x-ray fluorescence (XRF) and vacuum ultraviolet absorption spectroscopy (VUVAS) [3], respectively.
X-ray diffraction (XRD) measurements revealed that a-ITO films are fabricated even at high temperature of 350°C using nitrogen. For the ITO films fabricated at N_2 flow rate ratios of 0–7%, diffraction peaks from In_2O_3 (222) plane are observed at 30.5°, while, no peaks are observed for the films fabricated at N_2 = 10–20%, indicating the films have amorphous structure. We found from VUVAS and XRF measurements that despite the high density of N atom in the plasma of 10^{11} cm^{-3}, being one order of magnitude higher than O atom density, N contents in the films are only a few at.%. These results suggest that the amorphization is caused not only by the N atoms incorporated into the films that disorder the bixbyite In_2O_3 structure, but by the adsorbed N atoms that inhibiting the crystal nucleation, which are eventually desorbed from the surfaces. Owing to the amorphous structure, the a-ITO films have smooth surface with the root mean square (RMS) roughness of 0.8 nm, which is half of that of films fabricated without N_2. The most remarkable feature of the a-ITO films is the high carrier mobility of 66 cm^2/Vs. We consider that the high-temperature deposition leads both to increased film density and to enhanced short- and mid-range ordering in the amorphous structures, resulting in such high mobility.

Broken Symmetries and Emergent Magentoelectricty in Multiferroics Sang Wook Cheong; Rutgers, The State University of New Jersey, United States

We will first discuss the general connection between broken symmetries and emergnet phenomena, especially magnetoelectricty in multiferroics in the framework of symmetry operational similarity (SOS). As a specific example of new phenomena associsated with SOS, we will discuss toroidal magnetoelectricity in chiral and polar BaCoSiO4.

11:00 AM *EQ10.01.02
Electric Field Control of Magnetism—What Does It Take to Get to 100 mV Switching? Ramamoorthy Ramesh; University of California, Berkeley, United States

Among the large number of correlated oxide materials, there exists a small set of materials which exhibit multiple order parameters; these are known as multiferroics, particularly, the coexistence of ferroelectricity and some form of ordered magnetism (typically antiferromagnetism). The scientific community has been able to demonstrate electric field control of both antiferromagnetism and ferromagnetism at room temperature. Current work is focused on ultralow energy (1 attoJoule/operation) electric field manipulation of magnetism as the backbone for the next generation of ultralow power electronics. We are exploring many pathways to get to this goal. In this talk, I will describe our progress to date on this exciting possibility. My specific focus will be on the materials physics behind getting to 100mV switching of magnetism (and ferroelectricity).

11:30 AM EQ10.01.03
Cryo-STEM Imaging of Charge Order Textures in a Manganite Ismail El Baggari[1,2], David Baek[2], Michael Zachman[3,2], Di Lu[4,5], Yasuyuki Hikita[6], Harold Y. Hwang[5,6], Elizabeth Nowadnick[7] and Lena Kourkoutis[2]; [1]The Rowland Institute at Harvard, United States; [2]Cornell University, United States; [3]Oak Ridge National Laboratory, United States; [4]Northwestern University, United States; [5]Stanford University, United States; [6]SLAC National Accelerator Laboratory, United States; [7]University of California, Merced, United States

In complex oxides, charge-ordered states involve a complex interplay between charge, spin, orbital and lattice degrees of freedom, and modulate important macroscopic phenomena such as magnetic order, metal-insulator transitions and colossal magnetoresistance. The intra-unit-cell arrangement within charge order superlattices can lead to even richer physics by breaking additional symmetries and allowing novel couplings. In half-doped manganites, for instance, charge order can reside on the sites (site-centered) or on the bonds (bond-centered), with each possibility leading to a distinct orbital and magnetic order arrangement. Previous theroetical work also predicts a third possibility: the formation of a mixed (or intermediate) state combining both site and bond orders [1]. This state leads to the formation of finite electrical dipoles within each supercell and is therefore predicted to be polar and possibly multiferroic. However, determining if such a state exists and distinguishing between various charge-ordered textures remain a challenge.

Here we demonstrate that atomic-resolution cryogenic scanning transmission electron microscopy (cryo-STEM) enables the visualization of charge-ordered states in manganites through the lens of the complex, picoscale lattice distortions that entwine with electronic transitions. In the model charge-ordered system $Nd_{1/2}Sr_{1/2}MnO_3$, we addresse the longstanding question of whether charge order resides on the sites or on the bonds. In addition to observing that the system hosts site-centered charge ordering, we discover the nanoscale coexistence of an intermediate state which mixes site and bond orders. In agreement with the theroetical proposals, we confirm that this intermediate state breaks inversion symmetry. Finally we show that nonlinear couplings of distinct lattice modes locally control the selection between these competing ground states [2].

SESSION EQ10.02 Magnetoelectrics I
Session Chairs: Eckhard Quandt and Nian Sun
Tuesday Afternoon, November 30, 2021
Hynes, Level 2, Room 206

1:30 PM *EQ10.02.01
Enabling Low-Voltage Multiferroics and Magnetoelectrics Lane W. Martin; University of California, Berkeley, United States

Applications in advanced, beyond CMOS computing are driving researchers and industry alike to explore a broader set of materials than ever before. While industry has maintained, in some form, their ability to continually meet the demands of Moore's law by increasing the number of transistors on chip, largely in part from efforts in scaling and size reduction of the transistors themselves and the associated circuit area, the same cannot be said for energy scaling. In the last fifteen years, scaling has deviated from Dennard's trend which states that the power density of circuits stays roughly the same as transistors get smaller, assuming, concurrent voltage reductions are made. Herein lies the challenge – while we have reduced transistor and circuit size, voltages of operation have not been scaled at the same rate. As a result, power and energy dissipation now stands as one of the most pressing challenges for advanced nanoelectronics. This has motivated renewed attention to a wide variety of routes to reduce the voltage of operation of next-generation logic. Such approaches have thrust materials – including multiferroics and magnetoelectrics – back into the mix as candidates for beyond CMOS computing.

Despite considerable research on multiferroic and magnetoelectric materials in the last decade and advances in our ability to synthesize, control, characterize, and fabricate these materials, the requirements of beyond CMOS computing are already pushing these materials to their limits. Here, we will explore recent efforts to reduce the operating voltages of multiferroic and magnetoelectric devices including exploring both new and old materials in ever decreasing sizes. We will focus on thin-film versions of magnetoelectric composite structures based on piezoelectric/ferroelectric materials. For example, we will explore thin film ferromagnet/relaxor heterostructures and routes to quantify magnetoelectric coupling in small scale devices. Specifically, in $Fe_{0.5}Rh_{0.5}$/(0.68)$PbMg_{1/3}Nb_{2/3}O_3$-(0.32)$PbTiO_3$ (PMN-PT) heterostructures, we will demonstrate routes towards 100 mV actuation and magnetoelectric coefficients similar to those observed in other composite structures. In turn, we will discuss the implications of thin-film geometries for such applications and how substrate clamping impacts the response of materials. For example, we will explore how different types of relaxors (*e.g.*, PMN vs. $BaZr_{0.5}Ti_{0.5}O_3$) respond differently to substrate constraints and thus provide an impetus for the use of some relaxors over others in thin-film geometries. At the same time, we will explore how releasing such materials from the substrate – thereby producing free-standing versions of them – further changes their response to applied stimuli and could provide a pathway to the desired effects. Finally, we will explore the design of novel thin-film relaxor materials. We will look at how thin-film heterostructuring (namely as superlattices) could provide a novel route to improved relaxor behavior. To end, we will discus where these ideas could lead us next and what metrics can be met using these materials and methods.

2:00 PM *EQ10.02.02
Room Temperature Multiferroicity in Orthoferrite Films and Nanocomposites Caroline Ross and Shuai Ning; Massachusetts Institute of Technology, United States

Multiferroic materials and nanocomposites offer the promise of electrically-controlled magnetism and a path towards magnetoelectric memory and logic devices. Multiferroicity may be obtained in a single phase material or in a composite material consisting of a magnetic phase and a ferroelectric phase coupled by strain. Most research on single phase multiferroics has centered on BiFeO3, but we show here that room temperature multiferroicity can be produced in a single phase orthoferrite as a result of antisite defects. Ferroelectricity is obtained in thin films of Y-rich $YFeO_3$, yttrium orthoferrite (YFO), a perovskite-structured canted antiferromagnet. The ferroelectricity is attributed to Y_{Fe} antisite defects which facilitate a non-centrosymmetric distortion. This mechanism is predicted to work analogously for other rare earth orthoferrites, with a dependence of the polarization on the radius of the rare earth cation. We then demonstrate the growth of two-phase epitaxial nanocomposites consisting of YFO and a magnetic spinel, CoFe2O4 (CFO). A nanocomposite consisting of pillars of CFO embedded epitaxially in a YFO matrix exhibits both robust ferroelectricity and ferrimagnetism at room temperature, as well as a strain-mediated magnetoelectric coupling effect. This work expands the range of materials available for multiferroic and magnetoelectric applications.

2:30 PM *EQ10.02.03
Magnetic Domain Wall Activity in High Sensitivity Magnetic Field Sensors—Magnetic Noise and Magnetic Domain Control Jeffrey McCord, Cai Müller, Phillip Durdaut, Elizaveta Golubeva, Viktor Schell, Anne Kittmann, Matic Jovičević Klug, Dennis Seidler, Lars Thormählen, Benjamin Spetzler, Dirk Meyners, Franz Faupel, Eckhard Quandt and Michael Höft; Kiel University, Germany

Magnetic domain formation reveals fascinating physics and is of great relevance for technological applications. Recent advances in thin film devices adopting magnetic films as sensing layers offer promising routes for sensing ultra-low magnetic signals, e.g. with magnetoelectric (ME) cantilever sensors or surface acoustic wave (SAW) devices. As the sensors are operated by external stimuli of various frequencies, the complex physics of magnetic domain and domain wall activity at these modulation frequencies are one of the most important factors that determine the performance of the magnetic field sensors.
In-operando magnetic domain observation sheds light on the irreversible and hysteretic magnetization changes due to domain nucleation, domain wall resonances, domain wall flexure modes, precessional magnetization effects, and spin-wave like phenomena. Using time-resolved magneto-optical Kerr effect microscopy with time resolutions down to picoseconds, we show the effect of magnetic domains on the noise performance of ME, ΔE-effect, and SAW sensors. With the spatial and temporal domain analysis during sensor operation together with complementary electrical measurements, the micromagnetic origins are determined.
We identify specific magnetic domain wall processes as sensor-intrinsic noise sources. Magnetic noise originating from magnetic domain wall activity is the most relevant figure-of-merit for improving sensor performance. Even minimal magnetic domain activity restricts the achievable limit of detection. On various sensor specific examples, we demonstrate that understanding the magnetic domain physics and actively controlling magnetic domain behavior is key to improving sensor performance. The magnetic domain wall activity is directly related to magnetic losses. The presented data prove the significance of micromagnetic processes for real-world applications. Strategies for the elimination of domain wall activities and magnetic losses will be discussed.
We acknowledge funding through DFG CRC 1261 "Magnetoelectric Sensors: From Composite Materials to Biomagnetic Diagnostics".

Control Of Unconventional Spin Torques in Epitaxial IrO_2 Thin Films Michael V. Patton[1], Tianxiang Nan[2], Lu Guo[1], Ding-Fu Shao[3], Gahee Noh[4], Saba Karimeddiny[5], Phillip Ryan[6], Evgeny Y. Tsymbal[3], Si-young Choi[4], Dan Ralph[5], Mark Rzchowski[7] and Chang-Beom Eom[1]; [1]University of Wisconsin-Madison, United States; [2]Tsinghua University, China; [3]University of Nebraska–Lincoln, United States; [4]Pohang University of Science and Technology, Korea (the Republic of); [5]Cornell University, United States; [6]Advanced Photon Source, Argonne National Laboratory, United States; [7]University of Wisconsin–Madison, United States

Spin orbital torques (SOT) which are generated by a spin current are key to magnetic switching in spintronic applications. These SOTs can be generated by a spin source material via intrinsic mechanisms such as the spin Hall effect and can switch magnetizations without the need for external magnetic fields. Conventionally, the spin polarizations of these SOTs are limited due to the symmetry of the material allowing only for efficient in-plane magnetic switching. Unconventional SOTs arising from novel spin current polarizations however, have the potential to switch an arbitrary magnetization direction. Such SOTs have been reported in lower symmetry materials such as antiferromagnetic materials and transition metal dichalcogenides (TMDs) [1,2]. Here, we report the control of unconventional spin torques in epitaxial IrO2 thin films. IrO2 films with (001) and (111) orientation were grown by RF magnetron sputtering with a Py ferromagnetic overlayer and characterized using spin torque ferromagnetic resonance (ST-FMR). We find that the (001) orientation heterostructures have a conventional spin Hall conductivity (SHC) consistent with theoretical calculations and other experimental results [3]. The (111) orientation heterostructures show both conventional and unconventional spin torques consistent with trends predicted in our theoretical calculations. When charge current is applied along either of the crystallographic axes ([1-10] or [-1-12]), we see a noticeable unconventional contribution to the ST-FMR angular dependance from spins polarized along the charge current direction. We attribute these unconventional spin torques to the lower symmetry resulting from triclinic distortions in the (111) films. This work could provide further understanding of unconventional spin torques as well as controlling SOTs via epitaxial design.

Electrical Tuning of Spin to Charge Conversion Efficiency in Metal/$SrTiO_3$ Two-Dimensional Electron Gases for Future Spintronic Devices Srijani Mallik[1], Luis Moreno Vicente-Arche[1], Maxen Cosset-Cheneau[2], Paul Noel[2], Diogo Vaz[1], Felix Trier[1], Tanay Gosavi[3], Chia-Ching Lin[3], Dmitri Nikonov[3], Ian Young[3], Anke Sander[1], Agnès Barthelemy[1], Jean-Philippe Attané[2], Laurent Vila[2] and Manuel Bibes[1]; [1]Unité Mixte de Physique CNRS/Thales, France; [2]Université Grenoble Alpes, France; [3]Components Research, Intel Corporation, United States

Recent studies on oxide spintronics rely exceedingly on the efficient spin-charge interconversion property of the two-dimensional electron gases (2DEGs) possessing a finite Rashba spin-orbit coupling. $SrTiO_3$-based 2DEGs are usually generated by the deposition of epitaxial oxides like $LaAlO_3$ or of reactive metals such as Al [1, 2]. Such 2DEGs are highly promising for the interconversion between charge and spin currents through the direct and inverse Edelstein and spin Hall effects. Here, we compare the formation and properties of 2DEGs generated in $SrTiO_3$ by the growth of Al, Ta, and Y ultrathin films by dc magnetron sputtering [3]. Both in-situ and ex-situ X-ray photoelectron spectroscopy studies revealed the quantification of reduced Ti states associated with 2DEG formation, their reoxidation by exposure to the air, and the transformation of the metal into its binary oxides. The carrier densities are extracted from magnetotransport measurements. Finally, we investigate the spin-charge conversion as a function of gate voltage by performing spin-pumping ferromagnetic resonance experiments on similar metal/$SrTiO_3$ samples with a capping of an extra NiFe layer. The trends for the spin to charge conversion efficiency for different metal/$SrTiO_3$ systems provide a systematic study as a function of the carrier density and the transparency of the metal oxide tunnel barrier [3]. Our results strongly influence the path to choose the correct metal/$SrTiO_3$ interface to achieve higher spin to charge conversion for future spin-based information readout e.g. Magneto Electric Spin-Orbit (MESO) logics proposed by Intel corporation.

Emergence of Ferroelectricity at the Morphotropic Phase Boundary of Ultrathin $BiFeO_3$ Johanna Nordlander[1,2], Bastien Grosso[1], Marta D. Rossell[3], Aline Maillard[1], Elzbieta Gradauskaite[1], Nicola Spaldin[1], Manfred Fiebig[1] and Morgan Trassin[1]; [1]ETH Zürich, Switzerland; [2]Harvard University, United States; [3]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Multiferroic $BiFeO_3$ possesses a rich phase diagram of metastable phases that allows strain tuning of its room-temperature multiferroic properties in thin-film form. In particular, at large compressive strain a supertetragonal phase with giant polarization can be stabilized alongside the more common rhombohedral structure. Although $BiFeO_3$ in this mixed-phase regime is recognized as highly technologically relevant for multifunctional device integration, little is known about its ferroelectric state during the thin-film synthesis. Here, we demonstrate the robustness of polarization in ultrathin,

compressive-strained $BiFeO_3$ single layers and heterostructures during epitaxial thin-film growth. Using in-situ optical second harmonic generation (ISHG), we explore the emergence of ferroelectric phases at the strain-driven morphotropic phase boundary of $BiFeO_3$ in the ultrathin limit. Strikingly, we find that the epitaxial films grow in the ferroelectric tetragonal (T-) phase without exhibition of a critical thickness. The onset of monoclinic distortion of this T-phase and subsequent appearance of coexisting phases characteristic of the morphotropic phase boundary are confirmed only to develop post deposition and upon sample cooling. The robustness of polarization in the high-temperature T-phase against depolarizing-field effects is furthermore demonstrated during the growth of capacitor-like (metal|ferroelectric|metal) heterostructures. Our results show that strain-driven T-phase stabilization in multiferroic $BiFeO_3$ yields a prominent candidate material for realizing ultrathin ferroelectric devices with a well-defined polarization state.

Novel Solid-Source Metal Organic MBE for Highly Perfect Metal and Metal Oxide Films Sreejith Nair, William Nunn, Hwanhui Yun, Anusha K. Manjeshwar, Anil Rajapitamahuni, Dooyong Lee, Andre Mkhoyan and Bharat Jalan; University of Minnesota, Twin Cities, United States

A fascinating consequence of electron correlation is the emergence of a wide range of quantum phases including superconductivity in perovskite oxides such as cuprates and ruthenates. In partiular, ruthenates are difficult to grow in molecular beam epitaxy (MBE) due to the ultra-low vapor pressure of Ru. Additionally, Ru has high electronegativity which further makes it difficult for achieving complete oxidation, $Ru \rightarrow Ru^{4+}$ state under standard MBE conditions. The former issue has been dealt by supplying Ru using the electron-beam source whereas the oxidation issue is addressed by using highly reactive ozone. The use of electron-beam and ozone has adverse consequences on the stability of Ru beam-flux, which is critical for obtaining electronic-grade materials. Here, we show a novel solid-source metal-organic MBE approach that circumvents these issues by supplying a Ru contaning metal-organic compound as a solid source of Ru for the growth of RuO_2.
Single crystalline, epitaxial RuO_2 films with scalable thicknesses were grown on a variety of substrates including r-Al_2O_3 and TiO_2 (110), (101), (100), and (001) as evident from high-resolution X-ray diffraction and scanning transmission electron microscopy (STEM). RuO_2 films with rocking curve full-width-half-maxima as low as 0.05° were obtained on TiO_2 (110) at substrate temperature of 300°C. Atomic force microscopy revealed atomically smooth film surfaces with a root mean square (rms) roughness value ~ 3 Å.
All films revealed metallic behavior down to 1.8 K with room temperature resistivities being comparable to bulk (35 μΩ-cm) for films as thin as 10 nm. The effect of film thickness, orientation, strain, and defects such as oxygen vacancies on the electrical properties will be discussed.
Finally, we also show the versatility of this novel MBE technique by demonstrating the growth of epitaxial and atomically smooth (001) platinum (Pt) films on $SrTiO_3$ (001). These films exhibited room-temperature resistivity of ~ 15 μΩ-cm, which is again comparable to that of the bulk single crystals. Importantly, these films showed a residual resistivity ratio (RRR) of 27, which is the highest reported value among Pt films grown to-date. We argue that the solid source MOMBE approach may potentially open up new physical vapor deposition (PVD) pathways (not just MBE) for "stubborn" materials such as delafossites, iridates, tungstates which contain elements that have low vapor pressures and are hard to oxidize in low pressure PVD approaches.

Room-Temperature Ferroelectric Switching of Spin Hall Effect in GeTe Sara Varotto[1,2], Luca Nessi[2,3], Stefano Cecchi[4], Jagoda Slawinska[5,6], Paul Noel[7], Simone Petrò[2], Federico Fagiani[2], Alessandro Novati[2], Matteo Cantoni[2,3], Daniela Petti[2], Edoardo Albisetti[2], Marcio Costa[8], Raffaella Calarco[4,9], Marco Buongiorno Nardelli[5], Manuel Bibes[1], Silvia Picozzi[9], Jean-Philippe Attané[7], Laurent Vila[7], Riccardo Bertacco[2] and Christian Rinaldi[2]; [1]CNRS\Thales, France; [2]Politecnico di Milano, Italy; [3]Istituto di Fotonica e Nanotecnologie IFN-CNR, Italy; [4]Paul-Drude-Instit für Festkörperelektronik, Germany; [5]University of North Texas, United States; [6]University of Groningen, Netherlands; [7]Université Grenoble Alpes, France; [8]Fluminense Federal University, Brazil; [9]Consiglio Nazionale delle Ricerche, Italy

Spin-to-charge conversion has been designated by Intel as a viable solution for beyond-CMOS computing elements [1], with very favourable scaling laws. In this context, ferroelectric Rashba semiconductors (FERSCs) provide a way for the non-volatile electric control of spin-to-charge conversion, of great importance for such computing elements.

The parent compound of FERSCs is germanium telluride (GeTe), a CMOS-compatible semiconductor characterized by a giant Rashba-type spin-orbit coupling at room temperature, arising from the symmetry breaking induced by ferroelectric displacement. Importantly, calculations revealed that the spin orientation of each Rashba sub-band is inverted upon ferroelectric polarization reversal [2]. Such prediction has been already demonstrated experimentally in epitaxial GeTe(111) thin films on silicon, by our spin and angle resolved photoemission measurements on two surfaces with inward or outward spontaneous polarization [2]. Thus, FERSCs allow for ferroelectric control of the spin-resolved band structure in semiconductors, with intriguing implications on the spin transport properties.

Here we demonstrate the non-volatile, ferroelectric control of spin-to-charge conversion at room temperature in GeTe epitaxial films [3]. First, we demonstrate the feasibility of the ferroelectric switching, despite the high density of free carriers. The switching is induced by voltage pulses applied to a gate electrode, while the readout of the written state is performed by electro-resistive measurements of the GeTe/metal junction. Using spin-pumping experiments, we measured a sizeable spin-to-charge conversion efficiency comparable to Pt. We show that the sign of the generated charge current is reversed for two opposite ferroelectric states controlled by a gate. Density functional theory calculations reveal the consistency of these observations with spin Hall effect in thin GeTe films.

Our results open a route towards devices combining spin-based logic and memory integrated into a silicon-compatible material, where ferroelectricity can be employed as a state variable to tune the spin-to-charge conversion.

Exchange Biased, Electrically Modulated Magnetoelectric Thin–Film Sensors Towards Biomagnetic Measurements Patrick Hayes, Eric Elzenheimer, Lars Thormählen, Elizaveta Golubeva, Jeffrey McCord, Gerhard Schmidt, Michael Höft, Dirk Meyners and Eckhard Quandt; CAU Kiel, Germany

Contact-less biomagnetic sensing constitutes the next frontier for advanced healthcare, creating novel diagnostic abilities using multichannel magnetocardiography (MCG) and magnetoencephalography (MEG) either as a single source of information for rapid patient screening or as fusion with

established methods such as electrocardiography and electroencephalography as a source for additional information. The main obstacle towards clinical biomagnetic diagnosis using magnetic imaging techniques is the lack of readily applicable sensor technology offering extremely low magnetic noise floors; realtime MCG measurements demand for a limit of detection (LOD) lower than 10 pT/√Hz, reaching below 100 fT/√Hz enables even MEG signal acquisition. Such extremely minute amplitudes which are six to seven orders lower than earth's permanent magnetic field, demand lowest noise sensor technology as the low frequency signal regime below about 500 Hz is strongly affected by 1/f-noise.

In the presented work the piezoelectric (PE) phase of thin film magnetoelectric (ME) composites is actively excited, thus exploiting the converse ME effect [1], remedying shortcomings of the direct ME effect. The experimental work involves bulk micromachined thin film cantilever composites of mesoscopic scale (25mm x 2.5mm x 0.35 mm) of which high frequency mechanical resonances at about 500 kHz are studied. These resonances show high mechanical quality factors of about Q≈1000. This mechanical oscillation, being rigidly coupled into the magnetostrictive (MS) material phase leads to a voltage induced in a pickup coil surrounding the sensor composite. This converse ME voltage response with respect to small external fields shows high sensitivities in the order of kV/T and linearity up to a field magnitude of several µT, no external magnetic driving field is required.

The signal components of MCG lie in the range from 3 to about 150 Hz with vanishingly small amplitude < ~ 100 pT, this regime is targeted by this research. The entirely passive readout combined with low power requirements makes the presented ME sensor system suitable for integration into sensor arrays as anticipated for future biomagnetic imaging purposes. Using single layer MS FeCoSiB material, the measured noise floor in the low frequency regime shows an abrupt increase as soon as an excitation threshold of about 200 mV is reached. Intense magnetization activity in the MS phase poses the dominant source of noise, practically limiting the LOD at 10 Hz to about 70 pT/√Hz [1]. Using sophisticated magnetic layer systems such as exchange bias[2] enables to effectively lower the magnetically dominated noise, even at high drive levels, while maintaining high magnetic sensitivities.

In this contribution, we demonstrate the performance of electrically modulated thin film ME composites, using magnetron sputtered exchange biased, amorphous FeCoSiB films driven by aluminum nitride. This approach allows composite magnetoelectrics to detect low DC as well as AC magnetic fields of amplitudes down to ~ 10 pT/√Hz @ 10 Hz without the requirement of an external magnetic AC or DC bias field. In a human patient trial conducted in a magnetically shielded room, using averaging it was even possible to perform an MCG recording.

Polarization Switching Dynamics—A Molecular Dynamics Study Rajan Khadka and Pawel Keblinski; Rensselaer Polytechnic Institute, United States

In this work, we use molecular dynamics simulations to investigate the polarization switching dynamics in the single domain and 180º bidomain (i.e., including the preexisting domain wall) models in $BaTiO_3$ and $KNbO_3$. In a single domain study, for both materials, we observed that the hysteresis loop is essentially no-existent in the highest temperature non-cubic phase. We attribute this behavior to the observation of spontaneous local polarization fluctuations leading to the elimination of the nucleation barrier. Interestingly, in the case of the case of the bidomain structure, while we observe domain migration driven by the electric field, at high fields new domain nucleation is severely suppressed by comparison with the single domain simulations. This behavior is explained by the suppression of simulation dimension fluctuations due to the presence of the two domains. We give further credence to this conjecture by demonstrating that artificial suppression of the simulation cell dimension fluctuations in the case of a single domain switching also suppresses new domain nucleation.

High Data-rate Communication Enabled by Mechanical Non-Linear Response of Very Low Frequency (VLF) Magnetoelectric Antennas. Yifan He, Cunzheng Dong, Xianfeng Liang, Huaihao Chen and Nian Sun; Northeastern University, United States

The newly demonstrated very low frequency (VLF) magnetoelectric (ME) antennas [1] based on two-phase ME heterostructure have shown their capability and advantages in device miniaturization, ultra-sensitive magnetic field detection and communication in harsh environment. In this work, the authors utilized the non-linear electric field versus strain response of electrostrictive phase to achieve frequency mixing effect and intermodulation in the ME antenna. The proposed modulation scheme required simply an electrically applied superposition of carrier signal and baseband signal. To make the experimental demonstration, 5 layers of highly magnetostrictive Metglas foil were stacked and epoxy-bonded on both sides of a PMN-PT slab with a dimension of 50×5×0.2 mm, forming a two-phase ME heterostructure. The ME antenna had its maximum ME coefficient under 5.7 Oe DC magnetic field bias and the corresponding resonance frequency was 28. 73 kHz. With a 30 Vpp carrier signal at 28.73 kHz and a baseband signal at 5 kHz with various amplitudes applied across the PMN-PT slab, two modulated frequency components at 23.73 kHz and 33.73 kHz were observed in picked-up near field signal. The analog modulation depth can be controlled by the amplitude of the baseband signal. The digital modulation test was also performed with a binary digit sequence of "0101…" at a data rate of 5 kbps as baseband signal, the picked-up modulated signal was successfully demodulated by an on-board demodulator, which indicated the potential application of high data rate communication using the proposed modulation scheme and PMN-PT material-based VLF ME antenna.

Describing Hysteresis for Non-Switching Fields in Epitaxial Monoclinic PZT Films Using Polarization Rotation Model Philip Lucke[1], Muharrem Bayraktar[1], Andrey E. Yakshin[1], Guus Rijnders[2], Fred Bijkerk[1] and Evert P. Houwman[2]; [1]Industrial Focus Group XUV Optics, MESA+ Institute of Nanotechnology, University of Twente, Netherlands; [2]Inorganic Material Science, MESA+ Institute of Nanotechnology, University of Twente, Netherlands

Hysteresis is a limiting factor for the actuation accuracy of $PbZr_{1-x}Ti_xO_3$ (PZT) ceramics and thin films. Explanation of hysteresis for these materials using phenomenological models such as Rayleigh model is a common practice. On the other hand, application of Rayleigh model and its variants results in significant discrepancies in explaining the hysteresis behavior in epitaxial thin films. Here, hysteresis in application-relevant, epitaxial, monoclinic $PbZr_{0.55}Ti_{0.45}O_3$ films were investigated for non-switching AC excitation fields at zero and 20 $kVcm^{-1}$ DC bias cases. The hysteresis, loss and nonlinearity in the strain and polarization response of the films show unique features that is not expected from the Rayleigh model. The strain exhibits a hysteretic behavior and is linear with the excitation amplitude. However, the polarization is hysteretic and highly nonlinear over the investigated frequency range from 70 Hz to 5 kHz. The application of the bias shows almost no change for the strain response, whereas the loss tangent and nonlinearity of the polarization are significantly reduced.

The observations are explained by a new model, the so called polarization rotation model. This model describes the film properties as a result of the nonlinear rotation of the polarization vector within the monoclinic unit cell in response to the applied electric field, accompanied by a viscous interaction of the domains. The model can describe the scaling of the loss tangent and (non)linearity of the strain and polarization in an amplitude and frequency range that is far exceeding the applicable range of the Rayleigh model. It is shown that the nonlinear response and the hysteretic loss can be ascribed to two separate processes. The nonlinearity stems from the nonlinear nature of the rotation of the polarization vector. On the other hand, the hysteresis and ferroelectric loss stems from viscous interactions of domains during the rotation of the polarization vector.

EQ10.03.07

Observation of Topological Antiferromagnetic Phase at the Interface of Sputtered TI/FM Heterostructures Nirjhar Bhattacharjee[1], Adrian Fedorko[1], Valeria Lauter[2], Alexander Grutter[3], Alexandria Will-Cole[1], Donald Heiman[1] and Nian Sun[1]; [1]Northeastern University, United States; [2]Oak Ridge National Laboratory, United States; [3]National Institute of Standards and Technology, United States

Topological Insulators (TI) possess Dirac Surface Conducting States which are protected by Time Reversal Symmetry (TRS) [1]. However, a gap opening in the surface state bands through braking of TRS is needed for realization of Quantum Anomalous Hall Effect (QAH) which in turn can give rise to and Axion Insulator States and topological magnetoelectric effect [2-3]. Magnetic phase has been reported in TIs using doping [4-5] and proximity effect [6]. Recently, intrinsic magnetic TI (MTI) phase has been theoretically predicted in MBi_2Te_4 (M = Mn, Ni, Eu, V) family of compounds [7-8] and experimentally observed in $MnBi_2Te_4$ [9]. Here, we report growth of highly c-axis oriented TI, Bi_2Te_3 with nominal surface roughness (~1.3 nm) using sputtering and formation of a topological antiferromagnetic phase at the interface of $Bi_2Te_3/Ni_{80}Fe_{20}$ (Permalloy, Py) heterostructures. We grew samples of 40 nm c-axis oriented Bi_2Te_3 at 250 C followed by 20 nm of Py at room temperature. Since the growth of the FM on TI is carried out without breaking vacuum, the topologically nontrivial surface states are accessible to the FM species in their pristine condition. We observed large diffusion of Ni from Py and formation of distinct interfacial phase of $Ni_xBi_yTe_z$. TSS catalyzed reaction [10] possibly leads to formation of a topologically non-trivial interfacial phase because of solid state reaction between Ni and Bi2Te3 and proximity effect. Zero Field Cooled (ZFC) magnetic hysteresis loop measurements at low temperatures showed a large spontaneous exchange bias which suggests presence of FM/AFM coupling in the samples. Further, Field Cooled (FC) measurements with field cooling at 1 T showed enhanced exchange bias field values of ~160 Oe. We characterized the Neel Temperature of the AFM phase at ~63 K. We further identified the antiferromagnetic phase at Ni intercalated Bi_2Te_3 interfacial layer using Polarized Neutron Reflectometry (PNR). The large exchange bias in the Ni intercalated Bi2Te3 interfacial layer clearly suggests a large exchange energy which is characteristic of super-exchange mediated VdW MTI compound [8]. The observation of magnetic phase at the interface layer further raises the possibility of QAH state and paves the way for further exploration of TI/FM based heterostructures and applications for energy efficient spintronic devices. Also, growth of high crystalline quality TI using sputtering opens up the path towards integration of crystalline TIs in industrial CMOS devices.

Low-Field Large Magnetocaloric Effect in Self-Assembled Iron Nanoparticles Embedded in Titanium Nitride Thin–Film Matrix Kaushik Sarkar, Surabhi Shaji, Manosi Roy and Dhananjay Kumar; North Carolina A&T State University, United States

A field-dependent transition from the superparamagnetic-to-superparamagnetic blocked state is realized during magnetization (M) versus temperature (T) measurements by controlling the size of the iron (Fe) particles in the confined layers of titanium nitride (TiN) thin-film matrix. The nanoscale Fe particles of uniform size and shape are embedded in a TiN/Fe/TiN multilayered pattern using a pulsed laser deposition (PLD) method. Crystallographic studies carried out using x-ray diffraction have indicated the epitaxial nature of TiN film. Applying the Maxwell relation to the M-T curves at various fields, $\delta M/\delta T$ vs. H plots are acquired, the integration of which provides quantitative information about the isothermal entropy change in the Fe nanoparticulate system. Our experimental data shows that a positive magnetocaloric effect (MCE) with a maximum entropy change of $\sim 2.27 \times 10^3$ J/K m^3 can be achieved for the magnetic field in the range of 0.002 - 0.5 T for the TiN/Fe/TiN sample having Fe particles of the size ~15 nm. All the change in entropy curves clearly shows a peak in the vicinity of blocking temperature. A broad isothermal entropy change over a wide range of temperature has been found for the same sample with a refrigeration capacity value of 8.9×10^4 J/m^3.

Electronic and Structural Characterization of Microstructured NdNiO3 Thin Films Patrick A. Singleton, Grace Pan, Dan Ferenc Segedin, Julia Mundy and Ismail El Baggari; Harvard University, United States

NdNiO3 (NNO) is a member of the perovskite rare-earth nickelates whose phase diagrams host metal-insulator transitions and various magnetic orders [1]. These transitions can be tuned using a variety of knobs such as rare-earth substitution, epitaxial strain and dimensionality. Even more, reducing the dimensions of NNO devices can modulate the drops and jumps in resistivity across the metal-insulator transition [2]. Here we perform temperature-dependent electrical transport measurements to further examine the effect of the lateral dimensions of thin films of NNO on the metal-insulator transition. Focused ion beams microstructuring is used to reduce the dimensions of the device towards sizes comparable to the metallic and insulating domains near the transition temperature. In addition to measuring the temperature-dependent resistivity, we image the domain structure of NNO films at low temperatures using scanning transmission electron microscopy to investigate the relationship between the metal-insulator transition and the structural changes at the atomic level. These complementary measurements may reveal the interplay between atomic-scale changes, nanoscale domain arrangements, and the macroscopic properties of rare-earth nickelates and transition-metal oxides in general.

Late News: Electric Field Control of Phonon Angular Momentum in BaTiO3* Kevin Moseni, Richard Wilson and Sinisa Coh; University of California, Riverside, United States

We studied the angular momentum of phonons in BaTiO3 from first principles. We find that in the tetragonal phase of BaTiO3 the average phonon angular momentum is significantly larger in directions perpendicular to polarization than parallel. Furthermore, there is additional anisotropy within the plane perpendicular to polarization. We analyze the interatomic force constants and build a simple effective model to reveal the origin of the anisotropies. Finally, we suggest experiments using BaTiO3 as an electric field controllable phonon angular momentum reservoir.

Late News: *Ab Initio* Calculation of Magnetoelectric Tensors in Known Magnetoelectric Materials Louis Alaerts and Geoffroy Hautier; Dartmouth College, United States

Magnetoelectricity (ME) is the property of certain materials to exhibit a coupling between their electric and magnetic properties. This enables the control of magnetization with electrical fields, a process whose energy cost is order of magnitude lower than the direct control of magnetization with magnetic fields, paving the way towards low-power devices. Nowadays, ME has been reported in a large variety of materials but most of them are characterized by weak coupling constants. Furthermore, the effect only appears at low temperatures, putting heavy limitations for practical applications. One of the main challenges in this field is to develop materials with stronger coupling with higher operating temperatures.
The strength of the magnetoelectric coupling is given by the tensor α_{ij} which describes the magnitude of the polarization (magnetization) built by a magnetic (electric) field. The magnetoelectric coupling can be computed nowadays with ab initio techniques within the density functional theory (DFT) framework. Here, we present results on the ab initio computation of the ME tensor on a few known ME materials such as $Fe_2Mo_3O_8$, $GaFeO_3$ or Ni_3TeO_6. We compare the results to experimental data and discuss the importance of the electronic, ionic and strain components to the magnetoelectric tensor.

A 3D-Printed Molecular Ferroelectric Metamaterial Yong Hu and Shenqiang Ren; University at Buffalo, The State University of New York, United States

Solution-processable molecular ferroelectrics, which show ferroelectric properties approaching inorganic perovskites, have amassed much recent attention due to their lightweight, tunable electro-optic and electromechanical coupling effects (*1, 2*). Spontaneous polarization and the ability to switch the electromechanical activity by an external electric or mechanical stimulus is of prime importance, establishing the basis for many metamaterial technologies (*3, 4*). Over the past decade, elastic metamaterials with resonant inclusions have gained significant traction owing to their unique response to incident dynamic loads, ranging from subwavelength band gaps, back-scattering immune wave guides, and topological pumps, to the design of logic gates, nonreciprocity, and diode-like formations. Despite their theoretical promise, such mechanical metamaterials remain hindered by the lack of adaptive stimuli-responsive materials which can be effectively tuned “on-demand” across the time and length scales dictated by such metamaterials. We present a continuous rapid printing strategy for the volumetric deposition of water-soluble molecular ferroelectric metamaterials with precise spatial control in virtually any three-dimensional geometry by means of an electric-field–assisted additive manufacturing (*5*). We demonstrate a scaffold-supported ferroelectric crystalline lattice that enables self-healing and a reprogrammable stiffness for dynamic tuning of mechanical metamaterials with a long lifetime and sustainability. A molecular ferroelectric architecture with resonant inclusions then exhibits adaptive mitigation of incident vibroacoustic dynamic loads via an electrically tunable subwavelength-frequency band gap. The findings shown here pave the way for the versatile additive manufacturing of molecular ferroelectric metamaterials.

Controlled Light Scattering on Domains Enabled by Ferroelectric Phase Transformations in PIN-PMN-PT Thomas R. Mion[1], Peter Finkel[1], Markys Cain[2], Margo Staruch[1], Jakub Kolacz[1], Alex Moser[1], Paul Thompson[3], Gareth Nisbet[4], John Daniels[5] and Sam Lofland[6]; [1]U.S. Naval Research Laboratory, United States; [2]Electrosciences Ltd., United Kingdom; [3]European Synchrotron Radiation Facility, France; [4]Diamond Light Source, United Kingdom; [5]University of New South Wales, Australia; [6]Rowan University, United States

It is generally accepted that most electro-optical materials are transparent and, often, piezoelectric by nature. Electrical switching of ferroelectric domains and consequent domain wall motion promotes a strong piezoelectric activity. However, light scatters strongly at refractive index discontinuities such as found at domain wall boundaries. Thus, simultaneously achieving high piezoelectric properties along with a high transparency remains elusive, until now. Here, we applied electrical and mechanical stresses to manipulate and reconfigure the domains in perovskite $Pb(In_{1/2}Nb_{1/2})O_3$ $Pb(Mg_{1/3}Nb_{2/3})O_3$-$PbTiO_3$ domain-engineered single crystals. We demonstrated that, via the stress induced ferroelectric-ferroelectric phase switching, a highly transparent crystalline state develops as the polydomain structure reconfigures to a monodomain ferroelectric state. The unprecedented optical properties are achieved at very low electric fields (less than 1.5 kV/cm) with the piezo crystal retaining an excellent piezoelectric performance. We demonstrate a robust method to enhance or suppress light scattering at ferroelectric domain boundaries, manipulated by external electrical and mechanical stresses, realizing *on-demand* optical transmissivity and piezoelectricity outperforming state-of-the art materials.

Magnetic and Electrical Transport Properties of Ni/NiO Composite Thin Films Bishwajite Karmakar[1], Sajal Islam[1], Ariful Haque[2,1] and Kartik Ghosh[1]; [1]Missouri State University, United States; [2]Texas State University, United States

In this paper, detailed magnetic and electrical transport properties of composite thin films consisting of antiferromagnetic (AFM) NiO and ferromagnetic (FM) Ni have been studied. Highly oriented NiO thin films were grown on sapphire (0001) substrate using pulsed laser deposition technique varying the growth parameters such as the oxygen pressure of the chamber and the substrate temperature. To obtain various percentage mixtures of Ni and NiO by means of introducing point defects (oxygen vacancies) into NiO crystal structure, the as-grown films were annealed in forming gas (Ar:96% and H2:4%) varying the temperature from 3000 C to 5000 C with annealing time from 10 minutes to 100 minutes. The X-ray diffraction (XRD) data show that the as-grown NiO films have the rock salt structure and are preferentially grown on the sapphire substrate along the (111) planes. The phase mixture of Ni/NiO was obtained by annealing and was confirmed by XRD, Raman spectroscopy, and SEM-EDS. Additionally, the film transmittance degraded as a conspicuous amount of NiO crystal structure was converted into preferentially oriented pure Ni detected by XRD as well as Raman spectroscopy. The very sharp peak at 44.4° on XRD indicates the face-centered cubic crystal structure of Ni. Detailed magnetic properties were investigated using a superconducting quantum interference device (SQUID) magnetometer. The temperature and field-dependent magnetization M (H, T) data show that pure NiO and Ni are antiferromagnetic and ferromagnetic, respectively. The Ni-rich samples show ferromagnetic behavior with lower saturation magnetization (1.2 x 10-3 emu) and higher coercivity of 150 Oe than pure Ni film. Ferromagnetism has also been observed in Ni-rich samples in the ferromagnetic resonance (FMR) experiment, and the FMR linewidth increases with decreasing Ni phase in the composite thin films. Pure NiO samples exhibit a very high resistivity of 812 Ohm-m, whereas, pure Ni just behaves like a normal metallic ferromagnet. However, the value of resistivity sharply decreases with increasing oxygen vacancies in NiO, and it behaves like a semiconductor. Finally, the behavior of the composite Ni/NiO thin films resemble a magnetic semiconductor leading to a promising application in the arena of spintronic devices.

Nanoscale Multi-Modal Imaging of Multiferroics in Three Dimensions Luis Ortiz[1], Jingfeng Song[1], Bryan Huey[1], Dayne Sasaki[2], Yayoi Takamura[2] and Ramamoorthy Ramesh[3]; [1]University of Connecticut, United States; [2]University of California, Davis, United States; [3]University of California, Berkeley, United States

Ferromagnetic and multiferroic nanostructures are promising for next generation memory, logic, sensors, actuators, and nanoelectronics. In this work, we apply advanced scanning probe microscopy techniques including Magnetic Force Microscopy (MFM), Piezoresponse Force Microscopy (PFM), and Tomographic Atomic Force Microscopy (T-AFM) for nanoscale characterization of three multiferroic systems: homogeneous $BiFeO_3$ thin films, self-assembled $BiFeO_3$-$CoFe_2O_4$ (BFO-CFO) vertically aligned nanocomposites, and Lanthanum Strontium Manganite (LSMO) nanoarrays. Correlations between domain nanostructure and microstructural and engineered feature geometries are studied. Additionally, correlations between ferroelectric polarization and interfacial strain are directly investigated in 3 dimensions. Such correlated, multi-modal nanoscale imaging is promising for future optimization of multiferroic devices.

Magnetoelectric Correlations in Multiferroics at the Nanoscale Manfred Fiebig; ETH Zurich, Switzerland

Magnetoelectric coupling phenomena in multiferroics were initially treated almost exclusively as bulk effects exhibited by homogeneous materials. In recent years, attention has moved to the nanoscale. On the one hand, magnetoelectric phase control ultimately happens on the level of the mostly sub-micrometer-sized domains. On the other hand, domain walls, interfaces and thin films are nanoscale objects that have been proving to be the source of intriguing magnetoelectric coupling effects. In my talk, I will therefore explore the fascinating world of magnetoelectric correlations at the nanoscale in a number of examples, the diversity of which is intended to demonstrate the enormous potential of the nanoscale perspective on multiferroics.

[1] We show that in multiferroics with separately emerging magnetic and ferroelectric order (type I), the microscopic magnetoelectric coupling can be intrinsically strong, even though the macroscopic leading-order magnetoelectric effect is forbidden by symmetry. In hexagonal manganites like $YMnO_3$ an imbalance in the competing superexchange contributions couples the antiferromagnetic to the ferroelectric domains. The associated domain walls are a source of topological vortex-like magnetic singularities. --- Nat. Comms. 12, 3093 (2021).

[2] In certain multiferroics with jointly emerging magnetic and ferroelectric order (type II), like $(Tb,Dy)FeO_3$, the multiferroic bulk state can be converted into multiferroic domain walls in a non-multiferroic environment. Electric or magnetic fields act on these confined multiferroic objects or return them to the bulk phase. --- Nat. Comms. 12, 2755 (2021).

[3] In epitaxial type-I multiferroic $YMnO_3$ thin films the coexistence of magnetic and ferroelectric order roots in the improper nature of the electrically polarized state. We find that its lattice-distortive origin permits to control the ferroelectric order via the mechanical clamping of the film to the substrate. This control is effective in the regime from a single monolayer to about 100 nm. Improper ferroelectrics hence offer additional degrees of freedom for tuning the magnetoelectric coupling in multiferroics. --- Nat. Comms. 10, 5591 (2019).

[4] As room-temperature multiferroic, $BiFeO_3$ is most promising for device applications. La alloying reduces the coercive field for magnetoelectric switching to the CMOS regime, but it also destroys the nano-domain patterning that is crucial for voltage-induced magnetization reversal. We show how the functionality of $(La,Bi)FeO_3$ films can be restored to the full potential of the BiFeO3 parent compound by an electric-field training procedure. The training also initiates a giant net-polarization enhancement that survives in a device-like capacitor geometry. --- submitted.

Training the Polarization in Integrated $La_{0.15}Bi_{0.85}FeO_3$-Based Devices Marvin J. Müller[1], Yen-Lin Huang[2,3], Saül Vélez[1], Ramamoorthy Ramesh[2,3,2], Manfred Fiebig[1] and Morgan Trassin[1]; [1]ETH Zurich, Switzerland; [2]University of California, Berkeley, United States; [3]Lawrence Berkeley National Laboratory, United States

The integration of magnetoelectric multiferroics, hosting coexisting and coupled ferromagnetic and ferroelectric orders, into magnetoelectric spin-orbit logic devices holds promises for unprecedented performance and energy consumption reduction by several orders of magnitude.[1,2] While static properties such as the coercive electric field are thoroughly studied and optimized, investigations on the evolution and coupling of the ferroic orders during electric-field cycling are sparse.[3,4,5,6]
Here, we study the evolution of the ferroelectric order of the technologically most relevant magnetoelectric material, $BiFeO_3$, and its chemically engineered relative $La_{0.15}Bi_{0.85}FeO_3$. Using operando optical second-harmonic generation microscopy, we directly access the polarization of the films integrated in technologically relevant capacitor heterostructures during electric-field cycling. We demonstrate that electric-field training results in a spontaneous domain ordering and a giant enhancement of the net polarization in $La_{0.15}Bi_{0.85}FeO_3$. Furthermore, we track the evolution of this ordered domain configuration operando in the device architecture during repeated switching and find that it is stable for more than 10^6 switching cycles. In conclusion, our operando investigations give unprecedented insights into the polarization evolution during real device conditions and, therefore, reveal hitherto hidden opportunities to probe the polarization dynamics and to optimize $BiFeO_3$-based integrated devices.

2:00 PM *EQ10.05.02
Sputter Deposited Magnetostrictive Multilayers for Advanced Magnetoelectric Sensors Dirk Meyners[1], Lars Thormählen[1], Dennis Seidler[1], Viktor Schell[1], Elizaveta Golubeva[1], Anne Kittmann[1], Frans Munnik[2], Jeffrey McCord[1] and Eckhard Quandt[1]; [1]Kiel University, Germany; [2]Helmholtz-Zentrum Dresden-Rossendorf, Germany

For different concepts of magnetoelectric sensors with sputter deposited magnetostrictive layers it could be shown that they can achieve low detection limits in the range of 100 pT/√Hz and below when used as magnetic field sensors in biomagnetically interesting frequency ranges [1-3]. To reach a further improved detection limit, during sensor operation a better control of the magnetization state of the magnetostrictive phase is required. This enables a reduction in magnetically induced noise contributions while maintaining the sensor sensitivity.
In the presented work, sensors are considered whose magnetostrictive phase is formed by $(Fe_{90}Co_{10})_{78}Si_{12}B_{10}$ single or multilayers. Such magnetic layers show comparatively low magnetic anisotropy together with a significantly high magnetostriction. Process-related influences during sensor fabrication, layer stresses for example, can therefore affect the magnetic properties. In this context, we compare amorphous, magnetostrictive FeCoSiB films prepared by RF and DC sputter deposition. The chemical and magnetic properties determined by elastic recoil detection and magnetooptical magnetometry, respectively, are correlated with the resulting magnetoelectric sensor properties such as noise level and detection limit.

Low-Voltage Magnetoelectric Coupling in Membrane Heterostructures Shane Lindemann[1], Julian Irwin[1], Gi-Yeop Kim[2], Kitae Eom[1], Bo Wang[3], Jianjun Wang[3], Jiamian Hu[1], Long-Qing Chen[3], Si-young Choi[2], Mark Rzchowski[1] and Chang-Beom Eom[1]; [1]University of Wisconsin–Madison, United States; [2]Pohang University of Science and Technology, Korea (the Republic of); [3]The Pennsylvania State University, United States

Relaxor ferroelectrics, such as $(1-x)Pb(Mg_{1/3}Nb_{2/3})O_3$-$(x)PbTiO_3$ (PMN-xPT), exhibit giant piezoelectricity which arises from the presence of multiple symmetries near a Morphotropic Phase Boundary (MPB). The MPB in PMN-xPT lies around x = 35% and separates a Rhombohedral (R) phase, with

spontaneous polarization along the <111> crystallographic directions, from a Tetragonal (T) phase whose polarization lies along <100>. [1] For compositions near the MPB, the presence of bridging Monoclinic (M) and Orthorhombic (O) phases help to facilitate large lattice distortions as the spontaneous polarization rotates between the competing symmetries in order to align with the applied field.
Bulk studies on (011) oriented PMN-PT single crystals have demonstrated non-volatile (i.e. permanent) 71/109 degree switching between in-plane and out-of-plane R polarization directions. [2] Such switching results in distinct strain states and forms the basis of low-power, ultrafast, memory storage devices when coupled with a ferromagnetic (FM) material. [3] Achieving low power, however, necessitates the use of thin films of PMN-PT. Additionally, the films must be removed from their substrates in order to prevent substrate clamping that eliminates their giant piezoelectricity. Here we demonstrate growth of epitaxial (011) PMN-PT thin films, followed by removal of the substrate via etching of a $Sr_3Al_2O_6$ (SAO) sacrificial layer. [4] By coupling with a FM Nickel overlayer, we demonstrate manipulation of in-plane magnetic anisotropy as seen by the Magneto-Optic Kerr Effect (MOKE). The coupling only requires 3V applied bias across the PMN-PT membrane, which is much lower than the >100V needed using bulk PMN-PT. However, we do not see evidence of the 71/109 degree bi-stable switching as observed in the bulk studies. Instead we find that the piezo-driven coupling is dominated by polarization rotation from the nominally <111> oriented R states towards the [011] O state along the applied field direction. Our findings have significant implications on the design of strain-mediated devices based on relaxor-ferroelectrics such as PMN-PT.

Exchange Biased Multilayers for SAW Magnetic Field Sensors Viktor Schell, Elizaveta Golubeva, Lars Thormählen, Anne Kittmann, Jeffrey McCord, Dirk Meyners and Eckhard Quandt; Kiel University, Germany

Surface acoustic wave devices have found a wide field of applications since it was discovered that they can be excited by interdigital transducers on piezoelectric substrates in 1965. One of these applications gaining more interest in the recent years is the sensing of magnetic fields. Especially for the measurement of biomagnetic signals surface acoustic wave devices are promising candidates due to their ability to detect magnetic fields below 100 $pT/Hz^{1/2}$ over a large frequency range of 1 Hz to 100 kHz [1]. This large bandwidth in combination with a wide dynamic range make them also interesting for artificial current sensing.

For the sensing of magnetic fields Love waves give much higher sensitivities than Rayleigh wave based sensors, due to the strong confinement of the acoustic wave in the magnetostrictive film [2]. Love waves are horizontal shear waves which are guided to the surface by a layer of higher acoustic impedance than the substrate. Operating in a delay line configuration the magnetoelastically induced change of shear modulus of the magnetostrictive layer yields in a corresponding phase shift of the acoustic wave. The magnetically generated 1/f noise of this magnetostrictive film on top of the guiding layer turned out to be the limiting factor regarding the limit of detection of the sensors. One approach to reduce magnetic noise is to exchange bias the ferromagnetic phase by the coupling to an antiferromagnetic phase [3, 4]. With this, a single or nearly single domain state can be achieved and domain walls reduced or eliminated as they are the main source of phase noise in these devices.

In this work a layer system consisting of $(Fe_{90}Co_{10})_{78}Si_{12}B_{10}$ / $Ni_{80}Fe_{20}$ / $Mn_{70}Ir_{30}$ is used, where $(Fe_{90}Co_{10})_{78}Si_{12}B_{10}$ is the magnetostrictive layer and $Ni_{80}Fe_{20}$ is a seed layer for the antiferromagnetic $Mn_{70}Ir_{30}$ which induces the exchange bias. All films are deposited by means of magnetron sputtering on ST-cut Quartz substrates and ST-cut Quartz based SAW sensors while a magnetic field is applied during deposition to induce the exchange bias. Challenges concerning the deposition process on piezoelectric substrates, the magnetic behavior as well as the noise performance of the sensors will be discussed. The successful reduction of magnetically induced 1/f noise in the low frequency regime brings SAW magnetic field sensors closer towards biomagnetic applications.

Control of Chirality in Magnetic Nanostructures via Nanosecond Electric Pulses Wael A. Aldulaimi[1], Baris Okatan[2], Kursat Sendur[1] and Ibrahim B. Misirlioglu[1]; [1]Sabanci University, Turkey; [2]Izmir Institute of Technology, Turkey

The stability of magnetism in reduced dimensions is a major scientific agenda in the pursuit of implementing magnetic nanostructures into spintronic devices. Methods to probe and control magnetization states of such structures in a deterministic manner include use of spin polarized currents, photon absorption and relatively recently, electric fields that tailor magnetoelectric coupling in multiferroic based structures. In theory, a short electric pulse is able to generate localized magnetic fields that can couple to the local magnetic dipoles electrodynamically. Here, using the Landau-Lifshitz-Gilbert (LLG) formalism of magnetism dynamics combined with continuum Maxwell relations we study the response of a ferromagnetic permalloy nanodisc to nanosecond electric field pulses [1]. The dynamics of the magnetic order during this process are examined and discussed. Ferromagnet nanodiscs can relax to a vortex phase as the ground state due to the demagnetizing field. Our results demonstrate that the planar chirality of such a ferromagnet nanodisc can be switched via a time-wise asymmetric electric field pulse on the order of a few ns duration that generates radially varying tangential magnetic fields. These fields couple to the vortex state of the nanodisc ferromagnet electrodynamically, revealing an effective and robust method to control chirality. The kinetics

of the chirality switching as a function of disc size is analyzed. We also go on to discuss the possibility to generate programmable metasurfaces based on the approach we develop where local magnetic states can be rapidly written onto thin magnetic films with ease and extraordinary precision.

Low Temperature Magnetic Transition and Spin-Lattice Coupling in epsilon-Fe_2O_3 Epitaxial Thin Films Zheng Ma[1], Nico Dix[1], Jesus López-Sánchez[2,3,4], Javier Herrero-Martín[5], Victor G. Ivanov[6], Vassil Skumryev[7,8], Florencio Sánchez[1], Pilar Marín[2,3], Jaume Gàzque[1], Jóse Luis García-Muñoz[1] and Martí Gich[1]; [1]Institut de Ciència de Materials de Barcelona (ICMAB-CSIC), Spain; [2]Universidad Complutense de Madrid UCM, Spain; [3]UCM ADIF, Spain; [4]ESRF European Synchrotron, France; [5]ALBA Synchrotron Light Source, Spain; [6]University of Sofia, Bulgaria; [7]Institució Catalana de Recerca i Estudis Avançats (ICREA), Spain; [8]Universitat Autònoma de Barcelona, Spain

The intriguing low temperature softening of the high magnetic anisotropy epsilon Fe_2O_3 (eFO) nanoparticles [1] has been also observed in epitaxial stabilized eFO thin films on $MgAl_2O_4$(111) and flexible fluorphlogopyte mica (001) substrates. The selection of an adequate substrate and buffer layer leads to an excellent film quality with sharp (00L) eFO X-ray diffraction peaks and the formation of 3 in-plane twin domains compatible with the 3-fold symmetry of the substrate surface. At room temperature, the *M(H)* hysteresis loops show a strong magnetic anisotropy and absence of step-like magnetization drop due to soft components. A reduction of the magnetic anisotropy and coercive field occurs on cooling below 200 K, which is reminiscent of that found in randomly distributed nanoparticles. The H_c collapse is less pronounced in the epitaxial films (-40%) than in nanoparticles (-96%), but the (00L) out of plane-texture allows a better observation of temperature dependence of frequency shifts of Raman modes. The trends primarily agree with the anharmonic model at temperatures above ~ 200 K, whereas a marked phonon softening can be observed below this temperature for different modes. The transition has been also studied by X-ray absorption spectroscopy (XAS) measurements in total electron yield and fluorescence modes and by X-ray magnetic circular dichroism (XMCD) and transport measurements.

Ferroelectric Control of Rashba States—Towards Non-Volatile Spintronics Driven by Ferroelectricity Manuel Bibes and Srijani Mallik; Unité Mixte de Physique CNRS/Thales, France

After 50 years of exponential increase in computing efficiency, the technology of today's electronics is approaching its physical limits, with feature sizes smaller than 10 nm. New schemes must be devised to contain the ever-increasing power consumption of information and communication systems, which requires the introduction of non-traditional materials and new state variables. As recently highlighted, the remanence associated with collective switching in ferroic systems is appealing to reduce power consumption[1]. A particularly promising approach is spintronics, which relies on ferromagnets to provide non-volatility and to generate and detect spin currents. However, magnetization reversal by spin transfer torques is a power consuming process. This is driving research on multiferroics to achieve a low-power electric-field control of magnetization, but practical materials are scarce and magnetoelectric switching remains difficult to control. In this talk, we will propose an alternative strategy to achieve low-power spin detection and generation, in non-magnetic systems combining ferroelectricity and Rashba spin-orbit coupling[2]. We will describe various materials strategies based on single materials, multilayers and two-dimensional electron gases. In particular we will show results on $SrTiO_3$-based electron gases in which a large electric field induces a ferroelectric-like state that enables a non-volatile control of its spin-orbit properties and spin-charge conversion capabilities[3]. These observations open the way to the electric-field control of spin currents and to ultralow-power spintronics, in which non-volatility would be provided by ferroelectricity rather than by ferromagnetism.

An Antiferromagnetic Metal Phase from a Correlated Insulator Qi Song[1,2], Spencer Doyle[1], Grace Pan[1], Hanjong Paik[2], Colin Heikes[3], Betül Pamuk[2], William Ratcliff[3], Padraic Shafer[4], John T. Heron[5], Charles Brooks[1], Luca Moreschini[4], Antia Botana[6] and Julia Mundy[1]; [1]Harvard University, United States; [2]Cornell University, United States; [3]National Institute of Standards and Technology, United States; [4]Lawrence Berkeley National Laboratory, United States; [5]University of Michigan–Ann Arbor, United States; [6]Arizona State University, United States

Antiferromagnetic materials hold great promise for next-generation spintronics due to the combination of stability in external magnetic fields and the potential for ultrafast switching. Here, we explore a new antiferromagnetic metal for spintronic applications. We begin with a correlated insulator, NdNiO3. NdNiO3 has a metal-to-insulator transition that is concomitent with a paramagnetic to antiferromagnetic transition. We demonstrate that electron doping can induce a new antiferromagnetic metallic phase in NdNiO3. We use a combination of neutron diffraction and resonant x-ray scattering to probe the magnetic order and angle resolved photoemission spectroscopy to demonstrate a new Fermi surface in the antiferromagnetic metal phase. Our materials show a large zero-field planar Hall effect and could find applications in heat-assisted magneto-recording.

Crystal symmetry in condensed-matter materials largely dictates their micro- and macroscopic properties, and new material functionalities can arise when inversion symmetry is broken and when symmetry changes. Thus, the ability to control crystal inversion symmetry on demand is of both fundamental and technological importance. Perhaps the most pervasive example of the manifestation of broken inversion symmetry is in ferroelectrics, where crystal structures that inherently break inversion symmetry directly lead to a switchable spontaneous electrical polarization. Recently, the ability to synthesize heteroepitaxial ferroelectric superlattice systems has enabled new methods to control ferroic order[1–4] and even crystal symmetry[5,6]. Here, by using $BiFeO_3/TbScO_3$ superlattices as our model system, we take advantage of (i) the discontinuity of the spontaneous polarization; (ii) the lattice mismatch; and (iii) the octahedral tilt frustration between the two layers to engineer crystal inversion symmetry. We stabilize both a non-centrosymmetric polar and a centrosymmetric antipolar phase mediated by a first order phase transition at room temperature. Both phases are identified and characterized using a combination of high-resolution and four-dimensional (4D) scanning transmission electron microscopy (STEM), piezoforce microscopy (PFM), and confocal second harmonic generation (SHG) over atomic and mesoscopic length scales. Moreover, applying orthogonal in-plane electric fields to this mixed-phase system results in the deterministic, nonvolatile interconversion of the centrosymmetric and noncentrosymmetric phases, resulting in a three order of magnitude change in the non-linear optical (SHG) response of the system. Demonstration of such an optically addressable, multi-state memory device presents new avenues for cross-functional devices which take advantage of the interconversion between ferro- and anti-ferroelectric states.

1:45 PM EQ10.07.02
Structural Tuning of Ferroelastic Domain Dynamics Induced by Thermal Stress Anisotropy John J. Scott[1], Blai Casals Montserrat[2], Ekhard K. Salje[2] and Miryam Arredondo[1]; [1]Queen's University Belfast, United Kingdom; [2]University of Cambridge, United Kingdom

Ferroics, namely ferroelastics, ferroelectrics, ferromagnets and multiferroics (more than one ferroic order), have been the subject of increasingly intense research over the best part of half a century; having applications as memory devices, mechanical switches and acousto-optic devices. All ferroics, when cooled below a critical temperature (Tc) between a high-symmetry paraphase and a low-symmetry ferrophase, develop energetically equivalent but differently orientated states (domains). Domains are separated by interfaces (domain walls), which exhibit properties unique to that of the bulk and often constitute the active component for novel devices.
Importantly, Ferroelastics play a vital role in the fundamental understanding of multiferroic switching, as a large majority of multiferroics exhibit a ferroelastic component which mediates many of the observed properties, such as (super-)conductivity[1] and magnetoelectricity[2].
Analogous to other ferroics, ferroelastics are defined by their hysteresis loop (strain vs stress). On a macroscopic scale the hysteresis can appear smooth, yet on a finer scale, is actually formed of small discrete jumps or 'jerks'.
Most driven systems exhibiting small discrete events, cover a broad range of sizes dubbed as 'crackling noise'[3]. Such distributions are examples of avalanches, where Mean-field theory allows for the statistical characterisation of domain wall movement by predicting the power law distribution of jerks as a scale-free process of the form $g(x)dx \sim x^{-\gamma}dx$, whereby g(x) describes the probability (g) of a jump (x) and the critical exponent is characteristic of that system[4]. Such exponents can be implemented to describe the statistics of certain observables, such as the energy released (E) or area spanned (α) by events. These power-law critical exponents are scale invariant (no characteristic size/ time scale) and demonstrate a behaviour that is independent of the microscopic properties of that system. As such, systems that share the same critical exponent values are of the same 'universal class', where the statistical behaviour of one class can be utilised to garner insight into another system that macroscopically appears to be much different or more intractable, such as tectonic activity and the crackling of sweet wrappers[5].
This study presents a new insight into the role that the aspect ratio (AR) has on of ferroelastic domain dynamics, by probing two $LaAlO_3$ (LAO) samples with different AR (high vs low). In-situ heating polarised optical microscopy was used on LAO bulk where the samples were heated from room temperature (RT) to beyond its Tc (~545C°) and back.
It was observed that the AR influences i) the resultant domain pattern at RT, where a clear preference is given to the orientation parallel to the longer axis of the high AR (HAR) sample vs the low AR (LAR) sample, which exhibits a more even split and complex configuration of domain variants that meet at the centre and ii) each AR display some similarities in their he dynamical behaviour at high temperatures while cooling down from Tc. At lower temperatures the AR induces distinct dynamic behaviour: the HAR samples display a propagating domain front that forms above RT and below Tc, leading to a global reconfiguration of the microstructure. This behaviour is explained in terms of thermal stress and the anisotropy present.
Moreover, statistical analysis shows that not only is there a difference in the overall criticality between the two samples, LAR:E=1.6 vs HAR:E=1.4, but that the HAR sample demonstrates a 'mixing' of the critical exponent before and after the global reconfiguration (E=1.66 to 1.33). This latter point is highlighted in the analysis of the maximum likelihood method statistics.

Ultra-High Room Temperature Carrier Mobility at Conducting Ferroelectric Domain Walls Measured by Corbino Disc Magnetoresistance Conor J. McCluskey, Matthew Colbear, James McConville, Raymond McQuaid and Marty Gregg; Queen's University, Belfast, United Kingdom

Recently, an abundance of novel transport physics has been found at interfaces, much of which promises to be key in the development of future technologies. The unusual electronic and structural environment at the interface can lead to behaviours which deviate wildly from that in the individual bulk constituents, while remaining confined to the interface. Electrically conducting homointerfaces, such as the domain walls that separate different orientations of electrical polarisation within the same band-insulator [1,2], are of particular interest, as they boast the ability to be created, moved and erased on demand [3,4]. Thus, they offer an additional dynamic degree of freedom when compared to conducting heterointerfaces (between dissimilar band insulators, e.g. $LaAlO_3/SrTiO_3$ [5]), which are fixed in place. Despite this, understanding of charge transport and fundamental aspects of conduction at domain walls is lacking in comparison to the current state-of-the-art in heterointerfaces. Here, we try to address this disparity by reporting on a geometric magnetoresistance measurement of carrier mobility in approximately conical 180° domain walls, which occur in partially switched ferroelectric thin film single crystal lithium niobate. We show that the domain microstructure, which is usually a hurdle to overcome when performing transport measurements on domain walls, results in a domain wall geometry which is equivalent to that of the "Corbino disc"; a textbook sample arrangement for geometric magnetoresistance measurements. Analysis of our magnetoresistance data reveals that these domain walls exhibit an extremely high room temperature Hall mobility of ~ $3{,}000 cm^2V^{-1}s^{-1}$. This value much larger than that seen at bulk or interface oxides before. Finally, we discuss the insight this measurement gives us in terms of understanding the transport at lithium niobate conducting domain wall homointerfaces.

Cross-Linking and Charging Molecular Magnetoelectronics Yulong Huang[1], Yuxuan Chen[2], Yong Hu[1], Travis Mitchell[1], Lu An[1], Zheng Li[1], Jason Benedict[1], Huashan Li[2] and Shenqiang Ren[1]; [1]The State University of New York at Buffalo, United States; [2]Sun Yat-sen University, China

Magnetoelectrics are witnessing an ever-growing success toward the voltage-controlled magnetism derived from inorganic materials. However, these inorganic materials have predominantly focused on the ferroelectromagnetism at solid-to-solid interfaces and suffered several drawbacks, including the interface-sensitive coupling mediators, high-power electric field, and limited chemical tunability. Here, we report a promising design strategy to shift the paradigm of next-generation molecular magnetoelectrics, which relies on the integration between molecular magnetism and electric conductivity though an in situ cross-linking strategy. Following this approach, we demonstrate a versatile and efficient synthesis of flexible molecular-based magnetoelectronics by cross-linking of magnetic coordination networks that incorporate conducting chain building blocks. The as-grown compounds feature an improved critical temperature up to 337 K and a room-temperature magnetism control of low-power electric field. It is envisaged that the cross-linking of molecular interfaces is a feasible method to couple and modulate magnetism and electron conducting systems.

2:30 PM EQ10.07.05
High-Throughput Computational Discovery of a New Magnetoelectric Multiferroic—The Anti-Ruddlesden-Popper Eu_4Sb_2O Maksim Markov[1], Louis Alaerts[2], Henriqu P. Miranda[1], Guido Petretto[1], Wei Chen[1], Janine George[1], Eric Bousquet[3], Philippe Ghosez[3], Gian-Marco Rignanese[1] and Geoffroy Hautier[2,1]; [1]Institute of Condensed Matter and Nanosciences, Université Catholique de Louvain, Belgium; [2]Thayer School of Engineering, Dartmouth College, United States; [3]Université de Liège, Belgium

Magnetoelectric multiferroic materials are greatly sought for their potential use in new devices. Combining ferroelectricity and magnetism in the same material has been a real challenge especially in perovskites. The search for new ferroelectric structural families beyond perovskites is one path towards the discovery of new multiferroic materials. Here, we report on our search for new ferroelectrics using high-throughput computing and a recently built database of more than 2,000 phonons[1]. Browsing the phonon database, we identify materials exhibiting dynamically unstable polar phonon modes, a signature of a potential ferroelectric. We identify one new family of ferroelectric materials: the anti-Ruddlesden-Popper phases of formula A_4X_2O with A: a +2 alkali-earth or rare-earth element and X: a -3 anion Bi, Sb, As, and P [2]. We show that the unique geometrically-driven mechanism of ferroelectricity involves the movement of an anion in a cationic cage.
This new mechanism leads in the case of Eu_4Sb_2O to a rare example of a material combining ferroelectricity and ferromagnetism.

A Narrowband Spintronic Terahertz Emitter Based on Magnetoelastic Heterostructures Shihao Zhuang and Jiamian Hu; University of Wisconsin-Madison, United States

Narrowband terahertz (THz) radiation is crucial for high-resolution spectral identification, but a narrowband THz source driven by femtosecond (fs) laser has remained scarce. Here we computationally predict that a metal/dielectric/magnetoelastic heterostructure enables converting a fs laser pulse into a multi-cycle THz pulse with a narrow linewidth down to ~1.5 GHz, which is in contrast with the single-cycle, broadband THz pulse from the existing fs-laser-excited emitters. We show that such narrowband THz pulse originates from the excitation and long-distance transport of THz spin waves in the magnetoelastic film, which can be enabled by a short strain pulse obtained from fs laser irradiation of the metal film providing that the thicknesses of the metal and magnetoelastic films both fall into a specific range. Our results therefore reveal an approach to achieving optical generation of narrowband THz pulse based on heterostructure design, which also has implications in the design of THz magnonic devices.

3:00 PM *EQ10.07.07
Magnetoelectric Antennas—A Novel Antenna Miniaturization Approach Hwaider Lin[1] and Nian Sun[2]; [1]Winchester Technologies, LLC, United States; [2]Northeastern University, United States

Antenna miniaturization is one of the fundamental challenges for decades. Conventional small antennas use electric current for radiation which relies on

electromagnetic wave resonance that leads to antenna sizes comparable to the electromagnetic wavelength l_0. Here we demonstrated a new antenna miniaturization approach that acoustically actuated nanomechanical magnetoelectric (ME) antennas with ferromagnetic/piezoelectric thin film resonators could successfully miniaturize the magnitude of 1 to 2 orders with one of the highest passive antenna gain within all nano to micro-scale antennas at a similar frequency. In this talk, we will present the ME antenna theory, calculations, comparison with conventional antennas, and a quick view of a bio-medical application example. These mico-antennas with ultra-high sensitivity, high selectivity of the magnetic field, the integrated capability to CMOS technology, and ground plane immunity have great potential applications for bio-implantable antennas, biomedical applications, the internet of things, etc.

3:30 PM EQ10.07.08
Dehybridization of Surface States and Enhancement of Spin−Charge Conversion in Ultrathin Topological Insulator Bi_2Se_3 Films Hanbum Park[1], Kwangsik Jeong[2], Jonghoon Kim[1], Seok-Bo Hong[1], Chul Kang[3] and Mann-ho Cho[1]; [1]Yonsei University, Korea (the Republic of); [2]Dongguk University, Korea (the Republic of); [3]Gwangju Institute of Science and Technology, Korea (the Republic of)

A three-dimensional topological insulator (TI) has spin−momentum locked surface states, in which an interconversion between spin and charge currents occurs. This spin−charge conversion (SCC) enables various applications of TI films in the fields of spintronics. However, when the thickness of the TI film is reduced to a few nanometers, a finite energy gap appears at the Dirac point and the magnitude of spin−momentum locking decreases owing to hybridization between top and bottom surface states. As a result, the weak antilocalization and SCC phenomena, hallmarks of TI surface states, are suppressed.
In this study, we modulated the hybridization effect in ultrathin Bi_2Se_3 films via interface coupling with transition metal oxide HfO_{2-x}. The unbonded Hf *d*-orbital states accompanied by oxygen-vacancy defects enhanced spin−orbit coupling and induced asymmetric surface states in Bi_2Se_3, which results in suppression of the hybridization effect. Accordingly, we observed a transition from weak localization to weak antilocalization due to the oxygen defects through magneto-transport measurements. In addition, we simulated the band structures of ultrathin Bi_2Se_3 as a function of the oxygen defects with density functional theory and observed reduced hybridization gap and enhanced spin−momentum locking. To investigate SCC phenomena, we introduced spintronic THz emission spectroscopy that is recently emerged as a unique technique for investigating ultrafast SCC in sub-picosecond timescales. Using the THz spectroscopy, we identified enhancement of SCC efficiency owing to the dehybridization of surface states. These results provide novel methods of controlling surface states of TI and developing TI-based electronic and spintronic devices.

SESSION EQ10.08 Multiferroics IV

8:00 AM *EQ10.08.02
Coupling of Metal-Insulator and Magnetic Phases at Nickelate Interfaces Claribel Dominguez[1], Bernat Mundet[1,2], Jennifer Fowlie[1], Alexandru Georgescu[3], Marta Gibert[4], Yajun Zhang[5], Alain Mercy[5], Adrien Waelchli[1], Michel Viret[6], Nicolas Jaouen[7], Andreas Suter[8], Philippe Ghosez[5], Andy Millis[3], Antoine Georges[3] and Jean-Marc Triscone[1]; [1]University of Geneva, Switzerland; [2]EPFL, Switzerland; [3]Flatiron Institute, United States; [4]University of Zurich, Switzerland; [5]University of Liege, Belgium; [6]Université Paris-Saclay, France; [7]Synchrotron SOLEIL, France; [8]Paul Scherrer Institute, Switzerland

Perovskite nickelates ($RENiO_3$, RE=Rare Earth, RE≠La) are fascinating materials, well-known, for their metal to insulator transition (MIT) and unique antiferromagnetic ground state [1-3]. In this talk, I will discuss the phase diagram of the system and the physics of the MIT before focusing on $NdNiO_3/SmNiO_3$ superlattices that display, depending on the thickness of the individual layers, a single or double MIT and a single or double magnetic transition. The electronic state of the materials was revealed at the unit cell scale by STEM [4]. The critical wavelength Λ_{cMIT} below which a single MIT is observed is 16 unit cells – the corresponding critical wavelength for coupled magnetic transitions is Λ_{cAFM} = 34 unit cells. This model system allows the origin of the coupling at such oxide interfaces to be studied. The key finding is that the critical length scales are not set by the length scale of the propagation of structural motifs (for instance Ni-O-Ni bond angles) across the interface between the two materials, which ab-initio calculations and STEM analyses suggest is minimal, but rather by the balance between the energy cost of having metallic-insulating – magnetic-non-magnetic – phase boundaries and the energy gain of the bulk phases [5].

Voltage-Controlled Magnetoelectric Spintronics and Devices Hao Wu, Bingqian Dai, Malcolm Jackson, Di Wu and Kang L. Wang; University of California, Los Angeles, United States

Spintronics is one of the most promising candidates for the next-generation memory and logic applications for integration with the complementary metal oxide semiconductor (CMOS) technology, such as the magneto-resistive random-access memory (MRAM). Compared to the electrical current-driven MRAM, [1,2] such as spin-transfer torque (STT) and spin-orbit torque (SOT), voltage-controlled magnetoelectric random access memory (MeRAM) and alike have the advantages of low-power, high-speed and high-density.
Here, in the first part, we will discuss the fundamental physics of voltage-controlled magnetic anisotropy (VCMA) and the mechanism of VCMA-induced magnetization switching of the perpendicular magnetization; then we will show the progress of VCMA-based MeRAM, [3,4] and the comparison of MeRAM, STT-MRAM, SOT-MRAM. In the second part, we will present the interfacial Dzyaloshinskii–Moriya interaction (DMI) in heterostructures and the voltage-controlled DMI (VC-DMI) effect, and its role on the voltage control of the motion of domain walls and other spin textures such as skyrmions. Based on the VCMA and VC-DMI effects, we develop a method to resolve the need of precise timing of write pulses with the use of chiral symmetry breaking by DMI in the graded magnetic system [5] to achieve the deterministic VCMA switching. Finally, we will discuss the perspective of magnetoelectric ferrimagnetic materials and structures for high-speed applications. The voltage-controlled spintronics has great potential for future low-power and high-density non-volatile memory and logic applications.

Probing Local Polarization, Electric Field and Charge Distribution in Ferroelectric Heterostructures and Polarization Vortices by Four-Dimensional Scanning Transmission Electron Microscopy Xiaoqing Pan[1,2]; [1]University of California, Irvine, United States; [2]University of California, United States

In ferroelectric/multiferroic heterostructures, intrinsic polarization and the resulting electric field generate a rich set of localized electrical properties that have recently begun to be studied by differential phase contrast imaging or four-dimensional scanning transmission electron microscopy (4D STEM). Due to the size of the probe in STEM, these emerging techniques are capable of imaging both the polarization and electric field over a wide range of length scales. But there is still much to be learned about how electron probe conditions affect the electric field measured with these techniques. Recently, we developed a real-space imaging technique that can directly map the local electric field and charge density of crystalline materials with sub-angstrom resolution, using scanning transmission electron microscopy (4D STEM) alongside an angle-resolved pixelated fast-electron detector. Using this technique, we image the interfacial charge distribution and ferroelectric polarization in a $SrTiO_3/BiFeO_3$ heterojunction in 4D, and reveal charge accumulation at the interface that is induced by the penetration of the polarization field of $BiFeO_3$. By performing Bader charge analysis on the acquired charge density maps, we demonstrate the existence of two-dimensional electron gas or hole gas (2DEG or 2DHG) at $BiFeO_3/TbScO_3$ interface, indicated by the fact that the charge state of each Fe/O column increases when the polarization points away from the interface and decreases when the polarization points toward the interface. Our charge-density imaging method advances electron microscopy from detecting atoms to imaging electron distributions, providing a new way of studying local bonding in crystalline solids.

By applying 4D STEM to image the electric field in $(PbTiO_3)_{16}/(SrTiO_3)_{16}$ superlattices, we demonstrate that measurements using electron probes of differing sizes reveal different electric field configurations. Using a picometer sized probe, we find the high-Z lead atomic columns exhibit a strong bias in the electric field correlated with the polarization direction. Using a nanometer sized probe, we find an electric field that is un-correlated with the polarization. Combining these results with phase-field simulations, we show that the dominant contribution of the electric field measured with 4D STEM changes from the dipole of individual unit cells, determined by the bonding structure of PTO, to the total electric field, determined by the strain and electrostatic boundary conditions, depending on the probe size. The separability of two different fields probed by 4D STEM offers possibility to reveal how each contributes to the electronic properties of the film.

Advanced X-Ray Characterization of Topological and Geometry-Induced 3D Spin Texture Peter Fischer; Lawrence Berkeley National Lab, United States

Spin textures and their dynamics hold the key to understand and control the properties, behavior and functionalities of novel magnetic materials, which can impact the speed, size and energy efficiency of spin driven technologies. Topology, frustration, and bespoke geometries that impact spin textures have recently attracted significant scientific interest and led to intense research addressing a broad spectrum of challenging scientific and technological questions, including stability, dynamics, nucleation, and transport in novel spin textures, such as chiral bobbers, magnetic hopfions and torons, skyrmion tubes, and curvilinear magnetism [1].
Advanced characterization tools that provide magnetic sensitivity to spin textures, disentangling the role of individual components in heterogeneous material at high spatial resolution, ultimately at buried interfaces and in all three dimensions [2], and at high temporal resolution to capture the spin dynamics across scales, are required to address those questions, and are therefore of large scientific interest.
Various magnetic soft X-ray spectro-microscopies [3] using polarized soft x-rays provide unique characterization opportunities to study the statics and dynamics of spin textures in magnetic materials combining X-ray magnetic circular dichroism (X-MCD) as element specific, quantifiable magnetic contrast mechanism with spatial and temporal resolutions down to fundamental magnetic length, time, and energy scales.
Current developments of x-ray sources aim to increase dramatically the coherence of x-rays opening the path to new techniques, such as ptychography [4] or x-ray photo-correlation spectroscopy (XPCS) [5] that allow unprecedented studies of nanoscale heterogeneity, complexity, and fluctuations.
I will review recent achievements and future opportunities with magnetic x-ray spectro-microscopies. Examples will address static properties and dynamic behavior of various magnetic skyrmion [6,7] and Hopfion [8] textures, including those on curved substrates [9] with potential application to novel magnetic logic and storage devices.

Magnetoelectric Magnetic-Field Sensors—Simulation Models and Sensitivity Analysis Martina Gerken; Univ of Kiel, Germany

Magnetic-field sensors based on piezoelectric and magnetostrictive composite materials offer a low limit of detection and a high dynamic range. Here, a theoretical investigation of the sensitivity behavior of such composite magnetoelectric sensors is presented. Our focus is on biomedical applications targeting magnetocardiography (MCG) and magnetomyography (MMG). For these applications, measurement frequencies on the order of 1 to 100 Hz and a limit of detection in the pT-range are relevant. The behavior of two types of composite sensors is investigated in simulations – resonant cantilever-type sensors and surface acoustic wave (SAW) sensors. By combination of the simulated sensitivity with a noise model the limit-of-detection is predicted. Theoretical predictions are compared to experimental results of fabricated sensors.

Analytic calculations are used to derive the scaling behavior of FeCoBSi-Si-AlN cantilever-type magnetoelectric sensors. Sensitivity, noise, and resulting detection limits display different behavior with functional and substrate layer thicknesses [1]. For an improved limit of detection, a higher quality factor or thicker functional layers are necessary. For higher-mode operation, the finite-element method (FEM) is used to calculate the charge distribution along the cantilever. For higher modes, a change of sign in the charge distribution reduces the sensor sensitivity [2]. To prevent this and obtain maximum performance, sensors with segmented electrode are designed.

1D, 2D, 2.5D, and 3D FEM models for Love-wave propagation in magnetoelectric SAW sensors were established [3]. Theoretical and experimental results show that SAW sensors with lower IDT pitches and thus higher frequencies have a higher sensitivity. With the higher frequency and staying at the same guiding layer thickness, there are higher order Love waves [4]. Their frequencies are even higher, but their sensitivity is lower compared to their fundamental mode. From simulations, it is observed that the wave energy is not as concentrated at the surface for the higher modes and thus has less overlap with the magnetostrictive layer.

Biomedical magnetic fields are typically not homogeneous. To analyze the effect of an inhomogeneous excitation, we conducted simulations of localized excitation by a small coil at different positions along the sensor axis [5]. The simulations predict a rich excitation-position-dependent and frequency-dependent response behavior.

In summary, geometry-dependent effects, higher-mode operation, and inhomogeneous excitation fields are evaluated for magnetoelectric sensors. It is demonstrated that magnetic-field sensors suitable for magnetocardiography and magnetomyography with a limit of detection in the pT-range are achievable. In combination with the high linearity of the composite ME sensors unshielded and uncooled operation for wearable sensor systems is within reach.

This work is supported by the DFG Collaborative Research Center SFB1261.

Interfacial Mechanical Coupling in $PbZr_{0.2}Ti_{0.8}O_3/LaNiO_3/SrTiO_3$ Heterostructures Claudia Lau[1], Cristina Visani[1], Stephen Albright[1], Zhan Zhang[2], Myung Geun Han[3], Yimei Zhu[3], Sohrab Ismail-Beigi[1], Ankit Disa[4], Divine Kumah[5], Charles Ahn[1,1] and Frederick Walker[1]; [1]Yale University, United States; [2]Argonne National Laboratory, United States; [3]Brookhaven National Laboratory, United States; [4]Max Planck Institute for the Structure and Dynamics of Matter, Germany; [5]North Carolina State University, United States

Large conductivity modulation by the coupling of ferroelectric polarization to the strongly correlated oxide $LaNiO_3$ has been demonstrated at an epitaxial ferroelectric-$LaNiO_3$ interface. High quality PZT/LNO on STO heterostructures were grown by MBE and off-axis RF magnetron sputtering and fabricated into all-oxide field effect devices. Using operando synchrotron diffraction measurements, we correlate changes in the conductivity with structural changes in the ferroelectric and conducting oxide as the ferroelectric polarization is switched. Comparing crystal truncation rods with half-order LNO Bragg reflections, we determine that the LNO oxygen octahedra are compressed and elongated while inside a comparatively rigid cation sublattice as the PZT ferroelectric polarization is switched. This finding is supported by DFT calculations. The LNO tetragonality change is accompanied by rotations of the LNO oxygen octahedra, with the tilt angles increasing and decreasing to modify the channel conductivity in a manner consistent with theory and transport.

Magnetic Susceptibility Particle Mapping (MSPM) for Imaging SPIONs in Biomaterial Scaffolds Christine Selhuber-Unkel; Heidelberg University, Germany

3D scaffolds are essential in biomaterials science to resemble the natural 3D environment of living cells. However, many of these scaffolds are non-transparent or too thick for being imaged with conventional light microscopy. In such applications it would be very beneficial to achieve a magnetic detection of the cells after tagging them with magnetic superparamagnetic iron oxide nanoparticles (SPIONs) so that non-invasive imaging becomes possible. An interesting method in this context is Magnetic Susceptibility Particle Mapping (MSPM), which is able to detect magnetic nanoparticles in a

lab scale device. Our system is based on magnetoelectric (ME) sensors utilizing the Delta-E effect in combination with a permanent magnet, which generates a bias field for the sensor and at the same time magnetizes the SPIONs. The permanent magnet is placed above the sensor, and the sample is rotated through the gap in between at a defined frequency. The SPIONs in the sample are magnetized by the permanent magnet and generate an additional magnetic field, which is recorded by the ME sensor. The detection threshold of our MSPM system is about 20 µg SPIONs in a volume of 200 mm^3, and the spatial resolution is in the range of a few mm. We have also equipped the MSPM system with a magnetorelaxometry extension by using a self-biased sensor, so that it is possible to distinguish between particles bound to a material and diffusing particles. To demonstrate the feasibility of the MSPM method, we will present data that show the distribution of cells in a hydrogel matrix and of magnetic particles in responsive hydrogels, which are interesting in the context of tissue engineering and soft actuators.

Geometric Control of Domain Structure Stability in Ferroelectric Nanotubes Aiden Ross, Shihao Zhuang, Kwon Lee and Jiamian Hu; University of Wisconsin-Madison, United States

The field of nanoscale ferroelectrics has utilized geometric confinement in thin films, nanodots, nanoislands, and strained superlattices to stabilize flux closures, vortices, skyrmions, and other topologically non-trivial polar states. Ferroelectric nanotubes provide a unique geometry with a large surface-to-volume ratio and vertical to lateral aspect ratio, and from these unique geometric properties, new polarization domain structures can be stabilized. Using phase-field modeling, we simulated the equilibrium polarization domain structure in $Pb(Zr_{0.52}Ti_{0.48})O_3$ nanotubes under different height and wall thickness conditions, and three unique domain structures were found. Each domain structure comprises an array of periodic flux-closures and anti-flux-closures pairs formed to minimize elastic and electrostatic energy. These domain structures differ by the frequency of the flux-closure/anti-flux-closure pairs along the perimeter and height. We demonstrate that the thermodynamic stability of these domain structures can be tuned by changing the nanotube geometry with wall thickness and height.

Hard Micromagnets for Microelectromechanical Systems Mani Teja Bodduluri, Thomas Lisec, Phillip Eckstein and Björn Gjodka; Fraunhofer Institute for Silicon Technology ISIT, Germany

Integration of high-performance and voluminous hard magnetic materials into microelectromechanical systems (MEMS) structures have prevalent potential applications in the areas of energy harvesting, loudspeaker, biomedical, and various other markets [1]. However, miniaturization of bulk hard magnets to hundreds of micrometers employing conventional top-down (micromachining, bonding, etc.) and bottom-up (sputtering, electro-deposition, etc.) approaches is challenging because of issues like high-temperature processes, patterning, the realization of complex structures, etc [2].

A novel technique based on the agglomeration of powder materials into rigid structures using atomic layer deposition (ALD), best adapted for MEMS fabrication processes, has been used to integrate high-performance and organic-free NdFeB micromagnets into MEMS structures [3,4]. 75nm of ALD deposited Al_2O_3 layer is ample to fully agglomerate the particles which are dry filled into the etched Si cavities (aspect ratios (t/l) of 0.25 to 5). Since the ALD process is a gas phase CVD technique it has the advantage to coat the particles detailedly with a homogeneous and conformal layer, as a result, the layer binds the particles together moreover protects them from corrosion.

In this study, we have investigated the salient factors and process parameters influencing the magnetic properties of the ALD agglomerated NdFeB micromagnets. A vibrating sample magnetometer was used to measure the magnetic properties. Low temperature (75°C) thermal ALD process of Al_2O_3 is developed to circumvent issues like oxidation during the deposition process and effects of thermal expansion mismatch. Besides fabricating micromagnets comprising of single hard magnetic material (NdFeB, SmCo) we fabricated hybrid micromagnets by mixing (in weight ratio) NdFeB, SmCo magnetic materials to improve the effective magnetic properties of the micromagnets. The hybrid micromagnets displayed better reversible temperature coefficients over a specified temperature range. We analyzed the susceptibility curves and recoil loops to understand the magnetic mechanism. Additionally, magnetic interactions in the agglomerated particles were interpreted from Henkel plots by measuring dc demagnetization remanence and isothermal remanence. The δM plot indicates negative values elucidating magnetostatic type of interactions.

Effect of Bi-Axial Strain on Cation Rotations and Electronic Band Structure of the Antiperovskite Mn_3GaN Roman Malyshev[1], Ingeborg-Helene Svenum[2,1], Sverre M. Selbach[1] and Thomas Tybell[1]; [1]NTNU – Norwegian University of Science and Technology, Norway; [2]SINTEF Industry, Norway

Strain-engineering is a powerful technique to control the properties of perovskite oxides. The effect of bi-axial strain is effectively a rotation/tilt of the oxygen octahedra, altering bond angles and lengths. Antiperovskite materials, functional materials that can possess properties such as antiferromagnetism, superconductivity and topological effects, have a perovskite crystal structure. However, a cation is occupying the oxide anion position while the perovskite B-site is occupied by an anion. Recent progress in thin film deposition has advanced heterostructures of antiperovskites with oxide perovskites and other quantum materials. Here, a density functional theory (DFT) study of the effect of bi-axial strain on the cubic antiperovskite Mn_3GaN is presented. Mn_3GaN is antiferromagnetic with the Mn spins ordered in a Kagome Γ^{5g} structure. Contrary to perovskite oxides, the cation-octahedra of Mn_3GaN are resilient to strain and the system prefers to adjust into a centrosymmetric tetragonal structure. In order to understand this resilience, the implications of the intermetallic nature of antiperovskites are addressed, and a detailed mapping of how the chemical bonds are affected by strain in Mn_3GaN is compared to the effect of strain on the ionic bonds in the canonical cubic oxide perovskite $SrTiO_3$. The stiffness of the Mn_3GaN phonon structure to strain will also be compared to phonon modes that cause octahedral rotations in perovskites. Lastly, the effect of biaxial strain of Mn_3GaN on electronic properties will be addressed via band structure investigations.

6:30 PM EQ10.10.01
Late News: Freestanding Ferroelectric Bubble Domains Saidur R. Bakaul[1], Sergei Prokhorenko[2], Qi Zhang[3], Yousra Nahas[2], Amanda Petford-Long[1], Laurent Bellaiche[2] and Nagarajan Valanoor[3]; [1]Argonne National Laboratory, United States; [2]University of Arkansas, Fayetteville, United States; [3]University of New South Wales, Australia

Ferroelectric (FE) bubble-like domains contain specially ordered electric dipoles. These objects are considered as possible multifuntional topological defects[i],[ii] that may find revolutionizing applications in the field of microelectronics, due to their exceptional electronic and mechanical behavior. These nanoscale objects arise only in ultrathin complex oxide ferroelectric-dielectric-ferroelectric heterostructures that are epitaxially clamped with flat substrates. The parameter space (epitaxial strain, screening, built-in field, etc.) that favors their formation is quite narrow, and epitaxial growth is necessary. Due to the need for stringent growth conditions, the formation of bubble domains is therefore only possible on select complex oxide platforms. As such, integration of these functional objects with mainstream microelectronics substrates such as silicon and germanium is beyond the current capability of direct synthesis technique. Recently discovered epitaxial layer transfer techniques [iii],[iv],[v] can be a possible remedy in this regard. These techniques enable the epitaxially grown complex oxides to be freestanding by selectively detaching them from the host substrate. The freestanding complex oxides can be subsequently transferred to an arbitrary substrate.
In this work,[vi] we demonstrate that ferroelectric bubble domains can be stabilized in a freestanding epitaxial FE – DE – FE complex oxide heterostructure. We find that the FE bubbles are invariant to surface bending and mechanical perturbations up to a limit – suggesting the presence of an energy barrier to their breakdown. Local piezoresponse force mapping, together with field-dependent capacitance tuning and its agreement with calculations of capacitive response, confirm that the FE bubbles conserve their general electromechanical characteristics — this is in spite of a surface that is heavily rippled. We anticipate these results to be the starting point of a new paradigm for the exploration of electric skyrmions with arbitrary boundaries and physically flexible topological orders in ferroelectric curvilinear space.

Late News: Room temperature 0.55Pb(Zr0.52Ti0.48)O3-0.45Pb(Fe0.67W0.33)O3 Nanoscale Multiferroic Thin Films Prepared by Pulsed Laser Deposition Technique Karuna K. Mishra, Ivan Castillo and Ram Katiyar; University of Puerto Rico, United States

The discovery of single-phase magnetoelectric materials and studies of their coupling mechanisms between spin and polarization are important for next generation logic and memory devices. Highly (001) oriented $0.55Pb(Zr_{0.52}Ti_{0.48})O_3$-$0.45Pb(Fe_{0.67}W_{0.33})O_3$ (0.55PZT-0.45PFW) multiferroic thin films were deposited on $La_{0.67}Sr_{0.33}MnO_3$ (LSMO) buffer layer coated on $(LaAlO_3)_{0.3}(Sr_2AlTaO_6)_{0.7}$ (001) substrates by following two subsequent laser ablation processes in oxygen atmosphere employing pulse laser deposition technique. The 0.55PZT-0.45PFW films were found to grow in a tetragonal phase with orientation along (001) plane as inferred from x-ray diffractometry analysis. The temperature dependent dielectric measurements (80-730 K) on metal-ferroelectric-metal heterostructure capacitors in the frequency range of 10^2–10^6 Hz indicated broad and diffused dielectric peaks over a wide range of temperature 320-730 K and exhibits high dielectric constant ~2100 at 10 kHz at room temperature. The well saturated slim polarization hysteresis loop of the thin film capacitors suggests nano-scale ferroelectric ordering (relaxor type) in these films in accord with diffuse dielectric response results. An excellent high energy storage density with efficiency of ~62 % was estimated at an applied electric field of 1200 kV/cm. Magnetization studies involving Zero Field Cool and Field Cool magnetization curves on the thin films using PPMS down to 4 K indicated an irreversible magnetic ordering in the thin films. A saturated magnetization *M-H* loop with P_s value of 32 emu/cm^3 was observed at room temperature. The magneto-dielectric studies suggest robust direct evidence of magneto-electric coupling via strain at room temperature. These results suggest that our thin films are multiferroic (ferroelectric-ferromagnetic) at room temperature. These results will be presented in detail at the MRS Fall meetings.

7:00 PM *EQ10.10.03
Non-Trivial Orbital Torque in Ferromagnetic Metal/Cu/Al_2O_3 Junyeon Kim[1] and Yoshichika Otani[2,1]; [1]RIKEN, Japan; [2]University of Tokyo, Japan

So far, the orbital moment has not been seriously considered as an information carrier due to the orbital quenching in ordinary solid-state matters. However, as claimed in recent theoretical studies, we can expect nonzero orbital moment polarization against the orbital quenching whenever the orbital texture is formed in systems, e.g., surfaces or bulks [1,2]. Notably, the formation of orbital texture is irrelevant to the spin-orbit coupling strength (SOC). Thus we expect efficient orbital moment polarization even in a system composed of light elements. The magnetization of a magnetic layer feels a torque if the orbital polarization is transported to a magnetic layer. Hence, it is called orbital torque.
We systemically observe the orbital torque in ferromagnetic metal (FM)/Cu/Al_2O_3 trilayers [3]. Here we believe the Cu/Al_2O_3 interface is responsible for the orbital polarization. All samples in this study are prepared by the electron beam evaporation technique and photo-lithography. We utilized the ferromagnetic resonance technique to observe the torque efficiency. Interestingly, the orbital torque strongly depends on the FM materials. When the FM is CoFe or Fe, the torque efficiency reaches ~0.13, comparable to that for Ta or Pt. In contrast, the torque efficiency becomes almost zero when the FM is a Ni-based material.
Moreover, we find a significant annealing temperature dependence in the torque efficiency. After annealing at 400 C, the torque efficiency for the CoFe/Cu/Al_2O_3 trilayers becomes ~0.25, which is comparable to that for W. All these strong dependencies of torque efficiency on the FM materials and the annealing temperature reflect a characteristic transport of orbital moments. Commonly the change of the FM materials and the heat treatment modifies the interfacial/layer condition through the intermixing or separation. Since localized electrons transport information of the orbital moment, it is more sensitively affected by the material condition than spins.
Finally, we note that the spin Hall conductivity in the FM/Cu/Al_2O_3 trilayers is $3.4\times10^4\ \Omega^{-1}cm^{-1}$, about 10-100 times larger than that for spin Hall materials

or topological insulators. Thus, we believe the FM/Cu/Al_2O_3 trilayers are superb for spin manipulation with low power consumption. We will give further discussions during the symposium.

7:30 PM EQ10.10.04
Synthesis and Characterization of Bismuth Ferrite Using Conventional Ball-Milling, Nano-Agitator Milling and Calcination Methods Lyndon Smith[1], Jeffrey Shield[2], Rifat Mahbub[2], Vijaya K. Rangari[1] and Shaik Jeelani[1]; [1]Tuskegee University, United States; [2]University of Nebraska–Lincoln, United States

Bismuth ferrite is a well-known multiferroic ceramic. It shows ferroelectric and antiferromagnetic ordering at a Curie temperature of ~1100 K and a Néel temperature of ~653 K. Bismuth ferrites properties can be altered by varying shape and size of particles and also by doping other elements. In this study, bismuth ferrite was synthesized using three methods for comparison – a conventional high-energy shaker mill, a nano-agitator bead mill, and precipitation followed by calcination. Gadolinium (10%) and cobalt (10%) were used as dopants in the calcination method. The composition, morphology, and magnetic properties of the resulting particles were characterized with SEM, XRD, and VSM. The powders produced by both milling methods were weakly ferromagnetic. The particles produced from the nano-agitator mill process had a more uniform distribution of grain sizes than the conventional shaker mill process. The particles produced through calcination method were large polygons covered in smaller facets. This method is faster, but there are few options available for substitution of the B-site cation. The milling methods show fewer impurity phases than the calcination method.

Study of the Magnetocaloric Behavior of $La_{0.7}Ca_{0.3}MnO_3$-xMO (M=Ni,Cu,Co) Nanocomposites Surendra Dhungana, Dipesh Neupane and Sanjay R Mishra; The University of Memphis, United States

Magnetic refrigeration has drawn the attention of many researchers due to its advantages over significant drawbacks of conventional cooling methods. The search is for a material with substantial relative cooling power (RCP), high magnetic entropy change(ΔS_m) and can operate at room temperature. $La_{0.7}Ca_{0.3}MnO_3$ exhibits high RCP of 243.1 J/Kg [1] and maximum ΔS_m of 6.99 J/Kg.K [1]. It has been pre-established that the composite formation undergoes multiple magnetic phase transition resulting in increase of RCP and ΔS_m [2]. For example, it is reported that ΔS_m and RCP is 2.32 J/Kg.K and 299 J/Kg for $La_{0.45}Nd_{0.25}Sr_{0.3}MnO_3$-2.5%NiO composite [2] and ΔS_m and RCP is 1.95 J/Kg.K and 298 J/Kg for $La_{0.45}Nd_{0.25}Sr_{0.3}MnO_3$-2.5%CoO composite [2]. All of these are improvement over ΔS_m and RCP value of 1.79 J/Kg.K and 296 J/Kg for pure $La_{0.45}Nd_{0.25}Sr_{0.3}MnO_3$ sample. In case of $La_{0.45}Nd_{0.25}Sr_{0.3}MnO_3$-2.5%CuO composite, significant increase in ΔS_m is reported to 3.95 J/Kg.K in compensation for decrease in RCP to 245 J/Kg which is attributed to the proximity between the critical temperature of $La_{0.45}Nd_{0.25}Sr_{0.3}MnO_3$, 240K and the Neel temperature of the CuO, 230K [2]. The MCE study on LCMO-MO (metal oxide) composites is not widely reported and with superior ΔS_m value of 6.99 J/Kg.K for $La_{0.7}Ca_{0.3}MnO_3$ [1] as compared to that of 1.79 J/Kg.K for $La_{0.45}Nd_{0.25}Sr_{0.3}MnO_3$ [2] better results are expected for LCMO-MO composite. Also, the recorded critical temperature of $La_{0.7}Ca_{0.3}MnO_3$ of 256K is significantly different from Neel temperature of used NiO, CuO and CoO which should yield higher ΔS_m and RCP. Other literatures have also recorded the performance improvement in manganite by composite formation with metal oxides [4]. This study presents the structural and magnetocaloric study of $La_{0.7}Ca_{0.3}MnO_3$ composite with metal oxides; NiO, CuO, CoO.
The (1-x)$La_{0.7}Ca_{0.3}MnO_3$-xMO (x=0, 0.25, 0.5 ; M=Ni, Cu, Co) nanocomposite samples were synthesized through autocombustion using nitrate salts followed by calcination. X-Ray Diffraction (XRD) and Scanning Electron Microscopy (SEM) were used to study structural characterize the samples. The XRD plots show no secondary phases and respective increase of the metal oxide phases with increase of their content. A grain refinement of LCMO phase was observed with the increased metal oxide phase in the composite. To study the magnetocaloric properties of the composites, magnetic isotherms were collected in the temperature range 100-300K and field up to 5T. The data is currently being analyzed to compare the magnetocaloric performance of the composites.

Thermodynamic Stability of Polar Phases in $Hf_{0.5}Zr_{0.5}O_2$ Epitaxial Thin Films Bo Wang, Jianjun Wang and Long-Qing Chen; The Pennsylvania State University, United States

The discovery of robust ferroelectricity in ultrathin HfO_2-based materials has aroused surging interests in developing silicon-compatible ferroelectric nanoelectronics. To understand the fundamental origin of the ferroelectricity, epitaxial thin films of HfO_2-based oxides such as $Hf_{0.5}Zr_{0.5}O_2$ (HZO) have been successfully grown, wherein different polar phases have been detected, including the orthorhombic $Pca2_1$ phase and a newly discovered rhombohedral phase. However, it is not well understood how the misfit strains imparted by the substrate materials influence the stability of the polar phases. Here, we present a comprehensive thermodynamic model, developed based on our recently proposed strain phase separation theory, to predict and understand the stability and coexistence of polar and nonpolar phases in HZO epitaxial thin films. We demonstrate that the misfit strains imposed by substrates of different crystallographic structures (e.g., fluorite, perovskite, and hexagonal) can serve as a viable way to stabilize different polar phases. We establish film thickness – lattice constant phase diagrams for HZO thin films on different types of substrates, which can be utilized to understand the origin of ferroelectricity and guide the strain engineering of HfO_2-based ferroelectric thin films.

Acoustically Actuated Antennas Induced by Magnon-Phonon Coupling Yahui Ji and Tianxiang Nan; School of Integrated Circuits, Tsinghua University, China

Recently, acoustically actuated antennas based on the thin-film magnetoelectric heterostructures have been demonstrated with 1-2 orders of magnitude miniaturization over the conventional counterparts. However, it remains challenging to improve their radiation efficiency and develop the high quality antenna modulation technique. Here, we computationally demonstrate a fully coupled model describing the radiation mechanism, including Newton, Maxwell and Landau-Lifshitz-Gilbert (LLG) equations, together with piezoelectric and magnetostrictive constitutive relations. We theoretically propose that magnons, the quanta of spin waves, can be utilized to strongly enhance the radiation efficiency of acoustically actuated antennas when magnon and phonon modes are coupled. In the strong coupling region, our model shows that the radiation efficiency can be 100-time enhanced, and antenna modulation can be substantially simplified. Additionally, a right-hand circular polarization (RHCP) radiation field can be observed.

Late News: Boundary Conditions Manipulation of Polar Vortex Domains in BiFeO3 Membranes via Phase-Field Simulations Ren-Ci Peng[1], Xiaoxing Cheng[2], Bin Peng[1], Ziyao Zhou[1], Long-Qing Chen[2] and Ming Liu[1]; [1]Xi'an Jiaotong University, China; [2]The Pennsylvania State University, United States

Polar vortex domains have recently become an emergent research field due to the abundant physical phenomena and potential applications in high-density memories. Here, we explore the mechanisms of creating polar vortex domains in the $BiFeO_3$ membranes subjected to different boundary conditions using phase-field simulations. A major difference is that the vortex in membrane can be stabilized even under short-circuit electrical boundary conditions compared to vortex in other systems, such as thin film or superlattice. We found that (i) the formation of polar vortex domains at the membrane interior under bending is mainly driven by the reduction of elastic energy under short-circuit boundary condition, and the vortex chirality (namely, clockwise and counterclockwise) could be identified by *n*-shape and *u*-shape bending; (ii) in the unbent open-circuit $BiFeO_3$ membrane case, exotic trapezoid-shaped vortex nanodomains form at the terminations of 109^o domain walls (DWs) and partially charged 71^o DWs, which is driven by the local depolarization field and the interplay among electrostatic, elastic, and gradient and Landau energies. We also examine Kittel's law by establishing the dependence of vortex periods on the membrane thickness. These results give further understanding of the effect of boundary conditions on the formation of polar vortex domains, guiding experimental designs of vortex-based high-density memories.

Quantum Polar Skyrmions/Merons in Doped $SrTiO_3$ Heterostructures—A Topological Polaron Takahiro Shimada[1], Yuuki Ichiki[1], Tao Xu[2], Le Van Lich[3], Jie Wang[4] and Hiroyuki Hirakata[1]; [1]Kyoto Univ, Japan; [2]Chinese Academy of Sciences, China; [3]Hanoi University of Science and Technology, Viet Nam; [4]Zhejiang University, China

Realization of ultrasmall ferroics with nontrivial topological field textures such as vortices, skyrmions, and merons holds promise in novel technological paradigms. Such nontrivial ferroelectric orders and their functionalities, however, inevitably disappear below a critical size of several nanometers. In addition, very few topological structures can exist in ferroelectrics due to the lack of non-collinear interaction among electric dipoles, unlike the Dzyaloshinskii-Moriya (DM) interaction among spins in ferromagnetics. Here, we demonstrate from first-principles that "Polar Skyrmions and Merons" are formed in doped $SrTiO_3$ heterostructures. Doped (excess) electrons in $SrTiO_3$ are localized and form a polaronic state in the heterostructures (surfaces and grain boundaries), and give rise to skyrmionic and meronic dipole moments around the polaron formation sites due to the cooperative symmetry breaking of polarons and heterostructures. We further show that the topological number of polaronic state can be tailored by applied mechanical strain, i.e., strain engineering for polar topologies. Our discovery overcomes physical limitations of the critical size of 3-5nm where ferroelectricity disappears and the inability to form topological field (skyrmions, merons) of polarization due to absence of chiral interaction among electric dipoles, and realizes unique polar topological orders at ultimately electron(polaron)-scale. The clarified mechanism that local symmetry breaking via polaron formation coupled with heterostructures provides a novel approach to realize ultimate miniaturization of ferroic materials and opens up new fields to create the polar topological objects**.** Our result therefore adds a new class of functional polaron families as "Topological Polarons".

Tuning Anharmonic Phonon Coupling Using Magnetism in Magnetoelectric h-FeS Dipanshu Bansal[1,2], Jennier Niedziela[3], Stuart Calder[3], Tyson Lanigan-Atkins[1], Ayman Said[4], Doug L. Abernathy[3], Alexander Kolesnikov[3], Haidong Zhou[5] and Olivier Delaire[1]; [1]Duke University, United States; [2]Indian Institute of Technology Bombay, India; [3]Oak Ridge National Laboratory, United States; [4]Argonne National Laboratory, United States; [5]The University of Tennessee, Knoxville, United States

Magnetoelectric hexagonal iron sulfide (h-FeS) exhibits a fascinating coexistence of metal-insulator, structural and magnetic transitions, reflecting an intimate interplay of its spin, phonon, and charge degrees of freedom. Using comprehensive neutron and X-ray scattering measurements supported by first-principles electronic structure simulations, we show how a subtle competition of energetic and entropic free-energy components governs its thermodynamics and the sequence of phase transitions upon cooling.

We identify the critical role of the coupling between antiferromagnetic ordering and the instabilities of anharmonic phonons in the metallic phase in driving the metal-insulator transition. The antiferromagnetic ordering enables the emergence of two zone-boundary soft phonons, whose coupling to a zone-center mode drives the lattice distortion opening the electronic bandgap. Simultaneously, spin-lattice coupling opens a gap in the magnon spectrum that controls the entropy component of the metal-insulator transition-free energy. These results reveal the importance of spin-phonon coupling to tune anharmonic effects, thus opening new avenues to design novel technologically important materials harboring the metal-insulator transition and magnetoelectric behaviors.

Investigation of Magnetic Ordering and Magneto-Caloric Effect in Pr_2MnNiO_6 Rinku Kumar[1], Ankita Singh[2], Mohd. Anas[1], Ramesh Chandra[1] and Vivek Malik[1]; [1]Indian Institute of Technology Roorkee, India; [2]Tata Institute of Fundamental Research, Mumbai, India

This work deals with the structural, magnetic and magneto-caloric properties of double perovskite Pr_2MnNiO_6 (PMNO) material. The bulk material was prepared in a single phase using the solid-state reaction method. The structural characterization showed monoclinic symmetry with the P21 / n space group. The temperature-dependent magnetic measurements were performed in presence of an applied magnetic field of 500 Oe, which showed a phase transition from paramagnetic to ferromagnetic at ~ 200K. The saturation (ZFC) magnetization shows the change in the slope below ~ 50 K, which may be attributed to the strong interaction between A-site (Pr) and B-site (Mn-Ni network) ions. We carried out the isothermal M vs H (hysteresis curve) measurements in the temperature range of 2K-190 K in the presence of a 0-10 T magnetic field to determine the change in magnetic entropy. The estimated value of magnetic entropy ($-\Delta S_M$) is 1.6 J/Kg-K at 23 K under 10 T magnetic field. Interestingly, our report highlights the presence of low-temperature magneto-caloric effect in PNMO material.

Functionalizing the Néel vector in Collinear Antiferromagnets Ding-Fu Shao and Evgeny Y. Tsymbal; University of Nebraska-Lincoln, United States

Antiferromagnetic (AFM) spintronics is an emerging field of research which exploits the antiferromagnetic order parameter, known as the Néel vector, to control spin- and orbital-dependent transport properties. This talk will address three novel approaches to functionalize the Néel vector in collinear compensated AFM metals via their response in transverse or longitudinal conductivity. The first approach utilizes room-temperature AFM metal $MnPd_2$ that allows the electrical control of the Dirac nodal line by the Néel spin-orbit torque [1]. The reorientation of the Néel vector leads to switching between the symmetry-protected degenerate state and the gapped state which modulates the spin Hall conductivity. The second approach involves the nonlinear anomalous Hall effect that can be used to detect the Néel vector in most compensated antiferromagnets supporting the antidamping spin-orbit torque [2]. The magnetic crystal group symmetry of these non-centrosymmetric antiferromagnets, such as CuMnSb, combined with spin-orbit coupling produce a sizable Berry curvature dipole and hence the nonlinear anomalous Hall effect. The third approach highlights antiferromagnets exhibiting a non-spin-degenerate Fermi surface and thus momentum-dependent spin polarization which can be functionalized in AFM tunnel junctions [3]. Using RuO_2 as a representative example of such antiferromagnets, a giant tunneling magnetoresistance effect is predicted for RuO_2-based AFM tunnel junctions. These results broaden the scope of materials and approaches, which can be exploited in AFM spintronics.

Giant Nonreciprocity in Magnetoacoustic Devices Piyush Shah[1], Derek Bas[1], Ivan Lisenkov[2], Alexei Matyushov[3], Nian Sun[3] and Michael Page[1]; [1]Air Force Research Laboratory, United States; [2]Independent Researcher, United States; [3]Northeastern University, United States

Nonreciprocity, the property of merit for a variety of RF components such as isolators and circulators, is typically difficult to achieve with the magnitude required for applications. Many systems which demonstrate non-reciprocity are not suitable for scaling to the size, weight, and power required for applications, or do not exhibit a sufficient intensity of the effect for applications relevance. One such physical system which generally does not exhibit non-reciprocity is that of acoustic waves. Acoustic waves are an important medium for information transport, but they are inherently symmetric in time. By achieving non-reciprocity in an acoustic system, the decades of industrial research in this relatively mature field can be leveraged for new applications. The most promising route to accomplish this is by incorporating magnetic materials into surface acoustic wave (SAW) devices, as in the field of acoustically driven ferromagnetic resonance. While this field remained relatively small since the initial discovery, in the past year, many new reports investigating magnetic materials in SAW devices have been published. Motivated by this expanding field, I will discuss our recent work at the Air Force Research Laboratory on the discovery of giant nonreciprocity in the transmission of surface acoustic waves (SAWs) on a lithium niobate substrate coated with ferromagnet/insulator/ferromagnet (FeGaB/Al_2O_3/FeGaB) multilayer structure. I will discuss how this structure, with a unique asymmetric band diagram, can be exploited for very large non-reciprocal behavior. I will expand on magnetoelastic coupling theory to show how the magnetic bands couple with acoustic waves only in a single direction. In our devices, we measure 48.4 dB (ratio of 1:100,000) isolation which outperforms current state of the art microwave isolator devices in a novel acoustic wave system that facilitates unprecedented size, weight, and power reduction. Finally, I will discuss how these results offer a promising platform to study nonreciprocal SAW devices and other such magnetoacoustic devices.

11:30 AM EQ10.12.03
Influence of Boundaries and Geometrical Curvatures on Antiferromagnetic Textures Oleksandr Pylypovskyi[1,2], Artem V. Tomilo[3], Yelyzaveta Borysenko[3], Juergen Fassbender[1], Denis D. Sheka[3] and Denys Makarov[1]; [1]Helmholtz-Zentrum Dresden-Rossendorf e.V., Ukraine; [2]Kyiv Academic University, Ukraine; [3]Taras Shevchenko National University of Kyiv, Ukraine

A complex structure of magnetic subsystem in antiferromagnets (AFMs) determines challenges and technological perspectives for both, fundamental research and their applications for spintronic and spin-orbitronic devices [1]. In this respect, properties of the confined samples are of key interest because of the possibility to tune magnetic responses via effects of boundary and geometrical curvature [2]. Here, we consider textures in (i) AFM slabs with the Dzyaloshniskii-Morya interaction (DMI) of bulk symmetry [3] and (ii) the intrinsically achiral curvilinear spin chains arranged along space curves [4].

We derive a transition from spin lattice of G-type AFM to the sigma-model with the respective boundary conditions for the AFM order parameter [3]. The DMI influences a texture via boundary conditions modifying the ground state, domain wall shape and skyrmion profiles. Approaching the boundary in the slab with easy-axis anisotropy, the domain wall becomes broader and of mixed Bloch-Neel type near the top surface. Near the edges of the sample, the domain wall plane possesses and additional twist. Note, that the edge twists appear in achiral AFMs as well if the domain wall plane lies at an angle to the side faces [5]. Similarly, skyrmions of any radius become of the Bloch-Neel type approaching the top/bottom surfaces of the sample. The radius of narrow skyrmions changes up to 10% due to the boundary effects.

AFM spin chains arranged along space curves can model the simplest curvilinear nanoarchitectures. Their geometry is described by the curvature and torsion, determining local bends and twists of the curve. The geometry-driven anisotropy and inhomogeneous DMI render them as chiral helimagnets [6]. In addition, the exchange interaction generates the weakly ferromagnetic response, scaling linearly with curvature and torsion. The inter- and single-ion anisotropies in curvilinear AFM chains lead to the additional anisotropic contributions, scaling with curvature. The single-ion anisotropy leads to the homogeneous DMI mixing normal and tangential components of ferro- and antiferromagnetic vector order parameters. Both anisotropy models contribute to the additional easy axes, which determine the direction of the order parameters in spin-flop phase [4].

11:45 AM EQ10.12.04

Resonant Elastic X-Ray Scattering of Sr2CrReO6 Epitaxial Films Guillaume Marcaud[1], Alex T. Lee[1], Sangjae Lee[1], Adam Hauser[2], Fengyuan Yang[3], Zhan Zhang[4], Hua Zhou[4], Ignace Jarrige[5], Sohrab Ismail-Beigi[1], Frederick Walker[1] and Charles Ahn[1]; [1]Yale University, United States; [2]The University of Alabama, United States; [3]The Ohio State University, United States; [4]Argonne National Laboratory, United States; [5]Brookhaven National Laboratory, United States

Resonant Elastic X-Ray Scattering (REXS) is a powerful technique that combines X-Ray Diffraction (XRD) and X-Ray Absorption (XAS), which has elemental sensitivity to both the physical and electronic structure of materials. Due to the cross-section enhancement near an absorption edge, one can select for spin, charge, and orbital order. We apply this technique to rhenium-based double perovskite thin films, which are well known to possess an intricate interplay between structure and orbital electronic configuration. Especially, Sr2CrReO6 (SCRO) has been theoretically predicted to have order of the dxy and dyz orbitals on the rhenium sites. REXS has been performed on three SCRO thin films in different state of strain, compressive -1% on a (LaAlO3)0.3(Sr2AlTaO6)0.7 (LSAT) substrate, tensile +1% on a relaxed SrCr0.5Nb0.5O3 buffer layer on LSAT and free of strain on SrTiO3 (STO). We will discuss the presence and absence of orbital-order induced Bragg peaks in the three samples and compare Bragg peaks intensities as functions of the synchrotron energy through the L-II and L-III edges of Re in order to determine crystal site specific x-ray absorption spectra.

12:00 PM EQ10.12.06

Observing the Chiral Domain Boundaries in $PbTiO_3/SrTiO_3$ Superlattices Using Four Dimensional Scanning Transmission Electron Microscopy (4D-STEM) Sandhya Susarla[1], Piush Behera[2], Fernando Gómez-Ortiz[3], Benjamin Savitzky[1], Colin Ophus[1], Peter Ercius[1], Ramamoorthy Ramesh[2,1] and Javier Junquera[3]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States; [3]Universidad de Cantabria, Spain

Polar vortices in $PbTiO_3/SrTiO_3$ superlattices are unique topological textures where local electric dipoles are arranged in a spiral fashion.[1] These structures are formed via careful control of strain, electrical, and electrostatic boundary conditions.[1] The unique arrangement of electric dipoles results in two major emergent properties: negative capacitance and chirality.[2,3] While negative capacitance in this system is theoritically expected, the presence of the chirailty is unexpected as these textures are formed from achiral objects. In this work, we have investigated the origins of chirality in this system by examining the three dimensional polarization network. To extract three dimensional information, conventional high-resolution scanning transmission electron microscopy (HR-STEM) can't be used directly since it is based on two dimensional projection. Recently, it has been shown that the depth dependence of four dimensional scanning transmission electron microscopy (4D-STEM) can be utlized to extract the underlying polarization.[4] Utilizing 4D-STEM, we map out the three dimensional polarization network (lateral and axial polarization) in such textures. We found that the presence of the domain boundaries and dislocations influence the local handedness in these textures. The presence of the chirality is related to the local curvature of the domain boundary. We also find the ability to switch chirality is closely related to how the local polarization varies across the domain boundary. The emergence of chirality from the combination of non-chiral materials and ability to control the handed-ness has far-reaching implications for new electronics based on topological ferroelectric bits.

Induced Ferroelectricity in Epitaxial Nanocomposite $SrTiO_3$ Films E. Enriquez[1], A. P. Chen[2] and Quanxi Jia[3]; [1]The University of Texas Rio Grande Valley, United States; [2]Los Alamos National Laboratory, United States; [3]University at Buffalo—The State University of New York, United States

Over the past two decades, new discoveries and major advances have been made in the synthesis of oxide-based ferroic thin films and understanding their physical properties. Interface engineering, strain engineering, and defect engineering have been widely used to manipulate the physical properties of the ferroic films in classical lateral heterostructures. As a unique thin-film architecture, vertically aligned epitaxial nanocomposite films have also been widely studied in the past decade and great success has been achieved. However, strain-defect-microstructure-function correlation in such nanocomposite films has not been well-established yet. In this talk, we will overview our strategies in synthesis and characterization of vertically aligned epitaxial nanocomposite ferroic films. Using controlled synthesis, advanced probing, and theoretical modeling, we are able to understand the effect of interface strain on the induced ferroelectric properties in the vertically aligned epitaxial nanocomposite $SrTiO_3$ films.

Combined Hydrogen- and Oxygen-Based Magneto-Ionic Control in Ni Films Maksim Kutuzau[1,2], Stefan Topolovec[3], Markus Gößler[3], Roland Würschum[3], Sandra Schiemenz[2], Daniel Wolf[2], Jonas Zehner[1,2], Kornelius Nielsch[2,4] and Karin Leistner[1,2]; [1]Technische Universität Chemnitz, Germany; [2]Leibniz IFW Dresden, Germany; [3]Graz University of Technology, Austria; [4]Technische Universität Dresden, Germany

Magneto-ionic control targets a change in the magnetic properties of materials by electrochemical reactions, which usually occur at low voltage and at room temperature (1). The most actively studied ions for magneto-ionic systems are oxygen (2,3) and hydrogen (4,5). In most cases, the effect of either oxygen or hydrogen is studied, despite the fact that a dual ion-switch, in which the hydrogen- and oxygen-based mechanisms are combined, may increase the versatility of magneto-ionics. A dual-ion switch has so far been studied only in oxide systems, and in this case major effects were restricted to low temperatures. A transfer to magneto-ionic metal systems with high Curie temperature would boost the perspectives for practical applications (6).
We report combined hydrogen- and oxygen-based magneto-ionic control of electrodeposited nanocrystalline nickel films in an aqueous alkaline electrolyte. To determine and analyze the magneto-ionic effect, *in situ* SQUID and *in situ* MOKE magnetometry measurements were used.
We demonstrate simultaneous voltage-control of magnetic moment and coercivity, caused by hydrogen- and oxygen-based mechanisms, respectively. The significant change in coercivity (up to 52 %) is associated with the removal of oxide pinning centers at the surface. It shows a training effect and becomes stronger with an increased number of cycles. The relatively small changes of magnetic moment (about 0.26%) are in a good agreement with the amount of hydrogen loaded into the Ni films in 1 M KOH (7). Both changes are reversible and repeatable at room temperature and require only a low voltage difference of about 1 V.
This combined ionic mechanism to tune magnetic metals may initiate a new direction in room-temperature magneto-ionics and expand the range of its practical applications.

Phase-Field Modeling of Charge Transport and Defect Properties in Ferroelectric Perovskite Oxides Rui Wang and Long-Qing Chen; The Pennsylvania State University, United States

The stability and evolution of mesoscale structures in solids often involve not only lattice structural and chemical inhomogeneities but also inhomogeneous distributions of electronic, atomic, and ionic defects. We present a general phase-field framework of coupled defect and microstructure evolution of perovskite ferroelectric oxides. In particular, starting from well-established classic thermodynamics, it offers an explicit formulation to obtain the electronic and lattice defect contributions to the thermodynamic properties using statistical/classical thermodynamics. In this model, we treat the ferroelectric perovskite oxide as a wide band-gap semiconductor and we derive all well-known thermodynamic relations related to defect reactions, equilibria including redox and electronic recombination/generation reactions. The model is applied to $BiFeO_3$ as a prototypical ferroelectric perovskite oxide system to study the interplay between mobile charges and stability of ferroelectric domains. It is demonstrated that the charged domain walls in $BiFeO_3$ are more likely to be stabilized with a larger amount of mobile charged defects, and the conductivity on domain walls can be tuned by the interactions and types of the charges within the ferroelectric system. It is also found that the mobile defect charges are responsible to the formation of local conductive paths and the bound charge separation at domain walls. The model would give insights to explore the electric properties and applications in ferroelectric perovskite oxides.

Phase-Field Model of Light-Excited Carrier and Structural Dynamics of Ferroelectric Domain Structures Tiannan Yang and Long-Qing Chen; The Pennsylvania State University, United States

Charge carriers including electrons and holes as well as their dynamics play a significant role in determining material behaviors. Ferroelectric materials are quite commonly semiconductors, meaning that upon excitation by various stimuli such as light pulses, their carrier concentrations can be transiently raised by orders of magnitude from the equilibrium values, thus, giving rise to material properties and phenomena vastly different from those at equilibria. Here we develop a phase-field model for the dynamical phenomena of ferroelectric domain structures involving coupled charge carrier evolution and structural

responses under ultrafast external stimuli. As an example, we study the carrier and structural dynamics of various ferroelectric $PbTiO_3$ domain walls excited by a femtosecond above-band-gap light pulse. We find that the carrier concentration around charged domain walls relaxes with a two-component process at picosecond and nanosecond time scales for free carriers and carriers trapped at the domain walls, respectively. Meanwhile, a strong transient strain response is induced, which contains two fast oscillational components and a slower relaxational component, signifying rich dynamics involving domains, domain walls, and charges. The present work provides a general theoretical framework for studying carrier-mediated ultrafast processes in ferroelectric domain structures and thus for exploring dynamical functionalities of ferroelectric materials.

Tunable Switching Behaviors and Topological Phase Transitions of a Ferroelectric Supercrystal Cheng Dai[1], Vladimir Stoica[2,1], Sujit Das[3], Zijian Hong[4], Lane W. Martin[3], Ramamoorthy Ramesh[3], John Freeland[2], Haidan Wen[2], Venkatraman Gopalan[1] and Long-Qing Chen[1]; [1]The Pennsylvania State University, United States; [2]Argonne National Laboratory, United States; [3]University of California, Berkeley, United States; [4]Zhejiang University, China

Understanding the phase transitions and switching behaviors of mesoscale topological structures in ferroic materials is critical to realize their potential applications in next-generation high-performance storage devices. In this work, we study the kinetic evolution of a mesoscale supercrystal with 3-D nanoscale periodicity in a $PbTiO_3/SrTiO_3$ superlattice under thermal and electrical stimuli using a combination of phase-field simulations and X-ray diffraction experiments. We construct a phase diagram of temperature versus polar state, showing the formation of the supercrystal from a mixed vortex and *a*-twin state and a temperature-dependent erasing process of a supercrystal returning to a classical *a*-twin structure. Under an electric field bias at room temperature, the vortex topology of the supercrystal irreversibly transforms to a new type of stripe-like supercrystal under an in-plane electric field. Under an out-of-plane electric field, the vortices inside the supercrystal undergo a topological phase transition to polar skyrmions. These results demonstrate the potential for the on-demand manipulation of polar topology and transformations in supercrystals using electric fields. The findings provide a theoretical understanding which may be utilized to guide the design and control of mesoscale polar structures and to explore novel polar structures in other systems and their topological nature.

Structural Effects and the Formation of Small Polarons in of BiFeO3 Iflah Laraib and Anderson Janotti; University of Delaware, United States

The flexibility of manipulating the magnetic ordering and ferroelectric polariozation at room temperature through the magnetoelectric effect in $BiFeO_3$ has attracted great attention to potential device applications. However, basic properties such as the electronic structure of $BiFeO_3$ is not yet well established. Reported band gap of multiferroic $BiFeO_3$ has been a subject of debate, with values reported in wide range of 2.5 - 3.1 eV. Presence of oxygen vacancy defects is a common occurrence in the synthesis of multiferrioc $BiFeO_3$, which leads to room temperature conductivity that is often linked to polaron hopping. Using hybrid density functional theory calculations, we find a band gap of 3.4 eV for *R3c* $BiFeO_3$, which is slightly larger than a recent reported band gap of 3.1 eV for single crystals based on optical absorption and photoluminescence measurements. Our calculations reveals a strong dependence of the band gap and band edge positions on the antiferrodistortive rotations of the FeO_6 octahedra and ferroelectric displacement of Fe ions. The band gap decreases from 3.4 eV for the *R3c*, to 2.9 eV for the paraelectric *R3-c*, and to 1.6 eV for the cubic antiferromagnetic $BiFeO_3$, by significant lowering of the conduction band due to reduced O-2*p* Bi-6*p* coupling in the more symmetric structures, with simultaneous slight raising of the valence band that is dependent on Fe 3*d*-O 2*p* and Bi 6s-O 2*p* interactions. Lastly, we explored the formation of small hole and electron polarons in $BiFeO_3$ single crystals and propose a charge transport mechanism via polaron hopping, which can explain the observed room temperature conductivity in the material.

Voltage Controlled Néel Vector Rotation in Zero Magnetic Field Christian Binek[1,2], Ather Mahmood[1], Will Echtenkamp[1], Mike Street[1], Jun-Lei Wang[1], Shi Cao[1], Takashi Komesu[1], Peter Dowben[1,2], Pratyush Buragohain[1], Haidong Lu[1], Alexei Gruverman[1,2], Arun Parthasarathy[3] and Shaloo Rakheja[4]; [1]University of Nebraska-Lincoln, United States; [2]Nebraska Center for Materials and Nanoscience, United States; [3]New York University, United States; [4]University of Illinois at Urbana–Champaign, United States

Voltage-controlled switching of remnant magnetic states paves the way towards ultra-low power and non-volatile spintronics. In this presentation, I report on a journey, which took us from isothermal electric switching of exchange bias with the help of simultaneously applied electric and magnetic fields[1] to pure voltage-controlled antiferromagnetic spintronics in zero magnetic field and at CMOS compatible temperatures.[2]
Nonvolatile Néel vector reorientation in the absence of an applied magnetic field, *H*, is demonstrated at CMOS compatible temperatures in prototype device structures which exploit the multi-functional properties of thin films of boron (B) doped Cr_2O_3. Boundary magnetization associated with the Néel vector orientation serves as state variable, which is read via magnetoresistive detection in a Pt Hall bar adjacent to the B: Cr_2O_3 film. Switching of the Hall voltage between zero and non-zero values implies Néel vector rotation by 90-degrees. Combined magnetometry, spin resolved inverse photoemission, electric transport and scanning probe microscopy measurements reveal B-dependent T_N and resistivity enhancement, spin-canting, anisotropy reduction, dynamic polarization hysteresis and gate voltage dependent orientation of boundary magnetization. The combined effect enables H=0, voltage controlled, nonvolatile Néel vector rotation at temperatures as high as 400 K. Theoretical modeling estimates switching speeds of about 100 ps making B: Cr_2O_3 a promising multifunctional single-phase material for energy efficient nonvolatile CMOS compatible memory applications.

Domain-Wall-Induced Electromagnons in Multiferroics Laurent Bellaiche; University of Arkansas, United States

The high demand for the development of multifunctional devices as well as the interesting mechanisms behind the coexistence of ferroic order parameters within the same phase in multiferroic materials has launched a new wave of research in recent years. The unique properties of some multiferroics such as magnetoelectric (ME) coupling, which allows the cross control of electrical dipole moments by applying magnetic fields (or conversely magnetic moments by electric field), open opportunities for designing novel sensors and memory devices with significantly lower power consumption and higher efficiency. Moreover, the existence of domains and excitations, such as electromagnons, awards multiferroic systems with richer multifunctionalities as well as the potential of enhancing ME responses and designing novel devices such as *electrically-driven* configurable magnonic circuits. Here we report the prediction of dynamical couplings between magnons and optical phonons in systems possessing ferroelectric domain walls that leads to the emergence of new hybrid quasi-particles, namely *domain-wall-induced* electromagnons. These quasi-particles induce THz resonances in magnetoelectric responses and preferentially localize either near the domain walls or near the middle of domains as a result of scatterings. Such features can be exploited to reach strikingly large ME conversion and designing more reliable and ultrafast ME devices with less energy consumption and using, e.g., local probes.

5:00 PM EQ10.14.03
DFT-Based Resonant Inelastic Resonant Scattering Study of $LaCoO_3$, CoO and $LaCoO_3/LaTiO_3$ Superlattices Alex T. Lee, Sangjae Lee, Frederick Walker, Charles Ahn and Sohrab Ismail-Beigi; Yale University, United States

Cobalt cations in oxides can have multiple electronic configurations. While Co in CoO is in a 2+, high spin (S=3/2, t_{2g}^5 e_g^2) state, $LaCoO_3$ (LCO) has Co^{3+} that has multiple spin states depending on temperature: low-spin (S=0, t_{2g}^6 e_g^0), intermediate-spin (S=1, t_{2g}^5 e_g^1), and high-spin states (S=2, t_{2g}^4 e_g^2), which have nearly degenerate ground state energies. Recently, we have synthesized $LaCoO_3/LaTiO_3$ superlattices exhibiting strong orbital polarization [1]. Theoretical calculations show that Co is 2+ in these superlattices with two relevant low-energy spin states (low-spin S=1/2, t_{2g}^6 e_g^1 and high-spin, S=3/2, t_{2g}^5 e_g^2) [2,3].
Here, we combine Resonant Inelastic X-ray Scattering (RIXS), a powerful tool of local electronic states and low-energy excitations, with a DFT+U based theoretical approach to compute RIXS spectra. This approach is capable of describing both the broad, fluorescent features in RIXS (e.g., which are strong features for RIXS of LCO) as well as localized excitations (e.g., characteristic RIXS features of CoO). We find that this theoretical approach allows us to interpret the RIXS spectra for bulk materials and superlattices, and it also describes the changes of the experimental RIXS spectra as a function of the thickness of the cobaltate layers in the superlattices. We will briefly compare the DFT+U RIXS method to atomic and cluster calculations which do not describe the band-like features in condensed matter systems.

Vibrational Neutron Spectroscopy and Modelling using DFT of Organic Magneto-Ferroelectric TTF-BA Sanghamitra Mukhopadhyay; STFC Rutherford Appleton Laboratory, United Kingdom

Organic functional materials, particularly multiferroics, are very novel, because of their simultaneous magnetic and ferroelectric properties. These type of materials have many state of the art applications including flexible electronics, data and storage devices [1-4]. In these materials ferroelectricity can be tuned by applying magnetic fields. Since flexibility and multi-ferroicity rare combinations, organic multi-ferroics are candidates of intense research promising of designing new materials fit for the purpose. For these reasons these materials are in the focus of current research not only for fundamental scientific interests, but also of their potential use in new emerging technology, such as flexible electronics devices.

Generally, charge or proton transfer across chemically distinct donor-acceptor pairs, or movements of those protons in the centro symmetric to non-centrosymmetric positions are considered as the key mechanisms of the functionality of these materials [3]. In this context the dynamics of proton or the charge carriers are important to understand to do bespoke designing. Some of hydrogen bonded solids, namely croconic acid ($C_5O_5H_2$), 1-cyclobutene-1,2-dicarboxylic acid (CBDC, $C_6H_8O_4$) and 2-phenylmalondialdehyde (PhMDA, $C_9H_8O_2$) show high polarizability at room temperature [5]. As a continuation of our on-going effort in understanding dynamics of protons in ferroelectricity [6-10], in this work we investigate the dynamics of proton in tetrathiafulvalene-p-bromanil [$(H_2C_2S_2C)_2$ - $C_6Br_4O_2$] (TTF-BA). [2], which has shown its potential to be multiferroic at low temperatures. The motivation of this work to help not only to understand the finger print dynamics of ferroelectricity of these materials, but to design new organic ferroelectrics for technological use.

We have used inelastic neutron scattering (INS) to explore proton dynamics in TTF-BA. The INS experiment has been done at ISIS neutron and Muon Source. DFT based first-principles simulations have been done to model the INS spectrum to understand the mechanism of the multiferroic properties of this material. Both spin polarised and non-spin polarised calculations have been done using CASTEP code. PBE + GGA functionals have been used to determine the ground state structures. Quasi harmonic calculations have been performed to understand the mechanism of ferroelectricity. The responsible modes for ferrolectricity have been identified by normal mode and soft phonon analysis of these calculations.

The neutron spectroscopic experiment and DFT simulations indicate that C-H—Br bending modes carry the finger print signature of ferroelectricity of the molecule. In the talk the effect of spin polarisation on this mode will also be discussed.

Antiferromagnetic and Relaxor-Type Ferroelectric Behavior in Iron-Doped $GdCrO_3$ Jianhang Shi[1], Mohinder Seehra[2] and Menka Jain[1]; [1]University of Connecticut, United States; [2]West Virginia University, United States

Here we present a comparative study of the structural, magnetic, and dielectric properties of 960 nm thick film and bulk pellet of single-phase polycrystalline $GdFe_{0.5}Cr_{0.5}O_3$. The film was fabricated on a platinized-silicon substrate by solution deposition and spin-coating methods. The bulk pellet was synthesized by the citrate solution route. Magnetic measurements show *Néel* temperature~ 270 K for both the bulk and the film whereas dielectric measurements show ferroelectric to paraelectric transition with T_C ~ 525 K for bulk and 450 K for the film. The frequency dependent dielectric data of both samples is found to follow Vogel-Fulcher relation that implies relaxor-type diffusive ferroelectric behavior. Interfacial Maxwell–Wagner polarization was also observed at low frequencies. The electric polarization hysteresis loops, although leaky, are observed at room temperature revealing multiferroic nature. Details and discussions of these results will be presented.

5:45 PM EQ10.14.06
High-Tc Ferroelectricity in a New Molecular Magnetoelectric Ytterbium (III) Complex Arseniy M. Buryakov[1], Maxim Ivanov[1,2], Artur Avdizhiyan[1], Ekaterina Mamontova[3], Joulia Larionova[3], Paula Maria Vilarinho[2], Elena Mishina[1] and Jerome Long[3]; [1]RTU MIREA, Russian Federation; [2]University of Aveiro, Portugal; [3]Université de Montpellier, France

Magnetoelectric materials (ME) are multifunctional systems that combine magnetic and ferroelectric behaviors [1]. With the ability to switch ferroelectric (magnetic) domains by small external fields, ME create the basis for the development of low-consumption devices, including high-density data storage, spintronics, and optoelectronics [1]. For these applications, ME must have strong magnetoelectric coupling at room temperature and above, which rarely observed for classical inorganic ME materials such as metal oxides [1, 2]. Synthesis of such inorganic ME at the atomic level is also a difficult task [1, 2]. However, there are several studies showing that molecular ME based on metal-organic complexes can be an alternative to the currently actively studied ME systems, in particular, transition metal oxides [3-5]. In addition, molecular ME have a wide functionality due to their flexibility, non-toxicity, and high manufacturability. Earlier, we showed the presence of a strong ME-coupling in a new molecular ZnYb complex, which combines ferroelectric and paramagnetic properties at room temperature [5]. This work represents further required fundamental study on the determination of ferroelectric Curie temperature (Tc) in the ZnYb compound and its distinct ferroelectricity type (uniaxial or multiaxial).
Using nonlinear optical microscopy, we investigated anisotropic dependencies of the second harmonic generation (SHG) in the ZnYb single crystal. The ZnYb complex at room temperature is a monoclinic system described by the polar point group *2* [5]. In this case, the electric-dipole term is the main contribution to the SHG signal. Nonzero nonlinear susceptibility tensor components were defined for ZnYb complex. Temperature dependence of the SHG intensity in the range from 293 K to 493 K was obtained. To approximate thisdependence, we used the classical Landau theory. Found values of T_c and critical exponent β are 473 K and 0.5, respectively. The nonzero SHG signal in the region above T_c is because chiral structures can crystallize only in noncentrosymmetric space groups. According to Aizu notation [3], the paraelectric phase in ZnYb belongs the species of orthorhombic noncentrosymmetric group 222 among the 88 ferroelectric species. The 222 → 2 phase transition characterizes the ZnYb compound as a uniaxial ferroelectric system. This results is also in good agreement with the Folk's theory, where the value of the critical exponent $\beta = 0.5$ corresponds strongly to ferroelectric system with uniaxial dipole interaction [6].

The reported study was supported by the Russian Science Foundation (project No. 20-79-10233). E.D. M. acknowledges the support of the Ministry of Education and Science of the Russian Federation (state task No. FSFZ-0706-2020-0022).

Multiferroic Bismuth Ferrite Nanoparticles via Pulsed Laser Ablation Astita Dubey, Maisarah Ismadi, Friedrich Waag, Stephan Barcikowski and Doru C. Lupascu; University of Duisburg Essen, Germany

Single phase multiferroic Bismuth Ferrite (BFO) Nanoparticles (NPs) are potential materials for spintronic devices, photovoltaics, photocatalysis, and memory storage due to their advantageous ferro-electromagnetic properties at room temperature and narrow band gap. We outline the synthesis of BFO utilising pulsed laser ablation technique in liquid (PLAL). Thorough characterization of the ablated NPs including powder X-ray diffraction (XRD), high-resolution transmission electron microscopy (HRTEM), high-angle annular dark-field imaging (HAADF), scanning transmission electron microscopy (STEM), and magnetometry have been performed. Laser ablated NPs have spherical morphology and consist of two kinds of NPs: primary and secondary. The sizes of primary particles are around 5 nm and of secondary particles are around 20 nm. After post-thermal treatment at 500 °C for 5 minutes, the NPs

are in the size range of 18 ± 5 nm. These NPs exhibit single phase, rhombohedral (*R*3*c*) crystal symmetry and are highly crystalline. The HAADF and STEM images unveil a homogeneous elemental distribution and a single ferroelectric domain, respectively for the ablated BFO NPs. Laser ablated BFO NPs show an increase in magnetic moment as compared to sol-gel synthesized BFO NPs (~50 nm) which may be due to the large number of uncompensated spins at the surface in smaller NPs. The laser ablation technique can tailor the NP sizes at low cost. It is quite reproducible approach.

8:05 AM EQ10.06.03
Towards the Electrical Control of Skyrmionic Spin Textures Combined with $SrTiO_3$ Two-Dimensional Electron Gases Luis Moreno Vicente-Arche[1,2], Srijani Mallik[1], Karim Bouzehouane[1], Sergio Valencia[3], Nicolas Reyren[1], Agnès Barthelemy[1,2] and Manuel Bibes[1]; [1]CNRS/Thales, France; [2]Université Paris-Saclay, France; [3]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

$SrTiO_3$ (STO) two-dimensional electron gases (2DEGs) can be formed by depositing reactive metals such as Al onto STO single crystals: the metal oxidizes, forming oxygen vacancies in the STO and thus doping it in electrons[1]. Such 2DEGs can then be used to interconvert spin and charge currents with great efficiency[2]. In this presentation we will show that the metal oxide (e.g. AlOx) thus formed can be combined with ferromagnetic and heavy-metal-based ultrathin films to generate various types of magnetization configurations with in-plane or out-of-plane anisotropy, depending on their thicknesses. For specific compositions, these multilayers harbor magnetic bubbles, as imaged by magnetic force microscopy (MFM), X-ray photoemission electron microscopy (XPEEM), and NV-center microscopy, that likely have a skyrmionic character, due to the expected Dzyaloshinskii-Moriya interaction caused by the strong broken inversion symmetry. We will finally discuss how the Rashba spin-orbit coupling present in the 2DEG may be used to generate spin-orbit torques to manipulate spin textures.

Semiconducting Polymers for High Performance OFET and OECT Applications Iain McCulloch[1,2]; [1]University of Oxford, United Kingdom; [2]King Abdullah University of Science and Technology, Saudi Arabia

The evolution of organic electronics has now reached the commercial phase, with the recent market introduction of the first prototypes based on organic transistors and organic solar cell modules fabricated from solution. Understanding the impact of both the organic semiconductor design and processing conditions, on both molecular conformation and thin film microstructure has been demonstrated to be essential in achieving the required optical and electrical properties to enable these devices. Polymeric semiconductors offer an attractive combination in terms of appropriate solution rheology for printing processes, mechanical flexibility for rollable processing and applications, but their optical and electrical performance requires further improvement

in order to fulfil their potential. Synthesis of conjugated aromatic polymers typically involves carbon coupling polymerisations utilising transition metal catalysts and metal containing monomers. This polymerisation chemistry creates polymers where the aromatic repeat units are linked by single carbon-carbon bonds along the backbone. In order to reduce potential conformational, and subsequently energetic, disorder due to rotation around these single bonds, an aldol condensation reaction was explored, in which a bisisatin monomer reacts with a bisoxindole monomer to create an isoindigo repeat unit that is fully fused along the polymer backbone. This aldol polymerization requires neither metal containing monomers or transition-metal catalysts, opening up new synthetic possibilities for conjugated aromatic polymer design, particularly where both monomers are electron deficient. Polymers with very large electron affinities can be synthesised by this method, resulting in air stable electron transport, demonstrated in solution processed organic thin film transistors. We present an electrical, optical and morphology characterisation of polymer thin films, illustrating structure-property relationships for this new class of polymers. Additionally, we will discuss the role of non-covalent short contacts on polymer backbone planarity, the subsequent minimisation of energetic disorder, and its effect on charge carrier mobility.
Organic electrochemical transistors (OECTs) have been shown to be promising devices for amplification of electrical signals and selective sensing of ions and biologically important molecules in an aqueous environment, and thus have potential to be utilised in bioelectronic applications. The sensitivity, selectivity and intensity of the response of this device is determined by the organic semiconducting polymer employed as the active layer. This work presents the design of new organic semiconducting materials which demonstrate significant improvements in OECT performance, through operation in accumulation mode, with high transconductance and low operating voltage.

Nanostructured Large-Area Electronics for High-Frequency Applications Thomas D. Anthopoulos; King Abdullah University of Science and Technology, Saudi Arabia

The relentless downscaling of the silicon transistor has fuelled the continuous innovations witnessed in the semiconductor industry over the past fifty years. Unfortunately, adopting a similar approach to emerging forms of electronics is not straightforward both in terms of technology and economics. In this talk I will first discuss the main challenges that emerging technologies - such as printed large-area electronics (LAEs) - face in combing scalable manufacturing with the required performance. I will then present recent work from our laboratory on new materials and processing paradigms that enable the development of LAEs with numerous functionalities and performance characteristics superior to the current state-of-the-art. Emphasis will be placed on showcasing the key role of innovating additive manufacturing as an enabling agent for next generation LAEs.

11:30 AM *EQ11.01.03
Customizing the Polarity of Single-Walled Carbon Nanotube Field Effect Transistors Using Solution-Based Additives Maria Antonietta Loi; University of Groningen, Netherlands

The polarity control in Semiconducting Single-Walled Carbon Nanotubes field effect transistors (s-SWNT FETs) is important to promote their application in logic devices. The methods to turn the intrinsically ambipolar s-SWNT FETs into unipolar devices that have been proposed until now, require extra fabrication steps that make their preparation longer and more complex. Here, we demonstrate that by starting from a highly purified ink of semiconducting single-walled carbon nanotubes sorted by a conjugated polymer, and mixing them with additives we are able to achieve unipolar charge transport. The three additives used are benzyl viologen (BV), 4-(2,3-Dihydro-1,3-dimethyl-1H-benzimidazol-2-yl)-N,N-dimethylbenzenamine (N-DMBI), which give rise to n-type field effect transistors and 2,3,5,6-Tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F_4-TCNQ), which gives rise to p-type transistors. BV and N-DMBI transform the s-SWNTs transistors from ambipolar with mobility of the order of 0.7 cm^2/Vs to n-type with mobility up to 5 cm^2/Vs. F_4-TCNQ transform the ambipolar transistors in p-type with mobility up 16 cm^2/Vs.

An Organic N-Type Conductive Ink for Thermoelectrics and Logic Applications Chi-Yuan Yang[1], Marc-Antoine Stoeckel[1], Tero-Petri Ruoko[1], Han-Yan Wu[1], Xianjie Liu[1], Nagesh B. Kolhe[2], Ziang Wu[3], Yuttapoom Puttisong[1], Chiara Musumeci[1], Matteo Massetti[1], Hengda Sun[1], Kai Xu[1], Deyu Tu[1], Weimin M. Chen[1], Han Young Woo[3], Mats Fahlman[1], Samson A. Jenekhe[2], Magnus Berggren[1] and Simone Fabiano[1]; [1]Linköping University, Sweden; [2]University of Washington, United States; [3]Korea University, Korea (the Republic of)

Conducting polymers are opening new possibilities that are impacting several technologies such as organic thermoelectrics but also opto- and bioelectronics applications.[1] Among these polymers, PEDOT:PSS is the most successful one that can transport holes. With an electrical conductivity reaching thousands of S cm^{-1} and an exceptional ambient stability, this ionic/electronic conductor has been integrated in multiple applications spanning from conducting layer in organic solar cells or light-emitting diodes to active material in sensors and actuators, supercapacitors or thermoelectrics.[2] The versatility of the synthesis and processing of PEDOT:PSS is another reason of its success, being compatible with large scale deposition methods such as ink-jet printing or spray-coating, through an ink formulation that is water-based.
However, while PEDOT:PSS only transports holes (p-type), several opto- and bioelectronic applications include devices that require the integration of materials for transporting both charges; an n-type material able to transport electrons, combined with a p-type material that transport holes.
To fill this gap, several n-type polymers were developed, without entirely reaching the performances of their p-type counterpart PEDOT:PSS. Most of these n-type conducting polymers, when properly doped, demonstrates electron conductivity of tens of S cm^{-1}. However, their use at the industrial scale is extremely limited due to their processing involving halogenated solvents that are harmful for the environment. Moreover, they usually lack of ambient and thermal stability, and can be hardly overprocessed due to a poor solvent stability, resulting in mediocre performances. Various approaches are explored in order to enhance the electrical performances of this class of n-type materials, from design rationalizations and adjustments of the chemical structure to the careful choice of dopants. For instance, polymeric backbone planarization and increased rigidity is a strategy towards superior properties for high-performing n-type conducting polymers.[3,4]

Here we report on the use of the rigid ladder-type electron-conducting polymer poly(benzimidazobenzophenanthroline) (BBL) composing an n-type conductive ink for printed electronics.[5] The ink is alcohol-based and composed of nanoparticles of BBL produced from a solvent exchange process. This system is doped by the amine-based polymer poly(ethyleneimine) (PEI) and is processable by spray-coating in air. A thermal activation allows the BBL:PEI thin-film to demonstrate an electrical conductivity up to 8 S cm^{-1}, with an excellent thermal stability. Interestingly, this film is stable even when

washed with common organic solvents typically used for microfabrication. Finally, we employed this material as active layer in thermoelectric generators demonstrating a power output of 56 nW for a △T of 50 K per p-n pair, and as ion-electron conductor in an organic electrochemical transistor (OECT) working in n-type depletion-mode regime. This device, coupled with a PEDOT:PSS-based OECT, was used for ternary logic application.

1:45 PM EQ11.02.02
Molecular Design of Stretchable/Elastic Polymer Semiconductors with High Electrical Performance Yu Zheng and Zhenan Bao; Stanford University, United States

Polymer semiconductors have recently gathered considerable interests for their potential to produce stretchable electronics for wearable and implantable device applications. The key target yet major challenge is to maintain high electrical performance under mechanical deformation. However, polymer semiconductors are typically π-conjugated systems with semi-crystalline thin film morphology, most of which experience device failure under low strain. In order to address this discrepancy, we iteratively developed three molecular design approaches.

We started with an in-depth investigation of structure-property relationships for a family of diketopyrrolopyrrole (DPP)-based conjugated polymers bearing hydrogen-bonding conjugation breakers (CBs) with different hydrogen-bonding strength and linker flexibilities. We concluded that CBs with a hydrogen-bonding self-association constant >0.7 and/or a denser packing tendency are able to induce higher polymer chain aggregation and crystallinity in thin films, resulting in a higher crack-on-set strain and a lower degradation in mobility during stretching. Detailed morphological characterizations suggested that crystallites alignment and hydrogen-bonding breakage are the main strain energy dissipation mechanisms. Such understanding well correlated molecular-level dynamic interactions with thin-film morphology and mechanical properties of polymer semiconductors, although this approach compromised the electrical performance.

To obtain highly stretchable polymer semiconductor without sacrifice in mobility, we investigated the potential of a high-performance conjugated polymer idacenodithiophene-co-benzothiadiazole (IDTBT) with originally low crystallinity. The polymer chains in amorphous region get involved in dissipating strain energy through conformation change. With this mechanism, IDTBT was found to be highly ductile and maintain sufficiently stable mobility of ~0.6 $cm^2 V^{-1} s^{-1}$ at 100% strain without any crack formation. Despite its low crystallinity, the rigid and coplanar backbone configuration of IDTBT results in its efficient intrachain charge transport and thus high electrical performance. However, the plastic deformation of IDTBT leads to significant performance degradation after multiple stretching-releasing cycles due to wrinkle formation.

For realistic consumer electronics, robust elasticity is highly demanded. Therefore, we demonstrated a molecular design approach, covalently-embedded in-situ rubber matrix (iRUM) formation, which results in elastic semiconductors with high cyclic stability without comprising electrical performance. Additionally, iRUM approach can concurrently achieve solvent-resistance and photo-patternability, which are critical to realistic manufacturing. The rationally-designed good mixing of iRUM precursors with conjugated polymers significantly improves the crosslinking density of semiconductor films, serving as the key to achieve high elasticity. Besides, the charge transport is well maintained by leveraging reactivity difference between azide/C-H insertion and azide/C=C cycloaddition, leading to finely controlled competition between forming a rubber matrix and linking with conjugated polymer side chain. When applied in fully stretchable transistors, its mobility can be retained at 100% strain, and exhibits 0.93 $cm^2 V^{-1} s^{-1}$ record-high average mobility retention after 1000 stretching-releasing cycles at 50% strain. Unprecedented 5000 stable stretching-releasing cycles are achieved and such a cycle life is five times longer than any reported work. A fully patterned, elastic transistor array was fabricated via photo-patterning of iRUM-semiconductor, demonstrating its compatibility with solution-processed multilayer electronic device manufacturing. Our work represents a transition from soft/stretchable electronics to developing practical, long-cycling, and multifunctional electronics.

2:00 PM EQ11.02.03
Molecular Doping for High-Performance Organic Electronics Alberto Scaccabarozzi[1,2], Kalaivanan Loganathan[2], Thomas D. Anthopoulos[2] and Mario Caironi[1]; [1]Italian Institute of Technology, Italy; [2]King Abdullah University of Science and Technology, Saudi Arabia

The employment of organic semiconductors (OSCs) promises to widen the realm of electronics to countless new applications, thanks to the advantageous properties of soft matter. However, despite the plethora of fascinating opportunities, organic electronics has been progressing slower than expected due to difficulties in delivering high performance and reliability. In this framework, doping plays a fundamental role to overcome typical limitations. Indeed, even in the most successful organic-based technology -organic light-emitting diodes (OLEDs)- it was only when doped charge transport layers were introduced in standard device architectures, that the performance and the technological maturity required for industrialization of these devices were reached. Interestingly, in recent years there has been a progressive transition from the simple employment of dopants in highly conducting layers, to their use into other fundamental parts of the devices. Active layers in organic thin-film transistors (OTFTs), for instance, have been almost entirely relying, until very recently, on pristine (*i.e.*, non-doped) organic semiconductors. Extensive efforts in optimizing structure-property relationships in these layers led to a level of device optimization that pushed this approach to its limits. In this context, the addition of dopants enabled the demonstration of OTFTs with unprecedented performance owing to an improved charge transport and reduced contact resistance.[1–3] Similarly, molecular dopants have been successfully employed in bulk heterojunctions to fabricate solar cells[4] and photodetectors[5] displaying enhanced properties.
In this work we cover different materials systems and show how doping can lead to increased charge carrier mobilities owing to synergistic effects both in terms of electronic and structural properties. Indeed, the addition of low concentrations of molecular dopants to the channel of OTFTs can be accompanied by changes in their charge transport mechanism, with the onset of a band-like transport, besides the achievement of extremely high mobilities. Furthermore, we show how the microstructure of the OSCs can be controlled upon blending them with dopants aiding the transport. The improvements of our blend systems are not limited to transistors, but are also valid also for photodetectors, solar cells and diodes. The latter are in particular very promising, since high frequency rectifiers are a central component that determine the frequency of operation and the power conversion efficiency in wireless energy harvesting (WEH) systems. Here we present a novel strategy in which an adhesion lithography fabrication route, yielding to electrodes separated by nanogaps < 20 nm, is combined with doping to achieve co-planar nanogap Schottky diodes operating above 10 GHz.
Our results provide evidence that doping and innovative fabrication routes can pave the way towards future applications of GHz organic electronics.

Field Effect Transistors Based on Cumulenic sp-Carbon Atomic Wires—A New Paradigm for High Mobility Organic Semiconductors? Stefano Pecorario[1,2], Alberto Scaccabarozzi[1,3], Daniele Fazzi[4], Carlo S. Casari[2] and Mario Caironi[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Milano, Italy; [3]King Abdullah University of Science and Technology (KAUST), Saudi Arabia; [4]Universität zu Köln, Germany

The achievement of high charge carrier mobility in solution processable organic semiconductors is a fundamental requirement for the development of organic field effect transistors operating at high frequency, therefore enabling middle-range wireless communication for the next generation of flexible electronic devices.
For this reason, in the last decades extensive efforts have been devoted to the chemical design of conjugated polymers and molecular semiconductors, reaching effective field effect mobilities >10 $cm^2V^{-1}s^{-1}$, besides the employment of carbon nanostructures such as graphene and carbon nanotubes. Organic semiconductors consist in extended conjugated systems originating from overlapped π orbitals of adjacent sp2-hybridised carbon atoms. Herein, we report for the first time on the potential of sp-Carbon Atomic Wires as a new class of solution processable semiconductors for organic electronics. Carbon Atomic Wires are linear chains of sp-hybridized carbon atoms and represent the ultimate one-dimensional allotropic form of carbon. [1] They exhibit two possible isomeric configurations: cumulenes (sequence of double bonds) and polyynes (sequence of single and triple alternated bonds). Theoretical studies have predicted outstanding mechanical, optical and electronical properties for these structures. However, only a few experimental studies have investigated their electronic properties in solid-state devices and, so far, they have focused mainly on molecular junctions or monolayers. [2]
In this work we demonstrate the first example of organic field-effect-transistor (OFET) based on short cumulenic molecules, namely tetraphenylbutatriene [3]Ph. [3] Furthermore, we discuss on our latest achievements in understanding and optimizing charge-transport properties in solution processed thin films of [3]Ph. In particular, we show how the control of large-area thin-films deposited via wire-bar coating, a scalable printing technique, allows achievement of field-effect-mobilities above 0.1 $cm^2V^{-1}s^{-1}$. Moreover, our [3]Ph-based transistors provide excellent operational stability in dark conditions, therefore addressing one of the major concerns for the application of Carbon Atomic Wires, and in general of organic semiconductors, in ambient conditions.
An in-depth characterisation of films obtained with different processing parameters allows to correlate microstructural and morphological features with the OFETs electrical performance. Our analysis highlights how these devices, based on the shortest of the cumulenes series, symbolize a promising starting point towards the exploration of sp-Carbon Atomic Wires with superior charge carrier mobility.
These results pave the way for the use of cumulenes as active material for organic electronics and open new possibilities for the chemical design of performant organic semiconductors based on sp-hybridised molecules.

Printing High-Performance 2D Oxide Transistors from Liquid Metals William J. Scheideler, Andrew B. Hamlin, Youxiong Ye, Julia Huddy and Md Saifur Rahman; Dartmouth College, United States

High-frequency flexible electronics demands high mobility channel materials suitable for low-temperature deposition. We present high-performance 2D In_2O_3 transistors printed from liquid Indium metal at temperatures compatible with low-cost polymer substrates. These ultrathin (2-4 nm) In_2O_3 channel materials demonstrate performance unseen in low-temperature sol-gel or nanoparticle systems, with low-field mobility greater than 40 cm^2/Vs at 175 °C and 65 cm^2/Vs at 250 °C processing compatible with PEN and Polyimide, respectively. We show through comparative XPS and XRD studies that a principal advantage of liquid-metal (LM) printed oxides relative to sol-gels is the ability to achieve crystalline and highly conducting films *as deposited*, avoiding hydroxide-dominated intermediate phases and eliminating the thermodynamic barrier posed by precursor decomposition.

Low-temperature Hall measurements reveal that, *as deposited*, these quantum-confined In_2O_3 channels exhibit Hall mobility of 12-20 cm^2/Vs and electron concentrations of ~ $1*10^{19}$ cm^{-3}. Post-annealing in air further enhances electronic transport, allowing enhancement mode operation and tight control of the electronic density of states (eDOS) for monolayer and bilayer films, revealing the extremely steep band tail slope and lower deep state density of bilayer channels. Additionally, these devices exhibit ultra-low hysteresis and excellent current saturation, indicating the low defect density and stable back channel. This exceptional switching performance and the scalable simplicity of the LM printing method make these 2D oxide transistors promising devices for driving next-generation flexible electronic sensor and displays.

SESSION EQ11.03: Flexible Electronics—Fabrication
Session Chairs: Mario Caironi and Matteo Cucchi

1:45 PM *EQ11.03.01
Flexible Nanoscale Organic Transistors Hagen Klauk and Ute Zschieschang; Max Planck Institute for Solid State Research, Germany

Organic thin-film transistors (TFTs) can often be fabricated at temperatures around or below 100 degrees Celsius and thus on a wide range of unconventional substrates, including a variety of mechanically flexible and optically transparent polymers, such as polyethylene naphthalate (PEN). This makes organic TFTs a potential alternative to TFTs based on inorganic semiconductors, most notably low-temperature polycrystalline silicon (LTPS) and

indium gallium zinc oxide (IGZO), which typically require somewhat higher process temperatures that limit the choice of mechanically flexible substrate materials to ultrathin glass (which is prone to shattering) and polyimide (which has lower optical transmission compared with glass and PEN). For circuit and display applications, an important TFT parameter is the transit frequency, which is the highest frequency at which transistors are able to switch or amplify electrical signals. A field-effect transistor's transit frequency depends critically on the channel length and the parasitic gate-to-source and gate-to-drain overlaps. Most of the highest transit frequencies reported for organic TFTs to date have been achieved with channel lengths and gate-to-contact overlaps of around 1 µm. To explore the static and dynamic performance of flexible organic TFTs with nanoscale dimensions, we have used electron-beam lithography and fabricated low-voltage organic TFTs with channel lengths and gate-to-contact overlaps as small as 100 nm on flexible PEN substrates. These TFTs display useful static and dynamic characteristics, including on/off current ratios of nine orders of magnitude, subthreshold swings below 100 mV/decade, turn-on voltages of 0 V, negligibly small threshold-voltage roll-off, contact resistances below 1 kOhm-cm, and switching delays below 50 ns.

2:15 PM EQ11.03.03
Understanding the Effect of Processing on Structure Evolution and Dielectric Properties of Polymer Films Zeynep Mutlu, Mayank Jain, Venkat Kasi, Rahim Rahimi, Jiahao Mao and Mukerrem Cakmak; Purdue University, United States

Polymers have been used as flexible and easily processible dielectric materials for many years. Dielectric constant, dielectric loss and breakdown strength are critical for the successful application of a polymer dielectric. Numerous studies have been carried out to enhance the breakdown strength of polymers that have a reasonable dielectric constant. Taking advantage of their tailorability, this has been mainly achieved through the processing route where polymers are stretched to increase the orientation and superstructural organization, and hence the breakdown properties. This tends to lead to structural hierarchy forming tortuous path through thickness direction by the overlap of oriented crystalline and amorphous domains. However, it is challenging to understand the polymer responses under deformation. In this study we have investigated the effect of orientation on structural hierarchy (crystallinity, crystalline and amorphous chain orientation, superstructural organization) on the dielectric properties of Nylon 12. In addition to suppress the charge injection through the surfaces, SiO_2 coating was applied by using plasma enhanced chemical deposition.

2:30 PM EQ11.03.04
Modeling Rigidity in Conjugated Polymers Andrew T. Kleinschmidt, Tod Pascal and Darren J. Lipomi; University of California, San Diego, United States

Conjugated polymers are being asked to undergo more "polymer-like" behavior than ever before-- being strained, scratched, punctured, repeatedly elongated, and more. Computational modeling at the molecular dynamics level could speed up design of conjugated polymers considerably. However, these models must be able to consider "polymer-like" behavior as well. Accurate reflection of polymer nanostructure in molecular dynamics is key to determination of the polymer's mechanical properties. We find that the current state of modeling often neglects polymer rigidity. Forces meant to represent planarizing forces are often reduced or even eliminated by steric hindrance. We have thus developed a model that seperates out steric forces from forces associated with electron delocalization and internal conjugation. We additionally find that there are two key types of torsion present even in a neat polymer film-- improper and dihedral. Both of these forces must be dealt with simultaneously to achieve accuracy. Finally, we compare homopolymers to donor-acceptor polymers and find the difference in rigidity is less than might be expected.

2:45 PM EQ11.03.05
Nanosoldering of Sensing Components on Conductive Textile Fibers Edward Fratto, Zhiyong Gu, Ramaswamy Nagarajan and Xuejun Lu; University of Massachusetts Lowell, United States

Ongoing research into the miniaturization and optimization of electronic device manufacture has driven component study to the nanoscale, sparking interest in device design on nontraditional substrates for highly specific, targeted applications. The emerging field of smart 'e-textiles' examines the translation of traditional device manufacturing strategies onto flexible textile substrates, driven by commercial and fundamental interest in textile-nanomaterial integration and conductive network wiring within woven architectures to imbue useful functionality to worn garments. In the interest of adapting thermally driven electronic interconnection strategies to temperature-sensitive materials, we provide an investigation into the modification of textile surfaces with nanosolder-inks, establishing conductive channels for signal communication and joining resistive sensing elements through soldered interconnection. Low melting temperature tin/indium nanosolder particles were synthesized via aqueous chemical reduction and formulated into conductive ethylene-glycol based inks at various loading concentrations. These nanoinks were applied to individual threads of various fabric blends by dip-dry coating, with degree of coverage evaluated in relation to number of coats and associated thermal/electrical processing to improve adhesion. Printed threads were exposed to infrared heating, allowing for targeted melting of solder particles without harming the woven fiber structure, confirmed visually and via monitoring change in electrical resistance. After melting, threads modified by nanoinks with incorporated graphene oxide platelets demonstrated sensing capability for temperature, humidity, liquid phase salinity, and chemical vapors. Signal generated by these sensing fibers was transmitted via thread-to-thread soldered interconnection, establishing the conductive wiring groundwork for a textile device platform. This realization of non-destructive robust solder joining on thermally delicate textile substrates represents a significant step towards full translation of electronic device manufacturing strategies onto a woven garment.

3:00 PM BREAK

4:00 PM EQ11.03.07
Long-Wavelength Instability-Coupled Alignment in a Semiconductor-Elastomer Blend for Stretchable Electronics Peter Dudenas[1], Eliot Gann[1], Guillaume Freychet[2], Lee Richter[1] and Dean DeLongchamp[1]; [1]National Institute of Standards and Technology, United States; [2]Brookhaven National Laboratory, United States

Flexible electronics are poised to significantly change device technologies, with applications across biological/medicinal, environmental, consumer, and industrial markets. Devices that are thin, conformable, and compliant open myriad design opportunities that are currently infeasible with today's rigid electronics. Some of the most promising material systems with these characteristics are semiconducting-polymer/elastomer (SPE) blends. The semiconducting polymer phase segregates into nanofibrils upon spin or blade coating and under certain conditions these fibrils can be aligned for directional charge transport. SPE blends have been shown to maintain excellent electronic properties under large strain, and have the advantage of being solution processable, enabling economical manufacturing scale-up.

In addition to the economic advantage solution-based processing confers, it also provides a large parameter space to optimize device fabrication. Solvent identity, polymer concentration, coating temperature, and coating speed are a few notable parameters available to tune. This allows for flexibility in the formulation process, but also creates a parameter space that can be difficult to optimize, and the optimum is often different with different coating methods. Of the many coating methods, meniscus-guided techniques are becoming more ubiquitous because of their ability to create aligned materials and are more directly translatable from lab to industrial scale manufacturing.

Here, we report on a long-wavelength instability in the blade coating process that leads to significant variation in the local semiconducting polymer fibril alignment for a DPP-TT:SEBS blend. Near-edge x-ray absorption fine structure (NEXAFS) is used to quantify the molecular alignment of DPP-TT in the fibrils and the surface composition of the films. The optical dichroic ratio from wide-field polarization imaging is directly correlated to fibril alignment as quantified by AFM, which provides a spatially resolved measurement of DPP-TT nanofibril alignment. These measurements are correlated to thin-film transistor data to characterize the impact on charge transport. Quantifying and potentially controlling coating instabilities are important for device optimization, especially in the scale-up process.

4:15 PM *EQ11.03.08
Doping Organic Semiconductors by Lewis Acids—A "Complex" Story Thuc-Quyen Nguyen; University of California, Santa Barbara, United States

The ability to precisely control the equilibrium carrier concentration in organic semiconducting devices is of great interest. Solution processed doped layers are of extreme importance for high throughput production of organic electronic devices via roll-to-roll or ink-jet printing. In this talk, I will discuss tuning the conductivity of conjugated polymers containing Lewis basic sites by Lewis acids. Addition of the Lewis acid effectively p-dopes the hole transport in the parent polymer, leading to increases in the free hole density and conductivity. This methodology is advantageous since the polymer and Lewis acid have excellent solubility in organic solvents, negating the need for co-solvents that uses in molecular dopant such as F4TCNQ. We use a combination of techniques including electrical measurements, optical absorption, XPS, UPS, IPES, and electron paramagnetic resonance (EPR), electron-nuclear double resonance (ENDOR) and nuclear magnetic resonance (NMR) techniques in conjunction with density functional theory, to gain insight into the doping mechanism of 4,4-dihexadecyl-4H-cyclopenta[1,2-b:5,4-b′]dithiophene (CPDT) and 2,1,3-benzothiadiazole (BT)-based (PCPDTBT) by Lewis acids, BCF. We suggeste protonation of the CPDT moieties by the strong Brønsted acid BCF(H2O), followed by electron transfer from a neutral polymer chain segment to a protonated chain forming a neutral, protonated radical species and a positively charged radical species (a positive polaron or a hole). Neher et al Neher and colleagues investigated doping of poly(3-hexylthiophene) (P3HT) by BCF and suggested that the overall reaction resulted in formation of H2, rather than a radical species, as the final hydrogen-containing side product, with one possible route for H2 formation being reaction of two radical species. DFT calculations predict that the protonation reaction and H2 formation are highly endergonic. However, if we consider the formation of a larger anion, $[BCF(OH)(OH_2)BCF]^-$, in which $[BCF(OH)]^-$ is hydrogen bonded to another $BCF(OH_2)$ complex, the protonation reaction and H2 formation are exergonic.

SESSION EQ11.04: Designing UHF Printed Transistors

10:30 AM EQ11.04.01
Quasi-Self-Aligned Organic Thin-Film Transistors in Coplanar Top-Gate Configuration Jörn Vahland, Karl Leo and Hans Kleemann; TU Dresden - Institut für angwandte Physik, Germany

Besides charge carrier mobility and contact resistance, the parasitic overlap capacitance is a key factor limiting the dynamic behavior of organic thin-film transistors. The most effective away to reduce parasitic overlap capacitances between source/drain and gate electrode is to employ self-aligned transistor architectures. However, so far self-alignment in organic transistors has only been achieved using non-scalable or complex fabrication processes. Here, we demonstrate quasi-self-aligned OTFTs in a coplanar top-gate architecture fabricated with reliable and scalable state-of-the-art fabrication techniques such as wet-chemical etching. Self-alignment is achieved by carrying out a wet-chemical
etching process on top of the channel interface. We prove that for the right choice
of etchant, the charge carrier transport properties of the channel interface are not deteriorated. The benefit of the self-aligned design lies in the reduction of the specific overlap capacitances which are two orders of magnitude (0.13 nF cm^{-2}) lower than for non-self-aligned devices (15 nF cm^{-2}). Furthermore, we highlight the potential of this approach for high-frequency operation of organic transistors and quantify the gain in cut-off frequency compared to non-self-aligned devices.

10:45 AM EQ11.04.02
Organic Mixed Ion-Electron Conductors in Microwave Metadevices Giorgio Ernesto Bonacchini[1,2], Siew Ting Melissa Tan[1], Alexander Giovannitti[1], Tyler J. Quill[1] and Alberto Salleo[1]; [1]Stanford University, United States; [2]Istituto Italiano di Tecnologia, Italy

The field of magnetic metamaterials has spurred increasing interest since the first experimental demonstrations of a negative refractive index metamaterial[1]. The appeal of these photonic devices lies in the possibility to engineer media with tailored electromagnetic response, imparting them with unconventional wave propagation properties that cannot be achieved by 'natural' materials[2]. Examples of metamaterials-enabled applications include artificial magnetism, arbitrary wave-front shaping, and cloaking. To overcome the practical limitations of static metamaterials, recent efforts have focused on the integration of passive microwave metamaterials with a number of active tuning mechanisms. These dynamic metadevices grant unprecedented control over the propagation of microwaves, enabling for example real-time modulation of light intensity and phase, as well as tunable spectral selectivity[3].
A plethora of tuning strategies has been so far proposed for the realization of active metadevices. Among electrical strategies, established approaches such as the addition of lumped elements (e.g. varactor and pin diodes) to microwave resonators, or the use of materials such as graphene and III-V compound semiconductors, come with high fabrication complexity and cost compared to printed organic electronics[4]. Furthermore, these approaches cannot be easily translated into platforms where large-area formats and mechanical conformability are of essence.
A new device configuration has recently been proposed, where organic electrochemical transistors – based on the conductive polymer PEDOT:PSS – actively tune a set of sub-5GHz microwave metasurfaces and metamaterial-inspired structures[5]. These devices consist in individual (or multiple) microwave Split-Ring Resonators in which the split region is bridged by a transistor, gated through common electrolytes. This device configuration enables a fully reversible modulation mechanism, which requires very low voltages (<1 V) thanks to the mixed ion-electron transporting ability of PEDOT:PSS[6]. This tuning strategy can be readily implemented on different resonant configurations, including magnetic and electric resonators, frequency-tuneable SRRs, dual-band devices, and in a reconfigurable metasurface.
The promising results achieved with PEDOT:PSS encourage a wider exploration of the continuously growing library of organic semiconductors. In this work, we demonstrate a set of tunable microwave devices using different p-type and n-type organic electrochemical transistors. By chemically engineering the organic semiconductors, we are able to operate our devices in selected voltage ranges, with fine control over the voltage dependence of the metadevices' scattering properties. As an example of a possible application, we exploit this strategy within a wireless biosensing platform operating in the

2-2.5 GHz range.
In perspective, a metadevice tuning strategy based on organic electronic materials presents exciting opportunities for microwave technologies, possibly paving the way to a new generation of wireless interfaces for distributed sensing, fabricated on large-area flexible substrates via high-throughput techniques. Moreover, this class of metadevices could potentially complement other emerging neuromorphic technologies that are also based on organic electrochemical transistors, expanding the horizon of metamaterials research.

Self-Aligned Amorphous Indium-Gallium-Zinc-Oxide TFTs Breaking the GHz Threshold Christian Tückmantel, Utpal Kalita, Tobias Haeger, Manuel Theisen, Ullrich Pfeiffer and Thomas Riedl; University of Wuppertal, Germany

Thin-film transistors (TFTs) based on amorphous metal-oxide semiconductors have received enormous attention. While this technology has set new standards as backplane for flat-panel displays, there is a wide range of applications that only becomes accessible, if metal-oxide are capable of high-frequency operation. To this end, the transit frequency (f_T) and maximum oscillation frequency (f_{max}) become important figures of merit, which have not received adequate attention in metal-oxide based electronics, yet. These numbers are critically limited by parasitic elements in the device (such as capacitances). Compared to devices based on single crystalline silicon (c-Si) technology, the f_T of most metal-oxide TFTs in the literature is typically low. In fact, the best f_T of metal-oxide TFTs based on large area compatible and cost-effective standard lithography did not reach the GHz regime, as of yet. Here, we demonstrate the first a-IGZO based TFTs with a transit frequency $f_T > 1$ GHz. This is achieved by a rigorous reduction of parasitic elements (L_{ov} = 300 nm, $C_{GS} + C_{GD}$ = 800 fF/mm) and a channel length L as low as 0.8 µm, resulting from a substantially optimized self-alignment concept without sacrificing the typical advantages of optical lithography. At the same time, our TFTs set a new record in f_{max} of 3.1 GHz, which states a new high-frequency limit for power amplification in metal-oxide electronics.
We expect that our results will inspire metal-oxide based high-frequency circuit applications, such as communications systems, on large-area and even flexible substrates. As such, metal-oxide TFTs ultimately may become a meaningful platform for the realization of concepts discussed in the framework of the IoT.

Conformable, Internal Ion-Gated Organic Electrochemical Transistor (IGT)–Based Multiplexer with Megahertz Operation Claudia Cea, Zifang Zhao and Dion Khodagholy; Columbia University, United States

Organic transistor architectures that are able to interact with ions such as electrolyte-gated field effect transistors or electrochemical transistors are highly attractive devices for acquisition, transmission and processing of physiological signals. These devices are able to convert ions to electrons effectively and provide mechanical flexibility owing to their inherently soft channel materials. However, the temporal response of these devices, which directly translates into their operation speed, is defined by ion drift and mobility. As a result, they are limited to a few KHz speed regime. In addition, the lack of physically independent gate limits their ability to form integrated-circuits (ICs). Here we use internal ion-gated organic electrochemical transistors (IGTs) that are able to operate beyond the speeds dictated by ion mobility by creating local ion reservoirs inside the channel bulk. We demonstrate IGT-based amplifiers with uniform gain across their MHz range operation frequency. We characterize the electrical performance of these transistors with respect to various transistor sizes, contact area, and channel material composition, and determined the relationship between device geometry and gain, off current, leakage, and inter-transistor cross talk. Using these data and a high resolution vertical fabrication approach (capable of creating <1 µm transistors), we then created high-density IGT-based conformable circuits that performed time-division multiplexing at speeds comparable to silicon based ICs for physiological signal acquisition and multiplexing. The unique features of IGT-based devices facilitate potential applicability to a broad range of flexible circuits that require safe, chronic implantation in humans, including brain-machine interfaces, wearable electronics, and therapeutic responsive stimulation devices.

Tissue Equivalent, Conformal Medical Radiation Dosimeters Based on Organic Transistors Oana D. Jurchescu; Wake Forest University, United States

Radiation therapy is one of the most effective medical procedures for cancer treatment: high-energy ionizing radiation is very effective in destroying cancer cells, but the risks of malignancies induced by peripheral radiation in healthy tissues surrounding the target volumes represents a serious concern for all patients and doctors alike. Positioning of the patient, inhomogeneities in the target (muscles/bones/adipose tissue), and even minor movements (e.g. breathing), can alter the received dose and targeted volume, and thus affect the outcome of the procedure. Therefore, being able to measure radiation doses with high accuracy is a critical aspect of diagnostics and treatment. In this presentation I will introduce a new type of radiation dosimeter, the RAD-OFET (**RA**diation **D**etector based on **O**rganic **F**ield-**E**ffect **T**ransistor), which can validate in real time the dose being delivered and ensure that for nearby regions an acceptable level of low dose is being received.[1] The RAD-OFETs exploit trap generation/annihilation in organic semiconductors,[2] are sensitive to doses relevant to many radiation treatment procedures and are robust when incorporated into conformal large-area electronic applications. Placement of the sensor directly onto the human body, coupled with the similarity in the Z-number between the electronically active layer and the human tissue, allows for direct measurement of the radiation dose, eliminating the need for extensive data processing faced by current technologies. The direct consequence is a greater precision and lower complexity in the medical equipment: their adoption in clinical settings will facilitate the application of therapeutic radiation with high precision, a process that will increase the effectiveness on treating cancerous tissue and minimize the impact on the surrounding healthy cells. These results uncover new opportunities for organic circuits that will improve the quality of healthcare through better, lower cost *in vivo* dose monitoring during radiation therapy.

Imperceptible Energy Harvesting Device and Biomedical Sensor Based on Ultraflexible Ferroelectric Transducers and Ultraflexible High Frequency Organic Diodes Barbara Stadlober[1], Andreas Petritz[1,2], Esther Karner-Petritz[1,2], Philipp Schäffner[1], Takafumi Uemura[2,3], Teppei Araki[2,3] and Tsuyoshi Sekitani[2,3]; [1]Joanneum Research Forschungsgesellschaft mbH, Austria; [2]Osaka University, Japan; [3]AIST Advanced Photo-Bio Lab, Japan

Energy autonomy and conformability are essential elements in the next generation of wearable and flexible electronics for healthcare, robotics and cyber-physical systems. This study presents ferroelectric polymer transducers and organic diodes for imperceptible sensing and energy harvesting systems, which are integrated on ultrathin (1-µm) substrates, thus imparting them with excellent flexibility [1]. It was found that these ultraflexible ferroelectric polymer transducers (UFPTs) develop improved ferroelectric properties through thermal annealing resulting in an increased crystallinity. After poling the remnant polarization reaches values up to 70 mC/m2 in close correlation with the crystallinity and the decrease of the dielectric constant. Simulations show that the sensitivity of ultraflexible ferroelectric polymer transducers can be strongly enhanced by the use of the ultrathin substrate. The ultrathin substrate furthermore allows the mounting of the transducers on 3D-shaped objects and the stacking in multiple layers. Indeed, UFPTs have improved sensitivity to strain and pressure as compared to devices on rigid thick substrates with values up to 15 nC/N; they have a fast response (<< 20 ms/N) and an excellent mechanical stability with a bending radius down to 40µm. Accordingly, they can be used as imperceptible wireless e-health patches for precise pulse and blood pressure monitoring.
For harvesting biomechanical energy, the transducers are combined with full wave organic rectifier circuits made of ultraflexible organic diodes. These diodes are based on organic thin film transistors with short-circuited drain and gate and are fabricated on the ultrathin substrate as well. The diodes have an excellent on/off ratio up 10^7 and a transition voltage around 0V. Moreover they are exceptional in terms of operation frequency in the MHz regime. Transducers, diodes and ultrathin capacitors (needed as storage elements) were further combined to form an imperceptible, 2.5 µm thin, energy harvesting device with an excellent peak power density of 3 $mW \times cm^{-3}$. When placed on body joints like elbow or knee we estimate that over a day 100 -200 mJ can be generated by biomechanical motions like knee bending with such a system. This should be enough for vital parameter reading several times per day.

Data Storage and Information Processing from Roll-to-Roll Printed Conjugated Polymeric Electrochemical Memristors Benjamin T. Grant, Iurii Bandera and Stephen H. Foulger; Clemson University, United States

Conjugated polymeric electrochemical memristors (cPECMs) are a promising alternative towards next-gen bioinspired circuitry, such as memristive neuromorphic computers. Low gate switching voltages and low power consumption are easily achieved due to the wide range of redox potentials available. In the case of the p-type poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS), the conjugated PEDOT allows mobile holes to hop from one chain to another where, in the neutral form, holes are compensated by PSS anions. Major limitations of PEDOT:PSS devices are due to the inherent nature of the material to oxidize, which can impede the state retention and cycle stability of a device. In this effort, a water soluble, partially reduced self-doped PEDOT (S-PEDOT) that is synthesized and fabricated into an all-solid-state memristive device. This three-terminal device with a pre- and post-synaptic terminal is able to tune the device's conductance via electrochemical doping by means of voltage pulsing to the gate with a low power consumption for switching events (ca. 42 pJ/mm^2 for a 12 x 20 mm active area). S-PEDOT cPECMs are implemented to perform arithmetic and simple mathematics, execute information processing such as Boolean logic gates, display electrochromic behaviors, and can emulate essential artificial synaptic plasticities for learning and memory behaviors.

2:45 PM EQ11.05.04
Responsive Manipulation of Neural Circuit Pathology by Fully Implantable, Front-End Multiplexed Embedded Neuroelectronics Zifang Zhao[1], Claudia Cea[1], Jennifer Gelinas[2,2] and Dion Khodagholy[1]; [1]Columbia University, United States; [2]Columbia University Medical Center, United States

Implantable bioelectronics are poised to unravel causal relationships between neural activity and brain function due to their ability to directly interact with neurons over extended periods of time. To facilitate advancements in both these basic science and translational research avenues, responsive implantable electronics are required to perform high performance data acquisition, stimulation and low-latency digital signal processing to enable real-time manipulation of neural networks and affect behavior. We introduce a multiplex-then-amplify (MTA) scheme that in contrast to current approaches (which necessitate an equal number of amplifiers as number of channels), only requires one amplifier per multiplexer, significantly reducing the number of components and size of electronics in multi-channel acquisition systems. It also enables simultaneous stimulation of arbitrary waveforms on multiple independent channels. We validated the function of MTA by developing a fully implantable, responsive embedded system that merges ability to acquire individual neural action potentials using conformable conducting polymer-based electrodes with real-time onboard processing, low-latency arbitrary waveform stimulation, and local data storage within a miniaturized physical footprint. We demonstrate all of these features in chronically implanted freely behaving rats, verifying high quality neurophysiological signal acquisition from the hippocampal-prefrontal cortex network over weeks. We implement an automated kindling procedure to generate epileptic neural networks as well as previously established responsive neurostimulation protocols known to affect memory.
The MTA design enables effective, self-contained, chronic neural network manipulation with translational relevance to treatment of neuropsychiatric disease.

3:00 PM EQ11.05.05
Late News: High-Frequency Rectifiers Based on Highly Flexible, Fully Printed Organic Diodes Fabrizio A. Viola and Mario Caironi; Italian Institute of Technology, Italy

The diffusion of portable and wearable technologies results in a growing interest in electronic devices having features such as flexibility, lightness-in-weight and wireless operation. Organic electronics was proposed decades ago as a potential candidate to fulfill such need, in particular targeting pervasive Radio-Frequency (RF) applications. Still, limitations in terms of device performances at RF, particularly severe when large-area and scalable fabrication techniques are employed. In this work we demonstrated that rectification of an electromagnetic wave at 13.56 MHz thanks to a fully inkjet printed polymer diode is possible. The rectifier, a key enabling component of future pervasive wireless systems, is fabricated through scalable large-area methods on plastic. Thanks to fine tuning of the barriers at the semiconductor-metal interfaces, the diode has a rectification ratio higher than 10^6: at the best of our knowledge this is the first time that a fully inkjet printed diode wit
h these performances has been obtained. When integrated in an organic rectifier, the excellent dynamic properties of the diode allow to rectify sinusoidal

signals above 20 MHz, well covering the near-field communication range. As demonstrated in this work, our fully printed polymer diode opens the possibility to couple power to a plastic foil, or in future other non-rigid substrates such as paper, by rectifying a 13.56 MHz AC electromagnetic wave, as requested in near-field RFID applications.

3:15 PM EQ11.05.06
Late News: ZnO TFTs for Giga-Hertz Wireless Systems Without Sub-Micron Lithography—Maximizing fT, fMAX, and |ZOFF/ZON| Yue Ma, Can Wu, Yoni Mehlman, Sigurd Wagner, Naveen Verma and James C. Sturm; Princeton University, United States

We describe the key structure and material approaches towards recently demonstrated giga-Hertz large-area electronics (LAE) wireless systems using zinc-oxide (ZnO) thin-film transistors (TFTs) [1-4], and the resulting performance parameters. Today's LAE, such as flat-panel displays, operate at frequencies up to ~100 MHz. The next target is wireless applications [Internet of Things (IoT), 5/6G], where bringing LAE to the giga-Hertz regime opens new capabilities, enabling meter-scale radiative apertures for enhanced spatial resolution and power efficiency.
The two central performance goals that guide TFT design, fabrication, and in-circuit use, are: (1) for active device operation, achieving gain at high frequency, especially recognizing the potential for power gain (bound by f_{MAX}) rather than current gain (bound by f_T), and exploiting f_{MAX}-limited circuit operation to generate power at giga-Hertz frequencies; (2) for passive switch operation, achieving high off-to-on impedance ratio to reconfigure antenna elements. In terms of physical electronics, these goals are met in the following ways:
- f_T, the frequency up to which the TFT provides current gain, is determined by the electron transit time t between source and drain, and electron shunting by parasitic capacitances. t depends on electron mobility, channel length, and source/drain (S/D) contact resistance; while the shunting capacitances depend on the gate-source/drain (G-S/D) overlap regions. These are the knobs to turn for high f_T: the electron mobility is primarily set by the choice of semiconductor; minimal S/D contact resistance is achieved by selective etching; and channel length and G-S/D overlaps are minimized by self-aligning S/D to gate electrode. The f_T thus achieved is 0.4 GHz, for a typical ZnO TFT with channel length of 1um, biased at $V_{GS}=V_{DS}=6$ V with $V_T=2$ V.
- f_{MAX}, the frequency up to which the TFT provides power gain, depends on f_T, but can be made larger than f_T by reducing the sources of loss within the TFT. In practice, a factor that limits f_{MAX} is the power loss due to the gate resistance. This loss can be reduced by using a thick and highly conductive gate metal stack and multi-finger layout (putting fingers in parallel to reduce resistance along gate width). The f_{MAX} thus achieved is 2.0 GHz for the typical ZnO TFT and biasing.
- $|Z_{OFF}/Z_{ON}|$, the off-to-on impedance ratio of a TFT switch, depends on the conductance around an off channel, through G-S/D parasitic capacitances (which sets $|Z_{OFF}|$), as well as the t through the ZnO channel (which sets $|Z_{ON}|$). Conduction through the parasitic capacitances can be minimized via: (1) small G-S/D overlaps; and (2) the use of resonant inductors, which can be formed with high quality factor thanks to the sq. mm dimensions and low-loss substrates available in LAE. One important approach to reducing $|Z_{ON}|$ is to operate at high V_{GS} but low V_{DS}. This ensures high channel conductance while reducing TFT power dissipation to avoid thermal-induced breakdown [3]. The $|Z_{OFF}/Z_{ON}|$ thus achieved is ~48 at 2.4 GHz, with the half-bandwidth of ~350 MHz.
Based on these advanced ZnO TFTs, we demonstrated a cross-coupled LC oscillator operating at 1.25 GHz [1] and an LAE-based phased array system operating at 1 GHz with beamforming capability [2]. In a reconfigurable antenna with tunable directionality and operating frequency, ZnO TFT switches operate in the 2.4 GHz frequency band [3]. These giga-Hertz system performance results suggest that LAE is a promising candidate for wireless applications in IoT and 5/6G.

3:30 PM BREAK

4:00 PM EQ11.05.07
Late News: Designing with Process Variability—Optimizing 5G (X-band) RF Antennas and Waveguides for Intrinsic Variability Katherine Berry[1], Eric Brown[1], Samuel Fedorka[1], Alkim Akyurtlu[1], Craig Armiento[1], Gary Walsh[2] and Corey Shemelya[1]; [1]University of Massachusetts Lowell, United States; [2]U.S. Department of the Army, United States

As advanced manufacturing techniques evolve, the mass production of lightweight, flexible electronics requires one to evaluate the levels of production variability that can be expected both in geometric dimensions and in the overall print fidelity of a direct-write (DW) printed design. These variations, introduced by inconsistent material effects in both the printing and curing stages of manufacture, generate behavior different from traditional rigid copper-milled designs. Even the smallest of these divergences in a critical dimension can significantly alter the high frequency response of the printed RF design. As such, this project evaluates the feature fidelity of micro-dispensed RF antennas and waveguides at 5G frequencies (X-band) on flexible 0.127mm-thick ITera MT40 dielectric substrate with silver nano-inks to determine repeatability, critical dimensions, and acceptable geometric tolerances in 8 GHz patch antennas and microstrip waveguides. All printed designs were characterized for surface roughness, print thickness, and feature fidelity. Two measures of geometric accuracy were also used across multiple critical features: variation in average feature size from design dimensions, and standard deviation of a feature's size from its average within a single print. The critical feature dimensions were determined to be waveguide width and impedance matching "inlets." S-Parameters were used as a measurement of RF performance, with the experimental range of each of the five measured features plotted separately against the respective antennas' responses to illuminate any outstanding trends between single feature variation and performance. These results were compared to simulation sets in order to determine whether trends were due to the feature alone, or to combinations of interdependent geometric variations. Based on these assessments, acceptable "as-printed" ranges of feature dimensions were developed to produce consistent, acceptable RF performance.
It was found that surface roughness and print thickness have no significant effect on performance, and that the level of variation in the microstrip width does not degrade port-to-patch transmission. However, variation in the dimensions of the impedance matching junction between the transmission line and patch plays a significant roll in determining overall RF performance. In general, establishing the average standard deviation of printed traces in an RF antenna design determines the target transmission line width due to the non-linear effects of junction variability on impedance matching. By altering design parameters away from the traditional "ideal" dimensions and instead designing for a highly variable process, performance of up to -36dB was achieved in this study, with 70% of the dataset reaching -20dB or below. This is a significant improvement over traditional design dimensions which were predicted to range from -36dB to just -15dB. All printed results were compared to simulations and dual-clad copper laminate PCBs to verify process, design, and simulation accuracy.
Given the trends analyzed in this work, it is reasonable to expect that developing similar sets of feature dimensions can be applied to any DW printing process. Each DW process will introduce its own level of variability, but by designing the RF structures using the methods described here it becomes

possible to take full advantage of DW's compatibility with flexible substrates. The end result will be higher acceptable through-put while moving towards automated design and fabrication of flexible, on-demand, high-frequency systems.

4:15 PM EQ11.05.08
Late News: Multi-Material, Multi-Substrate, 5G RF Design for Flexible, Conformal and Non-Traditional Substrates Samuel Fedorka, Bradley Pothier and Katherine Berry; UML, United States

Samuel Fedorka[1], Bradley Pothier[1], Katherine Berry[1], Gary F. Walsh[2], Corey Shemelya[1]
1. University of Massachusetts Lowell, Printed Electronics Research Collaborative, 1 University Ave., Lowell, Massachusetts 01854
2. U.S. Army Combat Capabilities Development Command Soldier Center, 15 General Greene Ave., Natick, Massachusetts 01760
The past decade has seen a surge in additive manufacturing materials, devices, and applications bringing new form-factors to both new and existing technologies. Additionally, this unprecedented growth has led to a massive increase in the potential application space of printed electronics ranging from sensing to Radio Frequency (RF) antennas, systems, and components. As printed technologies advance, one must also examine the related RF designs, material systems, and fabrication techniques in order to adapt the technology to a variety of substrates and application environments. For example: a variety of new ink technologies and printable systems have been specifically designed to advance the field of AM, but there has been little research into designing fully integrated 5G RF systems with respect to these novel printing techniques. As such, these fully integrated solutions, i.e. materials, methods, design rules, and design constraints, required for the success printed RF systems/subsystems remains relatively unexplored in additive manufacturing (AM) research.
This work explores direct-write (DW) AM using silver nano-ink and RF-transparent spray coated THV Fluoropolymer on substrates ranging from "thick" laminated ultrahigh molecular weight polyethylene to standard "thin" flexible low-loss dielectric RF material. Using these techniques, an example RF circuit operating at 5G frequencies was designed and fabricated as a case study for DW RF sensing. This circuit consists of a 5G antenna, a Low Noise Amplifier, and an RF detector IC. All RF designs were simulated in ANSYS HFSS to ensure both printed and spray coated features produced the optimal RF response. Initial conducting elements were printed using a Nordson Pro4 direct-write, micro-pen dispensing system with final designs applicable to transition to an Optomec 5x as the processes/models are finalized for conformal geometries. The spray-coated fluoropolymer was shown to provide an RF transparent coating to improve component adhesion (i.e., capacitors, resistors, IC chips) and protect printed traces from external effects such as oxidation, without adversely affecting the RF performance. Also examined were additional 5G antenna designs on novel/alternative substrates (UHMWPE) where the spray coated polymeric layer was shown to be useful as a base layer in order to provide a smooth, "printable" surface (i.e., wettable surface) for printed RF antenna and waveguide systems. Additionally, the spray coated fluoropolymer was enabled full structural encapsulation through the deposition of subsequent layers.
This research is aimed to provide insight into how RF circuit design can be modified with new design constraints, substrates, and materials for a printed/flexible form factors while still maintaining high levels of performance. As such, we aim to present work that enables printed RF design/test to move from single component analysis to complete RF systems with integrated RF ICs, RF structures, DC components, DC ICs, novel substrates, and novel coatings in a variety of form factors.

4:30 PM EQ11.05.09
Optimization of Flexible Supercapacitors with Gel Polymer Electrolytes Hamidreza Fallahtafti, Banafsheh Hekmatnia, Haleh Ardebili and Alamgir Karim; University of Houston, United States

Flexible energy storage devices such as supercapacitors (SCs) and lithium-ion batteries (LIBs) have attracted great attention for promising performances, such as high longevity and cycle life, fast charging-discharging rate, and high-power density. As a result, all-solid-state supercapacitors (ASSSCs) are a great candidate for many applications, including wearable electronic devices, portable devices, and electric vehicles (EVs).
In this study, a high-performance flexible supercapacitor with gel polymer electrolyte was developed with optimal design, fabrication, mechanical, safety and electrochemical performance. The optimum ratio of materials was determined for durable, long cycle life, high performance, flexible, and environmentally friendly supercapacitors (SCs). A flexible thin film of electrolyte was fabricated with a thickness of 475 µm. Since the electrodes were composed of nanocarbon with a high specific area, the fabricated supercapacitor was lightweight, flexible, and low cost with high electrochemical performances.
Moreover, comprehensive mechanical testing of the electrolyte, such as stretchability, flexibility, yield stress, and ultimate tensile strength (UTS), was conducted by the MARK-10 apparatus. As a result, the elongation of the gel polymer electrolyte (GPE) was 355%. Besides flexibility, different design strategies were adopted to provide additional stretchability in the supercapacitors.
Furthermore, electrochemical tests, including cyclic voltammetry (CV) and galvanostatic charge and discharge (GCD), has been conducted to evaluate the performance of the fabricated supercapacitors. In addition, SEM, FTIR, and AFM were used to characterize the change in the performance while in different bending angles.

Solution-Processed Semiconducting Carbon Nanotubes for Transistors and Complementary Circuits Jana Zaumseil; Heidelberg University, Germany

Large volumes of highly purified dispersions of semiconducting single-walled carbon nanotubes have become readily available through polymer-wrapping and shear-force mixing. Such nanotube inks can be further stabilized by small molecule additives and thus enable the reproducible deposition (e.g., by aerosol jet printing, spincoating or zone-casting) of semiconducting nanotube layers of variable thickness from sparse to dense. These networks are employed in thin film transistors with high hole and electron mobilities (5-50 $cm^2V^{-1}s^{-1}$). Through intentional doping it is possible to create purely n-type or p-type transistors with on/off current ratios exceeding 10^7, which are suitable for complementary and high-frequency circuits. Here, we will discuss the basic charge transport properties and limitations of nanotube networks, novel n-dopants as well as routes toward low-voltage circuits on flexible substrates.

8:30 AM *EQ11.06.02
Factors Limiting Charge Transport in Highly Doped Conducting Polymers Henning Sirringhaus; Cambridge University, United Kingdom

Doping of semiconducting polymers has seen a surge in research interest driven by emerging applications in sensing, bioelectronics and thermoelectrics. A recent breakthrough was a doping technique based on ion-exchange, which separates the redox and charge compensation steps of the doping process. The improved microstructural control this process allows enables us for the first time to systematically address a longstanding but still poorly understood question: what limits the electrical conductivity at high doping levels? Is it the formation of charge carrier traps in the Coulomb potentials of the counterions, or is it the structural disorder in the polymer lattice? Here, we apply ion-exchange doping to several classes of high mobility conjugated polymers and identify experimental conditions that achieve near 100% doping efficiency under degenerate conditions with nearly 1 charge per monomer. We demonstrate very high conductivities up to 1200 S/cm in semicrystalline polymer systems, and show that in this regime conductivity is poorly correlated with ionic size, but strongly correlated with paracrystalline disorder. This observation, backed by a detailed electronic structure model that incorporates ion-hole and hole-hole interactions and a carefully parameterized model of disorder, indicates that trapping by dopant ions is negligible, and that maximizing crystalline order is critical to improving conductivity.

9:00 AM *EQ11.06.03
Development of High Performance Metal Halide and Perovskite Transistors Yong-Young Noh; Pohang University of Science and Technology, Korea (the Republic of)

Achieving high-performance and reliable transistors based on metal halide perovskites has been pursued for decades yet remains challenging because of the absence of highly qualified perovskite channels. Herein, we report inorganic perovskite thin-film transistors with exceptional performance using high-crystallinity and uniform cesium-tin-triiodide-based semiconducting layers with moderate hole concentrations and superior Hall mobilities, which are enabled by the judicious engineering of film composition and crystallization. The optimized devices exhibit high field-effect hole mobilities of over 50 square centimeters per voltage-second and large current modulation greater than 10^8 as well as high operational stability and reproducibility. Our results represent a key step towards employing printable perovskite semiconductors in cost effective transistors and circuits.

9:30 AM EQ11.06.04
Stable Twisting of Carbon Nanotubes into Semiconducting Chiralities by Low-Work-Function Contact Jiangtao Wang[1], Gregory Pitner[2], Xiang Ji[1], Jiadi Zhu[1], Jinchi Han[1], Han Wang[2], Lain-Jong Li[2] and Jing Kong[1]; [1]Massachusetts Institute of Technology, United States; [2]TSMC Corporate Research, United States

To realize the projected speed, efficiency, and scalability of carbon nanotube (CNT) based electronics, the key fundamental challenge is the growth of horizontally-aligned arrays of defect-free CNT with a semiconducting purity >99.99%. Until recently, selective CNT synthesis methods utilized either the native free energy or native stability difference between the growth of semiconducting CNTs (s-CNTs) and metallic CNTs (m-CNTs). However, such native energy separation is too small to sufficiently suppress the random thermal fluctuation at the 800-900°C growth temperature and fails to delivery semiconducting carbon nanotubes with required >99.99% s-CNT purity. Here we report an approach to open a larger gap in the free energy between m-CNT and s-CNT during both epitaxial growth and chirality change by contacting growing CNTs with low work-function electrodes such as Hafnium Carbide or Titanium Carbide. First, the remarkable difference of quantum capacitance between m-CNT and s-CNT separates the CNT free energy plot of CNTs into two branches. Second, when in contact with low work-function electrodes CNTs and tipped catalysts will be negatively charged (n-doped) due to the electrode work-function, which causes an increase in free energy gap between m-CNTs and s-CNT and a reduction of the twisting barrier from m-CNT to s-CNT. Third, the large aspect ratio of CNTs enables a strong local electric field generated by the charge stored at the CNT tip to contribute a prominent electrostatic effect that greatly affects the total free energy change. As a result, stable twisting of horizontally aligned CNTs from initially mixed m-CNT and s-CNT chiralities to s-CNT chiralities is achieved by applying a weak perturbation (10V/mm-alternating electric field). These results validate that a lower work-function contact does result in a higher selectivity towards s-CNTs at a reduced applied electric field. Our observations also open a possibility to select the catalytic pathway through the contact engineering and will pave the way for practical applications of CNT electronics.

Large Area Doped Rubrene Thin-Film Electronics Ilia Lashkov, Shu-Jen Wang, Hans Kleemann and Karl Leo; Technische Universität Dresden, Germany

Organic and molecular electronics is a promising field for many applications, particularly flexible electronics [1] [2], since it allows the processing of electronic circuits at low temperatures on a variety of substrates, including flexible sheets [3]. Despite continuous improvements in the charge carrier mobility of both n- and p-type thin-film transistors, the performance of these devices is not yet attractive enough for commercial applications.
A substantial hurdle to the realization of effective organic-based analog and digital circuits is the lack of scalable high-charge-carrier-mobility organic semiconductors with low contact resistances in transistors [4]. Devices based on organic single-crystalline rubrene with superior mobility of over 10 $cm^2V^{-1}s^{-1}$ have been previously shown [5]. However, such single crystals are difficult to grow and handle and are less suited for integrated electronics, which limits the commercial attractiveness of this material.
Here, we demonstrate vacuum-processed and, subsequently, thermally annealed highly crystalline rubrene thin films which enable the realization of large-area high-frequency circuits. We fabricate organic thin-film transistors (OTFTs) based on highly ordered rubrene films with different underlayers and reach charge carrier mobilities over 5 $cm^2V^{-1}s^{-1}$ (for a channel length of L = 100 µm and width of W = 1000 µm). Moreover, we significantly reduce the contact resistance of the transistors down to 1 kOhm cm by utilizing contact doping [6]. We analyze the uniformity of the crystals and show that such rubrene thin-film transistors are well suited for large-area electronics.

High-Speed Solution-Processed Organic Single-Crystal Transistors for Active-Matrix Flexible Mini-LED Displays Jun Takeya[1,2,3] and Tatsuyuki Makita[1,3]; [1]The University of Tokyo, Japan; [2]Organo-Circuit Inc., Japan; [3]Pi-Crystal Inc., Japan

Images such as large mammals have impacted psychology of human species since the beginning of their history. Indeed, demand for technologies of meter-size large-area digital advertisement has been essentially very large, though the current devices are not well-prevailed because of high cost, large weight, and high power consumption. We developed a method to produce LED pixels on printed backplanes of active matrices based on high-mobility organic semiconductors. Due to the light-weight film-based materials of low-cost printed organic active matrices, which is also very effective in reducing power consumption, the present technology meets the requirement for the large-area digital signage. The present devices are formed on a sheet of PEN film with the thickness of 0.1 mm, so that the large-area movies can be shown hung on the ceilings of buildings or under mobile drones.
High-performance solution-processed transistors are employed with recently developed technologies of ultrathin organic semiconductor single crystalline films suitable for large-area production with low energy consumption. The films are easily formed to large area from solution at relatively low temperature at 80 degrees centigrade [1]. Extremely thin crystal films are controllably grown to a-few molecular layers with the thickness of only 10 nm, so that material cost can be only 0.01 USD per cm^2. Such prospect bears increasing reality because of recent research innovations in the field of material chemistry, charge transport physics, and solution processes of printable organic semiconductors. Particularly important are new processing technologies for continuous growth of the organic single-crystalline semiconductor “wafers” from solution and for lithographical patterning of semiconductors and metal electrodes. The active-matrix transistors are successfully formed with 60-Hz frame rate and more than 1-mA on current to illuminate the LEDs, thanks to the high carrier mobility as high as 10 cm^2/Vs in the single-crustal organic semiconductors.

Establishing a Process Design Kit for Low Contact Resistance OTFT with MHz Switching Frequencies Simon Ogier, Dan Sharkey and Alejandro Carreras; SmartKem, United Kingdom

Organic thin-film transistor (OTFT) devices have been fabricated using a maximum processing temperature of 80 degrees Celsius, rendering them compatible with a range of low-cost, transparent and flexible substrates. Charge mobility at a transistor channel length (L) of 5 µm is 3cm^2/Vs. Such perfrormance is compatible with a wide range of voltage or current driven display device applications fabricated on plastic or glass. A small variation of mobility with channel length suggests a very low contact resistance (~100 Ohms), enabling good use of channel length scaling to increase operating frequencies in digital circuits. Current driven applications, such as local dimming mini-LED backlights, AMOLED or voltage driven displays and sensor arrays have been demonstrated using SmartKem’s OTFT materials. These are fabricated using process techniques common to flat panel display backplanes (sputtering, photolithography, dry/wet etching), providing a low cost of manufacture per unit area substrate.
The design of digital circuitry using transistor devices is aided by electronic design automation (EDA) tools which enable the accurate layout of a circuit using a process technology helping to deliver a consistent device performance. This presentation describes work to establish a process/technology design kit (PDK/TDK) for devices using the SmartKem OSC material stack. The PDK contains the device dimensions, overlaps, etc relating to the OTFT device and these are coded in software into parameterizable cells (p-cells). Device modelling and circuit simulations are used to predict electrical performance of the designs prior to tape out of the mask set for fabrication. PDK roadmaps are presented relating to improvements in device operating voltage and fabrication techniques, showing the potential for achieving circuits with higher operating frequency at a lower voltage in subsequent batch runs.

Flexible Sub-Micron Thin-Film Transistors Based on Oxide Semiconductors Niko Münzenrieder, Giuseppe Cantarella and Luisa Petti; Free University of Bozen-Bolzano, Italy

Wearable devices seamlessly integrated into everyday objects and able to conform to the movement of soft artificial and natural surfaces are considered one of the next major steps in the development of electronics for consumer products and industrial applications. The main application scenarios of such imperceptible electronics include the collection of data from the environment or the interaction with humans, to enable e.g. smart personalized healthcare devices or efficient Industry 4.0 processes. This requires the wireless transmission of data and the conditioning of a variety of analogue sensor signals using flexible, cheap, and environmentally-friendly components.
Thin-film transistors (TFTs), based on oxide semiconductors, most prominently amorphous Indium-Gallium-Zinc-Oxide (IGZO), and fabricated on large-area polymer substrates, are a suitable approach to fabricate active electronics if high bendability and electrical performance are required simultaneously. Such devices are investigated since more than a decade, hence their DC performance is well understood and reliable fabrication processes for systems, such as display backplanes, are established. However, the realization of highly scaled sub-micron devices on thermally and mechanically instable plastic substrates, together with the optimization of their analogue and high-speed performance, is less investigated. Here, various fabrication techniques and device structures, as well as theoretical models to predict the AC performance, resulting in flexible IGZO TFTs with channel length as short as 160 nm, are presented. Their AC performance is analysed, and it is discussed how analogue integrated circuits, such as amplifiers, buffers, or multiplexers made from these TFTs, can be used to realize front-end conditioning circuits for wearable sensors.
The IGZO TFTs presented here are manufactured on free standing polyimide foils. These TFTs are fabricated using high-k atomic layer deposition (ALD) grown Al_2O_3 insulating and passivation layers, metallic contacts, and RF sputtered IGZO with a stoichiometric composition of In:Ga:Zn:O = 1:1:1:4. The maximum process temperature used is 150°C. They exhibit state of the art DC performance including field effect mobilities up to ≈15 cm^2/Vs, on-off current ratios >10^8, subthreshold swings of ≈125 mV/dec., and threshold voltages allowing the operation of devices and circuits at voltages <5 V. The TFTs also stay fully functional when exposed to tensile or compressive strain induced by bending radii as small as 50 µm.
Here, the AC performance of these TFTs will be shown. All devices are designed with ground-signal-ground contact pads to enable their reliable AC characterization using a two-port network analyser. To minimize the channel length and hence to maximize the operation frequency of flexible IGZO TFTs, different fabrication methods are evaluated. These include conventional bottom gate TFTs, transistors structured by self-alignment, focused ion beam milling, or direct laser writing, as well as vertical TFTs and double gate TFT geometries.
The characterisation of all these devices showed that conventional bottom gate TFTs, with a channel length of 1 µm, and gate overlaps of 5 µm can exhibit a transit frequency up to 47 MHz. This value is in agreement with corresponding transconductance and gate capacitance measurements. At the same time, the AC performance is limited by the lateral dimensions of the TFTs. It was found that although traditionally smaller feature structures are beneficial, in the case of short and flexible IGZO TFTs, a careful optimisation of the capacitances and contact resistances is required. Consequently, the shortest transistors

do not exhibit the highest frequencies, but a transit frequency of 135 MHz is demonstrated for 500 nm long self-aligned transistors even while exposed to 0.5% tensile strain. These in turn, enable the fabrication of fully flexible circuits able to operate in the megahertz regime.

9:15 AM *EQ11.07.04
Organic Thin-Film Transistors for High Performance Logic Circuits—Realization of Short Channel, High Mobility, Low Contact Resistance and Threshold Voltage Control Masatoshi Kitamura and Yoshiaki Hattori; Kobe University, Japan

The organic thin-film transistor (TFT) is a key device for flexible electronics. The field-effect mobility for p-channel TFTs has reached up to 10 $cm^2 V^{-1} s^{-1}$, which is close to those of InGaZnO TFTs used in flat panel displays. We have been trying to realize short channel, high mobility organic TFTs for high frequency operation, and control the threshold voltage for actual applications.
A key issue for realization of short channel, high mobility organic TFTs is reducing contact resistance between organic channel materials and contact electrodes. We have used contact electrodes modified with benzenethiol derivative to realize low contact resistance. The modification demonstrated wide work function tuning for contact electrodes. The measured work function of modified Au electrodes was in a relatively wide range between 4.24–6.02 eV. We have applied modified electrodes to bottom-contact organic TFTs. The organic TFT having C10 DNTT as a channel material exhibited very high channel conductance. This is due to the low contact resistance, which is about 20 Ω cm under a gate voltage of −10 V.
We have used modified electrodes for high frequency operation in organic TFTs. The current-gain cutoff frequency was measured for evaluation of operational frequency in organic TFTs. The cutoff frequency was estimated by direct measurement of the gate and drain modulation currents. The measured cutoff frequencies for both C60 and pentacene TFTs increase consistently with reducing channel length. Cutoff frequencies of about 28 and 11 MHz were obtained from C60 and pentacene TFTs with a channel length of 2 μm, respectively.
The threshold voltage control is an important issue for actual application. We have reported the threshold voltage control in organic TFTs realized by oxygen plasma treatment. Exposing a SiO2 gate dielectric surface in organic TFTs to oxygen plasma shifted the threshold voltage to positive gate voltage. The threshold voltage shift depended on plasma treatment time, AC power for plasma generation, and gate dielectric thickness. The threshold voltage change was explained by negative charges induced on and/or near the surface of the gate dielectric. The threshold voltage change on the order of 1 V was roughly proportional to plasma treatment time. The predictable change enables the control of threshold voltage in this range. In actual, we used organic TFTs with controlled threshold voltages for application to logic circuits. Operation of logic inverters consisting of organic TFTs with different threshold voltages was demonstrated as an application of TFTs with controlled threshold voltage. Furthermore, a ring oscillators consisting of organic inverters operated at supply voltages in the range of 15–25 V. Combination of techniques about short channel, high mobility, low contact resistance, and threshold voltage control will realize high performance circuit consisting of organic TFTs.

Circuit Design Approaches for Different Thin-Film Technologies Kris Myny[1], Hikmet Çeliker[1] and Wim Dehaene[2]; [1]imec, Belgium; [2]KU Leuven, Belgium

The necessity of higher operation speed in electronic circuits is inevitable as there is a big amount of data being produced and transferred in our daily lives through different ways of digital communication. This argument is valid for silicon based integrated circuits as well as for thin-film-transistor based integrated circuits. Improvements in device processes have equal importance as circuit design techniques in order to achieve high frequency operation within the field of thin film transistors (TFT). In this invited presentation, we will provide an overview of different circuit design approaches specifically focusing on fast operating thin-film circuits combined with two main technology aspects: scaling and higher mobility materials.
Transistor downscaling has been proven to be key for Si CMOS electronics to obtain better figures of merit and consequently improve the operating speed of the integrated circuits. A analogy can be made for TFT-based circuits, whereby the minimum achievable channel length of TFTs on flexible substrates is mainly depending on photolithography accuracy, limiting it in many cases to μm-ranges. A self-aligned amorphous Indium-Gallium-Zinc-Oxide (a-IGZO) TFT technology allows n-type only TFTs to have a channel length down to 1.5 μm. Thanks to the self-aligned structure, overlap the capacitance between source/drain and gate of a TFT are mostly eliminated. These have been instrumental in demonstrating an ISO14443-A compatible flexible NFC barcode tag operating at 13.56 MHz [1].
Besides scaling of the transistor footprint, upscaling of the number of routing metals also helps increasing the operation speed and reducing footprint of thin-film ICs. Combining the design strategies already available for unipolar technologies with these process developments, performance and robustness of digital thin-film ICs have been increased continuously. One example is a Two-Stage Resistor-Load Logic standard cell library for digital applications [2]. We have demonstrated that this logic topology shows better speed performance than the conventional one-stage resistor-load topology. It is also more robust against the impact of global variability. To demonstrate this, a 4-bit digital multiplier using the new topology with 0.8 μm channel length TFTs is fabricated. It shows a speed performance up to 1 MHz.
The second important technology factor in the performance of thin-film ICs is the semiconductor material. For instance, Low-temperature polysilicon (LTPS) is attractive because of its higher mobility and the availability of complementary transistors. Because of its polycrystalline structure, minimum channel length of LTPS TFTs is larger than a-IGZO devices. In the presentation, we will show a performance comparison between logic gates realized with a-IGZO and LTPS technologies. Having complementary transistors enables circuit designers to use similar techniques as used in silicon CMOS designs. To demonstrate the capabilities of LTPS, we will also compare the measurement results of two different flip-flop architectures in terms of speed performance and power consumption.

Organic-Inorganic Nanomaterials Based Piezoelectric Nanogenerator for Self-Powered Structural Health Monitoring Md. Masud Rana[1,2], Asif

Abdullah Khan[1,2], Guangguang Huang[1], Nanqin Mei[1], Resul Saritas[1,2], Boyu Wen[1,2], Steven Zhang[1], Weiguang Zhu[1], Peter Voss[3], Eihab-Abdel Rahman[1,2], Zoya Leonenko[1], Shariful Islam[3] and Dayan Ban[1,2]; [1]University of Waterloo, Canada; [2]Waterloo Institute for Nanotechnology, Canada; [3]Shimco North America Inc, Canada

Recently Structural Health Monitoring (SHM) is being widely assessed by the aerospace industry to enhance the safety and consistency of aircraft structures. The use of built-in sensor networks coupled with continuous structural integrity monitoring on an aircraft can provide vital real-time information concerning the condition, damage state, and/or service environment of the structure, which could significantly reduce the cost compared to scheduled manual inspection. Sustainable and durable piezoelectric nanogenerators (PENGs) with good flexibility, high performance, and superior reliability under inconsistent environments are a promising candidate for modern Wireless Sensor Network (WSN)-based SHM application. Numerous materials have been used to fabricate PENGs such as lead zirconate titanate (PZT), barium titanate (BaTiO3), ZnO, Na/KNbO3 and ZnSnO3 nanoparticles have great piezoelectric coefficients and superior energy conversion efficiencies. However, research progress is often impeded due to fragility, heavyweight, low durability, complex synthesis and fabrication process, and high toxicity of many of these materials. This research demonstrates the prospect of comprehending a self-powered wireless sensing system based on a piezoelectric nanogenerator (PENG) which is prominently anticipated to address the aforementioned issues. Here we present a flexible self-powered PENG sensor for the quantitative measurement of abnormal vibration based on WSN with the distinctive mesoporous structure via a drop-cast technique, and successfully demonstrated proof-of-the-concept applications. The well-dispersed and controllable size of ZnO nanoparticles (NPs) endows the composite film with the advantages of ZnO NPs and the virtues of the poly vinylidene fluoride (PVDF) matrix. A high voltage electrical poling of the porous PVDF film was performed with an electric field of 70-120 Vμm-1 for 5-6 hours with a DC voltage of 0-6 kV. No short circuit or noticeable voltage fluctuation was detected up to the maximum voltage of 6 kV. The poled porous PVDF composite films were sandwiched between electrodes. For the characterization purpose, the electrical connections were made from both of the top and bottom electrodes by very thin and flexible copper conductors. The self-powered wireless structural health monitoring system is a combination of an energy generation part, a part of sensing, and an integrated circuit (IC) part. A custom-made IC is placed on top of the PENG device, which is driven by the PENG device, monitors the surrounding environment automatically and transfers the signal to a receiver wirelessly. The performance of PENG based on the porous PVDF is systematically studied. The open-circuit voltage of the PENG device of 50wt.% ZnO was measured within a frequency range from 10Hz to 50Hz (varied frequency by Vibration Research's VR9500 Revolution unit) to examine the feasibility which is close to oscillation frequencies under a practical environment. The peak-to-peak output open-circuit voltage of the PENG was measured to be 84.5V at 30 Hz frequency. The peak output power ($P=I^2R$) 78μW and the corresponding peak power density of 12μW/cm^2 were achieved at a load resistance of 7MΩ, which is sufficient for driving the entire system. Such a PENG device produces electrical energy from the shaker vibration, and charge an input capacitor (1 μF) through a rectifier circuit. When the charging voltage of the input capacitor reaches ~ 5V, which was regulated by a zener diode, it discharges energy through a buck converter module to an output storage capacitor (220 μF). The charging and discharging cycle of the input capacitor continues until the output capacitor is charged up to ~ 3.1V, and by then, it empowers the whole system and sends the signal to a remote receiver. These results demonstrate the great potential of porous PVDF based film for the simple and cost-effective fabrication of high-performance piezoelectric energy harvesting devices.

8:45 AM EQ11.08.03
Thermal Management of Flexible Electronics Enabled by Programmable Liquid Metal Microstructures A B M Tahidul Haque, Ravi Tutika and Michael D. Bartlett; Virginia Polytechnic Institute and State University, United States

Emerging flexible electronics technologies including wearable biodevices, soft robotics, and stretchable sensors demand efficient thermal management to dissipate and distribute heat. One significant challenge in these systems is that the low thermal conductivity of flexible substrates limits device functionality by accumulating heat which leads to deteriorated charge transport and unstable electro-mechanical performance. To overcome these challenges, liquid metal (LM) dispersed elastomers have shown unique combinations of soft mechanical response with exceptional electrical and thermal functionalities. However, approaches to control LM microstructure in composites are needed to further enhance properties to enable heat dissipation and improved interfacial compatibility in flexible electronic systems. Here, we present an innovative approach to control LM microstructure in soft composites to enhance heat distribution while maintaining the soft, mechanical characteristics needed for flexible electronics. Through a mechanical reconfiguration and thermal relaxation process, we orient and elongate LM droplets in elastomers at high concentration (up to 70% by volume). Through this microstructural control in soft composites, we demonstrate a material which simultaneously achieves a high thermal conductivity of 13 W/mK (> 70 × increase over polymer matrix) and low modulus (< 1.0 MPa) in stress-free conditions. As a lightweight, conductive, and transferrable medium for flexible substrates, we also extend the LM morphology programming concept for micron sized thin films. The thickness tunable (30-70 μm) thin films are composed of disk-shaped LM droplets which can be electrically activated for circuit integration. This enables high stretchability (strain limit > 700%) and metallic electrical conductivity (sheet resistance < 0.1 Ω/sq) in soft films. We demonstrate these materials for rapid heat dissipation of high-power devices on flexible substrate, wearable robotics, and electronics integrated flexible circuits. We envision that the material, process, and device development strategy using the LM programmed composites will enable next-generation high-frequency flexible transistors, stretchable electronics, and soft robotics.

9:00 AM EQ11.08.04
Flexible Triboelectric Laminate for Mechanical Energy Harvesting as an Energy Source for Electronics Kaspars Malnieks, Andris Sutka, Artis Linarts and Linards Lapčinskis; Riga Technical University, Latvia

Triboelectric generator (TEG) devices have attracted considerable interest in the field of mechanical energy harvesting due to their low weight and mechanical softness. The charge transfer in TEG devices has been attributed to electron transfer, ion transfer, and material transfer [1] with the discussions still ongoing. There are many innovative TEG devices from low-cost materials presented in the literature for mechanical energy harvesting from human motion, vibrations, wind, water flow, and waves.[2-4] However, all TEG devices as a rule contain movable parts to magnify the dipole moment between triboelectric charges obtained from contact-separation. This specific requirement complicates the integration of TEG devices into energy harvesting systems. Alternative soft materials that exhibit bulk electromechanical response are piezoelectric polymers and their nanocomposites. For example, fluoropolymers such as polyvinylidene fluoride (PVDF) and PVDF co-polymers exhibit the piezoelectric d_{33} coefficient as high as 20–28 pC N^{-1} due to large dipole polarization between hydrogen and fluorine atoms.[5] However, to obtain high electromechanical response, the poling procedure at high electric fields (10–30 kV cm^{-1}) for prolonged periods (24 h or more) has to be applied. The necessity to apply high electric field limits moreover, the alignment of dipoles in the polymer is not stable and depolarization of PVDF is often observed over the course of days even at room temperature. Herein we are presenting the triboelectric laminates where the polymer bilayers with different triboelectric properties are stacked to form laminates, together with the separator mesh between each bilayer and for an electrodes we use flexible polyisoprene conductive carbon black composite . The proposed design ensures the formation of aligned macroscopic dipoles across the volume of triboelectric laminate and provides the desired electromechanical response. When the force is applied, the triboelectric charges on opposite surfaces of bilayers are formed due to triboelectrification. The mesh provides the macroscopic dipole formation between the distinct triboelectric layers. Different triboelectric surface properties of polymer bilayers result in dipole alignment. Triboelectric laminate generates the open-circuit voltage (V_{OC}) of 29 V and short-circuit current (I_{SC}) of 15 nA. Volumetric energy density of 21.13 μJ cm^{-3} and a peak average power density of 46.19 μW cm^{-3} are observed. Triboelectric laminate shows an effective piezoelectric constant d_{33} of 9.83 pC N^{-1} , higher than reported for piezoelectric polymer like nylon-11 and there is no need to apply an external electric field to polarize the material and to observe the piezoelectric response. In addition, the electromechanical response of the triboelectric laminate does not disappear over

time. The triboelectric laminate is produced from cheap, mechanically flexible materials that can be produced in large quantities.

Low Temperature Crystallization of Ge Thin Films for Channel Layers of Thin-Film Transistors by Gold-Induced Layer Exchange Narin Sunthornpan, Kenjiro Kimura and Kentaro Kyuno; Shibaura Institute of Technology, Japan

Fabricating high quality semiconductor thin films on plastic substrates is becoming increasingly important which is crucial in realizing high-speed electronic devices on plastic substrates. Germanium (Ge) thin film is one of the promising candidates among semiconductors which can be fabricated on flexible substrates at low temperature. Ge has many excellent properties such as higher electron and hole mobilities and smaller energy bandgap compared to silicon (Si), which is advantageous in applications such as thin-film transistor, solar cell, and next generation MOSFET. Metal-induced crystallization (MIC) technique by gold (Au) catalyst is one of the promising candidates to crystallize Ge films because of its low crystallization temperature. Nevertheless, further knowledge about the crystallization process is needed to improve the quality of the film. In this work, the Au layer thickness dependence of the crystallization process has been investigated in detail. It is found that the grain size, crystal orientation and crystallization temperature are sensitive to the Au layer thickness. Ge films crystallized with thinner Au films show lower crystallization temperature and higher (111) crystal orientation. A hole mobility as high as 50 cm^2/Vs is achieved by annealing a Ge(30nm)/Au(9nm) bilayer at 220 °C, which is low enough to fabricate electronic devices on plastic substrates such as polyimide.

The Au and Ge films were fabricated by RF magnetron sputtering process on Si wafer with 100 nm thermally grown oxide (SiO_2) layer. Au films ranging from 9 to 34 nm were deposited on the wafer and subsequently Ge films (27 and 55 nm) were deposited on the Au layer. Au/Ge bilayers were crystallized by using MIC technique at 220 °C under N_2 ambient. Structural properties were examined by X-ray diffraction (XRD), scanning electron microscope (SEM) and electron backscattered diffraction (EBSD). Ge films crystallized with thinner Au film showed higher Ge (111) orientation, which was confirmed by XRD and EBSD observation. From the Hall effect measurement, p-type behavior and hole mobility as high as 50 cm^2/Vs was achieved for the Ge film crystallized by annealing a Ge(30nm)/Au(9nm) bilayer film. Transistor action was also demonstrated successfully by using these films as channel layers. These findings will open up the possibility to apply MIC technique to crystallize Ge thin film at temperatures as low as 220 °C, which is low enough to fabricate thin-film semiconductor on various inexpensive plastic substrates.

9:10 AM *EQ11.08.06
Scalable Growth of Doped Organic Thin-Film Crystals for High Frequency Applications Shu-Jen Wang, Michael Sawatzki, Hans Kleemann and Karl Leo; TU Dresden, Germany

The current generation of organic electronic devices such as the established OLED technology are based on amorphous thin-films with low carrier mobility due to their disordered molecular orientation. For high frequency device operation, higher carrier mobility is generally required. Here, we present the growth of highly crystalline organic thin-film crystals using vacuum deposition technique where the thickness of the films can be precisely tuned using epitaxy [1, 2]. In addition, organic dopants can be incorporated into the thin-film crystals during the deposition process that allow us to tune the properties of the individual layers. Finally, we integrate these doped highly crystalline thin films into devices to enable novel applications.

Toward Accurate Prediction of Transit Frequency in Organic Transistors Chang-Hyun Kim; Gachon University, Korea (the Republic of)

In this presentation, an analytical theoretical description of the ac transit frequency of organic field-effect transistors is proposed. The model is built upon an advanced physical description of the contact resistance as a key mathematical component. Such a treatment self-consistently and predictively correlates the transit frequency to a number of materials, geometrical, and operational parameters. By navigating a broad parametric space, it is found that the ambitious gigahertz operation is observable only in highly downscaled devices, and the intrinsic carrier mobilities and charge-injection barriers required to reach that regime are specified.

Polymeric Devices for Infrared Upconversion Imagers and Energy Storage Ning Li, Lulu Yao and Tse Nga Ng; University of California, San Diego, United States

The shortwave infrared spectral region is particularly powerful for a variety of applications including environmental monitoring and medical diagnosis,

enabling greater penetration depth and improved resolution in comparison to visible light. Upconversion imagers that combine photosensing and display in a compact structure are attractive since they avoid the costly and complex process of pixilation. Here, we have implemented polymeric upconversion imagers that combined photo-sensing and display in a compact structure, to extend the capability of human and machine vision to 1400 nm. The photoresponse exhibited a high external quantum efficiency of 35% at a low bias of ≤3 V with –3 dB bandwidth of 10 kHz. The large active area of 2 cm^2 enabled demonstrations such as object inspection, imaging through smog, and concurrent recording of blood vessel location and blood flow pulses. In addition to visualisation of infrared radiation, this class of narrow bandgap polymers showed highly delocalized redox states and operated as stable n-type anodes in energy storage devices. The redox polymer was used in supercapacitors and achieved a high areal power density of 227 mW/cm^2, allowing rapid charging and relevant to ac line filtering applications. The capacitance retention was 84% after 11,000 full redox cycles, offering the critical benefit of long cycle life. This work demonstrated the application of a new class of stable redox-active materials suitable to meet the energy storage needs for short-range wireless electronics.

Engineering OFETs Architecture Towards High Frequency Annalisa Bonfiglio, Piero Cosseddu and Andrea Spanu; University of Cagliari, Italy

Despite the impressive advances that organic electronics has faced in the past 30 years, which led to the introduction of a variety of devices for a great number of different applications (such as, for example, the mobile phone industry and the biomedical field), organic field effect transistors still suffer from undeniable limitations, and present clearly subpar performances, especially with respect to standard silicon-based devices. In particular, despite the many advantages that organic transistor have in terms of low fabrication costs, easy processing techniques (often from solution), flexibility, and large area deposition, their actual employment for high-performance applications is still slowed down by several issues, such as the low mobility of organic semiconductors, the not-so-easy miniaturization, and poor long term stability of organic molecules, which generally lead to not always trivial encapsulation steps in order to avoid early aging due to the extreme sensitivity of such molecules to oxygen and moisture. These limitations have repercussions in the use of OFET-based devices in applications where high operation frequencies are needed, such as IoT, where smart devices are thought to intercommunicate and exchange continuous information in real time, and front-end circuits developing. An obvious approach to somehow dodge this limitation, which is in fact due to the intrinsic nature of the employed materials, and thus obtaining transistors with a suitable switching rate, is related to finding new ways to shorten the transistor channel length. However, a further challenge is doing so without excessively complicating the fabrication process. In fact, a lot of effort has been put in the past 20 years towards the reduction of devices dimensions, which is generally obtained using rather complicated approaches.

In order to meet the aforementioned goals, an accurate design is mandatory in order to minimize all the side effects that could limit the operational frequency of these devices. In this work we will report the approach that we have developed along the years in order to improve OFET performances. First of all, cut off frequency is strongly limited by all the device parasitic capacitances, therefore, thanks to the transparency of the employed substrates we have developed a self-alignment process that allowed us to achieve operational frequencies, very close to the MHz even with relatively low mobility semiconductors. More recently, in order to further close the gap with standard semiconductor-based devices, we have developed and optimized an easy and upscalable procedure for routinely fabricating submicrometer size OFETs with limited parasitic capacitances. These two factors turned out to be crucial to achieve cut off frequencies well above the MHz even with the employment of low mobility semiconductors, and without the need of employing expensive high resolution techniques. The proposed approach, thanks to its versatility and impressive performance can open up interesting new paths in the field of organic electronics for logic and front-end circuits developing and IoT applications.

Integrated Complementary Organic Circuits and Ring Oscillators for Ultra-High-Frequency Logic Circuits Erjuan Guo and Hans Kleemann; Technische Universität Dresden, Germany

Relatively long channel lengths of lateral-channel dual-gate organic thin-film transistors typically leads to slow inverter operation. Vertical channel dualgate organic thin-film transistors are a promising alternative due to their short channel lengths, however, the lack of appropriate p- and n-type devices has limited the development of complementary inverter circuits. Here we show that organic vertical n-channel permeable single- and dualbase transistors and vertical p-channel permeable base transistors can be used to create integrated complementary inverters and ring oscillators. With operating voltages < 2.0 V, the threshold voltages of the n-type OPDBTs are
changed across a wide range from 0.12 to 0.82 V by varying the voltage of the additional base. Thus, the vertical dual-base transistors enable a widerange of switching voltage controllability of complementary inverters. In addition, the inverters exhibit small switching time constants at 10 MHz, and the 7-stage complementary organic ring oscillators exhibit short signal propagation delays of 11 ns per stage at a supply voltage of 4 V. This underlines the potential of vertical organic transistors for high-frequency logic circuit applications

The Role of Polarization-Induced Exciton-Polaron Quenching in Limiting OLED Efficiency Evgeny Pakhomenko and Russell J. Holmes; University of Minnesota, United States

Many common electron transport layer (ETL) materials employed in organic light-emitting devices (OLEDs) show a preferred orientation of molecular permanent dipole moments. This phenomenon is known as spontaneous orientation polarization (SOP), and leads to the formation of bound polarization charge, with polarons (typically holes) accumulating at the ETL/emissive layer interface to balance this charge. Previous study of phosphorescent OLEDs constructed using a polarized electron transport layer of tris-(1-phenyl-1H-benzimidazole) (TPBi) found that SOP-induced hole accumulation led to substantial exciton-polaron quenching *prior* to device turn-on. This quenching was found to reduce peak device external quantum efficiency by ~ 20%. This is in contrast with the prevailing understanding of exciton kinetics in OLEDs, where it is generally assumed that exciton-polaron quenching is only significant under high injection. This work examines the generality of this result by systematically probing polaron accumulation and quenching in phosphorescent OLEDs constructed using archetypical ETLs with varying degrees of SOP. Exciton quenching is quantified by the lock-in measurement of emitter photoluminescence during device operation. The use of a lock-in method allows emitter photoluminescence to be probed *in situ* even after turn-on by rejecting device electroluminescence. In comparison to device-efficiency based analyses of quenching, this technique decouples luminescence loss due to exciton-polaron quenching from inefficiencies in exciton formation. We find SOP-induced luminescence quenching to be a general phenomenon, here observed for devices based on several polar ETL materials. The onset-voltages for exciton-polaron photoluminescence quenching are in good agreement with conventional displacement current measurements, suggesting that this optical technique can be generally used to assess the magnitude of SOP. It is found that exciton quenching is a major limiting factor for determining peak internal quantum efficiency. These findings contrast the common practice of attributing lower-than-expected peak efficiency to charge balance losses and highlight the impact of SOP on OLED device efficiency, and the need to consider SOP-induced quenching in device design and analysis.

Singlet Heterofission in Tetracene-Pentacene Thin-Film Blends Luca Moretti[1], Clemens Zeiser[2], Daniel Lepple[2], Margherita Maiuri[1], Giulio Cerullo[1] and Katharina Broch[2]; [1]Politecnico di Milano, Italy; [2]University of Tubingen, Germany

Singlet fission (SF) is the photophysical process where an excited singlet state is converted into two triplets on the ultrafast timescales [1]. SF gained increasing attention in recent years due to the capability to overcome the Shockley-Queisser limit of single junction solar cells [2]. Different approaches to control the key parameters of SF (molecular arrangement, electronic coupling or energy balance) are often based on covalently bound dimers of SF chromophores. Another promising way to control the energy balance of SF and the optical bandgap is to combine two different chromophores. Here we focus on two prototypical SF chromophores pentacene (PEN, exothermic SF) and tetracene (TET, endothermic SF), and we exploit the advantage of intermolecular heterofission where two triplets are formed on different chromophores. In this work we investigate thin film blends with 5%, 25%, 50% and 75% of PEN with ultrafast transient absorption (TA) spectroscopy to study the impact of neighbouring TET molecules on the photophysics of crystalline PEN. We consider the TA of the neat compounds excited resonantly as references for understanding the interaction in the blends.
The results for PEN:TET blends performed with PEN excitation (to rule out energy transfer from TET to PEN) show a change in the relative position and intensity of the Davydov-components of the PEN photobleaching (PB) until the energetically higher one dominates at 5% PEN blend. The presence of excited state absorption (ESA) of triplets in all blends indicates that they are still being formed via SF despite the presence of TET. The 5% PEN blend shows a build-up of a negative signal around TET PB, as well as a disappearing SE at long delays. Global Analysis (GA) performed on the TA data, assuming SF to be the dominating channel, showed two different processes for the 5% PEN blend. The first one, occurring with 165 fs time constant was attributed to homofission of PEN, while a second 26 ps process was attributed to heterofission of PEN isolated among TET neighbours. The low heterofission rate can be explained by the endothermicity of the process. For PEN concentrations exceeding 5% there is no evidence of this process, since homofission outcompetes heterofission thanks to its exothermicity. Time constants from GA of the other blends confirm the robustness of PEN homofission [3] against the incorporation of weakly interacting compounds due the fact that SF in PEN proceeds via a coherent pathway where the triplet pair state directly mixes into the photoexcited bright state.
The study is completed with TA measurements exciting the TET, where the interpretation of TA and GA becomes complex as TET homofission and Förster resonance energy transfer (FRET) from TET to PEN additionally can occur. For high PEN concentration, FRET followed by PEN homofission outcompete TET homofission and heterofission [4]. The TA data for the 5% PEN blend present complex multi-exponential dynamics that reflect the relaxation of excited PEN and TET molecules via a multitude of channels. The persistence of the TET GSB at long delays is again evidence for TET triplets, which can be populated either via heterofission or TET homofission.
In conclusion we observe heterofission of a singlet from PEN to two triplets on one PEN and one TET, after direct excitation of PEN chromophores, showing that heterofission is observable in weakly interacting systems bridging the gap between studies of doped single crystals [5] and strongly coupled systems such as heterodimers [6]. Our approach allows continuous tuning of the optical bandgap along with the singlet and triplet energies by varying the mixing ratio without significant impact on PEN homofission time constants.

Transient Strain Induced Electronic Structure Modulation in a Conducting Polymer Imaged by Scanning Ultrafast Electron Microscopy Taeyong Kim, Saejin Oh, Usama Choudhry, Carl Meinhart, Michael L. Chabinyc and Bolin Liao; University of California, Santa Barbara, United States

Understanding the opto-electronic properties of conducting polymers under external strain are essential for their applications in flexible opto-electronic and photovoltaic devices. While prior studies have highlighted the impact of static strain applied on a macroscopic length scale, accessing structural relaxation under the local transient deformation was challenging due to the lack of spatiotemporal resolution using conventional methods. Here, we employ the newly developed scanning ultrafast electron microscopy (SUEM) to image the dynamical effect of the photo-excited transient strain in poly(3-hexylthiophene) (P3HT) facilitated by high space-time resolutions. We observe that the photo-induced SUEM contrast, corresponding to the local change of secondary electron emission, exhibits a ring-shaped spatial profile with a rise time of around 500 ps, beyond which the profile persists near the absence of spatial diffusion. We attribute the observation primarily to the electronic structure modulation induced by a local strain field owing to high elastic modulus, as supported by a finite-element numerical analysis. Our work provides insights into tailoring opto-electronic properties using transient mechanical deformation in conducting polymers, and demonstrates the versatility of SUEM to study photo-physical processes in various materials.

Energy Transport Processes in Hybrid Perovskite Nanomaterials William Tisdale; Massachusetts Institute of Technology, United States

Hybrid organic-inorganic halide perovskites are a newly rediscovered class of solution-processable semiconductor materials with surprisingly promising optoelectronic performance. When fabricated in a nanostructured form – either as layered 2D quantum wells or colloidal nanocrystals – hybrid perovskite nanomaterials exhibit a combination of interesting properties revealing both quantum mechanical and classical composite effects. In this talk, I will discuss the thermal, electronic, and excitonic properties of hybrid perovskite nanomaterials as a function of composition, structure, and temperature – and what these experimental observations tell us about the interactions between the organic and inorganic subphases of this interesting class of materials.

2:30 PM EQ12.02.05
Defects in Tin Halide Perovskites Antonella Treglia[1,2], Isabella Poli[1], Samuele Martani[1,2], Giulia Folpini[1], Alex Barker[1] and Annamaria Petrozza[1]; [1]Istituto Italiano di Tecnologia (IIT), Italy; [2]Politecnico di Milano, Italy

Tin halide perovskites (THPs) have emerged as a promising alternative to Lead Halide Perovskites (LHPs). The interest has grown not only because of the reduced environmental toxicity, but also due to the narrow bandgap (between 1.3 and 1.4 eV). We have recently reported that the optoelectronic quality of Sn-based perovskites is inherently comparable to LHP.[1] Despite this, device efficiency and stability are still limited. [2] Sn-based perovskites show a very interesting interplay of shallow and deep defects that can be either stable in the bulk or at the surface of the material. The dominant effect of one or the other can be tuned by differentiating the fabrication process. Even though there is general agreement on the beneficial effect of additives (mostly SnF_2 [3,4]) the mechanisms at the basis of the observed improvement in optoelectronic properties are yet not understood.

We have unraveled the optoelectronic properties of $FA_{0.85}Cs_{0.15}SnI_3$ thin films providing a comprehensive picture of the competing radiative and non-radiative recombination processes with a combination of steady-state, time-resolved, and pump-probe spectroscopic techniques. We also discuss the origin of these competing processes in relation to the presence of additives. The interpretation of experimental results is supported by simulations describing free and trapped-carrier dynamics in a simplified system.

We show that the content of Sn^{4+} in the precursors' solution has a critical effect on optoelectronic properties drastically reducing the radiative efficiency. We suggest that surface Sn(IV), incorporated in the film from solution, might act as an electron trap enhancing non-radiative recombination that results dominant over doping-induced monomolecular radiative recombination.[5] A moderated improvement of optoelectronic properties upon SnF_2 addition could still not match the performances of the pristine sample. This suggests that the introduction of the additive on one side might reduce the doping but conversely introduces additional non-radiative decay channels that fundamentally limit the radiative efficiency. The optimal percentage is not generally fixed but depends on the initial oxidation state of the precursors. We eventually show that an excess of the additive creates a Sn-rich growth condition that might result in the formation of deep defects[6], with an overall detrimental effect on optoelectronic performances.

2:45 PM *EQ12.02.06
Hot Exciton Dynamics in Two-Dimensional Organic-Inorganic Hybrid Perovskites Daniel Straus[1,2], Sebastian Hurtado Parra[1], Natasha Iotov[1], Qinghua Zhao[1], Michael Gau[1], Patrick Carroll[1], James Kikkawa[1] and Cherie R. Kagan[1]; [1]University of Pennsylvania, United States; [2]Princeton University, United States

Two-dimensional, organic-inorganic hybrid perovskites (2DHPs) are stoichiometric compounds composed of alternating sheets of corner-sharing, metal-halide octahedra and organoammonium cationic layers. We study 2DHPs containing single lead iodide layers separated by intervening substituted,

phenethylammonium (PEA) cations with the chemical structure (x-PEA)$_2$PbI$_4$, where x=F, Cl, Br, or CH$_3$. These 2DHPs form type-I heterojunctions in which excitons and carriers are strongly confined to the lead halide layers with exciton binding energies > 150 meV. We use x-ray diffraction and variable-temperature steady-state and time-resolved absorption and photoluminescence (PL) measurements to uncover the correlation between their structure and photophysical properties. (PEA)$_2$PbI$_4$ excitonic absorption and PL spectra at 15 K show splittings into regularly spaced resonances every 40-46 meV [1]. Anti-Stokes hot exciton PL is observed at the same energy as the optical absorption resonances. Replacing a single atom in the *para* position of the PEA-cation phenyl group increases its length and therefore the interlayer spacing, but leaves the cross-sectional area unchanged and results in structurally similar metal halide frameworks [2]. As the cation length increases, the absorption spectra broaden and blueshift, but the PL spectra remain invariant. Substitution in the *ortho* position with progressively larger cations increasingly distorts and strains the inorganic framework [3]. Ortho substitutions change the number of and spacing between the discrete excitonic resonances and increase the hot exciton PL by >10X. By correlating the atomic substitutions on the cation with changes in the excitonic structure, we show that the origin of the discrete excitonic resonances is consistent with a vibronic progression caused by strong exciton-phonon coupling to a phonon on the organic cation. The properties of 2DHPs can be tailored by the selection of the cation without directly modifying the inorganic framework.

Multidimensional Coherent Spectroscopy of Perovskite Nanocrystals Steven Cundiff[1], Albert Liu[1], Gabriel Nagamine[2], Diogo Almeida[2] and Lazaro Padilha[2]; [1]University of Michigan, United States; [2]Universidade Estadual de Campinas, Brazil

Perovskite nanocrystals have attracted much attention recently because of their high luminescence quantum efficiency compared to traditional nanocrystals. We have used multidimensional coherent spectroscopy to study excitonic states in perovskite nanocubes and nanoplatelets at low temperature.

The studies reveal coherences involving triplet states of a CsPbI$_3$ nanocube ensemble [1]. Picosecond time scale dephasing times are measured for both triplet and inter-triplet coherences, from which we infer a unique exciton fine structure level ordering composed of a dark state energetically positioned within the bright triplet manifold.

In an ensemble of colloidal CsPbI$_3$ perovskite nanoplatelets, we determine the homogeneous line broadening [2]. We demonstrate a dependence of not only their intrinsic line widths but also of various broadening mechanisms on platelet geometry. We find that decreasing nanoplatelet thickness by a single monolayer results in a 2-fold reduction of the inhomogeneous line width and a 3-fold reduction of the intrinsic homogeneous line width to the sub-millielectronvolts regime. In addition, our measurements suggest homogeneously broadened exciton resonances in two-layer (but not necessarily three-layer) nanoplatelets at room-temperature.

These results provide new insight into the coherent dynamics of excitonic states in perovskite nanocrystals as well as information about the underlying electronic states.

4:30 PM EQ12.03.02
Nanoscale Chemical Heterogeneity Dominates the Optoelectronic Response over Local Electronic Disorder and Strain in Alloyed Perovskite Solar Cells Kyle Frohna[1], Miguel Anaya[1], Stuart Macpherson[1], Jooyoung Sung[1], Tiarnan A. Doherty[1], Yu-Hsien Chiang[1], Andrew Winchester[2], Keshav M. Dani[2], Akshay Rao[1] and Samuel D. Stranks[1,1]; [1]University of Cambridge, United Kingdom; [2]Okinawa Institute of Science and Technology, Japan

Halide perovskites perform remarkably in optoelectronic devices including tandem photovoltaics [1,2]. However, this exceptional performance is striking given that perovskites exhibit deep charge carrier traps and spatial compositional and structural heterogeneity[3-5], all of which should be detrimental to performance. In this presentation, I will discuss how we resolve this long-standing paradox by providing a global visualisation of the nanoscale chemical, structural and optoelectronic landscape in halide perovskite devices[6]. This was made possible through the development of a new suite of correlative, multimodal microscopy measurements combining quantitative optical spectroscopic techniques and synchrotron nanoprobe measurements. We show that compositional disorder dominates the optoelectronic response, while nanoscale strain variations, even of large magnitude (~1 %), have only a weak influence. Nanoscale compositional gradients drive carrier funneling onto local regions associated with low electronic disorder, drawing carrier recombination away from trap clusters associated with electronic disorder and leading to high local photoluminescence quantum efficiency. These measurements reveal a global picture of the competitive nanoscale landscape, which endows enhanced defect tolerance in devices through spatial chemical disorder that outcompetes both electronic and structural disorder.

Understanding the Mechanistic Role of Atomic Doping in Perovskite Nanocrystals to Enhance Their Luminescent Properties Sascha Feldmann; University of Cambridge, United Kingdom

Nanocrystals based on halide perovskites offer a promising material platform for highly efficient lighting and as quantum emitters. Using transient optical spectroscopies supported by ab initio calculations, we study excitation recombination dynamics in atomically doped lead halide perovskite nanocrystals which exhibit dramatically improved luminescent properties.
Unexpectedly, we find an increase in the intrinsic excitonic radiative recombination rate upon doping, which is typically a challenging material property to tailor. We can attribute the enhanced emission rates to increased exciton localization through lattice periodicity breaking from dopants, which increases exciton effective masses and overlap of electron and hole wavefunctions and thus the oscillator strength.
The important interplay between electronic and structural effects involving dopant and halide ions will be elucidated. Our report of a generalizable strategy for improving luminescence efficiencies in perovskite nanocrystals will be valuable for maximizing the performance of light-emitting applications.

5:00 PM EQ12.03.04
Observation of the Chiral Phonon Activated Spin Seebeck Effect Kyunghoon Kim[1], Eric Vetter[1], Liang Yan[2], Yu Yang[3], Xiao Li[3], Lifa Zhang[3], Jun Zhou[3], Wei You[2], Dali Sun[1] and Jun Liu[1]; [1]North Carolina State University, United States; [2]University of North Carolina at Chapel Hill, United States; [3]Nanjing Normal University, China

Utilization of the interaction between spin and heat currents is the central focus of the field of spin caloritronics. The recent emergence of chiral phonons possessing angular momentum arising from the broken symmetry of the lattice creates the potential for generating spin currents at room temperature in a non-magnetic material in response to a thermal gradient, precluding the need for an applied magnetic field or polarized ferromagnetic contacts. In this talk, we will show the observation of spin currents generated by chiral phonons in a two-dimensional layered hybrid organic-inorganic perovskite semiconductor implanted with chiral cations when subjected to a thermal gradient. Identified by transient magneto-optical Kerr effect measurements, the spin polarization direction shows a strong dependence on the chirality of the semiconductors. Our findings indicate the potential of chiral phonons for spin caloritronic applications and offer a new route toward spin generation in the absence of magnetic materials.

Probing Carrier Dynamics in Liquid Phase Exfoliated Graphene via Terahertz Spectroscopy Harrison Loh, Alan D. Bristow and Kostas Sierros; West Virginia University, United States

Liquid phase exfoliation (LPE) of graphene nanosheets from bulk graphite powders is of interest in materials science for graphene production because of the potential for environmentally benign production using green and non-toxic solvents in addition to well defined and controllable chemistry. Graphene flakes are suitable for many solution processing and fabrication methods such as direct ink writing for applications ranging from printable electronics and energy storage to optoelectronics and sensing. Because many of the desired applications for graphene are centered around its electrical conductivity and hence carrier transport, it is important to measure carrier conductivity and mobility, and correlate the finds with the LPE procedures for optimizing and tailoring the synthesis. To this end, terahertz time-domain spectroscopy is employed as a non-contact method of probing the carrier transport for a variety of graphene layers and graphite powders. Fitting the data to transport models, such as variants of the Drude model, provide conductivity and mobility characteristics that can be linked to microscopic scattering mechanism that are related to the LPE process. This characterization is expected to inform the preparation of exfoliated flake materials for more desirable properties for electronic and optoelectronic applications.

Composite Fast Scintillators Based on Fluorescent Metal–Organic Framework Nanocrystals Angelo Monguzzi; Università degli Studi di Milano-Bicocca, Italy

Scintillators are materials that produce light pulses upon interaction with ionizing radiation, therefore they are widely employed in radiation detectors. In advanced medical-imaging technologies, fast scintillators enabling a time resolution of tens of picoseconds are required to achieve low-noise and fast imaging at the millimeter length scale. [1] Because, commonly used bulk and nanostructured materials, both organic and inorganic, does not offer the synthetic versatility required to have full control over the properties affecting the time resolution, composite systems are currently intensively investigated with the aim to overcome the performance traditional scintillators. [2]

We demonstrate that composite materials based on fluorescent metal–organic framework (MOF) nanocrystals can work as fast scintillators. We present a prototype scintillator fabricated by embedding MOF nanocrystals in a polymer. The MOF comprises zirconium oxo-hydroxy clusters, high-*Z* linking nodes interacting with the ionizing radiation, arranged in an orderly fashion at a nanometric distance from 9,10-diphenylanthracene ligand emitters. Their incorporation in the framework enables fast sensitization of the ligand fluorescence, thus avoiding issues typically arising from the intimate mixing of complementary elements. This proof-of-concept prototype device shows an ultrafast scintillation rise time of ~50 ps, thus supporting the development of new scintillators based on engineered fluorescent MOF nanocrystals. We further developed the scintillating MOF concept by realizing hetero-ligand

fluorescent nanocrystals with large Stokes shift of 750 meV showing a fluorescence quantum efficiency as a large as 70%. The Stokes shifted emission is successfully activated by diffusion-mediated non-radiative energy transfer within the crystalline framework between the co-ligands, thus obtaining a fast scintillator with zero re-absorption effects that it strictly required for high-resolution medical imaging and other applications involving the detection of high energy radiation and particles.

Resolve Temporal Changes in the Excited State Lifetimes of Single Quantum Dots by Statistical Methods Yonglei Sun and Jing Zhao; University of Connecticut, United States

A mechanistic understanding of the photo-excited states in colloidal quantum dots (QDs) is the essential step toward unleashing their full potential in various optoelectronic applications. Fluorescence spectroscopy at the single-particle level is a powerful tool to study the excited states in QDs and has revealed a number of phenomena such as photoluminescence (PL) intensity blinking and lifetime blinking in recent decades. However, interpreting fluorescence data of single QDs is still challenging to date. For one thing, excited state lifetimes and PL intensities of single QDs are correlated, but unfortunately the fluctuation of PL intensity in single QDs is non-ergodic. Moreover, the PL signal from single QDs is often weak and noisy because the single QD emission is intrinsically weak, and current detection efficiency of single-photon detectors is far from perfect. These effects become even more pronounced when studying excited state lifetimes of single QDs, for the accuracy and reliability of derived lifetimes depend upon the purity and size of the data. So far, most studies analyzed excited state lifetimes of single QDs without preselecting the data or preselected the data by setting subjective bins and/or thresholds. As a result, the excited state lifetimes were actually derived from mixed states and lack reproducibility, from where the true photophysics may be blurred. To overcome these difficulties, we utilize statistical methods to derive well-defined excited state lifetimes of single QDs. We employ change-point analysis to break down the arrival time series of compact CdSe/CdS core/shell QDs so that the consecutive bins that belong to the same state could be analyzed altogether. We then perform multi-exponential fitting and tests of significance to verify that in the single QD PL decay curves there is an additional lifetime component whose value is roughly half of that of the single exciton lifetime. The additional lifetime component in this type of QDs is assigned to lifetime blinking that happens too fast to be detected by traditional binning analysis methods. We propose that lifetime blinking happens when a negative trion forms in the core of a QD after photoexcitation while non-radiative processes are not activated. However, the easy accessibility to efficient non-radiative processes results in the short durations of lifetime blinking events in this type of QDs.

Ultrafast Pump-Probe Microscopy Investigation of the Carrier Dynamics in Anisotropic Rhenium Disulfide (ReS_2) Nanoflakes Sarah Sutton, Jason Malizia, Alexis Glaudin, Cullen Walsh and John Papanikolas; University of North Carolina at Chapel Hill, United States

We have studied the anisotropic optical and electronic properties of ReS_2 flakes using ultrafast pump-probe microscopy. In contrast to other highly symmetric TMDCs like MoS_2 and WS_2, ReS_2 remains a direct bandgap semiconductor regardless of the number of layers due to its low-symmetry distorted 1T crystal structure. This low symmetry also gives rise to anisotropic optical and electronic properties. We have used polarization-resolved pump-probe microscopy to investigate the anisotropic carrier dynamics in ReS_2 nanoflakes. In these experiments, a localized region on a single nanoflake is excited with a linearly polarized 440 nm femtosecond laser pulse focused through a microscope objective. A second 880 nm laser pulse with variable arrival time and polarization probes how the excitation evolves in time. Carrier recombination dynamics were studied by measuring the difference in the transmission of the 880 nm probe as its time delay increases with respect to the initial 440 nm pump. At fixed time delays, changes due to polarization were resolved by rotating the probe polarization. The resulting polar plots illustrate how changes in excited carrier population influence the anisotropic optical properties in ReS_2 nanoflakes.

Late News: Spin-Orbit Driven Terahertz Optical Response in Ferromagnetic Fe-Co-Al Alloys Ming Lei and Sinisa Coh; University of California, Riverside, United States

We study the optical conductivity response of simple ferromagnetic alloys driven by spin-orbit coupling. The spin-orbit coupling leads to a band splitting near the Fermi surface in the range of 10-100 THz. This band-splitting energy range provides an opportunity to study the optical conductivity in the THz regime. The optical conductivity response is sensitive to the details of the structure and chemical composition. For simple alloys, like Fe-Co alloys, we find that there is not much dependence of optical conductivity response in the THz range. However, we find the optical conductivity response changes sign from positive in Fe to negative in Fe-Al alloys. Furthermore, those features are washed away at 10 THz but remain only at 100 THz because of the short electron lifetime.

11:45 AM EQ12.04.06
Probing Structural and Compositional Parameters on Hafnia Nanoparticles with Up-Conversion Xavier H. Guichard and Alessandro Lauria; ETH Zurich, Switzerland

NIR-Vis up-conversion (UC) plays a key role in many emerging applications such as theranostics, solar energy harvesting, sensing and others.[1] While rare earth (RE) up-conversion luminescence in fluoride nanoparticles is extensively studied,[2] fewer reports are available on RE-doped metal oxide UC nanoparticles, despite their high chemical stability. In particular, HfO_2 nanocrystals seem to be a promising alternative because of their high inertness and biocompatibility.[3] Nevertheless, the polymorphism observed in hafnia when high RE doping levels are used, prevents a clear understanding of the parameters relevant for controlled and improved UC. Therefore, a finer control over doping levels and crystal structure is necessary to optimize the optical performance.

In this work, we studied the influence of structural and compositional modifications on the up-conversion luminescence (UCL) recorded in Er/Yb co-doped hafnia nanocrystals obtained by a colloidal solvothermal synthesis. The up-conversion characteristics of the materials were monitored in dependence of structural parameters such as crystal size and lattice symmetry, determined by means of X-ray diffraction and transmission electron microscopy (TEM), and originating from the multifunctional doping.[4] We report that the cubic polymorph of hafnia expresses much higher up-conversion efficiency with respect to monoclinic nanoparticles. On the other hand, the elemental analysis carried out by TEM energy diffusive X-ray spectroscopy (EDS) allowed us

to correlate the composition of Er/Yb/Lu:HfO_2 with the main UC features like efficiency and the ratio between green and red emission deriving from radiative recombination on Er^{3+} centres. These results give useful insights about the phenomena responsible for UCL features in hafnia nanocrystals, enabling their employment in various fields, thanks to improved UC intensities and control over the emission profile. Moreover, the experimental platform described here permitted to possibly explain the inhomogeneity of doping in mixed polymorphs by analysing UCL profiles as probes of the local rare earth environment.

SESSION EQ12.05: Strong Light-Matter Interactions and Quantum Phenomena I
Session Chair: Carlos Silva
Wednesday Afternoon, December 1, 2021
Hynes, Level 2, Room 207

1:30 PM *EQ12.05.01
Nanostructured Materials for Infrared Light-Emission Stephane Kena-Cohen; Polytechnique Montreal, Canada

In this talk we will describe recent advances in our group towards developing efficient infrared emissive devices using nanostructured materials. First, we will discuss the realizing of ultrastrong light-matter coupling in microcavities containing dense films of single chirality semiconducting nanotubes. We will show that this allows for hybridization with the K-momentum dark exciton and the bright direct exciton mediated by the optical field. As a result, new opportunities arise for enhancing the luminescence efficiency by bypassing losses associated to the optically forbidden dark exciton transition.

We will then describe our work on the spectroscopy and realization of LEDs using the two-dimensional (2D) semiconductor black phosphorus (BP). Black phosphorus is unique amongst 2D materials in that it possesses a direct bandgap, which is highly tunable from 0.3 eV in the bulk, to ~2 eV at the monolayer level. In addition, it possesses significant in-plane anisotropy, with the transition dipole moment strongly oriented along the armchair direction. We will describe the first realization of LEDs based on BP, which rely on the use of BP/Molybdenum disulfide heterojunctions. These emit at 3.8 um with an internal quantum efficiency of ~1%. Then, we will discuss strategies for increasing the scalability of black phosphorus devices through the use of solution-processing technique and the realization of cm x cm-scale homogeneous thin films of BP-fullerene via the Langmuir-Blodgett technique. This will highlight an outstanding problem in the community in understanding the strong discrepancy between the optical response of nanosheets as compared to bulk crystals. We will postulate on the likely origin of this discrepancy.

2:00 PM EQ12.05.02
Charge Accumulation Driven by Fluid-Like Flow of Quasiparticles in a Semimetal WTe_2 at Room Temperature Young-Gwan Choi[1], Manh-Ha Doan[1], Maxim N. Chernodub[2,3] and Gyung-Min Choi[1,4]; [1]Sungkyunkwan University (SKKU), Korea (the Republic of); [2]Université Tours, France; [3]Far Eastern Federal University, Russian Federation; [4]Institute for Basic Science, Korea (the Republic of)

Recently, the fluid-like behavior of charge carriers in condensed matter systems has attracted much interest. For example, the ultraclean graphene can host a hydrodynamic charge flow at low temperatures, when momentum conserving carrier-carrier scattering is much faster than momentum relaxing scattering. In analogy with whirlpools in flowing water, the viscous electronic flow generates vortices in the electronic fluid in graphene. The vortices drive electric current against an applied field, resulting in a negative nonlocal voltage near current sources and drains. The alternating, sign-flipping pattern in the *voltage* close to the contacts is an experimentally detectable signature of the electronic viscous behavior.
We observe visually similar *charge*-alternating accumulation patterns in tungsten ditelluride in the semimetallic phase at room temperature by using a polarization-sensitive laser microscopy technique with an electrical bias. To observe charge distribution, we utilize an electro-optical effect, which is a polarization variation resulting from optical refractive index change due to the local carrier density variation. The spatial charge distribution shows exceptionally long relaxation profiles, ~1.4 μm, which are much more extended than a charge screening length in conventional semimetals (usually a few nanometers). We analyze that the nonlocal negative charge current and the sizeable spatial size of the charge domains are supported by the long recombination time of electron-hole pairs in this nearly-compensated two-component Weyl semimetal.
We show theoretically that these peculiar charge accumulation patterns appear due to the unbalanced diffusive behavior of electrons and holes. Our analytical calculations in a two-component model indicate that the Ohmic electric current can produce hydrodynamic-like whirlpool structures in the neutral electron-hole current close to the injection contacts. The whirlpools in the neutral current spatially correlate with the charge accumulation regions. We argue that it is the backflow of a neutral current which leads to the experimentally observed exotic alternating charge distribution near the contacts. Moreover, the fluid-like behavior of the neutral quasiparticle current can be described in terms of a modified Navier-Stokes equation equipped with higher-derivative terms.
We find that the extremely long relaxation length and alternating distribution of charge in semimetal WTe_2 can be described by the pseudo-hydrodynamic flow of neutral quasiparticle. We expect that the unconventional flow of neutral quasiparticle in WTe_2 is responsible for many interesting physical effects at room temperature.

2:15 PM EQ12.05.03
Molecular Polaritons Generated from Strong Coupling between CdSe Nanoplatelets and a Dielectric Optical Cavity Liangyu Qiu, Arkajit Mandal, Ovishek Morshed, Mahilet Meidenbauer, William Girten, Pengfei Huo, Nick Vamivakas and Todd Krauss; University of Rochester, United States

Coupling electronic states of molecules or nanoparticles to the quantized radiation field inside an optical cavity creates a set of new photon-matter hybrid excitations, called polaritons. As opposed to atoms, the vibrational modes of molecules provide new degrees of freedom to mediate the quantum transduction between electronic and photonic states, offering new paradigms for quantum materials and chemical science. We will discuss the formation of CdSe nanoplatelet (NPL) exciton-polaritons in a distributed Bragg reflector (DBR) cavity [1]. The molecule-cavity hybrid system is in the strong coupling regime with an 83 meV Rabi splitting, characterized from angle resolved reflectance and photoluminescence measurements. Mixed quantum-classical dynamics simulations are used to investigate the polariton photophysics of the hybrid system by treating the electronic and photonic degrees of freedom (DOF) quantum mechanically and the nuclear phononic DOF classically. Our numerical simulations of the angle-resolved photoluminescence (PL) agree extremely well with the experimental data, providing a fundamental explanation of the widely-observed asymmetric intensity distribution of the upper and

lower polariton branches. Our results also provide mechanistic insights into the importance of phonon-assisted nonadiabatic transitions among polariton states, which are reflected in the various features of the PL spectra. This work provides a facile and direct path for the coupling of nanoparticle electronic states with the photon states of a dielectric cavity to form a hybrid system, and provides a new platform for investigating cavity-mediated physical and chemical processes, providing the emerging quantum information science field the knowledge for preparing next generation quantum systems.

Elucidation of Ultrafast Photophysics in Carbon Nanotube Exciton-Polaritons Using 2D White-Light Spectroscopy Minjung Son, Ryan Allen, Abitha Dhavamani, Michael Arnold and Martin Zanni; University of Wisconsin–Madison, United States

Semiconducting carbon nanotubes (CNTs) are promising candidates for next-generation optoelectronic and photovoltaic devices due to their strong absorptivity and easily tunable photophysical properties. However, device performance is typically limited by sub-10 nm exciton diffusion lengths as well as energy loss via trap states and non-radiative pathways. An emerging approach that has the potential to overcome these limitations is to utilize hybrid light-matter states known as exciton-polaritons, where the strong coupling between photons and excitons leads to energy delocalization over the length of the entire cavity, which is typically hundreds of nanometers. We demonstrate the fabrication of a donor-acceptor polaritonic system bearing semiconducting single-walled CNTs with two different band gap energies, and characterization of the energy flow therein using transient reflection and two-dimensional white-light (2DWL) spectroscopies. The CNT layers are spatially separated by a 150-nm thick insulating polymer layer, ruling out the possibility of energy transfer due to direct donor-acceptor contact. The transient and 2DWL spectra reveal a 300-fs growth of the lower-polariton excited-state population upon photoexcitation into the higher-lying upper-polariton state, indicative of a polariton-assisted long-range energy transport process over a ~300-nm distance. These results highlight the potential of polaritonic microcavities as a tool for tailoring and optimizing material properties toward desired device performance.

2:45 PM EQ12.05.05
Modification of High-Harmonic Generation in Non-Relativistic Quantum Electrodynamics Davis Dave Welakuh Mbangheku and Prineha Narang; Harvard University, United States

Experiments at the intersection of condensed matter physics and chemical dynamics are now able to control and alter the properties of quantum matter on demand in regimes of strong-coupling. In such experiments, strongly coupling the complex matter system to a mode of an optical high-Q cavity leads to the emergence of hybrid light-matter states that influence the physical, chemical and spectroscopic properties of the matter system. An example of a physical process that can be modified is second-harmonic generation (SHG) where the efficiency of the process can be increased by strongly coupling to photons [1, 2]. To date, an *ab initio* approach to this process has not been investigated in the context of strong light-matter coupling. In this context, we present an *ab initio* strong light-matter description of SHG from a molecular system within the framework of quantum-electrodynamical density functional theory (QEDFT) [3, 4]. We investigate the efficiency of the process for a single molecular system coupled to a cavity mode as well as for the case of collectively coupled molecules. From these first principles calculations, we deduce how collective strong coupling influences non-linear properties of the matter system. Also, we show the spectrum of the photon field of the corresponding SHG in this talk.

First *In Situ* THz Measurements on Organic Electrochemical Transistors—Accessing Intrinsic Conductivity of Bipolarons and Polarons Gonzague Rebetez, Dimitra Tsokkou, Olivier Bardagot, Julien Réhault and Natalie Banerji; University Bern, Switzerland

Organic electrochemical transistors (OECTs) are highly sensitive sensors used in increasingly challenging biologic applications such as wearable textiles with integrated biosensors and *in vivo* recording of brain activity.[1,2] They can be described as an ionic circuit embedded with an electronic circuit. When gating the OECT with a voltage bias, ions penetrate and modifiy the doping level of the organic channel thereby changing its conductivity at both macro- and microscopic scales.

One of today's challenges to further develop this promising technology lies in the fundamental understanding of the interplay between doping level and conductivity. [3] Previous investigations have addressed this question via macroscopic approaches which are inherently sensitive to the device geometry and morphology.[3-4] In this work, we propose an innovative *in situ* bottom-up approach that alows the determineation of the intrinsic conductivity of bipolarons and polarons.

We use UV-VIS-NIR absorption spectroelectrochemistry combined with a multivariance curve resolution (MCR) analysis [4] to extract the neutral, polaron and bipolaron populations at different voltages. The microscopic conductivity is then probed via *in situ* THz spectroscopy [5], which represents the first measurement of this kind on OECTs. For archetypal PEDOT:PSS-based OECTs, we find that bipolarons are slightly more localized than the polarons and thus demonstrate a lower microscale mobility. However, the higher density of charges in bipolarons counterbalances their lower mobility and explains why bipolarons largerly contribe to the total microscale conductivity.

Finally, we will present the two main perspectives of this new THz measurement technique in the field of OECTs:

1. Combined with macroscopic conductivity measurements, microscopic conductivity offers the prospect to disentangle underlying mechanisms limiting long-range charge transport such as device geometry and/or morphological features.

2. Determining the fundamental conductivity properties of doped species like bipolarons and polarons represents a necessary step to push microscale modelling of devices by linking the doping level and conductivity at the smallest possible level.

Spectrally Resolved Ion Dynamics in Mixed Ionic-Electronic Conducting Polymers with High Spatial and Temporal Resolution Scott T. Keene[1], Raj Pandya[1], Iuliana P. Maria[2], Maximillian Moser[2], Christopher Schnedermann[1], Iain McCulloch[2,3], Akshay Rao[1] and George G. Malliaras[1]; [1]University of Cambridge, United Kingdom; [2]University of Oxford, United Kingdom; [3]King Abdullah University of Science and Technology, Saudi Arabia

Mixed ionic-electronic conducting polymers have recently emerged as a promising material choice for bioelectronic devices due to their low impedance, soft mechanical properties, and ability to transduce ionic signals to electronic currents.[1] The unique behaviour of mixed conducting polymers arises from ion intercalation through the bulk of the material which can modify the oxidation state, and therefore charge carrier concentration, of the semiconducting polymer backbone. However, the physics of ion-doping in polymers is still unclear[2] with increasingly complex experiments and models being developed to capture the internal electric fields,[3] ionic distributions,[4] and structure-property relationships.[5] Here, we utilize the electrochromic response of mixed conducting polymers to monitor ion motion optically at the length scales (from 1 μm to 500 μm) and timescales (from 1 ms to 10 s) relevant to device operation. We fabricate devices with polymer/electrolyte interface orthogonal to the substrate to limit ionic penetration to single plane, similar to previously investigated “ionic moving front” geometries.[6] Using spectrally- and time-resolved transmission microscopy, we monitor the change in visible light absorption of mixed conducting polymer backbone as it is doped/de-doped when ions flow out of/into the bulk. Contrary to previous work at much larger distances (several mm) and longer times (from 5 s to 1 min),[6,7] we observe a linear relationship between time and the distance of the doping front from the polymer/electrolyte interface. Furthermore, the results reveal unintuitive relationship between the phase-front velocity and the applied electrochemical potential, with larger de-doping potentials resulting in slower electrochromic transitions. We explore a range of organic mixed conducting materials, both p-type and n-type, with varying degrees of swelling during bulk doping to identify the structure-property relationships for ion dynamics in mixed conducting polymers. Finally, using finite element analysis, we reconstruct the internal electric field evolution near the polymer/electrolyte interface based on the experimental results. This work helps resolve the fundamental physics of electrochemical doping in mixed conducting polymers and provides guidance for optimizing the polymer microstructure and chemical functionality for improved bioelectronic devices.

Resolving Mixed Electronic-Ionic Transport at Nanometer Length Scales in Polymer Electrochemical Cells Using Color Impedance Spectroscopy Zhiting Chen[1] and Erin L. Ratcliff[2]; [1]The University of Arizona, United States; [2]University of Arizona, United States

Conductive polymers exhibit hybrid electronic-ionic transport properties that are critical to understanding functionality in electrochemical devices for energy conversion and storage and biosensing. Electrochemical impedance spectroscopy enables the resolution of charge transport in both the frequency and energy domains, but often is complicated by complex circuit analysis necessary to estimate non-Faradaic (double layer) and Faradaic (charge transfer) contributions, often where these two events are coupled together. Optical spectroscopies offer specificity but often lack the sensitivity of electrochemical techniques. Ultimately, neither EIS nor spectroscopic methods alone afford the sensitivity and specificity to confidently isolate charge transfer and transport processes in conductive polymer/electrolyte systems.
Herein we demonstrate the use of color impedance spectroscopy (CIS) to resolve electrolyte effects on electrical charge transport in a prototypical material: poly(3-hexylthiophene) (P3HT). In CIS, the modulated transmittance tracks the motion of Faradaic charges in the films via the optical signatures attributed to P3HT polarons with resolution in both energy and frequency. This approach allows for characterization of the dynamics of charge transport in the context of Coulombic binding effect between counterions and polarons. Using CIS, we observe that at low doping potentials, only a small fraction of polarons are actually mobile and respond to electric field modulation at moderate frequencies. We attribute this to the localization of the polarons via long-range Coulombic interactions with counterions; i.e. Coulombic trapping. Increasing the electrochemical doping increases the steady-state carrier density and increases the fraction of mobile carriers. This is consistent with a more homogenous energetic environment, i.e. the reduction in quantity and/or trap energy. The chemical information gained and the CIS method development described here should be instructive for future efforts to quantify charge transfer/transport structure-property relationships, with applications to energy conversion and storage and biosensing.

Study of Structural, Electrical and Optical Properties of Copper Oxide Phase Mixture Thin Films Grown by Pulsed Laser Deposition Rifat Ara A.

Shams[1], Jacob Berry[1], Ariful Haque[2] and Kartik Ghosh[1]; [1]Missouri State University, United States; [2]Texas State University,, United States

CuO and Cu_2O, both being small and direct bandgap materials, have been studied and implemented individually as an active layer of solar cell from early age of manufacturing. A mixture of these two-phase contents at different ratios can bring variance in absorbance and electrical conductivity which can present new and diverse aspect in solar cell fabrication with added efficiency. Previous works was successful to vary the phase mixture and the nanoparticle (NP) structure provided very high absorption co-efficient but poor electrical conductivity. By controlling the PLD parameters and subsequent processing steps we figured out a way to vary the phase mixture of copper oxide thin films to maximize the electrical conductivity and absorption in the solar spectrum. Phase mixture with different CuO/Cu2O ratios was obtained using pulsed laser deposition through varying growth parameters such as oxygen pressure in the chamber and temperature of the substrate. i. To obtain the structure-property correlation we have performed the X-ray diffraction, Raman spectroscopy, scanning electron microscopy, electrical measurements and optical transmittance measurements by UV-VIS spectroscopy on the samples. The TOPAS analysis of the XRD data from all the samples has shown various percentage of CuO and Cu_2O and one of the samples also had metallic Cu phase. Owing to the change in the phase content in the copper oxide thin films we have observed some consistent variations in the electrical and optical properties. And so far, a thin film copper oxide phase mixture (CuO 61.60%-Cu_2O 38.15%) with a thickness of 200 nm yielded an absorption co-efficient of 7.02E+6 cm^{-1} which is greater than that of commercially available pure CuO (1.19E+5 cm^{-1}). The measured resistivity of this sample was obtained to be 0.034 Ω-m indicating a doped semiconducting composite. This phase mixture, with the maximum absorption coefficient and suitable electrical property, can be implemented as the absorption layer of a solar cell which would help attaining maximum efficiency in the copper oxide based low-cost heterojunction solar cell. Moreover, the presence of Cu in one of the sample hints the possibility of NP incorporation with more controlled and reduced amount of copper in the film.

EQ12.07.03
Synthetic Advancements to Control Size, Morphology and Optical and Electrical Properties of Blue-Luminescent Two-Dimensional Silver Phynylselenolate Watcharaphol Paritmongkol, Woo Seok Lee, Tomoaki Sakurada, Wenbi Shcherbakov-Wu, Seung Kyun Ha and William Tisdale; Massachusetts Institute of Technology, United States

Silver phenylselenide (AgSePh) is a blue-emitting two-dimensional (2D) semiconductor with in-plane anisotropy, large exciton binding energy, non-toxic and earth-abundant elemental composition, and a scalable synthetic method that is compatible with modern microelectronics. Unlike transition metal dichalcogenides and 2D layered perovskites, AgSePh features covalent bonding between its organic and inorganic components, becoming a *truly hybrid* organic-inorganic semiconductor with chemical stability and a unique bandgap tunability through organic modification. Although AgSePh contains multiple desirable characteristics for modern electronics, its performance is still limited by the crystal size and quality produced by conventional synthetic methods. In this presentation, we will show two synthetic advancements to produce AgSePh thin films with controllable grain size from <200 nm to >5 µm and AgSePh microcrystals with improved crystal size from ~2 µm to >1mm. Systematic optical and electrical characterizations to confirm higher crystalline quality with lower defect densities in these samples will be presented. Furthermore, mechanistic insight into the improved syntheses will be elucidated, and an application of this knowledge to grow single crystals will be shown. We expect these improved synthetic methods to facilitate the studies on the fundamentals and applications of this exciting new material.

Late News: Photodegradation of Organic Dyes in Single and Multi-Component in the Presence of Titanium Dioxide Nanoparticles Alondra A. Lugo Ruiz, María J. Paz Ruiz and Sonia J. Bailón- Ruíz; University of Puerto Rico at Ponce, United States

Over 17% of water contamination in the world is due to the discharge of wastewater from textile and dyeing industries. These industries use a large portion of organic dyes, which are found to be toxic, carcinogenic, and can be difficult to remove. Conventional treatments have been studied and found to be ineffective for the removal of the dyes. However, one effective way to remove them from our water sources is by a photocatalytic degradation process using semiconductor nanoparticles. Titanium dioxide (TiO_2) is a semiconductor material with intrinsic optical and electronic properties and is one of the most used photocatalyst for the degradation of these organic contaminants. The photocatalytic capacity of TiO_2 nanostructures is based on the generation of electron-hole pairs due to the Ultraviolet (UV) excitation of TiO_2. The objective of this investigation is to assess the organic dyes individually and combined, in the presence of Titanium Dioxide nanoparticles. Photodegradation studies were evaluated in the presence of dyes like Malachite Green Chloride (MG) and Methyl Violet (MV) at different concentrations of TiO_2 nanoparticles (10, 15, 25, and 50 ppm). Following the UV irradiation of the dyes at certain time intervals, it was found that 15 ppm TiO_2 degraded MG and MV more swiftly than the other concentrations, with a result of ~90% and ~98%, respectively. Our future studies include evaluating the photocatalysis of the mixture of both dyes (multi-component) in the presence of TiO_2.

Late News: Electrical Conductivity and Optical Properties of ITO Powder Surface-Modified with Nano-Ni Particles Jeong Hye Jo, Su Hyeong Kim and Young Soo Yoon; Gachon University, Korea (the Republic of)

Generally, ITO thin film is deposited by sputtering which is required a high-vacuum and high-temperature process, resulting in high manufacturing costs. On the other hand, spin coating method has advantages such as efficient cost, simplicity, fast and mass production. So, it can be another method for manufacturing ITO thin films. However, Since the ITO thin films deposited by spin coating method has a porous surface, electrical conductivity is lower than that of ITO thin films deposited by sputtering.
The electronic conductivity of nickel-plated ceramic is improved by electroless Nickel plating, and it is verified that nickel increase conductivity. [1]. In this study, We confirmed with 4-point probe that spin-coating Nickel plated ITO (ITO@Ni) increase electrical conductivity. [2-4] The composition and morphological of nickel deposited on ITO were characterized by transmission electron microscope (TEM) and SEM-EDX analysis. ITO@Ni powder becomes the source of ITO@Ni colloid ink to be used in spin coating. Particle size and ink dispersion were measured by electrophoresis light scattering (ELS). ITO@Ni was deposited by spin coater. Transmittance and conductivity was respectively measured with UV-Visible Spectrophotometer and 4-point probe. When pure ITO and ITO containing 10wt% of nickel were deposited as one layer, the transmittance was lowered from about 97% to 90%. Sheet resistance of ITO@Ni multilayer appears less than 30ohm/square.
As a result, Transmittance and conductivity had a trade-off relationship according to nickel ratio. It is expected that spin-coating ITO@Ni can be used as a transparent electrode without high vacuum and high temperature process.

Late News: Production of Tin Dioxide Nanoparticles in Aqueous Phase Fabio Santiago, Alondra A. Lugo Ruiz and Sonia J. Bailón- Ruíz; UPR Ponce,

Puerto Rico

When mentioning emerging fields, nanoparticle research is at the forefront due to their unique physical and chemical properties. Tin dioxide (SnO_2) is a n-type semiconductor with potential photocatalytic properties, based on the fact that they exhibit a large surface area. Additionally, tin is a nontoxic material and a safe alternative in the cleaning of bodies of water. Considering these facts, this research aims at the production of SnO_2 nanoparticles in aqueous phase to study their spectroscopic properties using characterization techniques, specifically UV-vis and spectrofluorometer analysis.
Tin dioxide synthesis was made in the presence of tin chloride ($SnCl_2$), cetyltrimethylammonium bromide (CTAB), ammonium hydroxide and deionized water. The reaction time was optimized to 6-hours and the fluorescence was studied by using a spectrophotometer evidencing a peak at 403nm when excited at a wavelength of 280nm. While, UV-vis analysis denoted a peak at 303nm.
Taking into consideration SnO_2 spectroscopic properties and expected photocatalytic tendencies, future studies will be focused on the degradation of organic dyes.

Late News: Effect of Various ZnO Interfacial Layer on the Nanostructured Photovoltaic Properties Based on Organic Materials JunYoung Kim, JaeMin Jeon and DongYeol Shin; Gyeongsang National University, Korea (the Republic of)

Recently, research on nanostructured photovoltaic cells based on organic materials has been actively conducted to improve power conversion efficiency through the development of new device structures, synthesis of new organic materials and applied to charge extraction layer. This study applies various ZnO thin films (sol-gel process based on high and low temperature and nanoparticle process) as electron extraction layer in nanostructured photovoltaic cells based on PBDB-T:ITIC, and the correlation between ZnO and photovoltaic cells performance was analyzed. When the ZnO thin film was formed by the high temperature(450°C) sol-gel process, the sheet resistance of ITO electrode was increased up to 5 times. As a result, the power conversion efficiency was low at 4.12%. In the nanoparticle process, butanol-based ZnO has better dispersion and surface properties than IPA-based ZnO, resulting in improved polymer solar cell performance (PCE of 6.35% and 4.58% with butanol and IPA-based ZnO respectively). In addition, ZnO precursor solution with a low-temperature (150°C) sol-gel process was developed, and as a result of applying it as an electron extraction layer of a nanostructured photovoltaic cells, the device performance was greatly improved (PCE of 8.89%). The main reason for the improvement of the device performance is that the ripple-shaped surface is formed, which facilitates extraction of electrons and has excellent surface roughness.

EQ12.07.08
Dichalcogenide Monolayer-Plasmonic Heterostructures Haydee Pacheco and Deirdre O'Carroll; Rutgers, The State University of New Jersey, United States

Investigating the optical properties of transition metal dichalcogenide (TMDs) monolayers has recently become a promising research direction towards direct bandgap two-dimensional (2D) semiconductor applications. Monolayer 2D-TMDs emit light efficiently in the form of two distinct excitonic emission features, referred to as the A–peak (ground state) and B–peak (higher spin-orbit split state). These emission peaks can be tuned to promote a higher intensity ratios and therefore, to reduce the opportunity for undesirable intervalley scattering. Our work provides insight into the degree of valley polarization in MoS2 monolayers and of MoS2/plasmonic/heterostructures that can help maximize the optically–induced valley polarization by inducing a population imbalance between the two inequivalent valleys. Our monolayers are produced by lithium intercalation as well as by epitaxial growth on sapphire, while the heterostructures are fabricated using plasmonic nanostructures such as Ag nanoparticles. We observe that high quality samples produce enhanced emission from the B–exciton relative to the A–exciton, which corresponds to an increased degree of valley polarization. As it turns out, the relative optical orientation of these peaks, occurring at 612 nm and 675nm in MoS2 monolayers, remains efficient even at room temperature. We take advantage of this fact and make use of a modified circular polarization luminescence (CPL) emission spectroscopy system. More specifically, our system consists of a static achromatic quarter wave plate (QWP) that converts L–CPL and R–CPL light to orthogonal linearly polarized light; later both L–CPL and R–CPL states are analyzed by automated rotation of a linear polarizer prior to whole-spectra detection with a CCD spectrometer. We present the analysis of the A– and B–exciton photoluminescence intensity ratio of both intrinsic and induced circular polarization emission in these structures.

Structuring Exciton Transfer Pathways via Angular Control in Metal-Organic Frameworks Ruomeng Wan, Dong-Gwang Ha, Jinhu Dou, William Tisdale and Mircea Dinca; Massachusetts Institute of Technology, United States

Metal-organic frameworks (MOFs) are crystalline materials consisting of organic building blocks and metal clusters. Traditionally known as a versatile system for manipulating chemical processes, MOFs' potential has recently been extended beyond controlling the movement of molecules to structuring the flow of energy. The promise of MOF as a platform for photophysical studies lies in its ability to lock chromophores into a variety of packing distances and geometries. Since photophysical processes are highly sensitive to the communication among neighboring molecules, MOFs provide a synthetic handle for structuring exciton dynamics. Taking advantage of this unique opportunity, herein we present a strategy that allows inhibition of singlet exciton transfer in a spin-selective fashion. The angular arrangement of chromophores inside the donor-acceptor MOF is visualized with high resolution transmission electron microscopy, and the exciton dynamics are probed by time-resolved spectroscopy. Connecting the structural and photophysical properties demonstrates that spin-selective control over exciton transfer can be synthesized with long-range structural order. We envision that this strategy can be applied to increasing the efficiency of photophysical processes that involve interplay between transfer of excitons of different spin states, such as solid-state triplet-triplet annihilation upconversion.

EQ12.07.10
Non-Perturbative Nonlinear Optical Properties of Single Chirality Carbon Nanotube Thin Films Near the Exciton Resonance Pierre-Luc Thériault[1], Abitha Dhavamani[2], Louis Haeberle[1], Michael Arnold[2] and Stephane Kena-Cohen[1]; [1]Polytechnique Montréal, Canada; [2]University of Wisconsin Madison, United States

The lack of materials with large ultrafast nonlinearities currently limits the rise of optical information processing as a solution to efficiently process the ever-growing amount of data collected for big data and artificial intelligence applications. Optical processing schemes still need to interface with electronics for key functions which require nonlinear functions such as switching. Due to the weak nonlinear response of bulk materials, current optical switching technologies function at high threshold power which makes them unpractical. The development of efficient switching would be greatly helped by materials showing a fast and strong nonlinear optical response. Low-dimensional nanostructured materials like carbon nanotubes are predicted to have large and fast nonlinearities. Several groups have attempted to measure optical nonlinearities in single-walled carbon nanotube (CNT) thin films using the Z-scan technique. However, the use of a mixture of chiralities masked the resonant excitonic behavior and the analysis didn't account for the limited validity of common approximations when z-scan is used to study strongly nonlinear or absorbing films. In fact, the common approximations used in Z-scan fail drastically near electronic resonances.

In this work, we study the nonlinear optical properties of single chirality carbon nanotubes thin films using the Z-scan technique at wavelengths ranging from 917 nm to 1550 nm covering the near, on, and off-resonant excitation regime. Our investigation reveals a large enhancement of the nonlinear response near the excitonic resonance (1003 nm) of the film. In this regime, we observe a 15-fold enhancement of the nonlinear parameters. A nonlinear refractive index (n_2) as large as 3.4 +/- 0.2 cm^2/GW and -0.50 +/- 0.06 cm^2/GW are measured on the blue and red sides of the resonance respectively. Large changes in the imaginary refractive index attributable to saturable 1-photon absorption are also observed for the near and on-resonance regimes together. The changes are well into the non-perturbative regime, where variations of the real and imaginary refractive index are on the order of the linear index, for intensities of less than 5 GW/cm^2. To account for the non-perturbative nature of the response, we developed a numerical beam propagation code that extracts the nonlinear properties of the thin film from the transmittance measurement, for an arbitrary nonlinear refractive index model, free of approximations. The strength of the nonlinearities in high-density single chirality CNT thin films, together with their compatibility with the silicon photonics fabrication processes, makes them a promising material for the development of nonlinear devices for optical signal processing.

Late News: Ultrafast Dynamics ff Photoexcited Carriers in Two-Dimensional Transition Metal Oxides and Carbo-Oxides Erika Colin-Ulloa[1], Ryan Hanna[1], Michelle H. Frasch[1], Hussein Badr[2], Kiana Montazeri[2], Michel Barsoum[2], Ronald L. Grimm[1] and Lyubov Titova[1]; [1]Worcester Polytechnic Institute, United States; [2]Drexel University, United States

Enhanced light-matter interactions and high surface to volume ratio in two-dimensional (2D) materials makes them promising candidates for application in solar energy conversion and optoelectronics. Recently, we have reported on a scalable, near ambient bottom-up synthesis of 2D transition metal oxides and carbo-oxides from non-layered precursors. Here we investigate the nature and dynamics of photoexcitations in 2D $TiC_{1-x}O_{1+x}$ and 2D Mn_xO_y using a combination of time-resolved photoluminescence spectroscopy and pump-probe spectroscopy. Both classes of materials are indirect gap semiconductors with the gap as high as 4.1 eV for Ti-based films and as low as 2.37 eV for Mn-based films. However, even high band gap films have considerable optical absorption across the visible range due to pronounced band tail states. Some of the films also exhibit efficient optical emission. Tuning optical excitation from the ultraviolet to the infrared range, we study the transient changes in optical properties and the lifetime of photoexcitations to uncover the nature and origin of the optically active states that play critical roles in solar energy conversion processes.

Sensitive Time-resolved Luminescence Spectroscopy of CIGS Solar Cells Combined with Spatial Resolution Christian Oelsner, Eugeny Ermilov, Volker Buschmann, Frank Birke, Matthias Patting and Rainer Erdmann; PicoQuant, Germany

Over the years, luminescence spectroscopy has established itself as one of the fundamental methods for analyzing the photophysical properties of a variety of samples, ranging from simple organic molecules to semiconductor materials and photovoltaic (PV) devices. Combining spectral and lifetime information of a sample's luminescence signals provide a deeper insight into its photophysical processes. This can be further enhanced by including spatial information. Acquiring steady-state and time-resolved spectroscopic data at multiple, well defined points of interest (POI) of the sample can help in inferring structural-to-photophysical relationships in PV materials. Gathering such information is an important step toward the optimization of structure as well as preparation process of such materials in order to increase the performance of PV devices.

Here we will demonstrate the performance of a spectrometer-microscope assembly based on the FluoTime300 spectrometer and FluoMic add-on for investigating a Copper Indium Gallium Selenide (CIGS) based solar cell in terms of steady-sate and time-resolved luminescence spectroscopy at different micrometer sized POIs. We will show that acquiring data at well defined excitation / detection areas can provide deeper insights into relationships between structure and photophysical behavior of CIGS solar cells. This additional information are not readily available when investigating such a sample with a conventional spectrometer as the luminescence signal is averaged over a much lager area (typically 1 mm^2 or more).

PBI-Based Biomimetic Complex for Efficient Light-Conversion Unveiled via Ultrafast Spectroscopy Vasilis Petropoulos[1], Mattia Russo[1], Francesco Rigodanza[2], Luca Moretti[1], Andrea Sartorel[2], Maurizio Prato[3], Giulio Cerullo[1], Marcella Bonchio[2] and Margherita Maiuri[1]; [1]Politecnico di Milano, Italy; [2]University of Padova, Italy; [3]University of Trieste, Italy

Converting solar energy into chemical energy is a promising strategy towards the production of solar electricity and stored fuels. Until now, most of the supramolecular complexes that undergo symmetry breaking charge separation (SB-CS) process, mimicking the photosynthetic special pair, reveal strong competing pathways of long-lived excitons and/or excimeric traps. Recently, a new supramolecular framework was developed taking inspiration from the minimal component in the photosynthetic organisms, defined as "Quantasome" (QS) [1]. The artificial QS is composed of a self-assembled perylene bisimide (PBI) and a polyoxometalate (POM) catalyst as a guest, building highly ordered three-dimensional (3D) noncovalent assemblies in water.
We study a series of QS assemblies, with a redox-inactive and a redox-active POM catalyst as guest, Q-1 and Q-2 complexes respectively. Structural information extracted from Powder X-Ray Diffraction (PXRD) proves that the QS structures are mimicking the organization of the thylakoids in the granum domain of the chloroplasts.
We perform Ultrafast Transient Absorption (TA) spectroscopy to unveil the photo-physical pathways after photo-excitation. The samples are pumped with a sub-100 fs laser pulse peaked at 520 nm, while the probe pulse covers a broad spectral window spanning from 560 nm to 1000 nm. Q-1 and Q-2 complexes exhibit excited state absorption (ESA) bands originating exclusively from the superposition of PBI radical anion and cation. Our TA data show ultrafast (< 150 fs) and quantitative formation of symmetry-broken charge transfer (SB-CT) excitonic states, delocalized over a number of PBI units. After excitation, there is an evident sharpening of the line-widths accompanied by partial peak-shifts over 0.8 ps timescale, suggesting electronic relaxation towards a more localized lower-energy Charge Separated (CS) state. After the localization of the charges into CS states, the Q-1 and Q-2 complexes follow different excited-state pathways. The Q-1 undergoes bi-exponential recombination, involving photo-generated PBI+ and PBI-, with 80 ps and 1 ns lifetime components. In Q-1, the quantitative SB-CS is followed by long-lived charges with an unprecedented k_{CS}/k_{CR} ratio with respect to geminate rylene-based systems in literature [2]. On the contrary, the Q-2 undergoes 8 ps hole transfer from PBI+ to POM which is followed by bi-exponential recombination, involving photo-generated POM+ and PBI-, with 60 ps and >1 ns lifetime components. In this case, the presence of long-lived charges in the catalytic sites can lead to efficient water splitting.

To investigate the mechanism in QS structures leading to long-lived charges, we performed TA Anisotropy measurements. Anisotropy is sensitive to the relative polarization displacement of the photo-generated charges. We track the anion motion due to the anisotropy of the signal detected at the anion ESA peak (820 nm). The prominent depolarization for Q-1 and Q-2 complexes, suggests that the charges are not localized in the space they were created after photoexcitation, and instead they rapidly move in the 3D space [3]. The overall high anisotropic depolarization denotes that charge pairs in QS undergo an efficient dissociation and have a high mobility, consistent with the observation of long-lived CS states.
Hence, the ability to control the outcome application of the long-lived charges can be obtained through the suitable choice of the guest catalyst in the Quantasome-like self-assembly organization.

Short Excited State Lifetimes Mediate Charge Recombination Losses in Organic Solar Cell Blends with Low Charge Transfer Driving Force Rishi R. Shivhare[1], Gareth J. Moore[1], Andreas Hofacker[2], Sebastian Hutsch[2], Stefan Mannsfeld[2], Frank Ortmann[3] and Natalie Banerji[1]; [1]Department of Chemistry and Biochemistry (DCB), University of Bern, Switzerland; [2]Technische Universität Dresden, Germany; [3]Technische Universität München, Germany

The field of organic photovoltaics (OPV) has undergone a resurgence in recent years owing to the swift increase in efficiency values of the solar cells. Highly efficient OPV systems demand a concomitant increase in the short-circuit current density (j_{SC}) and the open-circuit voltage (V_{OC}). In order to optimize the V_{OC} losses, majority of the high-efficiency OPV systems employ donor:acceptor combinations with near-zero energetic offset for the interfacial charge transfer reaction. In our study, we have investigated a blend of a low optical-gap diketopyrrolopyrrole (DPP) polymer and a fullerene derivative: PC[70]BM, with a near-zero driving force of ~50 meV for the interfacial electron transfer. In order to probe a sequence of events that ultimately lead to the formation of free charges, we employ a series of complementary spectroscopic and theoretical tools. Using femtosecond transient absorption (TA) and electroabsorption (EA) spectroscopy, we quantify the charge transfer (CT) and recombination dynamics and as well as the charge transport at early timescales. Firstly, we observe unusually short S_1 and CT state lifetimes in the investigated system (~13-14 ps) and significant geminate charge recombination (gCR). Secondly, electron transfer is found to be ultrafast with a time constant of ~ 240 fs. The finding of ultrafast electron transfer was found to be consistent with a semiclassical Marcus-Levich-Jortner (MLJ) description at low driving force and low reorganization energy ($\lambda_{reorg.}$). At low S_1-CT offset, a short-excited state lifetime mediates charge recombination because i) back-transfer from the CT to the S_1 state followed by S_1 recombination can occur and ii) additional S_1-CT hybridization can decrease the CT lifetime as a result of intensity borrowing effects. Both effects were confirmed by density functional theory (DFT) calculations. In addition, we employed time-resolved electromodulated differential absorption (EDA) spectroscopy to probe the transport of charge carriers on a sub-nanosecond time scale. We observed relatively slow dissociation of charges (tens of picoseconds) from the interfacial CT state, in contrast to polymer:fullerene blends with high CT driving force. We identify low local charge carrier mobility as a primary reason for the slow rise of the free charge population. Lastly, we performed simulations using a four-state kinetic model using Gaussian manifold of states and thus entailing the effects of energetic disorder (σ). These simulations enabled us to discern the role of interfacial CT state disorder (σ_{CT}) and the energetic disorder in the bulk of the film (σ_{bulk}). Firstly, the simulations reveal that the free charge yield could be increased from the observed 12% to 60% by increasing the S_1 and CT lifetimes to ~ 150 ps. Alternatively, by decreasing the interfacial CT state disorder (σ_{CT}) and increasing the bulk disorder (σ_{bulk}) the yield of free charge generation can be enhanced to 65% despite short excited state lifetimes.

11:00 AM EQ12.08.03

Amplification of Optoelectronic Properties through Homoconjugation in Three-Dimensional Molecular Structures Iain A. Wright; Loughborough University, United Kingdom

The development of new molecular and macromolecular materials for organic light emitting devices (OLEDs) and organic solar cells (OSCs) is constantly evolving thanks to new insights into the interactions between light and matter. There is a great deal of work currently underway towards harnessing useful excited state properties of organic molecules and polymers such as room temperature phosphorescence,[1] thermally activated delayed fluorescence,[2] and singlet fission [3], making use of intermolecular interactions between individual donor and acceptor molecules which can yield efficient luminescence and simple devices.
The influence of three-dimensional molecular topology on the photophysical and electrochemical behaviour of organic semiconducting materials can be truly defining in how well such a molecule performs in any given application. Small changes in, for example, the dihedral angle between two rings in a molecule can make the difference between efficient or poor luminescence, charge transport, processability etc.[4-5]
Structure property relationships which take consideration of molecular geometry in three dimensions are required.
Here, the results of studies on new organic molecules which have been designed to make use of twisted, contorted or otherwise three-dimensionally defined structures will be presented. Using such 3D structures allows us to exploit or enhance photophysical processes towards obtaining higher efficiencies in organic electronic applications.
Particular focus will be given to the exploitation of homoconjugation – the through-space overlap of molecular orbitals – on the enhancement of defining photophysical parameters of new donor-acceptor compounds for use in OLEDs and OSCs. [6]

Energy and Carrier Dynamics in Radical Organic Semiconductors Sebastian Gorgon[1], Qinying Gu[1], Alexander Romanov[2], Feng Li[3], Emrys Evans[4] and Richard H. Friend[1]; [1]University of Cambridge, United Kingdom; [2]University of Manchester, United Kingdom; [3]Jilin University, China; [4]Swansea University, United Kingdom

Radical organic semiconductors have unpaired electrons, leading to unusual physics that can be utilised in next-generation optoelectronics. High stability and luminescence can be achieved by molecular design, thus taming the typical reactivity of radical systems. In particular, emitters based on the tris(2,4,6-

trichlorophenyl)-methyl (TTM) radical moiety have recently been shown to fluoresce within the spin-doublet manifold with near-unity internal quantum efficiency. The ground state open-shell electronic structure, in combination with strong light absorption and emission, makes these materials promising for organic light-emitting diodes and photovoltaics with eliminated triplet losses. The integration of radicals into devices requires a detailed understanding of their fundamental energy and electron transfer mechanisms.

Here, a model system of closed-shell energy donor and open-shell acceptor is used to study energy transfer into radical materials via time-resolved optical spectroscopy, and signatures of direct triplet to doublet energy transfer are observed. In combination with temperature-dependent time-resolved photoluminescence measurements and modelling, these results allow us to propose the mechanism and yield for this process. Additionally, we present new insights into the photophysics of TTM derivatives on picosecond timescales. This work demonstrates a new method of harvesting dark triplet states, enabling lowering efficiency losses in optoelectronic devices.

Non-Destructive Photoluminescence Investigation of PV Devices with High Spatial Resolution Microscope Techniques Christian Oelsner, Volker Buschmann, Felix Koberling, Matthias Patting and Rainer Erdmann; PicoQuant, Germany

Investigations of photovoltaic devices and semiconductors are essential to enhance the efficiency of preparation methods as well as their electronic and optical properties. Different parameters define these properties, e.g., number of defects and trap states, interface interactions, energy and electron transfer behavior and, of course, absorption properties and response to photon stimulation.

Surface characterization of such materials is usually done with scanning electron, scanning tunnel and atomic-force microscopes, which can gather information about homogeneity, conductivity, carrier mobility and defect center of films, semiconductors or within devices. But there still is a lack of information about important parameters that are necessary for understanding and optimizing the preparation and efficiencies of these materials.

We present here how combining time-resolved laser scanning microscopy – offering a broad range of techniques – with a spectrometer results in a valuable and powerful toolbox. This combination of microscopic (e.g., FLIM, PLIM, fast switch between widefield and confocal resolution, or carrier diffusion measurements) and spectroscopic methods (such as time-resolved photoluminescence or wavelength dependent emission scanning) allows investigating the photophysical properties of semiconductors, nanoparticles, QDs, polymers, solid-states as well as nanostructures on a whole new level. This additional information enables gaining a deeper understanding of both photophysical processes as well as structure-property relationships, which will help for the optimization of properties and efficiencies in practical applications.

2:00 PM EQ12.09.02
Plasma-Induced Heating—Interaction Between a Low-Temperature Plasma and Graphene Carla Berrospe Rodríguez, Joseph Schwan and Lorenzo Mangolini; University of California, Riverside, United States

The energetic interaction between low-temperature plasma and the surface of materials produces a phenomenon commonly refer as plasma heating. This phenomenon, which plays a critical part in many plasma-driven processes [1], is very difficult to characterize and therefore poorly understood. Low-temperature plasma is used to activate several important surface reactions, since it can accelerate the surface kinetics, leading to processes such as reactive ion-etching, atomic layer deposition and heterogeneous chemistry, among others. One interesting example is the heat induction due to the recombination of atomic hydrogen at the surface nanoparticles in dusty plasmas to synthetized refractory materials [2]. However, the low rate of heat dissipation from the particles to the background gas, leads to a significant temperature increment and therefore, leaving unknow the real contribution of plasma heating into the temperature profile.
In this work, we present a Raman spectroscopic approach to quantify plasma-induced heating on a two-dimensional material as a surface-sensitive temperature probe. We use graphene because it is atomically thin, and it has a well characterized Raman signature. In addition, is well known that graphene has been implemented into a variety of fields such as sensing, graphene-based catalysis or electrochemical energy conversion and others [3]. The temperature of the plasma- exposed graphene surface is obtained by Raman thermometry characterization [4]. We simultaneously measure the signal intensity of the Stokes and anti-Stokes G Raman band, while plasma impinging in the surface. The measurements are calibrated bringing the graphene temperature up 200 °C, by means of a vacuum chamber-heater, to increase the thermal population of the vibrational modes and therefore enhance the anti-Stokes signal, which is significantly low compared to the Stokes signal at room temperature. When graphene is exposed to a radiofrequency (RF) argon plasma, its temperature raises to approximately 350 °C and its linearly dependent on the plasma input power. We strength our experimental results using a heat transfer model in COMSOL, where we discard the possibility of temperature increment due to gas heating by the plasma. In addition, we find a heating dependence on the plasma composition, where hydrogen-diluted argon decreases the surface temperature as hydrogen concentration increases in exponential-like behavior. Finally, we show evidence of anisotropic etching by hydrogenation, increasing disorder in the material structure and reducing the size of graphene domains. This study highlights the potential of two-dimensional materials, particularly graphene, to understand better plasma related phenomena.

Origin of Photoluminescence from Carbon Dots Nasir Javed, Zhongkai Cheng and Deirdre O'Carroll; Rutgers, The State University of New Jersey, United States

Carbon-based luminescent nanoparticles, which are usually referred to as carbon dots (CDs), are becoming increasingly popular for light-emitting applications due to their attractive optical properties and low-cost synthesis. CDs exhibit strong excitation-wavelength-dependent and -independent photoluminescence (PL) emission that can be tuned throughout the visible spectrum. However, their structure and the origin of their PL emission is still debated. In this study, CDs are synthesized by a solvothermal method using citric acid and 1,5-diaminonaphthlene, and X-ray photoelectron spectroscopy (XPS), UV-visible absorption, PL emission, Fourier transform infrared (FTIR), and Raman spectroscopies are used to investigate their structure and the origin of PL emission. The average size of the purified CDs is 19.5 nm with the majority of particles in the size range of 10 nm to 25 nm. XPS shows that the CDs also contain oxygen (31%) and nitrogen (9%) in addition to carbon (60%). FTIR and nuclear magnetic resonance (NMR) spectroscopy analysis show that the CDs are composed of aromatic as well as aliphatic carbon.
To investigate the photonic properties of the CDs, PL emission from the CDs is studied using different excitation wavelengths in different water-miscible solvents. Two distinct excitation-wavelength-independent PL emission bands are observed from the CDs: one deep violet emission band at 400 nm and another green emission band at ~520 nm. The PL quantum yield (QY) varies from 3.5% to 9.4 % with polarity of the solvents. Time-resolved PL (TRPL) emission measurements reveal that the CDs have short PL lifetime ($\leq$ 8 ns) with a double exponential decay. The excitation-wavelength-independent PL emission, and the short PL lifetime imply that the CDs are likely to be composed of molecular clusters instead of graphitic crystals. Double exponential decay suggests that the CDs may be composed of two different types of fluorophores. The structure and optical properties of individual fluorophores are studied for the first time by dissolving the CDs in low-polarity, water-immiscible solvents, and separating the green-emitting molecules by solvent extraction. The PL QY of the green-emitting molecules after separation increases to 53.6%, and TRPL emission of these molecules decays with a single exponential with a lifetime of 5.8 ns. The structure of the green-emitting molecules is determined by using 1D (^{1}H and ^{13}C) and 2D (^{1}H-^{1}H correlation spectroscopy, ^{1}H-^{13}C heteronuclear multiple quantum coherence and ^{1}H-^{13}C heteronuclear multiple bond correlation) NMR spectroscopies, which reveal that the molecules mainly have aromatic structure with pyridinic nitrogen doping. Finally, time-dependent density functional theory (TD-DFT) calculations are carried out to further study the excited states in the green-emitting molecules and to confirm that the green emission arises from the same molecules. From this study, it is concluded that the CDs are mainly composed of molecular fluorophores and that PL arises from individual molecules within the CD clusters.

Dynamics of Photoexcited Carriers in Single-Crystal BiOI(001)—Interplay Between Charge Carriers, Interfaces and Environment Amy M. Welch, Julia Martin, Erika Colin-Ulloa, Kateryna Kushnir, Leonardo N. Coelho, Katarina M. Himmelberger, Ronald L. Grimm and Lyubov Titova; Worcester Polytechnic Institute, United States

With a 1.8 eV band gap in the red region of the visible spectrum, bismuth oxyiodide (BiOI) may be viable as a top absorber in tandem-junction photovoltaics or a non-toxic photocatalyst for degradation of environmental pollutants. Viability requires understanding the interplay between interfacial chemical states, ambient atmosphere, and the resulting dynamics of photoexcited carriers in this 2D layered material. We synthesized single-crystal BiOI(001) via vapor transport and explored the behavior of optically excited carriers using time-resolved THz spectroscopy (TRTS) and time-resolved photoluminescence spectroscopy (TRPL). Under inert environments or chemical passivation, above-band-gap excitation with UV or blue light yields free carriers with mobilities that rival crystalline silicon, and hundreds-of-picosecond lifetimes that recombine with both band-edge and defect-related emission. In contrast to in vacuo behavior, PL intensities show a rapid and irreversible attenuation with increasing exposure to the 485 nm excitation light. We discuss the results in the context of BiOI for energy harvesting and sensing applications, and highlight pathways for chemical passivation for stable, efficient operation under illumination in air.

Near-Field Optical Microscopy of Silicon Arrays Composed of Subwavelength Light Funnel Arrays Ankit Chauhan[1] and Gil Shalev[2,1]; [1]Ben-Gurion University of the Negev, Israel; [2]Ben-Gurion University of Negev, Israel

Light trapping in arrays composed of subwavelength light funnel arrays (LF arrays) is a promising approach towards efficient broadband absorption of the solar radiation and surface arrays of subwavelength structures has an additional advancement towards ultra-thin photovoltaic (PV) cells. In the following we examine the origin of light trapping enhancement in LF arrays as compared to nanopillar (NP) arrays and we show that light trapping enhancement is due to favorable strong optical coupling between adjacent light funnels which is not realized in NP. We suggest that the enhanced light trapping and absorption in dense LF arrays is governed by strong modal excitation coupled with high filling ratio, unlike the absorption in dense optimized nanopillar arrays which is governed by weak modal excitation and high filling ratio. Finally, we make the distinction between two types of optical overlap: weak overlap in which the coupling between the sparse array modes and the impinging illumination increases with array densification, and strong overlap where the array densification introduces new highly absorbing modes. Finally, the study of the resonant behaviour of silicon non-imaging light concentrators (NLCs) provide a new route for achieving efficient control of both electric and magnetic components of light. We use near-field scanning optical microscopy (NSOM) to measure the near-field light intensity as function of array geometry.

3:00 PM EQ12.09.06
Surface-Mediated Ensemble Energy Transfer in Core-Only CdSe NCs Minhal Hasham and Mark W. Wilson; University of Toronto, Canada

Semiconductor nanocrystals (NCs) exhibit bright, narrow, and size-tunable emission across the visible and infrared spectrum with large absorption cross-sections and high quantum yields. A recent use for NCs gaining interest is triplet fusion based incoherent photon upconversion (TUC), which is a rising strategy to generate emissive spin-singlet states from two spin-triplet excitons. While TUC motifs have found success in biomedical imaging applications and have recently been employed to initiate photochemical transformations, an understanding of sensitization mechanisms is required.

Here NCs are promising sensitizers due to their small exchange splitting and facile surface functionalization routes. These factors allow for minimal energy loss and direct injection of triplets to surface bound transmitters, along with the ability to load >1 transmitter per NC. In the archetypal core-only CdSe/9-anthracenecarboxylic acid (9-ACA), the role of the commonly observed trap during triplet sensitization remains unclear, as do the energetics of this surface-oriented trap state.

Here, we use time-resolved photoluminescence to probe energy transfer in hybrid CdSe/10-(4-methoxyphenyl)anthracene-9-carboxylic acid (MeOPh-ACA) systems. We observe rapid transfer from both band-edge and trap states and show that transfer occurs from states which would appear to be thermodynamically uphill if their photon energy was a faithful proxy of chemical potential. Notably, we observe comparable quenching from band-edge and trap states, with similarly rapid kinetics. Further, we synthesize MeOPh-ACA, a 9-ACA derivative with stabilized frontier orbitals with respect to bare 9-ACA. When paired with a sufficiently small (<2 nm) CdSe NC sensitizer, both Dexter-like correlated energy transfer and sequential charge transfer are thermodynamically favourable mechanisms to sensitize the spin-triplet state on the organic ligand. Even with this new available pathway, we observe no change in the rate of energy transfer, while continuing to observe comparable quenching from band-edge and trap states. Finally, we find that these trap states are not pathological for TUC, and observe upconverted photon emission when our system is paired with free-floating annihilator.

Our results suggest that the deeply Stokes-shifted photoluminescence from these nanocrystals arises from energetically shallow surface-oriented states which localize the exciton shortly after irradiation, but that selection rules for exchange-mediated transfer qualitatively differ. Our observation of commensurate quenching from band-edge and trap states suggests that the band-edge and trap band are in rapid thermal equilibrium and supports the hypothesis that traps in CdSe NCs are 'shallow' i.e., of comparable energy to the band-edge. Taken together, these observations have the practical implication that the trap band can be used as a surrogate to monitor the population of band-edge excitations. These findings indicate that surface traps in core-only CdSe NCs may not hinder energy transfer during triplet sensitization and that the trap photon energy is not an honest representation of its free energy.

Finite-Temperature, Anharmonicity and Duschinsky Effects on the Two-Dimensional Electronic Spectra from *Ab Initio* Thermo-Field Gaussian Wavepacket Dynamics Jiri Vanicek and Tomislav Begušić; Ecole Polytechnique Fédérale de Lausanne, Switzerland

Accurate description of finite-temperature vibrational dynamics is indispensable in the computation of two-dimensional electronic spectra. Such simulations are often based on the density matrix evolution, statistical averaging of initial vibrational states, or approximate classical or semiclassical limits. While many practical approaches exist, they are often of limited accuracy and difficult to interpret. Here, we use the concept of thermo-field dynamics to derive an exact finite-temperature expression that lends itself to an intuitive wavepacket-based interpretation. Furthermore, an efficient method for computing finite-temperature two-dimensional spectra is obtained by combining the exact thermo-field dynamics approach with the thawed Gaussian approximation for the wavepacket dynamics, which is exact for any displaced, distorted, and Duschinsky-rotated harmonic potential but also accounts partially for anharmonicity effects in general potentials. Using this new method, we directly relate a symmetry breaking of the two-dimensional signal to the deviation from the conventional Brownian oscillator picture.

Monte Carlo Simulation of Secondary Electron Emission under Photoexcitation Wenkai Ouyang, Xiangying Zuo and Bolin Liao; University of California, Santa Barbara, United States

Understanding the photogenerated charge carrier transport in semiconductors is crucial, particularly for applications toward high-efficiency photovoltaic cells and photosensors. Scanning ultrafast electron microscopy (SUEM) is an emerging technique that can visualize photocarrier transport by measuring the spatial-temporal change of secondary electron emission as a result of photoexcitation. Despite the increasing demonstrations of SUEM capability, the physical picture of the image contrast mechanisms of SUEM remains incomplete. In this work, we implement Monte Carlo simulation based on the Mott elastic scattering cross section and Landau's theory of statistically distributed energy loss for inelastic collision; we simulate the secondary electron yield (SEY) of doped silicon under photoexcitation. Photoexcitation will induce both photocarriers in the bulk and the surface photovoltaic voltage (SPV) effect that modifies the surface band bending. Photoexcited carriers result in the change of the inelastic scattering cross section which is determined by the electron energy loss functions (ELF). Time-dependent density functional theory (TDDFT) is applied to evaluate the ELF for both n-type and p-type Si with different doping concentrations and transient electronic temperatures, but only marginal changes of SEY are observed. In contrast, SPV effect changed the surface transmission probability for secondary electrons, and SEY of n-type Si had a 3% ~5% increase while p-type Si had a 3%~5% decrease. This study provides a detailed understanding of SUEM image contrasts and lays the foundation for precise interpretation of ultrafast electron microscope images.

This work is based on research supported by the Army Research Office Young Investigator Program under the award number W911NF-19-1-0060.

Late News: Structural, Electrical and Optical Properties of Electroless Silver Plated LaxBa1-xSnO3 for Transparent Electrode Using Non-Vacuum Process Su Hyeong Kim[1], Jeong Hye Jo[1] and Sun Hee Kim[2]; [1]Gachon university, Korea (the Republic of); [2]Incheon National University, Korea (the Republic of)

Transparent electrodes for electronic devices have to unique properties such as transmittance of more than 80% in visible light and sheet resistance of less than $10^3\Omega$. ITO (Indium Tin Oxide) is the TCO (Transparent Conductive Oxide) used in almost transparent electrodes. ITO uses indium, which is a rare earth, and has the drawbacks of high cost and low mobility.[1] Consequently, the many research of TCO like ZnO, STO ($SrTiO_3$), BSO ($BaSnO_3$) to replace ITO were being studied. LBSO ($La_xBa_{x-1}SnO_3$) is a transparent conductive oxide candidate to replace ITO due to its wide bandgap of 4.05 eV, high transmittance in visible light, mobility, and carrier density. [2], [3] For high crystallinity, these properties of LBSO required a vacuum process that had drawbacks such as high cost, low deposition rate, shadow effect, etc. Thus, a thin film deposition method using a non-vacuum process has been studied, but there are problems in depositing several layers and having lower performance compared to vacuum processes [4] High resistance of thin film using non-vacuum process can be improved by electroless silver plating, and it is confirmed that silver nano particle increase conductivity. [5] In this research, using

non-vacuum process improve of low deposition rate and high equipment cost in vacuum process, and overcome low thin film quality and high sheet resistance in non-vacuum process deposition method through electroless silver plating. It has been verified that LBSO thin films deposited using non-vacuum process have a sheet resistance of less than 10^3 Ω, a work function of more than 5 eV, and a transmittance of more than 80% in visible light. The above-mentioned LBSO can also open new ways toward intrinsically next-generation transparent electrodes to replace ITO.

Asymmetric-Donor (D_2D_2')–Acceptor (A) Conjugates for Simultaneously Accessing Intrinsic Blue-RTP and Blue-TADF Harsh Bhatia[1,2] and Debdas Ray[2]; [1]University College London, United Kingdom; [2]Shiv Nadar University, India

The development of new photoluminescent (PL) materials with simultaneous room-temperature phosphorescence (RTP) and thermally activated delayed fluorescence (TADF) features is highly desirable for bio-imaging, security applications and sensors due to the involvement of both singlet and longer lived triplet states.[1] In this work we have systematically designed two multiple donors and single acceptor based molecular systems which can simultaneously harness the triplet state via two different channels. We designed the molecules by taking cue from the idea that the free lone pair of electron containing phenoxy donors when linked to the phthalonitrile (PN) acceptor gives rise to RTP emission. When carbazole connects angularly with PN acceptor, it give rise to TADF emission. In this work we have connected both the donors to the single acceptor PN. Here we discuss the photophysical studies of two carbazolyl-phenoxy-phthalonitrile conjugates (CPPN, CPPNF).[2] The detailed spectroscopic studies of CPPN and CPPNF along with two daughter compounds of phenoxy-phthalonitrile (PPN, PPNF) in polar and non-polar hosts confirmed efficient blue-RTP from the higher-energy locally excited (LE) triplet state (T_{PPN}) due to the phenoxy-phthalonitrile (PPN) part. While the blue-TADF was observed via the reverse intersystem crossing from the low-lying charge transfer triplet state (T_{CzPN}) of the carbazolyl-phthalonitrile (CzPN) part to the singlet (S_1) charge transfer state of the same CzPN part. Moreover, it was observed that the higher lying LE triplet state (T_{PPN}) acts as an intermediate for spin–vibronic coupling[3,4] to cause the reverse intersystem crossing. Such PL characteristics are observed due to the energetic proximity of $^3LE_{PPN}$, $^1CT_{CzPN}$ and $^3CT_{CzPN}$.[5] In the hydrogen-bonded matrix and crystals, we found faint persistent green-RTP characteristics of the PPNF due to supramolecular interactions and aggregation of the molecule. This study paves the way to understand the involvement of different excited states associated with TADF and RTP processes of asymmetric-donor–acceptor systems.

EQ12.11.07

Reverse Intersystem Crossing Enhancement in Organic Devices via Heavy-Atom Effect in Host Molecules Alexandre Malinge[1], Shiv Kumar[2], William Skene[3], Eli Zysman[2] and Stephane Kena-Cohen[1]; [1]Polytechnique Montréal, Canada; [2]University of St Andrews, United Kingdom; [3]Université de Montréal, Canada

The performance of Organic Light-Emitting Diode (OLEDs) has considerably improved with the discovery of Thermally-Activated Delayed Fluorescence (TADF) materials that can harvest dark triplet excitons. In TADF molecules, the triplet excitons are transferred to emissive singlet excitons by a process called reverse intersystem crossing (rISC). However, the collection of triplet excitons remains a challenge for OLEDs that suffer from a poor efficiency at high current (roll-off). Indeed, the drop of the performance is mainly due to polaron-exciton deactivation and exciton-exciton annihilation coming from the high density of triplet excitons and their relatively long lifetime. In order to overcome that problem, the rISC process can be faster in order to decrease the density of triplet excitons to limit their interactions. It is shown that this process can be enhanced by a stronger spin-orbit coupling, generated by a heavy-atom effect in the host molecules.

Derivatives of 1,3-Bis(N-carbazolyl)benzene (mCP) were synthesized by adding bromine or iodine atoms in order to increase the heavy-atom effect in the mCP host. It results in a greater phosphorescence of the host due to a better transfer between singlet and triplet states. Then, photophysical studies were carried out on different TADF guest molecules. The lifetime of the excitons has been reduced while keeping a high photoluminescent quantum yield when using halogenated molecules as host and the rate of rISC has been multiplied by a factor of 10. The use of spin-orbit coupling through the heavy-atom effect in the host molecule could be a solution to the strong roll-off and degradation observed in OLED devices.

Tunable Electronic Properties of Two-Dimensional Hybrid Organic-Inorganic $AgSe_nTe_{1-n}Ph$ by Composition Control Woo Seok Lee, Watcharaphol Paritmongkol, Tomoaki Sakurada and William Tisdale; Massachusetts Institute of Technology, United States

Silver phenylselenolate (AgSePh) is an emerging hybrid organic-inorganic two-dimensional (2D) semiconductor due to its unique properties such as narrow blue emission, in-plane anisotropy and high exciton binding energy. To expand an application of this novel 2D semiconductor, a systematic method for precisely controlling its band gap, which determines electronic and optical properties, is required. One of the simplest and the most effective way to tune the band gap is making an alloy and controlling its composition. Herein, we show that the chemical transformation reaction between silver film and the mixture of diphenyl diselenide (Ph_2Se_2) and diphenyl ditelluride (Ph_2Te_2) vapors produces 2D silver phenylchalcogenolate alloy ($AgSe_nTe_{1-n}Ph$) thin films with controllable Se to Te ratio depending on partial pressure of Ph_2Se_2 and Ph_2Te_2 vapors during reaction. Systematic structural and optical characterization to confirm tunable structural and optical properties as well as homogeneity of alloys will be presented. Furthermore, the emission mechanisms of $AgSe_nTe_{1-n}Ph$ alloy films depending on chalcogen ratio will be discussed. This work provides an insight to design novel 2D hybrid organic-inorganic semiconductors with desirable optical properties.

EQ12.11.09

Real-Time and *In Situ* Viscosity Monitoring in Industrial Adhesives Using Luminescent Cu(I) Phenanthroline Molecular Sensors Ankit Dara[1], Derek Mast[1], Anton Razgoniaev[2], Felix Castellano[3] and Alexis D. Ostrowski[1]; [1]Bowling Green State University, United States; [2]Duke University, United

States; [3]North Carolina State University, United States

Monitoring the viscosity of polymers in real-time remains a challenge, especially in confined environments where traditional rheological measurements are hard to apply. In this study, we have utilized $[Cu(diptmp)_2]^+$ (diptmp = 2,9-diisopropyl-2,4,7,8-tetramethyl-1,10-phenanthroline) as an optical probe for real time sensing of viscosity in various adhesives during the curing process (viscosity increases) via changes in luminescence. The emission lifetime of the triplet metal to ligand charge transfer (^{3}MLCT) state of $[Cu(diptmp)_2]^+$ in epoxy adhesive increased exponentially similar to viscosity values obtained from oscillatory rheology. The longer lifetime in higher viscosity materials was attributed to changes in the excited state deactivation processes from a known Jahn-Teller distortion in the Cu(I) geometry from tetrahedral in the ground state to square planar in the excited state. The real-time viscosity was also monitored reversibly by emission lifetime during polymer swelling (viscosity and lifetime decrease) and unswelling (viscosity and lifetime increase). Monitoring emission lifetime, unlike absorption lifetime in our previous study, allowed us to measure viscosity in opaque samples which scatter light. The optical probe $[Cu(diptmp)_2]^+$ in Gorilla Glue™ adhesive, showed a clear correlation of emission intensity or lifetime to viscosity during the curing process. We have also compared these lifetime changes using $[Ru(bpy)_3]^{2+}$ (bpy = bipyridine) as a control. $[Cu(diptmp)_2]^+$ showed not only higher emission lifetime but also more ubiquity as a real-time viscosity sensor.

EQ12.11.10
Robust Estimation of Charge Carrier Diffusivity Using Transient Photoluminescence Microscopy Narumi Wong, Seung Kyun Ha, Kristopher Williams, Marc A. Baldo, James W. Swan and William Tisdale; Massachusetts Institute of Technology, United States

Studying charge transport in emergent semiconducting materials is particularly challenging as structural inhomogeneities in the material can play an influential role, leading to dynamics that require resolution of sub-diffraction limited length-scales and femtosecond time-scales. Transient photoluminescence (PL) microscopy can provide the spatial and temporal resolution required to image diffusion of excitons and free charge carriers in optoelectronic materials. In excitonic materials, extraction of key material parameters such as diffusion coefficients can be simplified as the bound electron and hole move together. However, in materials where transport is dominated by free charge carriers, extracting diffusivities accurately from this multi-dimensional data requires good physical models coupled with statistically robust fitting algorithms. In this work, I present a detailed numerical framework for modeling the free charge carriers in transient PL microscopy experiments, and provide model and parameter analyses using a Markov Chain Monte Carlo sampler as part of the fitting algorithm. This approach is applied to lead-halide perovskites and transition metal dichalcogenides to obtain statistically confident estimates of ambipolar charge carrier diffusivities for these materials.

Time-Dependent Photoluminescence of Titanium Carbo-Oxide Nanostructures Ryan Hanna[1], Erika Colin-Ulloa[1], Michelle H. Frasch[1], Kateryna Kushnir[1], Hussein Badr[2], Michel Barsoum[2], Ronald L. Grimm[1] and Lyubov Titova[1]; [1]Worcester Polytechnic Institute, United States; [2]Drexel University, United States

Nanostructured metal oxides such as TiO_2 or ZnO represent state-of-the-art photocatalysts for water splitting and waste treatment. While highly efficient, they are limited by the need for ultraviolet illumination. Recently, we have developed a simple one pot approach for fabrication of nanostructured titanium carbo-oxide $TiC_{1-x}O_{1+x}$ (x=0.25-0.5) which is photocatalytically active under visible excitation. Here we investigate the photophysical properties of $TiC_{1-x}O_{1+x}$ films using time-resolved photoluminescence spectroscopy. UV-VIS spectroscopy shows an indirect band gap at ~ 4.1 eV, higher than that of TiO_2, and sub-gap states that absorb in the visible range. Excitation with below band gap, 485 nm light results in a broadband optical emission centered around ~ 2.1 eV. Its decay is bi-exponential, with the ~ 1ns fast component in all studied films, and the slower component that varies in 5-12 ns range depending on synthesis duration. We hypothesize that radiative recombination at the nanostructure surfaces is responsible for the slower process, with longer processing yielding smaller nanostructures and higher surface recombination rates. Lifetime of optically excited carriers has major implications for photocatalysis and other applications, and we demonstrate here that it can be tuned it during one-pot titanium carbo-oxide nanostructure synthesis.

1:00 PM *EQ12.12.01
Nanoscale Stroboscopic Tracking Microscopy of Electronic and Thermal Energy Through Optical Elastic Scattering Naomi S. Ginsberg[1], Hannah Weaver[1], James Utterback[1], Milan Delor[2], Cora Went[3], Joeson Wong[3], Harry A. Atwater[3], Dipti Jasrasaria[1], Eran Rabani[1], Aditya Sood[4], Burak Guzelturk[4] and Aaron Lindenberg[4]; [1]University of California, Berkeley, United States; [2]Columbia University, United States; [3]California Institute of Technology, United States; [4]Stanford University, United States

I will describe our transient optical approaches to directly image the nanoscale transport dynamics of various types of quasiparticles in a wide range of hierarchical semiconducting and conducting materials. For example, by characterizing the mean squared expansion of initially localized charge carriers, bound electron-hole pairs, heat, and sound, we elucidate the impact of various material heterogeneities on electronic and thermal transport and also the interplay between heat and charge distributions.

1:30 PM *EQ12.12.02
Spatial and Temporal Imaging of Exciton Transport in Two-Dimensional Heterostructures Libai Huang; Purdue University, United States

Charge-transfer (CT) excitons at hetero-interfaces play a critical role in light to electricity conversion using nanostructured materials. However, how CT excitons migrate at these interfaces is poorly understood. Atomically thin and two-dimensional (2D) nanostructures provide a new platform to create architectures with sharp interfaces for directing interfacial charge transport. Here we investigate the formation and transport of interlayer CT excitons in van der Waals (vdW) heterostructures based on semiconducting transition metal dichalcogenides (TMDCs) employing transient absorption microscopy (TAM) with a temporal resolution of 200 fs and spatial precision of 50 nm.
We have investigated interlayer exciton dynamics and transport modulated by the moiré potentials in WS_2-WSe_2 heterobilayers in time, space, and momentum domains using transient absorption microscopy combined with first-principles calculations. Experimental results verified the theoretical prediction of energetically favorable K-Q interlayer excitons and unraveled exciton-population dynamics that was controlled by the twist-angle-dependent energy difference between the K-Q and K-K excitons. Spatially- and temporally-resolved exciton-population imaging directly visualizes exciton

localization by twist-angle-dependent moiré potentials of ~100 meV. Exciton transport deviates significantly from normal diffusion due to the interplay between the moiré potentials and strong many-body interactions, leading to exciton-density- and twist-angle-dependent diffusion length. These results have important implications for designing vdW heterostructures for exciton and spin transport as well as for quantum communication applications.
