Biopotential signals such as ECG, EMG and EEG are vital for diagnosis and rehabilitation. Long-term biopotential monitoring is important. However, the conventional Ag/AgCl gel electrodes are not suitable for long-term biopotential monitoring because of the vaporation of the liquid phase and poor contact to skin during body movemnt. Thus, wearable dry electrodes are needed for long-term biopotential recordings but are limited due to the problems related to their contact with the skin, especially during body movements and sweat secretions, leading to high skin/electrode impedance and motion artifacts. Here, I will present our recent an intrinsically conductive polymer dry electrodes with excellent self-adhesiveness, stretchability, and conductivity. The electrodes shows much lower skin-contact impedance and noise in static and dynamic measurement than the current dry electrodes and standard gel electrodes, and they can give rise to high-quality biopotential signals including ECG, EMG and EEG in various conditions such as dry and wet skin and during body movement. Therefore, these dry electrodes can be used for long-term healthcare monitoring in complex daily conditions.

Fatigue-Resistant Hydrogel Optical Fibers for Long-Term Light Delivery In Dynamic Organs Xinyue Liu, Siyuan Rao and Xuanhe Zhao; Massachusetts Institute of Technology, United States

Biophotonics offers promise for disease detection and treatment through the light transmission between the optical devices and tissues. However, integration of optical devices (optical fibers included) with dynamic tissues remains challenging, as those devices with limited deformability constrain the natural movement of the tissues or even body. Here, we report a fatigue-resistant hydrogel-based optically stimulating technology that utilizes nanocrystalline hydrogels as optical fibers for optogenetic control of the peripheral nervous system. The hydrogel optical fibers are soft and stretchable to conform to the flexible substrates, and meanwhile the formation of polymeric nanocrystalline domains in hydrogels confers fatigue-resistance to these hydrogel materials against repeated deformation (fatigue strength 1.4 MPa). In addition, hydrogels with polymeric nanocrystals exhibit high transparency that reduces light absorption or scattering and a relatively high refractive index that minimizes interfacial light leakage, which synergistically contributing to efficient light transmission. Light transmission ability, mechanical and optical stability, and stimulation functionalities are demonstrated in vitro, ex vivo and in vivo. The light pulses delivered from the light source through the long hydrogel implant were able to activate the mouse sciatic nerve for four weeks, during which the mouse experienced extra exercise and the hydrogel fiber underwent repeated deformation (> 30,000 cycles) in the mouse.

Fluorinated Elastomers as Soft and Long-Lived Dielectrics for Scalable Brain-Machine Interfaces Paul Le Floch[1], Siyuan Zhao[1], Nicola Molinari[1], Junsoo Kim[1], Ren Liu[1], Hao Sheng[1], Chanan Sessler[2,3], Guogao Zhang[1], Zhigang Suo[1], Boris Kozinsky[1], Xiao Wang[2,3] and Jia Liu[1]; [1]Harvard University, United States; [2]Broad Institute of MIT and Harvard, United States; [3]Massachusetts Institute of Technology, United States

This presentation will discuss the development of bioelectronics for brain-wide neural activity mapping at single-cell resolution, in a chronically stable manner, a tool that will greatly advance our understanding of brain, help to build advanced neuroprosthetics, and enable new forms of communication between brain and machines. High spatiotemporal resolution and large bandwidth brain mapping requires implantation of thousands to millions of nanoelectronic probes into the brain. While multiplexed microscale brain probes are realized by nanofabrication techniques for microelectronics, the large mechanical mismatch reduces their scalability and long-term biocompatibility in the brain. Therefore, development of scalable, soft, and stretchable nanoelectronics mimicking the mechanical and physiochemical properties of the neural tissues is crucial to further increase the bandwidth of communication between brain and electronics without any adverse effects over the years. In this lecture, I introduce soft nanoelectronics for scalable brain-machine interfaces by using fluorinated elastomers as ultra-soft dielectric insulation and biofluid barriers. I will first discuss the choice of fluorinated elastomers, incentivized by molecular dynamics simulations, which reveal that this class of elastomers displays an outstandingly low ionic diffusivity at body temperature and could lead to an ultra-low ionic conductivity. Then, I will show how this result is confirmed by two experiments to quantify the ionic conductivity in dielectric polymers exposed to biofluids, namely Electrochemical Impedance Spectroscopy (EIS) and a novel technique that we name External Electrolyte Conductimetry (EEC). The observed ultra-low ionic conductivity in fluorinated elastomers provides the long-term electrical insulation required for brain implants. Finally, I will present a novel nanofabrication process using a perfluoropolyether elastomer allows the fabrication of ultra-soft, scalable brain probes, which can record individual neuron's activity over the course of multiple months, with a vanishing immune response over time. This technology will provide stable and long-term brain-machine interfaces as an electrophysiological tool for neuroscience and biomedicine. Furthermore, the

material and fabrication procedures developed in this work will not only impact brain implantation, but also offer high-performances soft materials for soft robotics, epidermal electronics, regenerative medicine, and biomedical devices.

SESSION SB07.03/SB02.04: Keynote: Hydrogel Bioelectronics
Session Chair: Fabio Cicoira

5:00 PM *SB07.03/SB02.04.01
Keynote: Hydrogel Bioelectronics Xuanhe Zhao; Massachusetts Institute of Technology, United States

Whereas human tissues and organs are mostly soft, wet and bioactive; machines are commonly hard, dry and biologically inert. Merging humans, machines and their intelligence is of imminent importance in addressing grand societal challenges in health, sustainability, security, education and joy of living. However, interfacing humans and machines is extremely challenging due to their fundamentally contradictory properties. At MIT Zhao Lab, we exploit *soft materials technology* to form long-term, high-efficacy, multi-modal interfaces and convergence between humans and machines. In particular, hydrogels with similar mechanical and physiological properties as various biological tissues have been explored as an ideal material candidate for such human-machine interfaces and convergence. This talk will focus on *Hydrogel Bioelectronics*. I will first discuss the general principles to design hydrogels to be extremely tough, adhesive, strong, fatigue-resistant, and electrically conductive. I will then introduce a 3D printing method for the fabrication of various hydrogel bioelectronic devices, including wearable, ingestible and implanted devices. Thereafter, I will discuss in vivo tests on the long-term biocompatibility and efficacy of the hydrogel bioelectronics in rat and pig models. I will conclude the talk with a perspective on future human-machine convergence enabled by soft materials technology.

Transparent, Conductive and Skin-Adhesive PVA Organohydrogels for Strain Sensing and Wearable Technology Applications Jennie Paik, Boonjae Jang, Sunghyun Nam, Jiajie Li and L.Jay Guo; University of Michigan–Ann Arbor, United States

Conductive polymer gels can enable innovative wearable technologies due to their mechanical robustness and flexibility. However, biocompatibility and processability remain obstacles in realizing these materials' commercialization, while devices made from these materials must maintain sustained adhesion and electrical connectivity under duress so that sensing performance is not negatively impacted. Herein, we have addressed these challenges by developing a multifunctional PVA-based organohydrogel material for use as a transparent, skin-adhesive strain sensor for motion monitoring. While ice templated PVA hydrogels are biocompatible, they are neither transparent nor conductive, and their flexibility degrades due to water loss over time. The introduction of Zn^{2+} ions into the hydrogel imparts ion conductivity, while plasticization by Zn^{2+}-water complexes yields a fourfold increase in rupture strain. Partial solvent exchange with the high-dielectric-constant solvent glycerol improves skin adhesion twofold, reduces water loss up to 20%, and reduces electrical resistance from the megaohm (MΩ) to the kiloohm (kΩ) regime, resulting in a transparent, skin-adhesive, elastomeric, conductive organohydrogel. The material shows high gauge factor (1.69 at 21.5% strain), making it a potential low-cost candidate for a stretchable electronic material. Subsequent work will characterize the relationship between the electrical performance and gel microstructure using electrical, spectroscopic, and microscopic methods, which is believed to play a role in the transport of ionic species through the material. Due to the availability and biocompatibility of the component materials, we believe that our multifunctional organohydrogel is a promising development in making wearable technology more accessible to society at large.

SB07.04.02
Wearable Triboelectric Nanogenerators with Thermoplastic Polyurethane/Silver Nanowire Textiles for Human Machine Interface Doga Doganay[1], Melih O. Cicek[1], Mete Batuhan Durukan[1], Burak Altuntas[1], Erdem Agbahca[2], Sahin Coskun[3] and Husnu E. Unalan[1]; [1]Middle East Technical University, Turkey; [2]Tubitak Ulakbim, Turkey; [3]Eskisehir Osmangazi University, Turkey

Electronic textiles received considerable attention both in scientific field and in the market since early 2010s. Fabrication of electronic textiles over large areas is problematic and require urgent solutions. Functional materials should be homogenously decorated via low cost and scalable methods. These functional textiles must retain their functions after certain number of washing cycles. More importantly, these wearable electronics consume high power and necessitate large and bulky batteries that significantly reduce user comforts. Herein this study proposes a combined, facile, scalable and low cost solution for the aforementioned problems. Silver nanowires (Ag NW) were decorated onto conventional cotton textiles via dip and dry method. Thermoplastic polyurethane (TPU) films were then hot pressed onto these textiles and functioned as both the protection and electrification layer for machine washable wearable TENGs. TPU/Ag NW fabric TENG electrodes produced a maximum power output of 1.25 W/m^2 when polylactic acid/aluminum (PLA/Al) foil TENG electrodes were used as the top electrode. Electrical resistance, joule heating performance and voltage output of TPU/Ag NW fabric TENGs were monitored to investigate their washing stability. It was observed that the electrodes performed stably up to 15 washing cycles. Finally, a self-powered e-wristband was developed and used as a human machine interface, which showed the true potential of the TPU/Ag NW fabric TENGs.

SB07.04.04
Late News: An Electrically Recoverable, Sintering-Free Conductor for Intrinsically Stretchable Electronics Sun Hong Kim[1], Geunwoo Baek[1], Donghee Son[2] and Jeonghun Kwak[1]; [1]Seoul National University, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of)

There are have been many progresses of stretchable electronics for epidermal and wearable devices, soft robotics and implantable devices. Despite

remarkable progresses in conventional electronics, soft materials for skin electronics have been required due to its nature of skin-like properties enabling reduction of modulus mismatch. However, it is still challenging to achieve high conductivity and high stretchability of soft materials simultaneously. Herein, we present an electrically recoverable, sintering-free conductor for endurable electronic skin devices. As fabricated conductor shows electrical recovery under strains and high conductivity without any post treatments. With printing technology, we realized the system that features a rigid-island structure interconnected with our conductor, which is optimized by controlling the evaporation rate of solvent (~160% stretchability and ~18,550 S/cm conductivity). Devised design has potential to enhance both areal density and structural reliability while avoiding the thermal degradation of heat-sensitive stretchable electronic components. To show the feasible application, stretchable sensory-neuromorphic system, comprising a stretchable capacitive pressure sensor, a resistive random-access memory, and a quantum dot light-emitting diode, respectively. Even in the skin deformation range, each device operated well, accurately recognizing various patterned stimuli via an artificial neural network with training/inferencing functions. In the future, our work is expected to be an important step toward robust electronic skin system.

10:30 AM *SB07.05.01
Liquid Metal Enabled Soft, Healable and Stretchable Electronics Michael Dickey; North Carolina State University, United States

Gallium-based liquid metals have remarkable properties: melting points below room temperature, water-like viscosity, low-toxicity (unlike Hg), and effectively zero vapor pressure (they don't evaporate). They also have, by far, the largest interfacial tension of any liquid at room temperature. Yet, these liquid metals can be patterned into non-spherical shapes (cones, wires, etc) due to a thin, oxide skin that forms rapidly on its surface. This talk will describe recent efforts in our research group to harness this oxide to pattern and manipulate metal into shapes—such as wires and particles—that are useful for applications that call for soft and deformable metallic features, such as wearables. It is possible to pattern the metal in a number of ways, including injection into microchannels or by direct-write 3D printing at room temperature, to form ultra-stretchable wires, deformable antennas, and microelectrodes. Liquid metal conductors can be rendered into self-healing circuits by either (1) encasing liquid metal wires in a self-healing polymer, (2) using dielectrophoresis to assemble microdroplets of liquid metal into conductive paths that span damaged portions of circuits, or (3) harnessing shear from cutting to create autonomously healing circuits. Liquid metal circuits can also be designed to respond to touch in unique and useful ways. I will show how this principle can be utilized to create soft circuit elements that can perform simple logic in response to touch, which is interesting because such circuits can carry out logic operations without the use of conventional transistors. Taken in sum, this work has implications for soft and stretchable electronics; that is, devices with desirable mechanical properties for human-machine interfacing, soft robotics, and wearable electronics.

11:00 AM SB07.05.02
Dissolving Microneedles Delivering Cancer Cell Membrane Coated Nanoparticles for Cancer Immunotherapy Wonchan Park and Sei Kwang Hahn; POSTECH, Korea (the Republic of)

Recently, a variety of tumor vaccines and immune system stimulators such as toll-like receptors (TLRs) agonists have been widely investigated for cancer immunotherapy via transdermal delivery. Despite these great research efforts, low efficiency and discomfort remain a huge technical hurdle for the development of immunotherapeutics. Here, we design a facile method to deliver drugs to the skin through microneedles (MNs) to stimulate the immune system in two ways. As one of the tumor vaccines, cancer cell membrane proteins can act as tumor-specific antigens that are presented to antigen presenting cells (APCs) to activate the immune system. In addition, a toll-like receptor 7 (TLR7) agonist of imiquimod (R837) can suppress cancer cell growth by inhibiting angiogenesis. Using poloxamer 407 (F127) as a nanocarrier, F127 nanoparticles (F127 NPs) are loaded with R837 and then coated with cancer cell membranes (M). These F127-R837@M NPs are loaded in rapidly dissolving MNs and delivered through the skin. MNs loaded with F127-R837@M NPs show significant inhibition of cancer cell growth in both prophylactic vaccination and antitumor immunotherapy in vivo. The dual immune system stimulating F127-R837@M NPs would be effectively used for cancer immunotherapy.

11:15 AM SB07.05.03
Photo-Patternable, Large-Area Particle-Packed-State Liquid Metal Film Coated via Solution Shearing for Soft Electronics Gun-Hee Lee; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Liquid metal (LM) is considered one of the most promising conducting materials for soft electronics due to its unique combination of metal-level high conductivity with exceptional deformability and stretchability. However, their practical applicability has thus far been limited due to the challenges of generating chemically and mechanically stable film over a large-area and the need for non-standard fabrication approaches. Here, we report materials and manufacturing methods that enable multiscale patterning (from microns to centimeters) and multilayer integration of 'solid-state liquid metal (SSLM)' with the conventional cleanroom process. In this work, solution shearing of a polyelectrolyte-attached LM particle ink is used to generate SSLM films. The stabilized LM particles were observed to form a close-packed thin-film without particle rupture when coated under an evaporative regime. This is essential in enabling a subsequent photolithographic lift-off process at wafer-scale to produce high-resolution features (~10 μm) of varying thicknesses on various substrates. Demonstrations of wearable multilayer tactile sensing systems and stretchable skin-interfaced electronics validate the simplicity, versatility, and reliability of this manufacturing strategy, suggesting broad utility in the development of advanced soft electronics.

11:30 AM SB07.05.04
Late News: Partially Graphitized Synthetic Polyphenols Enables Wear-Resistant Antimicrobial Coating Kyueui Lee[1,2], Minok Park[2], Katerina Malollari[2], Jisoo Shin[2], Sally M. Winkler[2], Yuting Zheng[2], Jung Hwan Park[3], Costas Grigoropoulos[2] and Phillip Messersmith[2]; [1]Kyungpook National University, Korea (the Republic of); [2]University of California, Berkeley, United States; [3]Kumoh National Institute of Technology, Korea (the Republic of)

Grafting antimicrobial polymers on public surfaces may minimize the spread of diseases. For this, surface functionalization is essential. However, conventional approaches such as hydroxylation are limited to specific substances. Surface-independent multifunctional coating including polydopamine (PDA) can be a promising alternative, however, its inherently weak wear resistance prevents practical applications. To overcome this problem, we developed the laser annealing process that can partially graphitize PDA to induce mechanical enhancement while its inherent catechol functionality can be preserved. The post-treated functional coating showed significantly increased mechanical resistance compared to the original PDA, which was confirmed by scratch testing using a nanoindenter. Surprisingly, the laser-annealed coating showed even better wear resistance compared to strong inorganic materials

(e.g., quartz and TiO2). To further introduce antimicrobial ability, thiolated polyethylene glycol (PEG) was grafted on the coating. Due to the presence of catechol functional groups on the surface, the PEG-SH was easily grafted through Michael-type addition. The bacterial attachment was significantly reduced (5-fold) on the PEGylated laser-annealed PDA compared to PEGylated PDA. This was found to be due to the delamination of the PDA layers under ambient conditions. We believe that our work can provide an insight into designing antimicrobial surfaces that can slow down pandemics including COVID-19.

11:45 AM SB07.05.05
Fully Bioresorbable, Leadless, Battery-Free Cardiac Pacemaker Yeonsik Choi[1], Rose T. Yin[2], Igor Efimov[2] and John A. Rogers[1]; [1]Northwestern University, United States; [2]George Washington University, United States

Temporary cardiac pacemakers provide critical functions in pacing through periods of need during post-surgical recovery. The percutaneous leads and externalized hardware associated with these systems present, however, risks of infection and constraints on patient mobility. Furthermore, the pacing leads can become enveloped in fibrotic tissue at the electrode-myocardium interface, which thereby increases the potential for myocardial damage and perforation during lead removal. Here, we report a bioresorbable, leadless, and fully implantable cardiac pacemaker for post-operative control of cardiac rate and rhythm during a stable operating timeframe that subsequently undergoes complete dissolution and clearance via natural biological processes. A combined set of *in vitro*, *ex vivo*, and *in vivo* studies across mouse, rat, rabbit, canine, and human cardiac models demonstrates that these devices provide an effective, battery-free means for pacing hearts of various sizes with tailored geometries and timescales for operation and bioresorption. These features enable programmable cardiac pacing in a manner that overcomes all of the key disadvantages of traditional temporary pacing devices. As such, this novel cardiac pacemaker may serve as the basis for the next generation of post-operative temporary pacing technology.

SESSION SB07.06: Soft, Healable Materials and Devices for Biological Interfaces and Wearables IV

1:30 PM SB07.06.01
Late News: Smart Materials for Flexible, Self-Healing and Conductive Interfaces Antonio Riul Jr[1,2], Gabriel Gaal[1], Anerise Barros[1,2], Maria Braunger[1], Mawin M. Jimenez[1], Carlos A. Avendano[2], Monica Jung de Andrade[2], Manuel Quevedo-Lopez[2], Fernando Alvarez[1] and Ray Baughman[2]; [1]University of Campinas, Brazil; [2]The University of Texas at Dallas, United States

Self-healing materials inspire the next generation of multifunctional wearables and IoT appliances. Nonetheless, it is crucial to fabricate thin films enabling seamless and conformational coverage irrespective of the complexity of shape and geometry of the surface for electronic skins, smart textiles monitoring body signals, soft robotics, wearables and storing energy devices. Within this context, the layer-by-layer (LbL) technique is a versatile approach for homogeneously dispersing materials into various matrices. Moreover, it provides molecular level thickness control and conformational configuration on virtually any surface. Poly(ethyleneimine) (PEI) and poly(acrylic acid) (PAA) are materials primarily employed in LbL structures due to their intrinsic ability to form self-healing coatings at room temperature. However, it is still challenging to achieve thin composite films having high conductivity, good healing strength, and controlled mechanical properties at ambient conditions. Here, PEI and PAA were mixed with conductive materials such as gold nanorods, poly(3,4-ethylene dioxythiophene) polystyrene sulfonate (PEDOT:PSS), reduced graphene oxide and multi-walled carbon nanotubes in distinct LbL film architectures. Electrical (AC and DC), optical (Raman spectroscopy), and mechanical (nano-indentation) measurements were performed to evaluate the impact of the different fillers in the electrical and mechanical properties of the multilayered structures. As a proof-of-concept a self-healing electronic-tongue was assembled using different geometries. We were able to distinguish basic tastes at low molar concentration, below the human threshold. We also tested the self-healing *e*-tongue setup as a glucose sensor, distinguishing different concentrations of glucose in artificial sweat, a first step towards a long-term wearable biosensor. The results are promising for the manufacture of self-healing conductors by design, as the mechanical properties were balanced with the healing and electrical efficiencies. The formed nanostructures have the potential for creating smart surface layers having unique features that solve technological challenges.

1:45 PM SB07.06.02
Self-Limiting Electrospray Deposition of Composite Gelated Electrospray Liquids (GELs) Michael Grzenda, Zhiyi Chen and Jonathan Singer; Rutgers, The State University of New Jersey, United States

In electrospray deposition (ESD), strong electric fields are applied to solutions exiting narrow capillaries in order to produce monodisperse droplets that are attracted to grounded substrates. Self-limiting electrospray deposition (SLED) is a recently discovered phenomena where insulating polymers below their glass transition temperature are deposited onto conductive surfaces. The growing film eventually cannot dissipate charge effectively which leads new material to be repulsed by the film, causing the incoming droplet to target uncoated conducting regions of the substrate. This targeting effect occurs on complex 3D objects, even on surfaces not facing the needle, as well as on small 2D and 3D features less than the characteristic size of the spray. The resulting polymer films demonstrate a wide range of complex morphologies, including nanowires forests and hollow shells. When nanoparticles are added to these morphologies, the self-assembly acts to separate the particles within the polymer network, allowing, for example, a conformal 3D composite foam of methylcellulose nanowires to display the single particle plasmon of embedded gold nanoparticles even at high loadings. In this work, we explore the use of SLED solutions as a carrier for unmodified functional nanoparticles with the goal of providing new functionalities to the target spray substrates. This is accomplished using a shear-thinning gelling agent in combination with a SLED-compatible polymer to form a gelated electrospray liquid (GEL). GELs can easily suspend nanoparticles, regardless of their composition for prolonged periods at particle loadings of up to 70 volume %, while the shear thinning capability maintains spray stability. This targeted nanoparticle delivery is envisioned as an advanced manufacturing technique ideal for upgrading and functionalizing conductive traces in flexible electronics with high efficiency or adding surface modification to soft robotic structures. The current work explores films created using GELs composed of several different nanoparticles, including silver electronic particles and mica pigments, and demonstrates corresponding changes in surface properties.

2:00 PM SB07.06.03
Sintering Liquid Metal Nanoparticles by a CO_2-Laser Cutter Sooik Im, Jan Genzer and Michael Dickey; North Carolina State University, United States

Liquid metals are intrinsically soft. They have been studied intensively as conductive materials in soft and wearable electronics. Among liquid metals,

eutectic gallium indium (EGaIn) is an alloy with 75 wt% gallium and 25 wt% indium, which has a low melting point (15.7 °C) low-toxicity, and near-zero vapor pressure at room temperature. EGaIn spontaneously reacts with oxygen in ambient conditions to form a few-nanometer thick gallium oxide layer at the surface. This oxide layer can even form in water with a low oxygen concentration (~ppm). When bulk liquid metal (~mm diameter) is sonicated, it breaks into nanoparticles (~100 nm) composed of a liquid core and an oxide shell. Films of these particles have poor electrical conductivity due to the oxide layer. Still, particles can merge to form conductive paths if the applied stress is enough to break the oxide [1]. A focused laser beam has also been used to sinter liquid metal particles. Kramer et al. proposed the laser beam provides a localized heat source to break the oxide layer and coalesce the particles [2]. They used a ytterbium pulsed fiber laser with a different sintering mechanism from a conventional laser cutter operated by a CO_2 laser. Here, we investigate CO_2 laser-sintered liquid metal nanoparticles to understand better how laser sintering works.
Liquid metal particles were prepared by sonication with isopropanol. Particle films were obtained by casting the solution on glass slides and subsequently evaporating the solvent. After sintering with a CO_2 laser, the EGaIn particle film had low resistance (~1 **Ω**), but the particle morphology only changed slightly, unlike reported previously [2]. We also found changes in rheological properties after sintering, indicating that the CO_2 laser beam broke the oxide of the particles. Lastly, since the particle film remained conductive on a latex glove after bending and stretching, particle films sintered using lasers have potential applications in soft wearable devices.

8:00 AM *SB07.07.01
Nanomesh Pressure Sensor Without Sensory Interference Takao Someya, Sunghoon Lee and Tomoyuki Yokota; The University of Tokyo, Japan

Precise measurement of finger manipulation is critical to understand and reproduce the sense of natural touch. Huge advances have been made in developments in soft and flexible sensors for finger motions monitoring helping to decrease physical interferences due to the sensor attachment. For example, a use of stretchable substrates and/or a reduction in sensor thickness have substantially improved the conformability of sensors to the skin enabling more accurate monitoring of finger touch. Recently, ultra-thin (a few μm) sensors have been also demonstrated, which significantly reduce the loss in sensation. However, there is still challenge to monitor finger touch while maintaining the natural touch feeling. Covering the skin with any object, even a super thin layer significantly affects sensory information which results in a distortion of the inherent control. Here, we succeeded in monitoring finger pressure with an undetectable effect on human sensation using sensors directly attached to the highly sensitive fingertip. To minimize sensory interference, we developed ultra-thin nanomesh sensors composed of compliant nanoporous structures. To objectively and quantitatively evaluate the effect of the nanomesh material on human sensation, we investigated the grip force during object grasp. The sensor-applied finger exhibits comparable grip forces with those of the bare finger, even though the attachment of a 2-μm-thick polymeric film results in a 14% increase in the grip force. Furthermore, this nanomesh structure allows the simultaneous achievement of high mechanical durability against shearing and friction over hundreds of kilopascals while the ultra-thin compliant structure preserves the human sensitivity. Our new methodology, which removes the effect caused by the electronics, offers the possibility to accurately monitor biological information in a natural state to a variety of fields such as biomedical, sports, and entertainment applications.

8:30 AM *SB07.07.02
Wearable Electronics Using a Textile-Centric Design Approach Yunyun Wu, Sara Mechael, Yiting Chen and Tricia B. Carmichael; Univ of Windsor, Canada

Clothing is ubiquitous in daily life, making textiles an ideal platform for the next generation of wearable electronics. New electronic textiles (e-textiles) will incorporate sensors to detect biometric data, light-emitting devices to display data, and integrated wiring and power sources. The fabrication of these e-textiles requires the integration of functional materials into the textile, while maintaining wearability, softness, and stretchability. The challenge with this integration is that the porous, 3D structures of textiles are obviously different from the flat and rigid surfaces conventionally used for device fabrication. Textiles present a non-planar surface for fabrication and readily absorb and wick solutions of functional inks, which can stiffen the textile and compromise wearability. In this presentation, we discuss the use of solution-based electroless metallization to fabricate conductive textiles. A key advantage of this approach is the ability of the aqueous plating solution to permeate into the textile structures to deposit conformal, uniform gold coatings on the surfaces of individual fibers that comprise the yarns, leaving the void structure of the textile intact. We also discuss how the ready availability of the considerable variety of textiles offers a great opportunity to advance the e-textile field by incorporating textile structures into the device design. In this textile-centric design paradigm, textiles play an integral role in the operation of e-textile devices rather than acting merely as passive device carriers. We discuss how the open structure of a low-denier nylon and spandex ultrasheer fabric can be used as a framework for highly stretchable transparent electrodes in wearable and stretchable light-emitting devices, and how the tufted structure of a velour fabric can form the basis for an architectural engineering approach to protect brittle electroactive materials from strain for the fabrication of stretchable textile-based lithium-ion batteries.

9:00 AM *SB07.07.03
Intrinsically Stretchable Healable Semiconductors for Skin-Inspired Electronics Jin Young Oh; Kyung Hee University, Korea (the Republic of)

In this talk, I will address molecular designs and material processing of intrinsically stretchable healable semiconductors for skin-inspired electronics.
1) Incorporation of dynamic intermolecular interaction unit into semiconducting polymers.
2) Blending of intrinsically stretchable semiconducting polymer and self-healable elastomer.
3) Applications for skin-inspired electronics.

9:30 AM SB07.07.04
Late News: A Highly Stretchable and Transparent Conducting Polymer and the High-Resolution Patterning for Large-Area Capacitive Sensors Tokihiko Shimura[1], Shun Sato[1], Kaoru Yamashita[1], Shuma Abe[1], Taizo Tominaga[1], Minoru Ashizawa[2], Hiroki Ishikuro[1] and Naoji Matsuhisa[1,3]; [1]Keio University, Japan; [2]Tokyo Institute of Technology, Japan; [3]JST PRESTO, Japan

Stretchable and transparent conducting polymers have been demonstrated in various applications, such as wearable/implantable devices and robotic skins, which enables biosensing for healthcare and facilitates human-machine interaction. Several approaches to achieve high-resolution patterning have been reported, including inkjet printing and photolithography.[1,2] However, it is difficult to simultaneously improve conductivity and stretchability due to the materials limitation in each patterning process. Therefore, a method of achieving precise patterning without compromising the electrical and mechanical characteristics has been desirable.
Here we have realized a highly conductive and stretchable polymer conductors, and the patterning in high-resolutions (tens of micrometers). The material consists of PEDOT:PSS and Lithium Bis(pentafluoroethanesulfonyl)imide (LiBETI), which improves its conductivity and stretchability, spin-coated on a thermoplastic polyurethane (TPU) substrate. Our conducting polymer doped with LiBETI showed a high conductivity of 328 S/cm at 0% strain, and 196 S/cm at 100% strain although that with Lithium Bis(trifluoromethanesulfonyl)imide (LiTFSI) showed 272 S/cm at 0% strain and 98 S/cm at 100% strain.[3] Moreover, our material showed a very high crack-on-set strain of 160%, which is the highest value among the previously reported stretchable conducting polymers to the best of our knowledge. It also showed high transparency of 86% (at a wavelength of 550 nm, including a TPU substrate). Furthermore, the high-resolution patterning (smaller than 20 μm) was achieved by UV-laser ablation which can be carried out over large areas at a high throughput.
The utility of our material was demonstrated by two types of sensors. One is a stretchable and transparent capacitive strain sensor. Our strain sensor showed high stretchability of 100%, and high linearity, which enabled radial artery pulse monitoring. Another is a stretchable, transparent, and large-area capacitive touch sensor matrix. Our 7 × 7 matrix sensor was able to detect single-point and multi-point touches even while sensor was stretched at 30% strain. Our transparent, thin-film sensors are expected to be used in next-generation human-computer interfaces which can be attached on the surfaces of humans and robots.

Printable Elastomeric Electrodes with Sweat-Enhanced Conductivity for Wearables Jian Lv, Gurunathan Thangavel and Pooi See Lee; Nanyang Technological University, Singapore

Human sweat has always been considered a negative factor for electrode conductivity because of the enhanced corrosion behavior of bulk metals in the presence of saline solution. Here, we designed printable, photocurable, and textile-based silver flakes-poly(urethane-acrylate) (Ag-HPUA) electrodes of which the resistance can be reduced by human sweat in both original and stretched states. The electrodes are composed of Ag flakes and HPUA binder with hydrophilic, photocurable, and high stretchable properties. The specially designed HPUA binder contains hard segments made up of carbamate groups (-NH-C=O-O-) and soft segments made up of aliphatic polyether (-O-) or polyester (-CO-O-) backbone that was capped with acrylate (C=C) functionality at each end. When the Ag-HPUA encounters the sweat, the lactic acid, and Cl- work synergistically to enhance the conductivity rapidly and permanently by removing the surfactant on the Ag flakes surfaces and sintering the exposed Ag flakes. The key factors (pH, Cl^-, and gradual sweating) and the mechanism of the reaction between the Ag-HPUA electrode and sweat have been elaborated. Sweat can also significantly improve the electrode's durability to stretching deformation. The on-body test has shown that the resistance of the electrode can be reduced from 3.02 Ω to 0.6 Ω after the subject started to secrete sweat. As an example, a type of stretchable sweat-based Zn-Ag_2O battery using Ag-HPUA as the current collector was directly printed on textile to supply energy for a wearable wireless temperature sensor. Apart from acting as the electrolyte, human sweat also enables the battery to operate under stretching. Our approach uses sweat that is unharmful to human skin as the sintering agent that reduces the resistance of printed stretchable electrodes during wearing, providing a new route in the design of printed stretchable devices.

SESSION SB07.08: Soft, Healable Materials and Devices for Biological Interfaces and Wearables VI

10:30 AM SB07.08.01
Bioinspired Flexible Microneedle Patches for Improved Transdermal Drug Delivery Jie Hao Tay[1], Yu Han Lim[1], Mengjia Zheng[1], Wen See Tan[1], Qian Shi[1], Chenjie Xu[2] and Juha Song[1]; [1]Nanyang Technological University, Singapore; [2]City University of Hong Kong, Hong Kong

Microneedle (MN) technology is well-known, extensively researched and has been growing in market size. However, designs to enhance the functionality of MN patches are still lacking. Most MN patches are fabricated as a stiff, single arrays. This is problematic as the human skin is intrinsically curved, and hyperelastic. Applying a stiff entity to dynamic surfaces of the skin results in geometric incompatibility and induces pre-stress conditions at the interface. After removal of the application force, the hyperelastic skin returns to its pre-stretched state, where the adhesive strength between skin and MN patch is lower than the recovery stress of skin, causing interfacial delamination. Particularly, anatomical regions with large surface area and complex surface topography are prone to causing interfacial problems, and exhibit low contact stability. Hence, there is a mismatch in current MN patch functionality and application requirements onto human skin, where patch delamination and partial MN penetration result in inconsistent and poor drug delivery efficiency. In this study, we propose a novel MN patch design – bioinspired by the multi-scale principle of naturally segmented fish armour systems – by translating stiff individual MN tips onto a macro-scale flexible assembly substrate, for an adaptive and highly flexible MN patch with enhanced drug delivery capabilities. Through this approach, microneedle patches showed significantly improved penetration efficiency, even under dynamic cyclic loading conditions. We confirmed improved contact stability, penetration efficiency and large surface coverage of those bioinspired microneedle patches, varying microneedle materials from fast dissolvable to slowly degradable polymers, through both *in vitro* and *in vivo* tests. We envisage that this bioinspired flexible microneedle platform can be used for various functional transdermal drug delivery platforms or long-term epidermal biosensors.

10:45 AM SB07.08.02
Late News: Soft, Miniaturized and Self-Adhesive Interface in Wearable Sensor Network for Systematic and Quantified Assessment of Full-Body Kinematics Young Joong Lee, Hyoyoung Jeong, Jae-Young Yoo and John A. Rogers; Northwestern University, United States

Early detection of atypical movement due to neuromotor pathology can expedite timely therapeutic intervention that promotes recovery. Continuous monitoring of body kinematics near surgical sites can provide safe recovery and rehabilitation process. A particular challenge in identifying and monitoring such neuromotor or physiatric assessment is in qualitative and subjective assessment. Advanced kinematic assessment and treatment rely on medical records, clinical exams, and imaging methods that require expert evaluations or expensive medical facilities and raise privacy issues. These requirements prevent broad access to the assessment due to cost and geographic proximity.
Here, we introduce a soft, flexible, and miniaturized skin-interfaced sensor network as an alternative solution, which are placed at strategic locations across the body to capture full-body kinematics of subjects as well as vital signs quantitively and continuously. Biocompatible, thin, and self-adhesive encapsulation (< 180 μm thickness) with a fiberglass fabric (< 20 μm thickness) embedded facilitates soft, intimate contact to the skin without irritation and disrupting signal sensitivity of the mechanoacoustic sensor which enables capturing of gross and subtle movements. The resulting quantitative measurements from time-synchronized wireless sensors integrated with 3-axis accelerometer and 3-axis gyroscope can be analyzed across the full range of spatio-temporal scales to identify body balance and motor behaviors of each body part such as the torso, arms, legs, and head. These quantitative measurements can serve as basis for 3D motion reconstruction in avatar form, enabling remote assessments by experts with de-identified means. The sensor network system presented here has potential applications in long-term tracking of atypical motor development in infants with elevated risks of neuromotor pathology, real-time tracking and feedback based on neck activity level in patients recovering from thoracic surgery to enhance personal awareness of health status, and guidance for posture correction in athletes' performances.

11:00 AM SB07.08.03
An Electroactive Filter with Tunable Porosity Vasileios Oikonomou[1], Johannes Gladisch[1], Maximilian Moser[2], Iain McCulloch[2,3], Magnus Berggren[1] and Eleni Stavrinidou[1]; [1]Linköping University, Sweden; [2]University of Oxford, United Kingdom; [3]King Abdullah University of Science and Technology, Saudi Arabia

Advanced materials with stimuli responsive volume change are of interest for a wide range of applications, from actuators, microfluidics and drug delivery. Conjugated polymers change their volume when electrochemically doped/dedoped via the exchange of ions and solvent with an electrolyte. Here, we demonstrate an electroactive filter with tunnelable porosity, composed of a metallic mesh coated with the conjugated polymer pg3T2. Pg3T2 is a polythiophene polymer with ethylene glycol side chains that reversibly expands by 300% upon addressing, relative to its previous contracted state, outperforming any other conjugated polymers. By optimizing the polymer coating on the metallic mesh, we achieved highly controllable porosity during electrochemical addressing. The pores reversibly opened and closed, and their diameter could be defined by the applied potential within a dynamic range of 40 μm. Among hundreds of pores from different samples 90 % of them could be completely closed while only less than 1 % were inactive. Finally, we demonstrate control of dye flow through the electroactive filter, highlighting the potential for controlled large molecule delivery applications

11:15 AM SB07.02.04
Nanophase Separation in Triblock Copolymers—A Strategy to Achieve Low Modulus, Elastic Deformation and Good Mobility in Polymer Semiconductors Franziska Lissel[1,2]; [1]Leibniz Institute of Polymer Research, Germany; [2]Dresden University of Technology, Germany

The elastic modulus of polymer semiconductors (PSCs) (0.1 - 1 GPa for typical PSCs) is still orders of magnitudes away from human skin (0.1 - 10 MPa). Also, PSCs are brittle and structurally fragile, prohibiting their application in mechanically strenuous environments, or leading to the break-down of electric functionality.

Different pathways were explored to lower the modulus of PSCs, e.g. non conjugated spacers [1], changing the regioregularity of the backbone [2], or modifying the sidechains [3], to name a few. Lowering the modulus is generally associated with a decrease in mobility, and balancing the requirements of high mobility and low modulus when designing a PSC is challenging.

Here, we draw on an old concept in polymer engineering to approach the problem: Covalently linking two polymer chains into a block copolymer leads to separation on the nanoscale due to the thermodynamic incompatibility of the chains. The phases retain their respective properties (Tg, etc). A similar approach was used before to realize elongability (plastic deformation) in PSCs [4].
Combining PSCs with biocompatible elastomers in block copolymers gives materials that have a low modulus, can be deformed elastically and retain good mobility [5]. We synthesized triblock co-polymers (TBCs) by covalently end-capping poly-diketopyrrolopyrrole-thienothiophene (PDPP-TT), a high-performance D-A PSC, with two elastomeric polydimethylsiloxanes (PDMS) blocks to combine favorable electrical and mechanical properties in one system. The resulting nanophase segregation of both components, preserves the features of both moieties (PDPP-TT and PDMS) in their respective domains. The TBCs are soft and durable: the TBC with the highest PDMS content has a low modulus (6 MPa) in the range of mammalian skin and shows no crack formation up to 85% strain. The TBC achieves a mobility of 0.1 $cm^2V^{-1}s^{-1}$, in the range of the fully conjugated reference polymer (0.7 $cm^2V^{-1}s^{-1}$). In a doped state, the block copolymer maintains electronic functionality over more than 1500 cycles at 50% strain. Also, the TBC can be shear-coated at high speeds (up to 10 s cm-1) and still reliably give smooth films [6]. While the high speeds result in increased film thickness (up to 600 nm), no degradation of the electrical performance was observed, as was frequently reported for polymer−based OFETs.
Finally, using physisorption, organic field-effect transistor (OFET)-based biosensors can be fabricated which detect both SARS-CoV-2 antigens as well as anti-SARS-CoV-2 antibodies in less than 20 minutes. The biosensor was produced by functionalizing an intrinsically stretchable and semiconducting tri-block copolymer (TBC) film either with the anti-S1 protein antibodies (S1 Abs) or receptor-binding domain (RBD) of the S1 protein, targeting CoV-2-specific RBDs and anti S1 Abs, respectively.. The device demonstrates a high sensitivity of about 19%/dec and limit of detection (LOD) 0.36 fg/mL for anti-SARS-Cov-2 antibodies, and at the same time, a sensitivity of 32%/dec and LOD of 76.61 pg/mL for the virus antigen detection [7].

1:00 PM SB07.09.02
Late News: (Garcia High School Student) Web Interface for the Operation of a Robotic Arm Audrey Wong[1], David Tarrab[2], Lauren Yu[3], Dyllan Hofflich[4], Matthew Garcia[5], Shubham Agrawal[6], Dasharadhan Mahalingam[6] and Nilanjan Chakraborty[6]; [1]Beckman High School, United States; [2]Ramaz Upper School, United States; [3]Brea Olinda High School, United States; [4]Pelham Memorial High School, United States; [5]Plainedge High School, United States; [6]Stony Brook University, The State University of New York, United States

Ailments like Parkinson's disease, carpal tunnel syndrome, arthritis, and cerebral palsy can leave individuals severely limited in mobility and unable to perform essential tasks. The diseases and impairments listed above all damage functionality in the upper arms. The use of a robotic arm to perform activities of daily living (ADL's) may be able to address these limitations.
The goal of this study is to control a robotic arm with eye-gaze technology or a Tongue Touch Keypad (TTK) through the shared context of a web interface. Created with HTML, CSS, and JavaScript, the interface was designed to facilitate clear communication between the user and robot arm. To allow the robotic arm to complete a task with missing information, the interface included a query-based system that would allow the user to supply additional information to aid the robot in performing a task. Important design decisions included the size and placement of buttons as well as the display of information on the interface to address the heightened error that follows eye-tracking.
This web interface will ultimately be built into the robot arm system to allow for its full testing and use by individuals. Two different pipelines will be present, the first using a wheelchair-mounted camera to acquire the coordinates of objects. The second will act upon the user's interactions with the interface as an object with a corresponding movement is selected; this information is then sent to the robot arm for the requested action to be executed. This backend development will be completed using ROS (Robot Operating System) and further project development will include optimizing communication between nodes, which include the web interface, camera, and various modalities of user interaction.

1:15 PM SB07.09.03
Late News: An Organic Electrochemical Transistor-Assisted Integrated Photodetector for Photoplethysmogram Signal Acquisition Yizhou Zhong, Diego Rosas Villalva, Luis H. Hernandez, Derya Baran and Sahika Inal; King Abdullah University of Science and Technology, Saudi Arabia

The unique characteristics of an organic electrochemical transistor (OECT) distinguish it from other transistors and make it a promising electrophysiological interface for a living system. In this work, we report a photodetector integrating an organic photodiode (OPD) and an OECT for physiological signal acquisition. The OPD module exhibits strong absorption in the visible and NIR wavelengths hole the OECT is a p-type enhancement mode device. The high gain of the OECTs endows the integrated photodetector with a ca. 200 times increase in the photocurrent generated and at least a 100 times improvement in both the response and the external quantum efficiency compared to the OPD alone. We evaluated the performance of the integrated photodetector as a reliable transducer for photoplethysmogram (PPG) signal acquisition and suggest its high potential as a wearable biosensor.

1:30 PM SB07.09.04
Lightweight and Flexible Conducting Polymer Sponges and Hydrogels for Excellent EMI Shielding Applications Biporjoy Sarkar and Fabio Cicoira; Polytechnique Montreal Canada, Canada

Conducting polymers have extensively being used in the soft wearable electronic devices, and, successfully replaced the conventional metals in electromagnetic interference (EMI) shielding applications. In the present work, three dimensional (3D) foams and hydrogels derived from the most popular conducting polymer poly (3,4-ethylene dioxythiophene) polystyrene sulfonate (PEDOT:PSS) have been used to study EMI properties in the frequency range between 8 to 12.4 GHz. The 3D PEDOT:PSS foams endowed a unique complex porous micro-features that offer excellent electrical response under compressive forces, due to the coalescence of micro-features in the foam structure. Interestingly, the compressive strain enhanced the shielding effectiveness (SE) value of PEDOT:PSS foam by 60% of the pristine value. For the first time, highly conducting PEDOT:PSS hydrogel films were developed to show the highest SE value of about 105 dB. Both reflection and absorption attributed to the total shielding effectiveness. These results would open a new horizon for the development of a new class of EMI shielding materials.

SESSION SB07.10: Soft, Healable Materials and Devices for Biological Interfaces and Wearable VIII

4:00 PM SB07.10.01
Supervised Folding of Origami Soft Actuators Enabled by Magnetic e-Skins Eduardo Sergio Oliveros Mata[1], Minjeong Ha[2], Gilbert Santiago Cañón Bermúdez[1], Jessica Liu[3], Benjamin A. Evans[4], Joseph B. Tracy[3] and Denys Makarov[1]; [1]Helmholtz-Zentrum Dresden-Rossendorf, Germany; [2]Electronics and Telecommunications Research Institute, Korea (the Republic of); [3]North Carolina State University, United States; [4]Elon University, United States

Reconfigurable[1], soft[2], and lightweight[3] actuators are expected to be implemented in robotic systems biomimicking the multifunctional and adaptive capabilities of living organisms. The integration of sensing elements in soft actuators enables smart motion events increasing reliability, efficiency, and safe integration in diverse environments[4]. Specifically, for origami-based systems[5], the tracking of the orientation and the readiness of the folding is important to achieve reliable assembly of the structures.

Integration of sensing elements with soft actuators is typically addressed with stimuli-responsive materials[6] and commercial sensors[7] that lack feedback capabilities and high compliancy, respectively. Recent approaches measuring strain[8], curvature[9], and optical[10] signals have been demonstrated for localized single folding in soft actuators. Until recently, there were no reports of an onboard sensing platform that enables the folding of multiple flaps as needed for origami.

Here, we will show the integration of flexible e-skins on magnetic actuators for supervision of the sequence and folding assembly of hinges defined on the fly. Highly compliant magnetic sensors (GMR and Hall effect) were laminated on ultrathin magnetic origami actuators enabling the detection of the readiness for actuation, the orientation, and the hinge folding process. The actuator, a magnetic composite based on a shape memory polymer with embedded NdFeB microparticles, actuates during a light softening and magnetic stimuli sequence[11]. We optimized the thickness (60 µm) and composition (NdFeB - 40 wt%) of the composite to achieve the 180 deg basic fold for origami structures. The capabilities of the system with laminated sensing e-skin

were demonstrated after self-guided assembly of the origami platform with multiple hinges into box- and boat-like layouts[12]. We envision that further development of alike self-supervised systems will bring closer the realization of adaptive mechatronic soft systems for different environments and even remote applications.

Mechanically Tough Ionogels for Stretchable Electroluminescent Devices Jinhwan Yoon; Pusan National University, Korea (the Republic of)

Double network (DN) ionogels comprising soft and brittle polymer networks were prepared to fabricate high-performance stretchable electronics such as electroluminescent (EL) devices. As a highly stretchable electrode, conducting ionogels of a double network structure which are further reinforced by the ionic and covalent crosslinking of the network were prepared. Based on their excellent mechanical properties and high conductivity, the developed ionogels are envisioned as stretchable ionic conductors for extremely stretchable EL devices. The EL device fabricated with the developed ionogel exhibits stable working operation under an ultrahigh elongation of over 1200% as well as severe mechanical deformations such as bending, rolling, and twisting. Furthermore, the developed ACEL devices also display stable luminescence over 1000 stretch/release cycles or at temperatures as harsh as 200 °C.

4:30 PM SB07.10.03
Flexible Magnetoreceptor with Tunable Intrinsic Logic for On-Skin Touchless Human-Machine Interfaces Pavlo Makushko[1,2], Eduardo Sergio Oliveros Mata[1], Gilbert Santiago Cañón Bermúdez[1], Mariam Hassan[3,4], Sara Laureti[3], Christian Rinaldi[5], Federico Fagiani[5], Gianni Barucca[4], Nataliia Schmidt[6], Yevhen Zabila[1,7], Tobias Kosub[1], Rico Illing[1], Oleksii Volkov[1], Igor Vladymyrskyi[2], Juergen Fassbender[1], Manfred Albrecht[6], Gaspare Varvaro[3] and Denys Makarov[1]; [1]Helmholtz-Zentrum Dresden-Rossendorf, Germany; [2]National Technical University of Ukraine "Igor Sikorsky Kyiv Polytechnic Institute", Ukraine; [3]Consiglio Nazionale delle Ricerche, Istituto di Struttura della Materia, Italy; [4]Università Politecnica delle Marche, Italy; [5]Politecnico di Milano, Italy; [6]Institute of Physics, University of Augsburg, Germany; [7]The H. Niewodniczanski Institute of Nuclear Physics, Polish Academy of Sciences, Poland

Flexible magnetoreceptive electronic skins are game changer for prospective personal appliances, human-machine interactions and augmented reality applications [1]. Mechanically compliant magnetoresistive sensors have been introduced as touchless human-machine interfaces enabling the interaction with magnetic objects by means of proximity sensing, motion, and orientation tracking features[2,3]. Although basic interactive functionality has been demonstrated, the current on-skin magnetoreceptors are not yet employed as advanced spintronics-enabled switches and logic elements for skin compliant electronics. The major limitation remains primarily due to the use of magnetic layer stacks, which are in-plane magnetized and, hence, are mainly sensitive to magnetic fields oriented within the sensor plane.
Introducing flexible Hall effect sensors[4,5] could provide a solution to this conundrum, however, they cannot be intrinsically tuned to be bistable as needed for switches, and thus require additional flexible electronic modules. Considering the lower performance of flexible electronics compared to their rigid counterparts in terms of integration density and speed[6], full-fledged interactive systems should be built based on smart sensors with intrinsic logic functionality, which can be tailored by the material properties rather than by the circuit design.
Here, we present the first mechanically flexible spin valve switch sensitive to the out-of-plane magnetic fields [7]. The spin valve device is realized on a flexible polyethylene naphthalate (PEN) foil relying on Co/Pd multilayers with perpendicular magnetic anisotropy and synthetic antiferromagnet as a reference layer. By tuning the strength of magnetic coupling between free and reference layers we can tailor the functionality of the flexible device to act as a momentary or permanent (latching) switch. We show mechanical stability of the devices as they retain performance upon bending up to 3.5 mm bending radius and withstand more than 600 bending cycles without sacrificing their functionality. Due to the intrinsic memory function, the magnetic latching switches can reliably operate in an environment with strong magnetic disturbances.
Unambiguous interpretation of the out-of-plane magnetic fields provides intuitive understanding of the input stimuli and prevents from false triggering. We demonstrate the performance of our device as a touchless interactive interface for augmented reality system as well as its tolerance to the magnetic field disturbances. We showcase the great potential of this new kind of flexible magnetoreceptive functional elements for realization as on-skin human-machine interfaces for virtual- and augmented reality applications.

Novel Electroactive Interfaces for Biomedical Applications Jadranka Travas-Sejdic; The University of Auckland, New Zealand

Conducting polymers (CPs) are emerging as one of the most promising functional materials for bioelectronics and biointerfaces due to their high biocompatibility, intrinsic electrical and ionic conductivity, tunable mechanical properties and the capability of being functionalized through chemical modification.
In this presentation, I will discuss novel bioelectronic materials and devices, based on conducting polymers, as well as a direct printing technique, useful in making both 2D and 3D polymer electronics. The examples will include: (i) electrochemically switchable, flexible, electrospun, microporous substrates for

selective captures and releases of intact extracellular vesicles[1] and (ii) 3D printed polymer microelectrode arrays for 3D electrical stimulation of neural stem cells[2].

9:00 PM SB07.11.02
Highly Conductive, Self-Healable and Stretchable Solid-State Ionic Conductors Minsu Kim, Dae Hyun Cho, Kyunggook Cho and Keun Hyung Lee; Inha University, Korea (the Republic of)

Solid-state nonvolatile ionic conductors, known as iongels, consisting of polymer network and ionic liquid have attracted significant attention as promising solid electrolytes for electrical and electrochemical devices because of their outstanding physicochemical properties including low vapor pressure, high ionic conductivity, and superior mechanical property including stretchability and elasticity. For the long-term operation of deformable devices, the active layers can properly function without performance degradation from the external mechanical stress including large and/or successive strain. The introduction of self-healing functionality in ionogels prevents physical and functional degradation from the mechanical breakdown and thus significantly improves their tolerance to the external stress. In this work, we developed highly conductive and self-healable solid electrolytes with outstanding stretchability (fracture strains more than 600%). The effect component ions on the mechanical and electrical properties were systemically investigated. In addition, these ion gels were successfully employed in stretchable strain sensors and the healed devices displayed nearly identical electrical signals compared to undamaged sensors.

9:05 PM SB07.11.03
A Textile-Based Stretchable Supercapacitor with Wide Temperature Tolerance for Wearable Application Hanchan Lee and Jeong Sook Ha; Korea University, Korea (the Republic of)

Along with the extensive development of wearable electronics for integration into the body or clothes, textile-based devices have attracted great attention. At the same time, the necessity for wearable energy storage devices stable under harsh environmental conditions of temperature and humidity as well as deformations of bending and stretching has been also increased, for a reliable application to daily lives. In this work, a textile-based stretchable supercapacitor with a tolerance over a wide temperature range between −30 and 80 °C is reported. The textile-based stretchable supercapacitor with MWCNT/RGO nanocomposite electrodes and ionic liquid-based gel-type electrolyte exhibits high electrochemical performance, temperature tolerance, and mechanical stability: High areal capacitances of 28.0, 30.4, and 30.6 mF/cm^2 are obtained at −30, 25, and 80 °C temperatures, respectively, while the capacitance remains stable over three repeated cycles of cooling and heating between −30 and 80 °C. The fabricated supercapacitor is stable under stretching up to 50% and 1000 repetitive cycles of stretching by 30%. With the supercapacitors, a temperature sensor and a liquid crystal display is simultaneously operated in the temperature range between −20 and 80 °C. The supercapacitors woven into a nylon glove drive a micro-LED under the bending of the index finger and retain the capacitance after being immersed in water for a few days. This work demonstrates the high potential application of our textile supercapacitor as a wearable energy storage device under severe conditions of high/low temperatures, high humidity, and movements of the body.

9:10 PM SB07.11.04
Stretchable QD-LED Array for Bio-Signal Monitoring Yonghui Lee and Jeong Sook Ha; Korea University, Korea (the Republic of)

Display device that can visually present various bio-signals is one of the future core technologies required for skin attachable wearable electronics. Quantum dot light emitting diode (QD-LED), which can be used for high performance display devices, exhibits many advantages such as a narrow bandwidth, a high color purity, a high environmental stability, easy and fast processing, and a high brightness at low voltages. In this study, we report on the fabrication of a stretchable QD-LED array for the visual display of the skin-attached sensor signals of the body movements and skin temperatures. On a stretchable elastomer substrate of Ecoflex/PDMS, an array of a rigid NOA63 islands is formed. Then, the array of CdSe/ZnS QD-LEDs are fabricated on top of the islands array and electrically connected by using liquid metal Galinstan interconnections. Of particular importance, a flexible and high-performance Au grid/Ethylene glycol doped PEDOT:PSS transparent electrode was used as a replacement of conventionally used ITO for stable performance of the QD-LEDs under deformations. Such a design architecture can minimize the strain applied to the QD-LEDs via concentrating the strain onto the soft elastomer film substrate and the Galinstan interconnections. As a result, the fabricated QD-LED array exhibits a stable operation under both 50% uniaxial and 30% biaxial strains. After attachment of the stretchable QD-LED array, the extent of knee bending, and the change of skin temperature are displayed as a change in the pattern of the QD-LED array. This work demonstrates the potential application of our stretchable array of QD-LEDs to facile and daily monitoring of health conditions in the form of visual display.

Self-Healable Organic Electrochemical Transistors Xihu Wu and Wei Lin Leong; NTU, Singapore

The use of conjugated polymers for bioelectronics applications is especially attractive due to their favorable properties, namely, chemical stability, facile processability, biocompatibility as well as enabling an amiable interface with living cells and tissues. One new class of devices that leverage these many attributes of conjugated polymers is organic electrochemical transistors (OECTs). Owing to their high transconductance and thus capable of amplifying

small biologicle or ionic signals into electronic output, OECTs are especially promising for diverse biomedical applications such as the detection of ions, metabolites, alcohol, DNA, and cells. Poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) has been extensively used as self-healable OECT channel layer and demonstrated outstanding transconductance values.[1] The OECT performances are influenced by the combination of ionic-electronic conduction properties of the active material. Although there are not many reports on self-healable PEDOT:PSS, there have been efforts to improve the mechanical properties of PEDOT:PSS. One of the challenges in developing self-healable conjugated polymers for organic electrochemical transistors (OECTs) lie in maintaining good both ionic and electronic properties. Incorporation of stretchable polymer matrix, such as polyurethan, polyacrylic acid, polyethylene glycol, natural rubber, have been done to boost the self-healability and mechanical properties of PEDOT:PSS films, however, these composites struggle with either poor ionic conductivity or poor electrical conductivity even with relatively high PEDOT:PSS content. In this text, we demonstrate a solid state OECT that is self-healable and possess good electrical performance, by utilizing a matrix of PEDOT:PSS and non-ionic surfactant, Triton X-100 as channel, and ion conducting poly(vinyl alcohol) hydrogel as a quasi-solid-state polymer electrolyte. Details of the self-healing mechanism, device performance including the transconductance, response time and electrochemical doping/de-doping stability before and after healing were presented. These findings will contribute to the development of high performing and robust OECTs for wearable bioelectronic devices.

9:20 PM SB07.11.06
Breathable and Waterproof Fibrous Organic Electrochemical Transistors for On-Skin Electronics Shuai Chen and Wei Lin Leong; Nanyang technological university, Singapore

Recently emerged on-skin electronics with applications in human-machine interfaces and on-body healthy monitoring call for the development of high-performance skin-like electrodes and semiconducting polymers. The development of waterproof and breathable membranes that can provide a high level of protection for human skins and a comfortable contact between electronics and human skin are the pressing demands for on-skin electronics. However, major challenges still remain such as the limited durability and permeability of gas and liquid, which hindering the long-term stability and reusability. Therefore, it is highly desirable to develop a type of. Herein, we reported a fibrous electrolyte membrane containing polymer matrix and ionic liquid by electrospinning method, which is highly robust, breathable, waterproof, and conformal with human skin, after bonding a parylene layer with fibers. In addition, the parylene layer can also improve the connection of junctions between fibers, which showed improved conductivity of electrodes and organic semiconducting layer. Serving as fibrous substrate and electrolyte of organic electrochemical transistors (OECTs), the ions can freely transport along the fibers and across the bridged fibers and the gate bias can control the ionic injection from the fibrous electrolyte to channel to modulate the conductivity of organic semiconductor. The waterproof and breathable capabilities of fibrous OECTs enable comfortable contact after attaching to human skin, which can also reduce the interfacial impedance to achieve local amplification of the high-quality electrocardiography signals. These results indicated that our fibrous OECTs have huge potential for on-skin electronics such as non-invasive medical monitoring, sophisticated electronics, and electronics textiles.

9:25 PM SB07.11.07
Interactive Electrochromic Display of Bio-Signals Dong Sik Kim and Jeong Sook Ha; Korea University, Korea (the Republic of)

We report on the fabrication of an interactive display system consisting of a stretchable array of electrochromic devices and temperature and strain sensors for visual display of a skin temperature and bending of wrist. The electrochromic device is prepared by coating poly(3-hexylthiophene) and tungsten trioxide as electrochromic materials on a flexible and transparent electrode of indium tin oxide coated polyethylene terephthalate, and subsequent assembly of thus prepared electrodes using a gel-type electrolyte of Li-doped 1-butyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide/poly(methyl methacrylate). The fabricated ECD exhibits three different colors due to the redox reaction of the electrochromic materials at the corresponding potential: magenta, violet, and blue at -1.5 V, 0.5 V, and 1.5 V, respectively. By using the patterned liquid metal Galinstan interconnections, a stretchable array of the ECDs is fabricated based on a strain relieving mechanism with an island-bridge design resulting in a mechanical stability under repetitive stretching up-to 30%.
A high performance strain sensor is fabricated by embedding fragmentized graphene foam (GF) inside poly(demithylsiloxane) thin film. Also, a temperature sensor is prepared by embedding multi-walled carbon nanotubes/polyaniline composite into poly(vinyl alcohol) film. With the integrated system, strains due to wrist bending and the skin temperatures measured by the sensors are displayed as the changes in the color pattern of the ECD array via an aid of an Arduino circuit. This work demonstrates a high potential application of our system to wearable healthcare devices with instant recognition of various bio-signals.

9:30 PM SB07.11.08
Room-Temperature Growth of Ultra-Flat Transparent Conducting ZnO Thin Films on the Morphologically and Chemically Surface-Modified Polymer Substrates for Flexible Optoelectronics Devices Tomoaki Oga[1], Naho Kaneko[1], Kenta Kaneko[1], Satoru Kaneko[2,1], Akifumi Matsuda[1] and Mamoru Yoshimoto[1]; [1]Tokyo Institute of Technology, Japan; [2]Kanagawa Institute of Industrial Science and Technology, Japan

The combination of flexible transparent polymer substrates and wide band-gap oxide semiconductors with superior electrical and/or magnetic properties is highly expected to be applied to the wearable optoelectronics devices. Most of the optoelectronics devices using the highly crystal orientated oxide semiconductors such as ZnO thin films are fabricated on the glasses or single crystal substrates at high temperatures. On the other hand, thermoplastic cyclic olefin polymers (COPs) used in this study have extremely low hygroscopicity, high transparency and relatively high heatproof temperatures (about 150°C), so they are the possible flexible substrates applied to the wearable optoelectronics and bioelectronics devices. For growth of the highly crystalline oxide thin films on the polymer substrates with irregularly roughened surfaces, we had better employ the thin film techniques to control the nucleation and growth direction of oxides at low temperatures as well as polymer surface modification.
So far, we reported the nanoscale smoothening and patterning on the polyimide or PMMA acrylic polymer substrates, which had the surfaces with 0.3 nm-high atomic steps and about 500 nm-wide ultra-flat terraces by applying thermal nanoimprinting using atomically stepped sapphire molds.[1] As a result, the crystallinity and surface roughness of oxide thin films deposited on the surface-controlled polymer substrates were greatly improved.[2] In this study, we investigated the effects of oxide buffer-layer insertion as well as nanoimprinted surface modification of the COP polymer substrates on the crystal growth manner and electronic properties of ZnO thin films deposited on the substrates at room-temperature. Development of the advanced low-temperature growth techniques of high-quality functional oxide thin films on the flexible polymers will open the new field in the application of oxide-polymer hybrid flexible and wearable devices.
In the experiment. thermoplastic COP (ZF16-188, ZEON; T_g~163°C, t~188 μm) sheets were used as polymer substrates. Two kinds of surface modifications of COP substrates were carried out successively as follows; (1) thermal nanoimprinting of 0.3 nm-height atomic-step array and terrace pattern using α-Al_2O_3 single crystal molds (2 MPa, 180°C, 5 min, in 10^3 Pa-Ar gas), and then (2) buffer layer insertion on the substrate by pulsed laser deposition (PLD) of an amorphous oxide thin film such as aluminum oxide or gallium oxide. Then, ZnO semiconductor thin films (t~40 nm) were grown at room-temperature on the surface-modified, and as-received COP substrates by PLD using a sintered ZnO target and a KrF excimer laser (λ=248 nm, d~20 ns) under O_2 gas of 10^{-3} Pa.
As a result, the ZnO thin film grown on the nanoimprinted and Ga_2O_3 buffered COP substrate exhibited an ultra-flat surface with 0.3 nm-high atomic step-and-terrace pattern and RMS roughness of about 0.15 nm. From XRD and RHEED measurements, it was found that the present ZnO thin film had a drastic improvement in c-axis oriented growth and crystallinity compared to that grown on the untreated COP substrate. Furthermore, the electric conductivity of

the ZnO thin films on the surface-modified COP substrate was increased by one-order of magnitude to 4×10^{-2} Ωcm than that on the untreated substrate. Thus, the present physical and chemical surface modification of the polymer substrate was considered to enhance the homogeneous nucleation and crystal orientation at the initial stage of oxide thin film growth, resulting in the development of the ultra-flat surface and c-axis oriented crystal growth of the ZnO thin film on the COP substrate.
[1] G. Tan et al., Nanotech., **27**, 295603 (2016), [2] T. Oga et al., Jpn. J. Appl. Phys., **59**, 128001 (2020).

9:35 PM SB07.11.09
Nano-Scale Growth Study of Calcium Phosphate Thin Films on the Nanopatterned and Chemically-Modified Polymer Sheets for Flexible Apatite-Based Biodevices Naho Kaneko[1], Yuto Maeda[1], Tomoaki Oga[1], Kazuki Watanabe[1], Kenta Kaneko[1], Tomohiro Hayashi[1], Evan Angelo Q. Mondarte[1], Satoru Kaneko[2,1], Akifumi Matsuda[1] and Mamoru Yoshimoto[1]; [1]Tokyo Institute of Technology, Japan; [2]Kanagawa Institute of Industrial Science and Technology, Japan

Biocompatibility of the devices is an important factor for application in the biomedical field. Calcium phosphate (Ca-P), particularly hydroxyapatite (HAp), is well known as bioceramics with high biocompatibility and Ca-P materials are used in biosensors due to unique protein adsorption [1]. Since flexibility and stretchability are essential factors for future wearable electronics, electronic skin, implantable biomedical devices, and soft robotics [2], combination of flexible polymer substrates and Ca-P thin film would contribute to development of new biodevices. On the other hand, the nanoscale size and shape of Ca-P crystals and aggregates are considered to play critical roles in their applications [3]. Deposition and growth characterization of Ca-P thin films on the nanopatterned polymer substrates is expected to lead to nanoscale control of Ca-P thin film growth.
So far, we have reported atomic-scale nanopatterning of polymer sheets such as polyimide (PI) and acrylic resin (PMMA) by applying originally developed thermal nanoimprint technique, in which we could fabricate the 0.3 nm-high atomically stepped patterns on the PI and PMMA sheets [4]. The nanoscale-aligned surface morphology on the polymer substrates was found to control the crystal nucleation and growth direction of functional inorganic thin films on their surfaces [5]. In this study, we investigated the nanoscale growth manner of calcium phosphate thin films on the nanopatterned and chemically-modified polymer sheets using the ex-situ and liquid-environment in-situ AFM for development of the flexible apatite-based biodevices.
In the experiment, the Ca-P thin films were grown on the polyethylene terephthalate (PET) sheets with atomically stepped patterns, which pattern was transcribed on a PET surface by nanoimprinting (pressure of 0.2 MPa for 5 min at 85°C in air) using a replica PI (Mitsui Chemicals Co., ECRIOS® VICT-Bnp, T_g=265°C). The nanopattern replica mold was fabricated by transcription of 1 nm-high bunching stepped sapphire mold [4]. Before thin film growth, the transcribed atomically stepped PET substrates were “modified” by treatment in NaOH aq. (0.1 M) at 60°C for 10 min to form carboxylate groups on the surface. The atomically stepped patterns were kept on the PET substrate even after the alkali-treatment. For Ca-P thin film growth, the surface-modified PET substrate was immersed in Hanks' Balanced Salt Solution (HBSS(+); Fuji-Film Wako Pure Chemical Co., No. 082-08961) at 37°C for 1 h. After deposition, the samples were picked up, cleaned with ultrapure water, and dried using nitrogen blower.
From ex-situ AFM observations, precipitation of nanoparticles was observed on the entire substrate. For the analysis of the particle, watershed algorithm was used. The particle distribution result indicated that the statistical mode radius and height of the nanoparticles were about 25 nm and about 3 nm, respectively. The size of the grown nanoparticles was similar to that of the aggregates of prenucleation clusters, that is, the basic unit of the final Ca-P crystals reported previously [6]. These AFM observations would be expected to advance understanding of the initial growth of Ca-P materials on the polymer substrates, leading to the nanoscale design of flexible apatite-based biodevices.

Soft, Self-Healing and Highly Adhesive Hydrogels for Human Healthcare Xin Zhou and Fabio Cicoira; Polytechnique Montréal, Canada

Soft, healable, and adhesive conductive materials with Young’s modulus matching biological tissues are highly desired for bioelectronics. Here, we report soft, self-healing, stretchable, highly adhesive and conductive hydrogels obtained by mixing polyvinyl alcohol, sodium tetraborate, and a commercial screen printing paste containing Poly (3,4-ethylenedioxythiophene) doped with polystyrene sulfonate (PEDOT:PSS) and diol additives. The as-prepared hydrogels exhibited high plastic stretchability (>10000%), high adhesion on pig skin (1.96 N/cm^2), a moderate conductivity, a low compressive modulus (0.3 - 3.7 KPa), and remarkable self-healing properties. Epidermal electrodes prepared using the hydrogel demonstrated high-quality recording of electrocardiography (ECG) and electromyography (EMG) signals compared to commercial Ag/AgCl gel electrodes.

9:45 PM SB07.11.12
Epidermal Graphene Sensors and Machine Learning for Estimating Swallowed Volume Beril Polat; University of California, San Diego, United States

Assessment of liquid intake is necessary to obtain a complete picture of an individual’s hydration status. Measurements using state-of-the-art wearable devices have been demonstrated, but none of these devices have combined high sensitivity, unobtrusiveness, and automated estimation of volume, i.e., using machine learning. Such a capability would have immense value in a variety of medical contexts, such as monitoring patients with dysphagia or the performance of athletes. Here, an epidermal sensor platform is combined with machine learning to measure swallowed liquid volume based on signals obtained from the surface of the skin. The key component of the device is a composite piezoresistive sensor consisting of single-layer graphene decorated with metallic nanoislands and coated with a highly plasticized form of the conductive polymer poly(3,4-ethylenedioxythiophene):poly(styrenesuflonate) (PEDOT:PSS). Surface electromyography (sEMG) signals obtained with conventional electrodes are used in concert with the strain measurements. The use of strain and sEMG measurements together both (1) improve the accuracy of estimated volumes and (2) permit the differentiation of swallowing from motion artifacts. In a cohort consisting of 11 participants, the combined measurements of strain and sEMG—processed by the machine learning algorithm—were able to estimate unknown swallowed volumes cumulatively between 5 to 30 mL of water with greater than 92% accuracy. Ultimately, this system holds promise for numerous applications in sports medicine, rehabilitation, and the detection of nascent dysfunction in swallowing.

9:50 PM SB07.11.13
Electrochemical and Operational Stability of Ion-Gel Gated Organic Transistors Mona Azimi and Fabio Cicoira; Polytechnique Montreal, Canada

Electrolyte gated transistors (EGTs) benefits from low operating voltage and high charge carrier mobility. However, concerns about the confinement of liquid electrolytes and inhibition of leakage of liquid are of utmost importance in the fabrication of EGTs. Ion gels are a suitable solution for solving the aforementioned problems. In this work, we fabricated a low voltage ion-gel gated organic transistors based on donor−acceptor copolymer, poly(N-alkyldiketopyrrolo-pyrrole-dithienylthieno[3,2-b]thiophene) (DPP-DTT). We studied the transistor characterization of ion-gel gated transistors using ionic

liquid-based gel and hydrogel. Gels based on ionic liquid composed of (1-ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide ([EMIM][TFSI])) and poly(vinylidene fluoride- co-hexafluoropropylene) (P(VDF-HFP)). Electrochemical and operational stability of ionic liquid-based gel gated devices in ambient condition were conducted, and the results revealed significant stability, most likely due to the well-ordered compact lamellar structure of the organic semiconductor. In addition, hydrogel-based on polyvinyl alcohol (PVA) and sodium chloride (NaCl) was used as gating medium. The operational stability of the hydrogel gated transistor is also studied in ambient and different relative humidity conditions. Totally, this study will contribute to development of highly stable organic transistors using ionic liquid-based gels and hydrogels as gating media.

Organic Electrochemical Transistors for Protein Detection Sahika Inal; King Abdullah University of Science and Technology, Saudi Arabia

Conjugated polymers provide a unique toolbox for establishing electrical communication with biological systems. In this talk, I will show how these materials are used in organic electrochemical transistors (OECTs) to detect biological species in physiological media. I will introduce two types of OECT based sensors; one that detects Alzheimer's disease biomarkers with performance exceeding the state-of-the-art,[1,2] and the other that detects coronavirus spike proteins at the physical limit.[3] Having challenged these sensors with patient samples, I will discuss areas where proof-of-concept organic biosensor platforms may fail. By tackling each of these problems, we improve device performance to a level that marks a considerable step toward biochemical sensing of infectious and noninfectious disease biomarkers. I will highlight that the advances in biosensor device design stem from in-depth investigations of the active materials' transport properties, device operation principles and carefully designed biorecognition units.

Development of Biomimetic Hydrogel Skin Interfaces for Sweat Extraction and Analysis in Wearable Devices Tamoghna Saha, Tate Knisely, Jennifer Fang, Sneha Mukherjee, Michael Dickey and Orlin D. Velev; North Carolina State University, United States

Sweat is an essential biofluid for monitoring individuals' health as it contains several key biomarkers. However, sampling sweat for analysis is still challenging as most of the commercially available sweat sensing devices are either invasive in nature or work only during active perspiration. We demonstrate a new principle for the design of flexible and wearable patches, based on biomimetic hydrogel interface. These devices are capable of extracting sweat under both resting and actively perspiring conditions using osmotic pressure difference for pumping, and evaporation for liquid disposal.[1] The patch is composed of silicone that hosts a polyacrylamide hydrogel disk and a paper channel with an evaporation pad at the end. The hydrogel, which contacts the skin, is pre-equilibrated with glycerin, glucose, or NaCl solution to build up the desired osmotic strength to extract sweat from the skin, which is then sampled on a paper channel.[2] We investigate the performance of the patch using a model biomarker (dye) solution. *In-vitro* testing with a gelatin-based model skin platform revealed that both glucose and glycerin-infused gels facilitate high analyte accumulation on the evaporation pad, with glucose hydrogels having the highest driving pressure. The cumulative dye collection also depends on the dimensions of the paper channel, hydrogel area and paper pore size. Human trials show the potential to extract sweat and analyze it for lactate under both resting and non-resting conditions within a period of two hours. We used lactate as a concept demonstrator, as sweat appears to be more informative medium for lactate quantification than blood. The ability to measure lactate enables monitoring metabolism and oxidative stress levels in athletes and military personnel. Our group is currently investigating how this hydrogel enabled sweat sampling concept can be integrated in continuously operating wearable devices using enzymatic electrochemical sensors[3], and with microneedle patches for long-term interstitial fluid (ISF) sampling.

8:45 AM SB07.12.03
Thermoplastic poly(2-methoxyethyl acrylate)-based Polyurethane and Its Antithrombogenicity Shunsuke Tazawa[1], Tomoki Maeda[1,2], Masamitsu Nakayama[1,3] and Atsushi Hotta[1]; [1]Keio University, Japan; [2]Ibaraki University, Japan; [3]Tokai University Graduate School of Medicine, Japan

In this study, thermoplastic poly(2-methoxyethyl acrylate)-based polyurethane (PMEA-based PU) with reversible crosslinkings constructed through hydrogen bonds, was synthesized by reversible-addition fragmentation transfer (RAFT) polymerization and polyaddition using diisocyanate. The newly synthesized thermoplastic PMEA-based PU possessed excellent antithrombogenicity.
Poly(2-methoxyethyl acrylate) (PMEA) is known as an excellent biocompatible liquid for its antithrombogenicity [1,2]. However, major applications of PMEA are always limited to antithrombogenic coating because the glass transition temperature of PMEA is around -30°C, meaning that PMEA is viscous liquid at room temperature. Therefore, by solidifying PMEA, the usage of PMEA will become significantly broadened as a bulk material. To obtain PMEA-based PU, hydroxyl-terminated PMEA (HO-PMEA-OH) was first synthesized by RAFT polymerization with a RAFT agent consisting of hydroxyl groups at both ends. Then, HO-PMEA-OH was reacted with diisocyanate to form urethane bonds for the introduction of hydrogen bonding. The synthesized HO-PMEA-OH by RAFT polymerization (the prepolymer of PMEA-based PU) was a viscous liquid. After the polyaddition reaction with diisocyanate, a solid standing film of PMEA-based PU could be obtained. The existence of the urethane bonds in PMEA-based PU was confirmed by NMR and FTIR. The existence of the hydrogen bonding in PMEA-based PU was also confirmed by FTIR.
Thermoplastic and mechanical properties of PMEA-based PU were analyzed by dynamic mechanical analysis (DMA). The storage modulus of PMEA-based PU was 2.3×10^5 Pa, while that of HO-PMEA-OH was 2.5×10^3 Pa. As for the thermoplastic property, the melting point of PMEA-based PU was 73°C, while HO-PMEA-OH was in the liquid state from 0°C to 100°C. All these results indicated that, by introducing reversible crosslinkings by hydrogen bonds, PMEA-based PU successfully became solid and thermoplastic.
Antithrombogenicity of PMEA-based PU was also evaluated through platelet-adhesion testing. The number of platelets on PMEA-based PU was 17 cells per 22,570 μm^2. In fact, the numbers of platelets on fluorinated diamond-like carbon (F-DLC), a well-known highly antithrombogenic material [3], and on polycarbonate, a commercially used material in the medical field (e.g., the blood circuit) were 73 cells and 295 cells, respectively. The results of the

platelet adhesion test confirmed that PMEA-based PU possessed excellent antithrombogenicity compared to the conventional antithrombogenic materials.

Dynamic Defects, Bacterial Biofilms and Medical Device Infections Dalal Asker, Tarek Awad, Desmond van den Berg and Benjamin Hatton; University of Toronto, Canada

Indwelling medical devices such as catheters, prosthetic heart valves and reconstructive implants are susceptible to microbial biofilm colony formation and serious infection. Does mechanical deformation of elastomer biomaterials (such as PDMS silicone) affect microbial surface colonization? Recently we found that bacteria prefer the tensile (convex) side of deformed silicone tubing, by about a factor of 3-4 times, over the compressive (concave) side. Why should this be? In general, there is not a very good understanding of microbial-surface interactions at early stages of growth. But we do know they're very sensitive to surface defects and roughness (scratches, grooves, etc). We have recently shown that elastomers such as silicone (polydimethylsiloxane, PDMS) or polyurethane form surface microcracks much more readily than has been previously recognized, and these surface defects become primary sites for initial microbial attachment. We show that even mild mechanical contact or deformation of PDMS materials, such as by surface wiping, is enough to generate these microcracks. The deformation of silicone tubing then appears to open up these microcracks, as dynamic defects that become sites for initial attachment of Pseudomonas aeruginosa. That a typical, mild deformation of elastomer medical devices can make them significantly more susceptible to infection appears to be a previously unrecognized mechanism for medical device-associated infections. We speculate that a wide range of elastomeric medical devices and components, from silicone breast implants to prosthetic heart valves and vascular grafts may be susceptible, and we present simulation data about localized strains in some typical devices that may be problematic.

Hybrid Approaches to Soft Electronics Benjamin C. Tee; National University of Singapore, Singapore

Wearable electronics closely contacts the skin interface to collect health parameters and understand the environment[1]. For devices that contact soft tissues such as skin, appropriate mechanical moduli is required to integrate more seamlessly into human activities. Simultaneously, exciting research in materials science and engineering of soft materials can enable self-healing functions in artificial materials that repair autonomously like biological skin[2,3]. In this talk, I will discuss our work in using a hybrid soft-hard approach to create soft devices that can bend and stretch. Such approaches can also lower the viscoelastic properties of soft materials for sensing applications[4]. These devices can be used in wearable or human-machine interface technologies for healthcare applications[5].

Pushing OECTs Toward Wearables—The Development of a Miniaturized Device Characterization System Xinyu Tian[1] and Shiming Zhang[1,2]; [1]The University of Hong Kong, China; [2]Terasaki Institute, United States

Portable and wearable devices are highly demanded to achieve the goal of decentralized and personalized healthcare. Organic electrochemical transistors (OECTs), which combine advantages of both an electrochemical cell and a microelectronic transistor, have high signal amplification ability and are energy efficient. OECTs have been widely explored for application in emerging research areas including health monitoring, bioelectronic interfacing, and neuromorphic computing. However, despite these advances, a miniaturized OECT characterization system is still missing, which is an indispensable building block to realize the feat of fully integrated OECTs for portable and wearable applications. The development of a miniaturized OECT characterization system is challenging because it requires transdisciplinary efforts among device engineering, microelectronics, embedded systems, wireless communication, and software engineering.

In this work, we report our recent breakthrough on the development of the world's first miniaturized system, namely "personalized electronic reader for electrochemical transistors" (PERfECT), for portable OECT characterizations. Our PERfECT is a coin-sized flexible module that measures an OECT wirelessly and is controllable with a personalized APP on a mobile. Experimental validation demonstrates that PERfECT can measure various kinds of electrolyte-gated transistors including ECTs and FETs, with a low current detection limit of 1 nA, a high sampling rate of 200K per second, a gate pulse as short as 20 uS. The figure of merits of PERfECT is comparable to that of lab-used bulky equipment. Moreover, PERfECT is equipped with all functions of an electrochemical workstation such as cyclic voltammetry (CV), amperometry, potentiometry, and electrochemical impedance spectroscopy (EIS). These merits, altogether, make PERfECT a highly pursued system for commercial uses.

PERfECT contributes to the OECT community by bridging the last-mile gap between OECTs and a fully integrated miniaturized system for portable and

wearable applications.

Localized Heating of Lab-on-Chip Devices by Flexible Transparent Electrodes Based on Silver Nanowire Networks Dorina T. Papanastasiou[1], Abderrahime Sekkat[1], Viet Huong Nguyen[2], Magali Le Goff[3], Carmen Jimenez[1], David Munoz-Rojas[1], Franz Bruckert[1] and Daniel Bellet[1]; [1]LMGP-Grenoble INP-CNRS-UGA, France; [2]Phenikaa University, Viet Nam; [3]Université Grenoble Alpes, France

In situ biological observations present challenges related to the accurate temperature control of the biological medium. Several heating elements have been coupled with microfluidic systems during fluorescence monitoring under a microscope. However, they are either complicated or costly to be mounted, or they are not transparent enough to facilitate the observations. Very few examples have reported the use of transparent heater (TH) devices for *in situ* experiments. Among them, traditional technologies, like the indium tin oxide (ITO), suffer from serious drawbacks like the scarcity of raw material and the brittleness of the film. Silver nanowire (AgNW) networks are one of the most promising alternative transparent electrodes (TE) since: i/ they exhibit excellent optical and electrical properties, ii/ they are very flexible, and iii/ they can be fabricated by low-cost, solution-based techniques suitable for large scale production.
In the present work we propose a transparent, flexible, light-weight transparent heater integrated to a lab-on-chip set-up. Using a low power-supply, we are able to accurately control the thermal cycles inside the microfluidic channels and reach efficient heating-cooling rates comparable to other laboratory and/or commercial instruments. In addition, localized heating with micrometric resolution can be achieved by using a single TH elements and applying the same voltage. To do so, we have used a simple approach of putting 3D-printed masks during the spray deposition of the AgNW networks. These patterned regions have different density, resulting to different local electrical resistance. This can be exploited for example for heating selectively different microfluidic channels at different temperatures. Physical modelling can be supplementary used to predict and design such transparent heaters. Meanwhile, in order to ensure a stable and reproducible performance, we have encapsulated the AgNW network with a thin, protective zinc oxide (ZnO) film. As already demonstrated in our previous studies, such AgNW/ZnO nanocomposites retains the high transparency and flexibility of bare networks. Developed by atmospheric-pressure atomic layer deposition (AP-SALD), it can be done in the open-air (i.e. without the need of a deposition chamber) and rather low temperatures, which makes it compatible with up-scalable processes and very promising for industrial implementation.

2:30 PM *SB07.13.05
Soft Rubbery Bioelectronics Cunjiang Yu; University of Houston, United States

Seamlessly merging electronics with biology is of imminent importance in addressing grand societal challenges in health and joy of living. However, the main challenge lies in the huge mechanical mismatch between the current form of rigid electronics and the soft nature of biology. Our approach is to create rubbery electronics to solve the challenge. Rubbery electronics is a new type of electronics, with tissue-like softness and mechanical stretchability, which is constructed all based on elastic rubbery electronic materials. Rubbery electronics allows seamless integration with soft deformable tissues and organs. The innovations in rubbery electronic materials and devices set the foundation for rubbery electronics, integrated system and their broad usages, such as wearables and implantables. The presentation will firstly briefly present our recent results on the development of materials, manufacturing and devices, including rubbery semiconductors, fully rubbery transistors, logic gates, integrated electronics, and sensors. It will then demonstrate rubbery implantable and wearable electronics to showcase their vast implications in biomedical area with their clear merits of being able to harmonically interface with soft human tissues and organs for sensing, diagnosis, preventing and therapy purposes. In particular, a rubbery bioelectronic epicardial patch and a drawn-on-skin (DoS) motion-artifact free wearable bioelectronics will be demonstrated.

Self-Healing Liquid Metal Composite for Reconfigurable and Recyclable Soft Electronics Ravi Tutika, A B M Tahidul Haque and Michael D. Bartlett; Virginia Tech, United States

Soft electronics and robotics are in increasing demand for diverse applications. However, in contrast to rigid electronics, which are protected with stiff external supports and enclosures when deployed, soft electronics must maintain extreme compliance and cannot use these traditional means of protection, which can render them vulnerable and lead to premature disposal. This creates a need for soft and stretchable functional materials with resilient and regenerative properties to survive in unstructured environments. Here we show a liquid metal-elastomer-plasticizer composite for soft electronics with robust circuitry that is self-healing, reconfigurable, and ultimately recyclable. This is achieved through an embossing technique for on-demand formation of conductive liquid metal networks which can be reprocessed to rewire or completely recycle the soft electronic composite. Through this approach we achieve a combination of high electrical conductivity, high stretchability, and robust tolerance to damage. The embossing approach further enables soft, stretchable wiring to be created with resistance tunability over two orders of magnitude, while achieving conductivities as high as 45,400 S/cm at large strains. These skin-like electronics stretch to 1200% strain with minimal change in electrical resistance, sustain numerous damage events under load without losing electrical conductivity, and are recycled to generate new devices at the end of life. These soft composites with adaptive liquid metal microstructures can find broad use for soft electronics and robotics with improved lifetime and recyclability.

4:15 PM SB07.14.03
Carbon Nanotube-Conducting Polymer Core-Shell Microfibers for Bioelectrical Energy Storage Devices Myung-Han Yoon; Gwangju Institute of Science and Technology, Korea (the Republic of)

Carbon nanotubes (CNTs) are one of the most commonly used electrodes for fiber-type energy storage devices as they exhibit mechanical flexibility/durability, light weight, excellent electrical conductivity, and thermal/chemical stability. Nonetheless, the relatively low electrical double capacitance have limited their practical applications to fiber- and/or textile-type supercapacitors. In this research, we developed the CNT-PEDOT:PSS (poly(3,4 ethylenedioxythiophene):poly(styrene sulfonate)) core-shell microfibers via yarning and self-fusion. The core-shell microfibers were fabricated by yarning multi-strands of PEDOT:PSS microfibers (shell) onto the CNT microfiber with enhanced wettability (core), followed by the self-fusion of PEDOT:PSS microfibers. The resultant core-shell microfibers showed high electrical conductivity (~6,000 S/cm), large capacitance (~0.2 F/cm), and stable charging/discharging behaviors with minimal voltage drop and capacitance degradation. We expect that these fibers can be beneficial for flexible power

sources in wearable and textile electronics and stimulation elecrodes in implantable bioelectronics.

4:30 PM SB07.14.04
Spider's Pad Inspired Dynamic Noise-Free Bioelectronics Byeonghak Park and Tae-il Kim; Sungkyunkwan University, Korea (the Republic of)

Soft materials such as elastomers and gels provide the potential for applications in bioelectronics that can be used in biophysiological monitoring. However, these applications are limited by the presence of dynamic mechanical noise artifacts in monitored signals under 30 Hz, for example due to walking and respiration. Although signal processing techniques such as bandpass filtering can be used to selectively remove such artifacts, this can compromise the distorted target signals after signal processing. Here, we present the "Selective frequency fading Hydrogel for a vIscoELastic Dampening (SHIELD)", composed of a mixture of chitosan and gelatin. This material was inspired by the viscoelastic cuticular pad in a spider, used to separate target biophysiological signals while minimizing mechanical noise. The SHIELD exhibits viscoelastic properties with a frequency-dependent phase transition that results in a rubbery state that damps low-frequency noise, and a glassy state that transmits the desired high-frequency signals. The relaxation time as a proxy of the transition frequency varies with temperature and molecular weight, enabling to modulate transition frequency and resulting in selective damping capabilities. Instead of the additional signal processing after detecting from conventional sensor and electrodes or damping materials, we show that the SHIELD can be integrated with mechanosensors for the detection of biophysiological signals, or can be used as an electrode for sensing electrophysiological signals under the noisy mechanical conditions that arise in real-world applications involving medical patients. The SHIELD offers the possibility of proceeding to the practical real-time interactions between humans and devices and expanding the potential of advanced biomedical applications.

4:45 PM SB07.14.05
Late News: Highly Compliant, Flexible, Transparent, sub 150 Nanometers Thick, Fully Solution Processed All-Organic Transistor Fabrizio A. Viola and Mario Caironi; Italian Institute of Technology, Italy

The advancements in the field of electronics have paved the way to the development of new applications, such as wearable or tattoo electronics, where the employment of ultra-conformable devices is required. One of the main strategies to improve the device mechanical conformability is the reduction of its total thickness, of which the substrate usually represents the biggest contribution. To this end, organic materials can be considered enablers, owing to their advantageous mechanical characteristics, not achievable with inorganic counterparts, and to the possibility to obtain films with thicknesses at the nanometric scale. To date most of the reported approach for ultra-thin organic devices are based on physical deposition techniques that are not cost-effective. In this work we have successfully fabricated ultra-flexible, 143 nm-thick all-organic field-effect transistors, based on an ultra-thin solution processable dielectric, adopting only solution based techniques, such as spin-coating and inkjet printing. The devices can operate at low voltages and, thanks to their very low thickness, can conform to human skin in an imperceptible way and sustain bending radii as low as 0.7 mm, thus setting a new limit in thickness and flexibility. Moreover, this is the first demonstration of ultra-thin fully solution processable transistors, including the substrate. The electrical characterization showed a very good reproducibility, and the stability test in air make the devices in principle compatible with single-day, disposable usage. Moreover, the employed materials and their very low thickness guarantee a high transparency of the device. Besides providing an alternative and valid technological solution for the cost-effective fabrication of ultra-thin devices, the proposed approach can be a candidate for a plethora of possible use ranging from wearable to tattoo/epidermal electronics where conformability, ultra-flexibility and transparency are necessary.

5:00 PM SB07.14.06
Leak-Tight Anastomosis Hydrogel Sealants Using Mutually Interpenetrating Networks Alexandre Anthis[1,2], Xueqian Hu[2], Martin Tobias Matter[1,2], Anna Neuer[1,2], Kongchang Wei[3], Andrea A. Schlegel[4], Fabian H.L. Starsich[2,1] and Inge K. Herrmann[1,2]; [1]ETH Zürich, Switzerland; [2]Empa-Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [3]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [4]University Hospital Birmingham, United Kingdom

Intestinal anastomotic leaking involving the release of chemically aggressive, microbially active fluids into the abdomen through defective suture or staple sites, remains one of the most dreaded postoperative complications of abdominal surgery. Depending on the site and the patient condition, incidence rates of up to 21% and mortality as high as 27% are reported. Currently available surgical sealants only poorly address the issue, with most commonly used fibrin-based glues failing due to insufficient adhesion and chemical instability.
In this study, a leak-tight, chemically highly resistive and mucoadhesive hydrogel sealant, which is grafted on the surface of the intestinal wall via the use of a mutually interpenetrating network, is presented. This latter traverses both hydrogel and tissue yielding tissue compatible, deep anchorage. In contrast to clinically used, fibrin-based sealants (such as Tachosil), the developed poly(acrylamide-methyl acrylate-acrylic acid) (P(AAm-MA-AA)) adhesive patch does not degrade and exhibits high performance tissue adhesion under the harshest digestive conditions present in the abdominal cavity. The biocompatible hydrogel patch effectively seals anastomotic leaks in human relevant, *ex vivo* intestinal models, greatly surpassing commercial sealants (time to patch-failure >24 hours compared to 5 minutes for commonly used Tachosil). Importantly, the developed adhesive patch paves the way for the application of both mechanically and chemically robust sealants suitable for the treatment and prevention of intestinal anastomosis leaks.

5:15 PM SB07.14.07
Predicting Temporal Evolution of Self-Healing and Mechanical Properties of Intrinsic Self-Healing Polymers Through Deep Learning Hashina Parveen Anwar Ali[1], Zichen Zhao[1], Yu Jun Tan[1], Yao Wei[1], Qianxiao Li[1,2] and Benjamin C. Tee[1]; [1]National University of Singapore, Singapore; [2]Agency for Science, Technology and Research, Singapore

The temporal evolution of self-healing intrinsic polymers is generally characterized through destructive testing of many samples as computational modeling and simulations cannot capture this phenomenon. We propose a new machine learning model called Self-healing Property Evolution using the Energy-functional Dynamical (SPEED) model to identify polymers' self-healing dynamics quickly. By training on a small set of experimental measurements, this model can predict the material property and understand the self-healing mechanics of polymers by using images of cuts dynamically healing over time. The potential and interface energies showing the effective physics behind the self-healing polymer are revealed by the SPEED model too. We validate this approach on toughness measurements of an intrinsic self-healing conductive polymer by capturing over 100,000 image frames of cuts to build the ML model. The close accuracy of our SPEED model predictions of toughness with experimental data over time shows that the SPEED model can be applied to predict the temporal evolution of macroscopic properties using few measurements as training data.

5:30 PM SB07.14.08
Intrinsically Stretchable Phosphorescence Organic Light Emitting Materials for Next Generation Stretchable Displays Je-Heon Oh and Jin-Woo Park; Yonsei University, Korea (the Republic of)

Stretchable electronics, especially stretchable organic light-emitting diodes (OLED), are one of the promising technologies in display industries. The stretchable OLEDs can be used in various applications such as stretchable smartphones, 3-dimensional tactile displays, and various bioelectronics devices

including optogenetics. Until now, stretchable light-emitting panels have been developed using stretchable interconnects and rigid OLEDs. However, this approach has critical limitations such as low diode density per unit area and complexity in the device fabrication process. Hence, stretchable light-emitting diodes consisting of intrinsically deformable materials should be developed for realizing the stretchable displays. Recently, we successfully fabricated an intrinsically stretchable fluorescent OLED. A commercial fluorescent polymer was blended with a non-ionic surfactant to significantly improve the mechanical properties without degrading the electrical properties of the OLED emission layer (EML). However, fluorescence emitting materials, in general, have the disadvantage of low internal quantum efficiency (IQE) of 25% at maximum in comparison to the phosphorescent emitting materials with IQE reaching up to 100%. In this work, we designed a solution-processable and intrinsically stretchable phosphorescent EML (*isp*-EML) by blending a small molecule emitting dopant together with the mixture of a polymer host, small molecule host and a plasticizer. The microstructure-modifying plasticizer enhanced the mechanical properties of the polymer but did not have any degenerating effect on the electrical and luminescent properties of the *isp*-EML. The crack onset strain of *isp*-EML was significantly improved from 5% to 100% and Young`s modulus of *isp*-EML was reduced from 2,870 MPa to 267 MPa as the weight % of the plasticizer increases. The morphology change of the polymer host according to the ratio of the plasticizer and small molecules was analyzed through transmission electron microscopy (TEM) and atomic force microscopy (AFM), and it was predicted that the change in the conformation of the polymer host improved the mechanical properties. Furthermore, in the light emission characteristics of *isp*-EML, the luminance and efficiency of the PHOLED with *isp*-EML showed higher performance (3,500 cd/m^2, 9.4 cd/A) than PHOLED without plasticizer at EML (2,452 cd/m^2, 7.0 cd/A). This was because of the change in solubility of the small molecule dopant in the host solution according to the presence of the plasticizer and the change in morphology inside the *isp*-EML.

10:30 AM *SB07.15.01
Self-Healable Elastomers and Gel-Based Materials for Wearables Pooi See Lee; Nanyang Technological University, Singapore

Elastomers and gel-based materials are attractive for epidermal hybrid electronics due to their tunable mechanical compliances and versatile properties. Many stimuli receptive interface for bidirectional human-machine interactions require tactile sensors that are intrinsically soft, skin conformable and dynamically deformable. While addressable touch input can be realized using capacitive, resistive, piezoelectric or triboelectric signals, the output signals often require integrated transduction mechanism or signal feedback channels on a compliant interface. In addressing these needs, we investigate the use of elastomers and ionic gel-based materials that provide the advantages of skin compliant, ease of processibility and added functionality such as self-healability.
Strategy to design self-healable and tough elastomer is pursued through the realization of dynamic hierarchical hydrogen bonds in the network of functionalized polyurethane. A high tensile strength with elongation break and high toughness elastomer is attained, and the self-healing efficiency can be enhanced by incorporation of plasticizers, making it attractive for rugged wearables. On the other hand, conductive hydrogel composites have been designed for the preparation of strain sensors. The use of hydrogel ionic conductor was shown to be effective current collector by harnessing the electrical double layer for triboelectric nanogenerators, allowing them to be mounted onto skin or curvilinear surfaces. Printable ionic gels with controllable rheological characteristics can be inkjet patterned into transparent deformable touch panels. The transparent touch interface is capable of remarkable signal fidelity under dynamic interactive conditions. We have also prepared thermally stable gels with self-healing ability and found applications in soft dielectric actuators for haptics and wearables.

11:00 AM SB07.15.02
Performance Comparison and Optimization of Stretchable Organic Electrochemical Transistors on Soft Substrates Dingyao Liu[1] and Shiming Zhang[1,2]; [1]The University of Hong Kong, China; [2]Terasaki Institute, United States

Organic electrochemical transistors (OECTs) based on poly(3,4-ethylene dioxythiophene) doped with polystyrene sulfonate (PEDOT: PSS) have attracted tremendous attention in the past decade due to their applications in bioelectronic interfaces, biomedical sensing, and neuromorphic computing. Moving forward, stretchable OECTs are demanded to promote their applications at soft biological interfaces to minimize their mechanical mismatch with the environments. However, despite recent advances, stretchable OECTs are suffering from lower performance than those fabricated on glass, attributable to the irregular and the impurified surface of the soft substrates.

In this work, we systematically benchmarked and compared the performance of stretchable OECTs on different soft substrates, including the commonly used polydimethylsiloxane (PDMS), styrene-ethylene-butylene-styrene (SEBS), polyolefin elastomer (POE), and thermoplastic polyurethane (TPU). We concluded that TPU, a widely used substrate in the soft electronics industry, is the best substrate to elevate the overall performance of stretchable OECTs. For example, the ON/OFF ratio of OECT on TPU is significantly higher than devices on other reference substrates and is comparable to the device performance on the glass. The fabrication process of stretchable OECTs on TPU was strategically simplified and standardized to ease its future integration with TPU-based soft electronics in the industry.

This work contributes to the OECT community by presenting a stretchable OECT unit with the highest performance so far. It serves as an indispensable building block to fill the gap between OECTs and soft electronics. This work motivates us to further develop fully integrated soft OECT arrays towards soft biosensing, bioelectronic interfacing, and neuromorphic computing applications.

11:15 AM SB07.15.03
Photothermal Enhanced Self-healing Liquid Metal Dielectric Elastomer Actuators Matthew Tan, Hyunwoo Bark, Gurunathan Thangavel and Pooi See Lee; Nanyang Technological University, Singapore

Infrared (IR) light has been used to stimulate a series of physiological reactions in the body for its recovery. Inspired by this approach, we utilize photothermal effects induced by IR light to restore the properties of dielectric elastomer actuators (DEAs) after damage by accelerating re-formation of hydrogen bonds through enhanced chain mobility. These actuators, often coined as artificial muscles are composed of carboxyl functionalised polyurethane films that display high fracture and mechanical toughness. With liquid metal (LM) nanoparticles inclusions, photothermal and dielectric properties of these composites can be drastically enhanced for accelerated self-healing and actuation respectively. Concurrently, a higher thermal conductivity (up to 800% increase) of LM composites imparts efficient heat dissipation with lower thermal drift under cyclic heating. Photothermal effects lead to on-demand

thermal softening behaviours that reduce electric field requirements (up to 40%) to achieve 50% area strains. By modulating the power of IR light from 200 to 800 mW cm^{-2}, these actuators can achieve a variety of stiffness that leads to greater control over actuation performances. Therefore, by applying photothermal effects on LM DEAs, not only can self-healing efficiencies and actuation performances be improved; but offers an alternative control strategy to tune the stiffness of DEAs on-demand to augment actuation.

11:30 AM SB07.15.04
Self-Adhesive, Stretchable and Non-Volatile Ionic Conductors Based on Associating Polymer Networks for Accurate Motion Monitoring Kyunggook Cho, Sol An, Jeong Hui Kim, Jieun Nam, Myungwoong Kim and Keun Hyung Lee; Inha University, Korea (the Republic of)

Interest in wearable and stretchable skin-type sensors has grown rapidly and its application scope has been expanded in many areas. However, insufficient contact between the sensors and the target object causes low-quality signals which is a major hurdle for precise monitoring of complex movement of the human body. Here in, self-adhesive, stretchable, and non-volatile ionic conductors, known as ionogels, composed of an associating polymer network and ionic liquid were demonstrated. The new networks were designed by noncovalent association of two diblock copolymers, where phase-separated micellar clusters are interconnected via hydrogen bonds between corona blocks. The optimized ionogels exhibit outstanding self-adhesive characteristics (lift-off force ≈ 93.3 N/m), stretchability (strain at break ≈720%), and thermal stability (≈150 °C) without solvent evaporation. These ionic conductors were successfully applied to stretchable on-skin strain sensors, generating accurate electrical signals in accordance with the active motions of body parts including wrist, finger, ankle, and neck while maintaining full contact with the skin.

11:45 AM SB07.15.05
Recovery of Macro Properties of Damaged Polymer Films Through Self-Healing Under Supercritical CO_2 Levent Sendogdular, Selda Topcu Sendogdular, Bilge Bozdogan and Berna Aktas; Erciyes University, Turkey

Most of the thermoplastic polymer thin films are known to perform linear dilation anomalies normal to the substrate (lamellar direction) under supercritical CO_2 ($scCO_2$), which fluctuates in correlation with glass transition temperature. In this study, polymer swelling was found to be taking place in three dimentional space (expansion) instead of just normal direction to the substrate. And this phenomena enables the self-healing of damaged polymer thin films under $scCO_2$ as plasticization process. Here, CO_2 has been chosen as *an universal and enviromentally friendly post-processing method* that is free of the polymer's nature and chemical structure.
Polymers' self-healing can be considered in different levels regarding polymer chain interactions where physical properties like electrical conductivity is known to be affected by intermolecular structure. Charge transfer is directly controlled with polymer chain order, crystallinity; therefore, recovery process has to take place on micrometer and even on nanometer scale.
Conjugated polymer thin films like P3HT films on substrate have two different chain orientations: lamellar (normal to the substrate) and π-π orientations (parallel to the substrate). And π-π chain stacking and order is more affective on polymer electrical conductivity than lamaller stacking; hence, in-situ x-ray and neutron studies showed that $scCO_2$ annealing promotes chains' swelling along with increased crystallinity on x-ray synchotron studies.
SEM and optical microscope results proved 100% recovery especially for the films of which thicknesses are coherent with the width of the discontinuity in the film. To further investigate the self-healing in nano-scale, electrical conductivity experiments were performed on damaged regioregular poly(3-hexylthiophene-2,5-diyl) (P3HT) films exposed to $scCO_2$. In conclusion, before and after $scCO_2$ conductivity tests supported microscope results showing full recovery of polymer film.

12:00 PM SB07.15.06
Flexible Multifunctional Sensorics for Strain and Magnetic Field Measurements Yevhen Zabila[1,2], Alexey Maximenko[2,3], Michal Krupinski[2], Arkadiusz Zarzycki[2], Marcin Perzanowski[2], Piotr Horeglad[2], Marta Marszalek[2] and Denys Makarov[1]; [1]Helmholtz-Zentrum Dresden-Rossendorf, Germany; [2]The Henryk Niewodniczanski Institute of Nuclear Physics Polish Academy of Sciences, Poland; [3]Jagiellonian University, Poland

As an alternative for conventional rigid electronics, there is tremendous progress in the area of mechanically soft electronics [1,2], where functional elements are fabricated on flexible and even elastic membranes that can be bent, folded, or twisted. This technology enables an appealing possibility to adjust the shape of the devices at will after their fabrication and paves the way to their use for smart skin, smart textile applications, where the functional elements should conform to a dynamically varying and curved surface of an object. Examples of soft functional elements include organic photovoltaics [3], light-emitting diodes [4], thin-film transistors [5], batteries [6], sensors and actuators [7] to name just a few.
Flexible magnetic field sensors [8,9] are crucial components of flexible interactive on-skin and wearable electronics as they allow to monitor of any type of motion. Typically, magnetic thin films are used for flexible magnetoelectronics to detect in-plane magnetic fields [10-14]. To acquire the sensitivity to out-of-plane magnetic fields, Bi-based Hall effect sensors have proven their efficiency for smart wearables and electromobility applications [15,16].
Semi-metallic Bi thin films reveal extremely high magnetoresistance (MR) and a strong Hall effect even at room temperature when patterned to a small lateral size. This is possible due to a much lower electron effective mass in bismuth in comparison to other metals. This results in the electron mean free path of the order of micrometres, which is lower only than the mean free path of graphene.
Here, we explore the extreme strain sensitivity of Bi thin films to realise a multifunctional flexible device, which can measure strain and magnetic fields simultaneously. The sensors are fabricated on 12-um-thick polyimide foils capped with Bi thin films of different thickness from 20 to 100 nm. The sensors are mechanically stable and withstand severe mechanical bending down to the radii of about 1 mm for 10.000 bending cycles. The fabrication method allows realising ultrathin and flexible Bi-based Hall effect sensors with the sensitivity of 5 Ohm/T, which is a record high for this type of sensors. We propose and validate the measurement sequence relying on the spinning current approach to decouple the signals measured by a single sensor element in transversal and longitudinal resistance channels. Furthermore, we developed a method to analyse the measured transversal and longitudinal resistances to assess the out-of-plane component of the magnetic field (Hall effect) and vector components of the in-plane strain (tensoelectric effect). We apply these sensors as a component of smart skin for soft robotics and human-machine interfaces.
In this presentation, we will demonstrate the key aspects linking the fundamental properties of Bi thin films with their practical implementation in flexible sensor devices for simultaneous strain and magnetic field sensing.

SESSION SB07.16: On-Demand
Sunday Morning, December 5, 2021
On-Demand

8:00 AM SB07.16.01
Wearable Multi-Functional Sensor Sheet with Feedback Alarm System Kuni Takei[1], Kaichen Xu[2], Yusuke Fujita[1], Satoko Honda[1], Yuyao Lu[1], Takayuki Arie[1] and Seiji Akita[1]; [1]Osaka Prefecture University, Japan; [2]Zhejiang University, China

Daily continuous health condition monitoring is now of great interests using multi-functional flexible sensors. In particular, vital signals from skin are most likely most convenient way to measure continuously data collections. For this purpose, flexible sensor sheets allow it to detect multiple information from skin precisely due to conformable covering over skin surface. To realize this platform, multiple developments including flexible sensors, wireless system, and potential application are required. In this study, we develop three sensors integrated with wireless and signal processing circuit system. The system makes a feedback alarm if abnormal human condition signals are detected. As a proof-of-concept, 10 directional tilt sensors, respiration sensor, and wet sensor attached onto a diaper are developed.
First, tilt sensor is discussed. To make simple tilt detections, conduction between two electrodes via a liquid metal of GaInSn (galinstan) is used. Depending on the tilt direction, galinstan encapsulated in a chamber formed by PDMS can be moved and makes the connection between the electrodes. By reading on and off state of the electrodes, tilt direction can be extracted. However, galinstan surface is often oxidized readily in air due to Ga-based metal, resulting in residue of galinstan on the surface. This residue sometimes causes the shortage between the electrodes. To prevent the malfunction of tilt sensor, laser-induced graphene (LIG) in PDMS was used. In addition, to make almost non-wettability between the LIG/PDMS and galinstan, laser treatment over the LIG/PDMS was applied. This treatment realizes the long stability for more than several months with high contact angle (>155 degree) and low sliding angle (<5 degree). After charactering fundamental properties, 10 directional tilt sensor was successfully fabricated.
Next, respiration and wet sensors are explained briefly. For the respiration sensor, LIG transferred into PDMS was used to monitor the resistance change under strain. Because the sensor sheet is attached on a rubber belt region of a diaper, strain caused by inflation and deflation of abdominal can be detected. The gauge factor was calculated to be 9, and hysteresis was confirmed to be almost negligible. For the wet sensor, stacked $ZnIn_2S_4$ (ZIS) nanosheets were used. Due to proton hopping on the surface of ZIS, conductivity is changed depending on the number of water vapor corresponding to humidity level. Resistance change ratio between RH 30 % and 70 % shows about 30 %. Importantly, this humidity sensor is stable for a long-time cycle test more than several days.
Finally, all sensors were integrated on a film and connected to a wireless circuit system. Output signal was transmitted to a smartphone via low-energy Bluetooth. The program was designed to make feedback alarm functions if the conditions are abnormal. When a baby sleeps in the prone position, alarm is initiated to notify a carer. In addition, when respiration stops more than 10 s or diaper is a wetting condition, each alarm is also started.
In conclusion, this study demonstrated a wireless body condition sensor sheet with feedback alarm function. Long-time stable tilt, respiration, and wet sensors are realized to be used for wearable device applications. Furthermore, wireless feedback alarm function is integrated with the flexible sensor sheets, which show the great advance for the flexible electronics.

Monday Morning, November 29, 2021
Hynes, Level 3, Room 304

9:45 AM *SB08.01.01
Bacterial Photoenzymes Entrapped in Polydopamine Thin Films for Photoconversion Gianluca M. Farinola[1], Danilo Vona[1], Rossella Labarile[1], Gabriella Buscemi[1,2], Roberta Ragni[1], Francesco Milano[3] and Massimo Trotta[2]; [1]University degli Studi-Bari Aldo Moro, Italy; [2]Institute for Physical-Chemical Processes (IPCF), CNR, Italy; [3]CNR-ISPA, Institute of Sciences of Food Production, Italy

Reaction Centers (RCs) are specific transmembrane proteins of photosynthetic microorganisms that convert photons into charge separated states, with extremely high photoconversion efficiency. Our research group has demonstrated that bioconjugation of tailored molecular organic antennas represents an efficient strategy to enhance the light harvesting capability of RC extracted from *Rhodobacter sphaeroides* R26 photosynthetic bacterium [1-3]. Moreover, RC based photoelectrochemical cells [4,5], photosensors [6] and photoactive transistors [7] have been developed. RCs have been also integrated in semiconducting thin films deposited onto metal electrodes [8], and stabilized in soft structures like vesicles and polymersomes [9] before integration in electronic systems. Recently, we have developed chemical methods to optimize the interface of *Rhodobacter sphaeroides* RCs with electrodes, avoiding protein denaturation. To this aim, an adhesive biocompatible polymer, polydopamine (PDA), has been used. PDA can be easily produced by oxidative polymerization of dopamine in mild aqueous aerated conditions. It acts as an efficient coating layer for RC photoenzymes, improving the electrode/protein interface without altering the enzyme photoactivity [10]. PDA can be further functionalized to improve its light transmittance, allowing an increase of photocurrent generation of PDA coated RCs [11]. Hence, this polymer can be envisaged as a promising biocompatible adhesive material to efficiently interface photoenzymes with electrodes in bioelectronic devices for solar energy conversion.

10:15 AM *SB08.01.02
Integrating Organic Bioelectronic Materials into Biological and Neuronal Systems Magnus Berggren; Linkoping University, Sweden

Applying organic electronics technology to biological systems, such as cells and neuronal tissue, is a promising strategy to answer many of the long-standing questions of biology and neuro-signaling. Further, such approach may also provide new solutions for therapy and prosthesis applications, especially to combat neurodegenerative disorders or diseases. The fidelity of such methodology depends heavily on the quality of interfacing foreign device technology with soft and complex biological systems. Several approaches have been conducted in the past to improve the matching between organic electronics and biology with respect to mechanical, chemical, electrical and signaling characteristics. Here, a novel approach is reported where organic electronic materials is applied to the biological system in the form as monomers, followed by bio-interfacing and in-situ polymerization. The resulting system is a self-organized electrode and device technology that integrates and interfaces with cells and tissues in a highly conformable and tight manner. The chemical approach, electrical characteristics as well as the performance when operating such in vivo-manufactured organic bioelectronics will be reported.

10:45 AM SB08.01.03
Granules-Enabled Tissue-Like Systems for Bioelectronics Jiuyun Shi, Yin Fang, Yiliang Lin, Aleksander Prominski and Bozhi Tian; The University of Chicago, United States

Biological tissues are multiscale, cooperative across different components, dynamically responsive, and in many cases strain-stiffening. One key challenge in creating bioelectronic devices with tissue-like features is to recapitulate the multiscale tissue architectures and the unique dynamic mechanical responsiveness. If these could be achieved, the bioelectronic devices would allow for seamless biointerfaces and the sensing or modulating of the biological signals with high efficiency. In this work, we designed a granules-enabled hydrogel composite, with multiple naturally occurring biopolymers and synthetic hydrogels as the key components. Mechanical and in-situ x-ray characterizations reveal that the strong inter-molecular and inter-granular interactions between the components give rise to the exceptional tissue-like strain-stiffening behaviors. Due to mechanical match with the real tissues, our tissue-like materials have enabled the pneumatically actuated bioelectronic devices for applications such as the recording of the heart electrocardiogram (ECG) signal ex-vivo.

11:00 AM SB08.01.04

A Universal and Facile Approach for Building Multifunctional Conjugated Polymers for Human-Integrated Electronics Nan Li, Yahao Dai, Yang Li and Sihong Wang; The University of Chicago, United States

Functional polymer semiconductors based on π-conjugated structures have shown distinct promise for the development of human-integrated electronics, owing to their solution processability for large-area fabrication, mechanical softness and even stretchability, as well as low cost. However, among the wide range of functional properties required for this application domain, which include, but not limited to, biochemical sensing, chemotherapeutic property, bio/immune-compatibility, micro-patternability, tissue/skin adhesion, stimuli-responsiveness, numerous of them face synthetic challenges to be imparted onto conjugated polymers and thus combined with efficient charge-transport property. Currently, the absence of these functional properties poses the major obstacle for taking advantage of the unique properties of conjugated polymers to benefit the development of human-integrated electronics. Here, we establish a "click-to-polymer" (CLIP) synthesis strategy for conjugated polymers, which enables the use of a click reaction for the facile and versatile attachment of diverse types of functional units to a pre-synthesized conjugated-polymer precursor. This can be utilized to realize both bulk and surface functionalization in/on the deposited thin films. Through demonstrating the applicability on four types of functional groups that each carry distinct emerging properties, for instance, ion conduction and immune-modulation, we show that functionalized polymers from this CLIP method can still retain good charge-carrier mobility above 0.1 square centimeters per volt per second. The obtained electrical performance is much higher compared to that from conventional synthesis approach for the incorporation of long polar groups. On the other hand, the surface functionalization does not cause any influence on the mobility while bringing in new surface properties. To demonstrate the usefulness of this CLIP strategy, we realized two highly desired functions on conjugated polymers: the direct photo-patterning with sub-10 μm resolution enabled by the incorporation of benzophenone groups; and the amplified biomolecular sensing enabled by the incorporation of *N*-hydroxysuccinimide (NHS) ester that can conjugate with enzymatic bioreceptors. Both the performances advance the state of the art of realizing these two types of functions on conjugated polymers. We expect the expanded use of this synthesis approach will largely enrich the functional properties from conjugated polymers and facilitate the electronic-biological interfacing in the future. (Under revision)

11:15 AM SB08.01.05
Hybrid Pneumatic–Magnetic Soft Actuator with Novel Channel Integration for Multiple Axis Actuation Ji Eun Lee, Yu-Chen Sun and Hani E. Naguib; University of Toronto, Canada

Soft actuators are garnering considerable attention, due to their ability to perform tasks that are difficult or impossible for traditional electromechanical robotic technologies. The flexibility and control exerted by soft actuators is ideal for biomimicking of the complex and delicate movements emerging from soft muscles. These soft actuators are often fabricated from smart materials, being able to respond and actuate when exposed to a specific external stimulus. With such advantages as flexibility, lightweight, and deliverance of a wide range of movement, smart materials based soft actuators can be utilized in applications from satellite mirror control to miniaturized medical devices and biomimetic robotic grippers.
This study reports a novel soft actuator that combines the advantages of pneumatic and magnetic responsive systems for achieving a multi-directional actuation behaviour. The fabricated Fe_3O_4/silicone hybrid actuator balances the two distinct pneumatic and magnetic stimuli responses by allowing each stimuli to overcome each other's disadvantages and optimizing these components. The micro soft pneumatic actuator is fabricated utilizing 3D printed wires to create unique singular motions, forming unique "S", "L", or a hook shape. The magnetic actuation is integrated into the silicone soft body through Fe_3O_4 nanoparticles and complements this pneumatic movement. It was reported that the Fe_3O_4 had a significant impact on the mechanical property of the silicone matrix, the incorporation reducing the elastic modulus of the silicone elastomers. This was favorable overall, allowing the pneumatic actuation to occur under a lower pressure requirement while producing a high blocking force. Additionally, it was observed that the magnetic nanoparticles alignment within the samples enhanced the magnetic deflection and susceptibility at a lower magnetic field. The demonstrated hybrid soft actuators could lift objects 3.4 times its own weight. Furthermore, a gripper system was designed with two operational soft actuators in parallel configuration. It could grab objects larger than the gripper width due to a secondary magnetic actuation. Using the advantage of the multi-directional pneumatic/magnetic actuation, such hybrid soft actuator has the capability to be utilized in biomimicking or biomedical applications where unique maneuverability and force control is required.

11:30 AM SB08.01.06
Gating Dual Channel Ionic Transport in Conducting Polymers via Hydrophobicity Tamanna T. Khan[1], Terry McAfee[2], Thomas Ferron[3] and Brian Collins[1]; [1]Washington State University, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]National Institute of Standards and Technology, United States

Mixed electron/ion transport in organic materials is enticing due to the potential applications in electrochemical transistors, bioelectronics, printed electronics, and sensors. PEDOT:PSS is a model mixed conductor with a morphology consisting of PEDOT:PSS-rich gel particles embedded within a PSS matrix. Our previous study reported heterogeneous ion mobility. However, the origins behind this heterogeneity were not explored in detail. We present the existence of two separate ion channels in PEDOT:PSS originating from a bilayer morphology that naturally forms from the differing surface energies of the two components during solution casting. A higher ion mobility occurs in a PSS-rich ~10 nm top channel versus a slower PEDOT-rich bulk. We demonstrate the ability to gate ion flow by using different ion barrier materials of increasing hydrophobicity that drives ions out of the top channel. By increasingly removing the PSS top channel, the ion mobility approaches that of the bulk. These results reveal that the measured ion mobility can be skewed without taking surface layers into effect. Finally, we demonstrate sensing of UV exposure over time through switching a hydrophobic barrier layer to hydrophilic, an effect that attracts ions into the fast channel and increases ion transport. Understanding how polymer nanostructure and hydrophobicity can control ion mobility and potentially transduction to electron transport will enable these devices to be used in wide-ranging sensing applications.

1:30 PM SB08.02.01
Shape-Morphing Materials for Deployable Intracortical Probes Mahjabeen Javed[1], Rashed T. Rihani[2], Joseph Pancrazio[2] and Taylor H. Ware[1]; [1]Texas A&M University, United States; [2]The University of Texas at Dallas, United States

Intracortical microelectrode arrays (MEAs) used for diagnostic and treatment purposes, such as prosthetic devices, are currently limited in their chronic reliability. Several biotic and abiotic factors have been identified that lead to device failure *in vivo*. Abiotic causes of failure include delamination, metal corrosion, and insulation damage. At the biotic level, failure occurs as a result of initial tissue damage caused by insertion and the immune response elicited by the chronic persistence of a foreign object, which leads to glial scarring and neuronal death. This foreign body response of the tissue leads to disruptions in the functionality of the implanted devices, interfering with their ability to stimulate or record. We are developing shape-changing, liquid crystal polymer (LCP) based ultramicroelectrode arrays where probes of minimal cross-sectional area deploy to predetermined locations, away from the site of implantation and the associated foreign body response. We hypothesize that the deployment of these flexible probes with subcellular dimensions will mitigate the foreign body response, allowing for a more successful long-term implantation. We have shown that liquid crystal polymers are highly resistant to degradation when exposed to accelerated aging conditions. Prior work demonstrated liquid crystal polymer-based electrodes deploying distances of hundreds of micrometers away from the site of implantation in agar brain phantom and rodent brain tissue. However, one limitation of this work was that due to the low elastic modulus of the liquid crystal polymer, the devices were of mm-scale (0.07 mm^2). Here, we aim to describe a novel approach to synthesize a semicrystalline liquid crystal polymer with increased elastic modulus, that may allow for the deployment of electrodes of much smaller size in a volume of cortical tissue. We employ a thiol-ene approach to synthesize liquid crystal polymer networks that crystallize after polymerization. Directed self-assembly can be used to pattern the molecular orientation of the liquid crystal monomer mixture prior to crosslinking. This alignment of molecular order enables controlled deployment of the device after insertion. Liquid crystal polymer substrates are synthesized where the crosslinker content is varied from 0% to 40% to optimize the mechanical properties. At 40% crosslinker content, Young's modulus of the liquid crystal polymer is 400 MPa, with an actuation strain of up to 130%. Electrode arrays can be fabricated on these crystalline liquid crystal polymer substrates using photolithography. We envision, that this approach to develop deployable neural interfaces will overcome some critical challenges that currently hinder the chronic functionality and longevity of intracortical devices.

1:45 PM SB08.02.02
Dual-Color Organic LEDs for Co-Located Optogenetic Activation and Inhibition of Cellular Activity Giuseppe Ciccone[1], Ilenia Meloni[2], Rodrigo F. Lahore[3], Hans Kleemann[1], Peter Hegemann[3], Karl Leo[1] and Caroline Murawski[2]; [1]Dresden Integrated Center for Applied Physics and Photonic Materials (IAPP) and Institute for Applied Physics, Technische Universität Dresden, Germany; [2]Kurt-Schwabe-Institut für Mess- und Sensortechnik Meinsberg e.V., Germany; [3]Institute for Biology, Experimental Biophysics, Humboldt-Universität zu Berlin, Germany

Photo-stimulation of neurons allows optogenetics to evoke and probe cellular activity with high spatial and temporal resolution. Light-responsive proteins are genetically expressed across the plasma membrane to control fluxes of ions in response to light with specific wavelength and intensity. Recently, light-sensitive proteins that combine two separate photosensitive cores into a single domain have been developed by covalent linking of a cation-conducting and an anion-conducting channel, to provoke neuronal excitation and inhibition with a single optogenetic tool[1]. Traditionally, light sources such as lasers or LEDs are used for addressing biological targets. Although these devices are adequate for *in vitro* studies, their bulkiness, low biocompatibility, and poor mechanical matching with biological systems make them less appealing for *in vivo* applications. Organic LEDs (OLEDs) may overcome these limitations, since they offer mechanical flexibility, excellent optical tunability, and can be patterned on the micron scale. Thus, OLEDs have the potential to increase the precision of optogenetic targeting while providing also a softer interface between light source and tissue[2]. Here, we present two stacked OLED architectures that can emit light with two different emission colors from the same pixel[3], addressing the single domains of bidirectional ion channels expressed in *Drosophila melanogaster* larvae and ND7/23 cells. Tuning of the OLED layers' thicknesses allowed us to well match the OLED emission spectra to the activation spectra of the tandem photo-sensitive proteins *GtACR2-Chrimson* and *GtACR2-ChRmine*. Our work shows that OLEDs can provide narrowband light emission with minimal crosstalk between sub-pixels, enabling us to switch between optogenetic activation and inhibition of *Drosophila* larvae and ND7/23 cells.

2:00 PM SB08.02.03
Porosity-Based Silicon Heterostructures for Modulation of Hearts and Nerves Aleksander Prominski[1,2,2], Menahem Y. Rotenberg[3] and Bozhi Tian[1,2,2]; [1]University of Chicago, United States; [2]The University of Chicago, United States; [3]Technion–Israel Institute of Technology, Israel

Biocompatible and leadless stimulation is the ongoing goal of bioelectronics research with a broad potential for clinical translation. New soft, thin, and efficient materials must be developed to achieve biological modulation suitable for medical treatments. Photosensitive semiconductor nanowires and patterned membranes were found to be suitable materials for wireless optical modulation. However, the preparation of p-i-n junctions is time-consuming, requires dedicated instrumentation, and may need additional metal modifications to achieve sufficient photoelectrochemical activity in saline. To this end, we sought a new approach for the generation of highly photoelectrochemically active materials fabricated directly from a thin crystalline silicon substrate. In this presentation, I will discuss our recent advances in the synthesis of nanoporous/non-porous silicon membranes and their application for remote non-genetic biological modulation with light. Specifically, we have developed a simple, wet processing technique to generate nanoporous silicon-based photoelectrochemical devices. We have shown how nanostructuring of the material surfaces can improve the modulation efficiency and biocompatibility at the device and tissue interfaces. We have successfully applied silicon devices to stimulate hearts and nerves in a rat model using light pulses. We have achieved highly efficient modulation in which the radiant exposure necessary for the modulation is on the same scale as in the approaches based on optogenetics. We hope that our materials designs and synthetic methods enable new tools for bioelectronic research and future clinical therapies.

2:15 PM SB08.02.04
Shape-Actuated Bioelectronics Christopher M. Proctor; University of Cambridge, United Kingdom

Significant advances have been made in the last two decades in interfacing electronic devices with the nervous system. Organic electronic materials in particular have emerged as ideal materials for interfacing with the neural tissues due to their flexibility, biocompatibility and moreover their electronic and ionic conductivity. To that end, significant research efforts are being pursued to develop minimally invasive, implantable organic electronic devices integrating recording, stimulating, and drug delivery features. Here we report recent developments towards such dynamic devices for neural interfacing that take full advantage of the favorable properties offered by conducting polymers and polymer substrates. It is shown that thin, flexible devices can incorporate microfluidic channels to enable actuated shape control. Furthermore, we show such features open the door to novel implantation strategies that can reduce the surgical footprint required for implantation of large bioelectronic devices. We anticipate this work will accelerate the development of a new generation of minimally invasive implants for neural interfacing.

2:30 PM SB08.02.05

Material and Device Designs in Biomimetic Polymer Electronics Sihong Wang; The University of Chicago, United States

The vast amount of biological mysteries and biomedical challenges faced by human provide a prominent drive for seamlessly merging electronics with biological living systems (e.g. human bodies) to achieve long-term stable functions. Towards this trend, one of the key requirements for electronics is to possess biomimetic form-factors in various aspects for achieving the long-term biocompatibility. To enable such paradigm-shifting requirements, polymer-based electronics are uniquely promising for combining advanced electronic functionalities with biomimetic properties. In this talk, I will introduce our new molecular-design, chemical-synthesis and physical-processing concepts for polymer semiconductors, which enabled the incorporation of multiple biomimetic properties with advanced electronic functionalities. Fundamental understandings that have been obtained about the structure property relationship on these unprecedented material designs are serving as the foundation for opening up this new research direction for polymer semiconductors. Furthermore, enabled by these new materials, we have also created new device designs and fabrication processes for building unprecedented functional devices (i.e., sensors and circuits) that are intrinsically stretchable with unperturbed performance when operating conformably on human bodies. Collectively, our research is opening up a new generation of electronics that fundamentally change the way that the humans interact with electronics.

SESSION SB08.03: Neurotech I

Tuesday Morning, November 30, 2021
Sheraton, 2nd Floor, Independence West

10:30 AM *SB08.03.01
Accessing Neurobiological Complexity with Multifunctional Fibers Polina Anikeeva; Massachusetts Institute of Technology, United States

The past decade has delivered unprecedented speed of development of neurotechnologies. Modern complimentary metal-oxide-semiconductor (CMOS) fabrication has yielded high-resolution electrophysiology and robust back-end interfaces for probes implanted in the brains of rodents and even non-human primates. Combining electrophysiology with modern opto- and chemogenetic approaches, as well as with the emergence of photopharmacological tools remains a challenge. Furthermore, multifunctional neural interfaces with organs other than the brain present additional challenges associated with dimensions, reduced redundancy, vascularization, and susceptibility to the immune response. In this talk, I will discuss our recent efforts in multi-material fiber design that address some of the challenges of the neurobiological complexity and create stable multifunctional interfaces to the central and peripheral nervous systems.

11:00 AM *SB08.03.02
Peripheral Nerve Interfaces—Optimizing Wireless Optoelectronic Stimulation Mary J. Donahue; Linköping University, France

The informational density and relative accessibility of the peripheral nervous system make it an attractive site for therapeutic intervention. Although electrode-based electrophysiological interfaces for peripheral nerves have been under development for over half a century, achieving spatial specificity and minimally invasive devices remains challenging. The value in tackling this challenge lies in the possibility to treat disorders such as, for example, chronic pain, overactive bladder, depression, and epilepsy. We aim to improve peripheral nerve interfaces through the use of wired flexible electrode arrays to intelligently design wireless organic electrolytic photocapacitor (OEPC) stimulation devices. Through the use of OEPCs we achieve capacitive stimulation pulses delivered by non-toxic materials as tissue-penetrating deep-red light is transduced into electrical signals. We therefore avoid faradaic reactions and the products thereof, and accomplish safe, non-invasive neuromodulation.

11:30 AM SB08.03.03
Conductive Polymer Coating on 3D Nanoprobes for High-Performance Neural Recording and Stimulation Ines Muguet[1,2], Ali Maziz[1], Laurent Mazenq[1], Fabrice Mathieu[1] and Guilhem Larrieu[1]; [1]LAAS-CNRS, France; [2]Université Paul Sabatier, France

Understanding the functioning of the brain and the mechanisms involved in neuronal networks is one of the biggest scientific challenges yet to overcome. Within this field, remarkable advances were made, thanks to the development of a new generation of *in-vitro* micro-electrode arrays, in which the sensing elements are miniaturized and 3D-structured. Such devices, called Nanostructured Electrode Arrays (NEAs), offer real benefits, as they possess a high spatial resolution and an important surface-to-volume ratio leading to a higher affinity with cells. This technology enables to stimulate and record the neuronal activity at the single-cell level. However, reducing the size of the electrodes diminishes their effective area, which increases their impedance, leading to a loss in signal resolution. It also negatively affects the charge injection properties, a key parameter for stimulation processes.

Here, we demonstrate for the first time the ability to selectively deposit a nanolayer of poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS), a conductive polymer, on metal 3D nanoprobes through electrochemical deposition. These polymer-coated nanoelectrodes have been fully characterized, both electrochemically and morphologically, to establish a direct relationship between the synthesis conditions, the final morphology, and the conductive features

First, nanowires-based NEAs were fabricated at wafer scale using a cost-effective top-down approach, combining conventional lithography tools, plasma etching, sacrificial oxidation, metal deposition, and chemical etching steps. All sensing electrodes are formed by 7 connected vertical platinum-silicide nanowires. Each nanowire is 4µm high and has a diameter of 400nm. All the conductive access lines are insulated from the liquid media and only the nanowires are in contact with the solution. The nanoprobes were coated with PEDOT:PSS via electrochemical deposition. Different polymerization routes have been investigated, from galvanostatic to potentiodynamic, showing a large range of layer morphology. After optimizing the coating conditions, conformal and homogenous PEDOT:PSS layers were successfully deposited, down to 75nm thin. Indeed, Scanning Electron Microscopy demonstrated that the nanowires were wrapped tightly by the polymer coating, keeping the high aspect ratio of the nanoprobes.

The recording properties of the probes were evaluated, by performing Electrochemical Impedance Spectroscopy measurements in saline media. The impedance values (at 1kHz) of the coated nanoprobes decreased by 2 orders of magnitude compared to bare nano-electrodes. Cyclic voltammetry and voltage transients experiments have also been conducted, to estimate the charge injection capabilities of the polymer-coated NEAs. Results indicated an enhancement in delivering a higher charge at the 3D electrode-electrolyte interface. In fact, the charge storage capacity increased up to 10 times and the charge injection limit doubled compared to bare electrodes.

Thanks to their improved performances, PEDOT-coated 3D-nanostructured devices open new perspectives to stimulate and record the *in-vitro* neuronal

activity with higher spatial and signal resolution.

1:30 PM *SB08.04.01
Manipulation and Integration of Sub-10kPa Materials for Neural Interfaces Michael Shur, Noaf Alwahab, Jennifer Macron and Stephanie P. Lacour; Ecole Polytechnique Federale de Lausanne, Switzerland

Neural tissues are non-linearly elastic materials that display viscoelasticity and plasticity. They are extremely soft with elastic modulus in the 100 Pa to several kPa. Hydrogels are a unique class of materials that may be tuned to mimic the mechanical properties of neural tissues. Their high-water content and porous micro-structure greatly resemble the natural structure of the extracellular matrix. On the other end, the very same features impose many challenges e.g. swelling, electrical insulation or mechanical robustness for their integration into microfabricated devices. This talk will report on our efforts to integrate hydrogels as coating or structural materials to design, manufacture and test biomimetic neural interfaces.

In air, hydrogels dry progressively, leading to massive shrinkage of the organic network. Kept in water, they can swell up to more than ten times their initial volume. When used as a coating, re-swelling of the hydrogel film results in important shear stress at the interface with the encapsulated device. When used as the bulk carrier, the soft material in vivo may display stiffer properties than those in vitro. In both cases, this significant volume change is not compatible with the cohesion of a multilayer system and has irreversible impact on the structural and functional properties of the soft neural interface.

We are engineering and manipulating several hydrogels ranging from low swelling poly(2-hydroxyethyl methacrylate) [PHEMA] to anti-fouling zwitterionic hydrogels via ultra-soft polyacrylamide (PAAm) gels. Our observations are that hydrogels improve the biomimetic design of neural interfaces but their integration triggers additional challenges related to process compatibility and stability and in vivo use that call for further optimization.

2:00 PM SB08.04.02
Late News: Selective Targeting and Electrophysiological Recording of Distinct Neural Cell Types with Mesh Electronics Theodore J. Zwang[1,2], Anqi Zhang[3] and Charles M. Lieber[4]; [1]Massachusetts General Hospital, United States; [2]Harvard Medical School, United States; [3]Stanford University, United States; [4]Harvard University, United States

Selective targeting and modulation of functionally distinct cell types and neuron subtypes is central to the bottom-up understanding of the complex neural circuitry. While the optogenetically engineered cells can express light-sensitive channelrhodopsins in a cell type-specific manner and enable targeted optical stimulation, such cell type specificity has not been demonstrated with implantable electronic probes. We address this challenge by modifying the surface of mesh electronics, an implantable neural probe that does not elicit chronic inflammatory immune response and allows for recording of neurons in deep brain structures for over one year. The device surface was functionalized with antibodies or aptamers capable of recognizing and targeting specific cell surface receptors for neurons, astrocytes, microglia, or dopaminergic neuron subtypes and was implanted in the hippocampus of mice. Time-dependent histology studies revealed the intimate association of the targeted cell types with the electronics, without affecting the distribution of other cell types. In vivo chronic electrophysiology showed that the identity of cells associated with the electronics had a significant influence on the properties of recordings. Recordings from electronics with modifications targeting dopaminergic neuron subtypes showed selective modulation under the influence of known dopamine receptor agonists and antagonists. These surface modifications may be extended to other neurotechnologies and could benefit the study of neural cells in model systems where genetic modifications are difficult or not possible.

2:15 PM SB08.04.03
Ti_3C_2 MXene Microelectrode Arrays with Tunable Optical and Electrochemical Properties Sneha Shankar[1], Brendan Murphy[1], Yuzhang Chen[1], Quincy Hendricks[1], Nicolette Driscoll[1], Tyler Mathis[2], Natalia Noriega[2], Hajime Takano[1], Yury Gogotsi[2] and Flavia Vitale[1]; [1]University of Pennsylvania, United States; [2]Drexel University, United States

Microelectrode arrays are widely adopted tools to investigate neuron-level and microscale circuit dynamics underlying brain function and disease. While standard microelectrodes enable detecting electrophysiological signaling, developing devices with optical stimulation, and recording capabilities, allows mapping neural dynamics at higher spatial and temporal resolution, and across multiple scales. Thus, there is a need of novel materials and processes to realize microelectrode arrays with tunable optical and impedance properties, while minimizing interference from photoelectric artifacts.
Here we demonstrate novel processing and fabrication approaches to develop low-impedance microelectrode arrays with tunable optical properties based on Ti_3C_2 MXene. Specifically, we explored several processing parameters and conditions, such as the concentration of the precursor solution as well as film thickness, to optimize sheet resistance, transparency, and electrochemical interface impedance of the Ti_3C_2 MXene films. The resulting films are ~20nm thick, have a 550 nm transmittance of 60% and sheet resistance of 60 Ω/□. The corresponding figure of merit is 14, which is comparable to or higher than other optoelectronic transparent films used for neural interfacing. Then we fabricated parylene C-based 4 x 4 micro electrocorticography (μECoG) arrays using microfabrication techniques and solution processing of MXene. The arrays have 50 μm x 50 μm recording sites spaced 500 μm apart and an overall footprint of 2.75 mm x 2.75 mm. Electrochemical impedance spectroscopy measurements at 1kHz show a predominantly capacitive response and an average impedance modulus ranging from 143 kΩ ± 157 to 555 kΩ ± 103 (5 devices, 68 channels) which is 2 to 5 times lower than previously developed transparent graphene interfaces. To evaluate the feasibility of acquiring multimodal signals *in vivo* in a relevant disease model, signal recording ability and quality, we tested the devices *in vivo* in an epilepsy mouse model. We were able to successfully record epileptiform activity and simultaneous monitor calcium fluorescence fluctuations. Continued work with electrodes will involve dissecting recorded data and probing neural dynamics through concurrent optogenetic stimulation of neuronal activity to understand disordered mechanisms.

Multi-Dimensional Fuzzy Graphene Based I/O Bioelectronics for Tissue Innervation Raghav Garg[1], Mehrdad Javidi[1], Daniel J. San Roman[1], Yingqiao Wang[1], Samuel Gershanok[1], Stephen Badylak[2], Douglas Weber[1] and Tzahi Cohen-Karni[1]; [1]Carnegie Mellon University, United States; [2]University of Pittsburgh, United States

Complete recovery from volumetric muscle loss injuries requires adequate structural regeneration of the lost tissues with proper innervation. Although

various tissue engineering strategies have been developed to facilitate regeneration, restoring adequate innervation remains an open challenge. Electrical stimulation has emerged as a promising intervention to enhance tissue innervation after trauma and restore motor control. This has been achieved via input/output (I/O) bioelectronics that interface engineered materials with biological entities. Recently, graphene and its composites have gained interest as building-blocks for bioelectronics due to their advantageous electrochemical properties and biocompatibility. However, graphene-based bioelectronics exhibit a two-dimensional (2D) topology resulting in limited electrochemical performance. Ideal bioelectronics need to leverage on three-dimensional (3D) topologies to maximize the exposed surface-area and enhance interaction with interfaced biological entities.
Here we report a breakthrough hybrid-nanomaterial based on nanowire-templated 3D fuzzy graphene (NT-3DFG) and poly(3,4-ethylenedioxythiophene)-polystyrene sulfonate (PEDOT:PSS), for functional I/O bioelectronics. The hybrid-nanomaterial leverages on high surface-area of free-standing graphene flakes of NT-3DFG and the high charge storage capacity of PEDOT:PSS. The resultant hybrid-nanomaterial exhibits lower electrode impedance, cathodic charge storage capacity (CSC_C) up to 24.87 ± 5.40 mC/cm^2, and charge injection capacity (CIC) up to 13.21 ± 3.6 mC/cm^2 with footprint as small as 20 µm. We interface the developed hybrid-nanomaterial with *in-vivo* systems to effect cellular- and tissue-scale electrophysiology via electrical stimulation; and record the resultant electrical activity as electromyograms (EMG). Through our platform, we demonstrate the importance of extending the topology of nanomaterials to 3D to develop the next generation of functional I/O bioelectronics.

Viscoelastic Surface Electrode Arrays to Interface with Viscoelastic Tissues Christina M. Tringides[1,2], Nicolas Vachicouras[3], Irene de Lazaro[1], Alix Trouillet[3], Stephanie P. Lacour[3] and David Mooney[1]; [1]Harvard University, United States; [2]Massachusetts Institute of Technology, United States; [3]EPFL, Switzerland

Living tissues are non-linearly elastic materials that exhibit viscoelasticity and plasticity. Man-made, implantable bioelectronic arrays mainly rely on rigid or elastic encapsulation materials and stiff films of ductile metals that can be manipulated with microscopic precision to offer reliable electrical properties. Here, we engineer a surface microelectrode array that replaces both the traditional encapsulation and conductive components with viscoelastic materials. Our entirely viscoelastic array overcomes previous limitations in matching the stiffness and relaxation behavior of soft biological tissues by using hydrogels as the outer layers. We introduce a novel hydrogel-based conductor made from an ionically conductive alginate matrix enhanced with carbon nanomaterials (e.g. graphene, carbon nanotubes). These high aspect ratio additives provide electrical percolation even at low loading fractions, and we fabricate ultra-soft viscoelastic conductive electrodes and electrical tracks that intimately conform to the convoluted surface of the heart or the brain cortex. Our combination of conducting and insulating viscoelastic materials, with top-down manufacturing, allows for the versatile fabrication of electrode arrays compatible with *in vivo* recording and stimulation.

Millimeter-Sized Wireless Bioelectronics Jacob T. Robinson; Rice University, United States

Millimeter-sized bioelectronic implants can provide advanced therapies with minimal invasiveness providing a potential alternative to traditional pharmaceuticals. To create devices with millimeter-sized form factors we must overcome the challenges of sending data and power to miniature battery-free devices. This is particularly challenging for devices implanted deep within tissue because the body absorbs electromagnetic radiation at frequencies typically used for wireless data and power transmission. Here, we describe how magnetic materials like magnetoelectrics and superparamagnetic nanoparticles can enable precise control of neural circuits and millimeter-sized bioelectronic devices. Specifically, we show that these materials can improve the speed, reliability, and power densities possible with miniature bioelectronics

3:30 PM BREAK

4:00 PM SB08.04.08
Ti_3C_2 MXene Flakes for Optical Control of Neuronal Electrical Activity Yingqiao Wang[1], Raghav Garg[1], Jane E. Hartung[2], Adam Gold[3], Dipna A. Patel[3], Flavia Vitale[4], Michael S. Gold[2], Yury Gogotsi[3] and Tzahi Cohen-Karni[1]; [1]Carnegie Mellon University, United States; [2]University of Pittsburgh, United States; [3]Drexel University, United States; [4]University of Pennsylvania, United States

Understanding cellular electrical communications in both health and disease necessitates precise subcellular electrophysiological modulation. Nanomaterial-assisted photothermal stimulation was demonstrated to modulate cellular activity with high spatiotemporal resolution. Ideal candidates for such an application are expected to have high absorbance at the near-infrared (NIR) window, high photothermal conversion efficiency, and straightforward scale-up of production to allow future translation. Here, we demonstrate two-dimensional (2D) Ti_3C_2 (MXene) as an outstanding candidate for remote, nongenetic, optical modulation of neuronal electrical activity with high spatiotemporal resolution. Ti_3C_2 photothermal response measured for the first time at a single-flake level resulted in local temperature rises of 2.31 ± 0.03 K and 3.30 ± 0.02 K for 625 nm and 808 nm laser pulses (1 ms, 10 mW), respectively. Dorsal root ganglia (DRG) neurons incubated with MXene film (25 µg/cm^2) or MXene flakes dispersion (100 µg/mL) for 24 h did not show a significant effect on cellular viability, indicating that MXene is non-cytotoxic. DRG neurons were photothermally stimulated using MXene films and flakes with as low as tens of micro-joule per pulse incident energy (635 nm, 2 µJ for film, 18 µJ for flake) with sub-cellular resolution. MXene's straightforward and large-scale synthesis will allow translation of the reported photothermal stimulation approach in multiple scales, thus presenting a powerful tool for modulating electrophysiology from single cell to three-dimensional (3D) engineered tissues.

SESSION SB08.05/SB11.03: Keynote Session: Biostimulation and Bioelectronics
Session Chairs: Herdeline Ardoña, Tzahi Cohen-Karni, Nicolette Driscoll, Raghav Garg, Sahika Inal, Jonathan Rivnay, Daniel San Roman, Flavia Vitale and Yingqiao Wang
Tuesday Afternoon, November 30, 2021
Sheraton, 2nd Floor, Independence West

5:00 PM *SB08.05/SB11.03.01
Keynote: Material Building Blocks for Bioelectronics—Micelles, Pores and Granules Bozhi Tian; University of Chicago, United States

Bioelectronics devices have the potential for realizing personalized medicine and brain-machine interfaces. While significant progress has been made in this area, there is still room for improving the material designs to achieve better functionalities at the interfaces with cells and tissues. In particular, applying biomimetic design principles enables the development of new devices with improved properties in terms of their signal transduction efficiency and biocompatibility. In this talk, I will present a few latest processes in our lab, where new material building blocks have been identified for building

bioelectronics systems. I will discuss a micelle-enabled self-assembly process to prepare a binder-free (i.e., monolithic), carbon-based, and flexible micro-supercapacitor-like system for various types of bioelectronic interfaces. The devices can operate under either micro-supercapacitor-like or a traditional monopolar electrode configuration under physiological conditions, yielding modulation of cardiomyocytes in vitro, excitation of isolated heart and retinal tissues ex vivo, stimulation of sciatic nerves in vivo, as well as bioelectronic cardiac recording. I will also present a newly developed nanoporous/non-porous heterojunction for improved biointerfaces. Without any interconnects or metal modifications, the heterojunction enables efficient non-genetic pulse stimulation of isolated rat hearts *ex vivo* and sciatic nerves *in vivo* with radiant exposure similar to that used in optogenetics. Finally, I will showcase a class of granules-enabled hydrogel composites, with multiple naturally occurring biopolymers and synthetic hydrogels as the key components. The composites have many tissue-like properties, such as strain-stiffening behaviors. The granules-enabled tissue-like materials have enabled the pneumatically actuated bioelectronic devices for applications such as recording the heart electrocardiogram signal *ex vivo*. At the end of my talk, I will present future material development in our lab.

10:30 AM *SB08.06.01
3D Conducting Polymer Scaffold Devices for Organ-on-Chip Applications Roisin Owens; University of Cambridge, United Kingdom

In vitro models of biological systems are essential for our understanding of biological systems. In many cases where animal models have failed to translate to useful data for human diseases, physiologically relevant in vitro models can bridge the gap. Many difficulties exist in interfacing complex, 3D cell biology models with technology adapted for monitoring function. Polymeric electroactive materials and devices can bridge the gap between hard inflexible materials used for physical transducers and soft, compliant biological tissues. An additional advantage of these electronic materials is their flexibility for processing and fabrication in a wide range of formats. In this presentation, I will discuss our recent progress in pushing conducting polymer devices, to 3D, to simultaneously host and monitor complex multi-cellular models of tissues and organs. Building on our previous work that showcased a bioelectronic model of the human intestine, we are now incorporating elements of the microbiome and the immune system as well as the enteric nervous system. Coupling this model with our model of the neuro-vascular unit (including blood brain barrier) currently in progress, will bring us to our goal of a physiologically representative in vitro model of the gut-brain-microbiome axis.

11:00 AM SB08.06.02
3D Conducting Polymer/ECM Scaffolds for the Maintenance and Differentiation of Human Neuronal Cells *In Vitro* Chiara Barberio and Janire Saez; University of Cambridge, United Kingdom

Advances in three-dimensional (3D) cell culture modeling have extensively contributed to generate new sophisticated cell culture configurations broadening our understanding of cellular physiology and pathology for a wide range of biomedical applications (e.g., drug discovery, tissue engineering and regenerative medicine). Compared to two-dimensional (2D) cell culture, which is overall too simplistic and lacking most of the cell-cell and cell-environment interaction occurring in the *in vivo* milieu, such 3D formats are capable of resembling the tissue microenvironment in a more biomimetic manner [1]. Scaffold-based systems integrating natural and/or synthetic materials are extensively exploited in tissue engineering to develop tissue-specific microenvironments for better supporting cell survival and outgrowth, by providing the chemical and physical cues of the natural extracellular matrix (ECM) [2]. Using a freeze-drying technique, we engineered porous 3D composite scaffolds consisting of poly (3,4-ethylene-dioxythiophene) doped with polystyrene sulfonate (PEDOT:PSS), containing ECM-derived proteins (i.e., Collagen, Hyaluronic Acid and Laminin) for hosting neural 3D cell culture. The highly porous microstructure of these scaffolds was characterised optically by scanning electron microscopy (SEM) along with confocal microscopy, and their conducting properties via electrochemical impedance spectroscopy (EIS). The resulting scaffolds exhibited remarkable mechanical stability and water uptake capacity, directly proportional to the increasing collagen/HA content. We further tested the cytocompatibility profile of these scaffolds and ultimately, their suitability for supporting neural differentiation of neuroblastoma-derived SH-SY5Y cells. We observed that the presence of ECM proteins within the scaffold backbone improves cell survival and proliferation rate compared to the pristine substrate, thus promoting cell propensity to differentiate into mature neurons and generate 3D neural networks. In conclusion, these conducting platforms used here for neuronal cell culture could be potentially amenable for regulating neuronal cell behaviour in a 3D configuration and customised for a variety of tissue engineering applications. Ultimately, to gain more insight into the effects of conducting polymers on neural firing, recording of electrophysiological activity of neurons cultured in 3D will be attempted via simultaneous EIS and MEA (microelectrode array).

Electrochemical Impedance Spectroscopy as a Tool for Monitoring Cell Differentiation from Floor Plate Progenitors to Midbrain Neurons in Real Time Aya Elghajiji[1], Bastian Hengerer[2], David Tosh[1] and Paulo R. Rocha[3]; [1]University of Bath, United Kingdom; [2]Boehringer Ingelheim Pharma GmbH & Co. KG, Germany; [3]University of Coimbra, Portugal

Spinal cord injuries constitute an important clinical target. Emerging therapies to treat central nervous system (CNS) injuries seek to implant neural progenitor cells (NPCs) to promote repair of the neural network subsequent to neural injury. A debilitating aspect of this approach is the inability to non-invasively monitor NPCs during migration and differentiation at injured spots, which critically affects the therapeutic efficacy of neural repair.

Here we show that electrical impedance spectroscopy (EIS) can be used as a non-invasive and real time tool to probe cell adhesion and differentiation from midbrain floor plate progenitors into midbrain neurons, on Au electrodes coated with human laminin. The electrical data and equivalent circuit modelling are consistent with standard microscopy analysis and reveals that within the first 6 hours progenitor cells sediment, and attach to the electrode within 40 hours. Between 40 and 120 hours midbrain progenitor cells differentiate into midbrain neurons, followed by an electrochemically stable maturation phase. The ability to sense and characterize non-invasively and in real time cell differentiation opens up unprecedented avenues for implantable therapies and differentiation strategies.

11:30 AM *SB08.06.04
Bioelectronics for Hybrid Tissues and Disease Modeling Brian Timko; Tufts University, United States

Hybrid bioelectronic systems offer a unique route toward achieving two-way electronic communication with living cells and tissues. In this talk, we will discuss recent advances in both devices and biomaterials that achieved stable and seamless interfaces with surrounding cells and tissues. We will first present an overview of our recent heart-on-a-chip platform which integrated both extra- and intracellular devices for monitoring cardiac electrophysiology during episodes of acute hypoxia. This system allowed us to monitor not only cell-cell communication (e.g., wavefront propagation) but also action potentials at several spatially-distinct regions simultaneously. Our platform provided a unique route toward undertraining the role of hypoxia on ion channel dynamics. For example, we found that APs shortnened during hypoxia, consistent with proposed mechanisms by which oxygen deficits activate ATP-dependent K^+ channels that promote membrane repolarization. We will next discuss routes toward extending our bioelectronic platform to 3D, enabling new classes of hybrid, devices-embedded tissues. We developed a Photo-crosslinkable Silk Fibroin (PSF) derivative that was compatible with conventional photolithography processes and enabled flexible scaffolds with well-defined geometries and cm-scale uniformity. Our freestanding PSF-based scaffolds supported bioelectronic devices, provided excellent electrical passivation, and adhered both cardiac and neuron model cells, opening new avenues toward engineered brain hybrids. Finally, we will present a new class of electromagnetic stimulation elements which achieved highly-localized cellular activation. Taken together, these research directions open new avenues for engineered, bioelectronics-innervated cardiac and brain systems.

SESSION SB08.07: Bioelectronic Devices

Materials for Bioelectronic Medicines—From Neuroregeneration and Drug Delivery to Cardiac Pacing John A. Rogers; Northwestern University, United States

Bioresorbable electronic materials form the basis for broad classes of temporary implants with unique capabilities that address unmet clinical needs. Such types of devices can provide therapeutic functionality during the time course of a natural biological process such as healing, and then harmlessly disappear into the body, without a trace. Here, bioresorption eliminates unnecessary device load on the body in a way that bypasses the need for secondary surgical extraction. This talk describes the latest advances in the active and passive materials components of these systems, with examples in devices for (1) neural stimulation, (2) cardiac pacing and (3) programmable drug release.

2:00 PM SB08.07.03
Ti_3C_2 MXene Enables High-Resolution, Gel-Free Electroencephalography Nicolette Driscoll[1], Brian Erickson[2], Meikang Han[2], Georgios Mentzelopoulos[1], Yury Gogotsi[2], John Medaglia[2] and Flavia Vitale[1]; [1]University of Pennsylvania, United States; [2]Drexel University, United States

Electroencephalography (EEG) is a widely used technique for clinical diagnostics and monitoring, for neuroscience research, as well as for non-invasive brain-computer interface (BCI) applications. Despite over 100 years of EEG research, the technology has benefitted from relatively few fundamental innovations in materials that enhance its resolution and form factor while maintaining high-quality signals. Today's EEG technologies have limited spatial resolution because the sensors are relatively large (~1 cm diameter) and they typically require the use of conductive gels or pastes to achieve sufficiently low electrode-skin interface impedance. Such gelled or "wet" electrodes are prone to shorting *via* gel-bridging when they are placed close together for dense spatial sampling, which has made it challenging to push the spatial resolution limits of EEG technology. Gel-free or "dry" EEG electrode technologies offer an alternative solution to the limitations of wet EEG sensors. Existing dry EEG technologies, however, rely on large-area electrodes with poor spatial resolution in order to reduce contact impedance, and rigid, uncomfortable pillar structures to contact the scalp. Here, we present a novel gel-free EEG electrode technology based on the 2D nanomaterial Ti_3C_2 MXene which is capable of recording high-fidelity EEG signals from dry electrodes with high spatial resolution. The electrodes comprise a MXene composite aerogel which is compliant to enhance subject comfort, and can be molded into 3D "mini-pillar" geometries for contacting the scalp through hair. The high conductivity of Ti_3C_2 MXene, along with the porous structure of the composite foam, gives the electrodes low skin contact impedance, allowing high-fidelity EEG recording from mm-scale electrodes with signal quality comparable to standard gelled electrodes. To demonstrate the ability to map scalp EEG at high density, we fabricated 16-channel high-density EEG grids with 3 mm-diameter MXene contacts and 3 mm spacing, which offers higher spatial sampling than the densest EEG systems available today. We used these grids to record EEG signals on human subjects in frontal regions while they completed a battery of attention and working memory tasks shown to have frontal EEG signatures related to task performance. In these experiments, the MXene electrode grids were centered over F3 and F4 EEG coordinates (10-5 system) such that we obtained a total of 32 channels of high-density EEG signal across two frontal regions. Using this paradigm, we explore whether current source density transforms of the ultra high-density enabled by MXene reveal more detailed and localized correlates of frontal attentional function than previously observed. Furthermore, we demonstrate that the MXene electrodes are compatible with magnetic resonance imaging (MRI) and transcranial magnetic stimulation (TMS) due to the low magnetic susceptibility of Ti_3C_2 MXene. The magnetic compatibility of Ti_3C_2 MXene opens up the possibility of concurrent structural or functional MRI, TMS, and EEG recording.

2:15 PM SB08.07.04
Rational Spatial Design of a Bioelectronic Interface Vedran Derek[1], Nikola Habek[1], Aleksandar Opančar[1], Marta Nikić[1], Anja Mioković[1], Malin Silvera Ejneby[2] and Eric Glowacki[3,2]; [1]University of Zagreb, Croatia; [2]Linköping University, Sweden; [3]Brno University of Technology, Czechia

Essential properties of the bioelectronic materials and interfaces, such and their abilities to exert effective stimulation or enable recording of biological signals, their interface electrochemistry and physiological stability, are widely studied and optimized from the individual perspective of the studied property. Lately, attention was focused on volume electrodes[1] and 3D structuring of bioelectronic devices[2] on all scales. We will demonstrate how optimizing the two-dimensional and three-dimensional structuring of the bioelectronic interfaces of a model device can amplify, suspend or channel the desired effects in comparison to trivial structures such as highly symmetric planar or rod-like electrodes. As a model device, we have used the organic electrolytic photocapacitor (OEPC), an organic semiconductor-based optoelectronic device capable of capacitive coupling with the excitable tissues. OEPCs have been shown to effectively modulate single cell membrane potentials[3], to elicit action potentials in explanted retinal tissue[4], and to chronically stimulate a peripheral nerve in a rodent model[5].
We will discuss the basic principles guiding the active and return electrode spatial design for enhanced stimulation intensity and improved and controlled

stimulation localization, demonstrated by the results of FEM numerical modelling, measurements of 3D transductive electric potential field maps in extracellular phantom, and in-vitro stimulation experiments. Multifold enhancement of the performance of the 3D micro-pyramid structured OEPC in comparison to the planar OEPC was observed, with the enhancement strongly depending on the micro-pyramid size and their density, while rationally designed 2D electrode shapes enabled localized and effective tissue stimulation, which would not be possible with the previously used simple designs. We will show how our optimization toolset can be extrapolated and applied to a more general class of bioelectronic interfaces.

2:30 PM SB08.07.05
High-Sensitivity and Real-Time Monitoring of Cell Layers with Dynamic-Mode Current-Driven OECT Katharina Lieberth[1], Daria Harig[1], Paschalis Gkoupidenis[1], Paul Blom[1] and Fabrizio Torricelli[2]; [1]Max-Planck-Institute for Polymer Research, Germany; [2]University of Brescia, Italy

To use the organic electrochemical transistor (OECT) as a biosensor is of great importance, as it is a state-of-the-art technique in the field of drug delivery.[1] Allowing ion-to-electron conversion and having a high amplification of gating due to volumetric capacitance, enables the OECT to operate with aqueous electrolytes at low voltages.[2] When utilizing the OECT as an inverter in a current-driven configuration, a constant current is applied at the channel by an external power supply. It was found that the OECT offers an enhanced sensitivity compared to standard transfer characteristics of an OECT.[3] Even small variations in the ionic current can be detected with the OECT, which is required to study changes in the cell layer morphology, such as tight junction modulation.[4] Tight junction barriers of epithelial cell layers impede the transcellular pathway of nutrients and drugs from organs into the blood.[5,6] Hence, monitoring tight junction modulations is crucial for drug delivery.[7] As a well-established model for oral drug delivery, the epithelial colon carcinoma (Caco-2) cell line,[8] found in the small intestine, was used to evaluate reversible modulation of tight junctions over time. Recently, we showed the suitability of OECTs to *in-situ* monitor temporal barrier modulation and recovery, which can offer valuable information for drug delivery applications.[9] Here, the origin of the enhanced sensitivity of OECTs with integrated barrier tissue in current-driven configuration is demonstrated. As next step, we have addressed both experimentally and theoretically the dynamics of OECTs operation. Understanding of the dynamics is a prerequisite to tune the sensitivity of the OECT in accordance with the resistance of the barrier under investigation. The quantitative agreement between experiment and modelling of the transient OECT characteristics allows us to directly translate the current-driven OECT characteristics into a resistance of the barrier tissue under investigation. [10]

3:45 PM *SB08.07.06
Transformable Cuff Electrodes for Closed-Loop Stimulation of Small Peripheral Nerves Lukas Hiendlmeier[1,2], Francisco Zurita[1,2], Tetsuhiko Teshima[2,1], Fulvia Del Duca[1,2] and Bernhard Wolfrum[1,2]; [1]Technical University of Munich, Germany; [2]NTT- Research, United States

Peripheral nerve interfaces are important for implementing neuromodulation strategies. For example, feedback loops can be employed to control the behavior of tissue by modulating the activity of the innervating input as a response to a biomarker. Cuff electrodes represent an important class of such nerve interfaces that are often used for applications in bioelectronic medicine. Large nerves, with diameters in the range of one mm or above, can be easily stimulated with appropriate cuff electrodes. However, the stimulation strategies often lack specificity as several fibers are typically addressed simultaneously. Stimulating small nerves, below 100 µm, can generate more specific responses but poses additional challenges for device development as well as handling during an operation. Here, we present a type of self-foldable cuff electrodes that can be readily applied *in vivo* for addressing small peripheral nerves. The devices are fabricated combining 3D printing and lithographic approaches employing strongly swelling materials. We demonstrate the usability of the nerve cuff electrodes after implantation on the extensor motor nerves by implementing a simple closed-loop strategy to control the angles of a locust's legs in real time. Extensor motor nerves are stimulated using trains of stimulation pulses with a gradual response of the leg position determined by the applied stimulation frequencies. We monitor the leg's angles using a flexible sensor and implement the feedback loop with a simple control algorithm on a microcontroller. The design of the cuff electrodes allows straightforward implantation and removal without impairment of the nerve functionality.

Fully Implantable, Ion-Gated, Organic Integrated-Circuits for Chronic, Closed-Loop Epileptic Interventions Claudia Cea, Zifang Zhao, Jennifer Gelinas and Dion Khodagholy; Columbia University, United States

Bioelectronic devices are increasingly required to not only acquire biologic signals, but also to process them in real-time. For a subset of patients with epilepsy, responsive neurostimulation in the form of implanted devices are promising form of treatment. However, the only components capable of performing these functions at present are silicon-based, non-biocompatible, bulky, and need rigid encapsulation in physiologic environments. Here, we demonstrate an fully implantable, soft, biocompatible, neural acquisition and processing device based on complementary internal ion-gated organic electrochemical transistors (IGTs). A key function of these responsive neurostimulation devices is accurate detection of epileptic discharges. This detection can be challenging due to the variable amplitude of the neural potentials based on the location of the recording electrode with respect to local dipoles and

the reference electrode. We combined a depletion and enhancement mode IGTs to create a non-linear rectification circuit that can be chronically implanted to recorded and detect epileptiform inter-ictal discharges (IEDs). This device was used to process signals acquired from the hippocampus of a freely moving epileptic rat. The IGT-based non-linear rectification circuit accurately detected epileptic discharges, with receiver operating characteristics that surpassed traditional filter thresholding methods. Therefore, IGTs and their ability to efficiently integrate enhancement and depletion mode devices within individual circuits can improve real-time processing of disease-relevant neurophysiological signals and have the potential to form fully implantable, conformable acquisition and processing units for bioelectronic devices. Overall, we have shown that e-IGTs can serve as reliable components for bioelectronic devices, with the potential to improve our ability to transduce and modulate physiologic signals. E-IGTs are also suitable for translation to use in humans, offering a safe, reliable, and high-performance building block for chronically implanted bioelectronics.

Ions-Based High-Bandwidth Communication for Bioelectronics Zifang Zhao[1], Claudia Cea[1], Georgios Spyropoulos[2], Jennifer Gelinas[3,3] and Dion Khodagholy[1]; [1]Columbia University, United States; [2]Ghent University, Belgium; [3]Columbia University Medical Center, United States

High-density neural interfaces are continuously progressing towards seamless integration of brain and electronics. As more effort has been dedicated to implantable devices, effective and non-invasive data communication between the implant and outside electronics becomes a critical unresolved issue, because biologic tissue absorbs most of the electromagnetic waves. Here we introduce the ionic communication (IC) that utilizes ions and water polarization for high-speed data communication. We describe the working principles of IC, and investigated the effect of material and geometrical properties such as area, material composition, ion type/concentration, and operating frequency and on the performance of the IC in the form of gain and spatial propagation. Based on these measurements, we developed a model to accurately estimate IC-based communication's propagation depth in the body and established a multi-line implantable IC with several hundred MHz bandwidth. We chronically implanted conformable IC devices with no extruding elements and were able to acquire and transmit high-quality electrophysiological data at the level of signal neurons' action potentials from freely moving rats. The IC and the resulting devices set the foundation for non-invasive, fully-implantable communication strategy for biomedical implantable systems, such as brain-computer interfaces, responsive neurostimulation devices, deep-brain-stimulators and cochlear implants that require a low consumption, high bandwidth wireless communication system.

High Energy Return on Investment—Efficient Natural Perspiration Based Biofuel Cells for Bioenergy Harvesting Lu Yin, Jong-min Moon, Juliane Sempionatto, Sheng Xu and Joseph Wang; University of California, San Diego, United States

Self-powered wearable systems relying on bioenergy harvesters commonly require excessive energy inputs from the human body and are highly inefficient when accounting for the overall energy expenses. A harvester independent from the external environment for sedentary states has yet to be developed. Herein, we present a touch-based lactate biofuel cell that leverages the high passive perspiration rate of fingertips for bioenergy harvesting. Powered by finger contact, such bioenergy harvesting process can continuously collect hundreds of mJ of energy during sleep without movements, representing the most efficient approach compared to any reported on-body harvesters. To maximize the energy harvesting, complementary piezoelectric generators were integrated under the biofuel cell to further scavenge mechanical energy from the finger presses. The harvesters can rapidly and efficiently power sensors and electrochromic displays to enable independent self-powered sensing. The passive perspiration-based harvester establishes a practical example of remarkably high energy return-on-investment for future self-sustainable electronic systems.

An Implantable and Flexible Multi-Electrode Neural Probe using Active Matrix Design of IGZO Thin-Film Transistors Array Jiwon Chae, Goeun Pyo, Sujin Heo, Kwonsik Shin, Sohee Kim and JaeEun Jang; Daegu Gyeongbuk Institute of Science and Technology (DGIST), Korea (the Republic of)

An implantable probe with an electrode array can precisely record brain signals from different groups of neurons simultaneously, yet maintaining high spatial resolution is still challenging. Each electrode of a dot matrix type needs an individual wire, and then, it is appropriate only for a few electrodes. A passive matrix design is better, since the total number of wires needed is C+R, where C is the number of columns and R is the number of rows in the passive array, respectively. However, the passive matrix design showed a cross talk issue among neighboring cells. In contrast, an active matrix design also needs C+R number of wires to fabricate C×R number of electrodes, but it can induce a good electrical isolation among cells. CMOS technology has been studied for high density electrodes. However, stiff silicon-based probes induce inflammation in the tissue. Therefore, flexible polymer-based probes can handle this problem by reducing mechanical mismatch between a probe and neural tissue and growth of the glial sheath. Here, we fabricated polyimide-based flexible neural probes with a 4×8 array of electrodes based on the active matrix design of a-IGZO thin-film transistors (TFTs) for neural signals recording. We measured electrical properties and conducted electrical signal recording tests. Our neural probe design has advantages in high spatial resolution, flexibility due to polyimide (PI) probe pattern, and high mobility of IGZO TFTs. We easily fabricated probes using photoresist PI (jsr-wpr 1201) by photolithography on a sacrificial layer. Then, back gate IGZO TFT was fabricated on the PI probe, followed by PI encapsulation layer photolithography. The sacrificial layer was wet etched, while the probe has 50μm spacing and 20μm diameter holes for large area undercut. Our 25μm thickness PI probe is flexible and can endure a-IGZO TFT annealing temperature. The cell size is 86μm×200μm and the electrode size is 40μm×80μm. To obtain a high signal-to-noise ratio (SNR), a high-performance transistor is studied. The width-length of the transistors is designed to 50μm/10μm, and the field-effect mobility is 20 cm^2 /V×s and on current is 7×10^{-5}A under a low driving voltage, 5V. The on-off ratio is $1.1\times10^7$and the threshold voltage (V_{th}) is 2.7V. The passive matrix design consists of one transistor in a cell. A gate line turns on the TFT applying 5V which is higher than the V_{th}, and a drain line senses the signal. For amplifying signals, the active matrix design consisting of two transistors in a cell is also fabricated. By applying 5V, the switching TFT is turned on, and the sensed signal can be measured on the drain line. One transistor works as a switch and another works as an amplifier. The shank, a sensing area of the probe, was placed in the PBS solution, and we recorded electrical signals using a function generator, an oscilloscope, and a power supply. Signals were recorded and compared to the dot matrix design. Our active matrix design probes successfully amplified the amplitude value of electrical signals. Therefore, our active matrix design TFT electrode array probe can be used for accurate neural recordings with high SNR and would open a new generation of flexible neural probes with high spatial resolution.

SB08.08.01
A Comprehensive 3D FEM Model of Excitable Tissue and Capacitive Electrode Interface Aleksandar Opančar, Anja Mioković, Nikola Habek and Vedran Derek; Department of Physics, Faculty of Science, University of Zagreb, Croatia

The interface of excitable cells and stimulation or recording electrodes is essential for bioelectronic applications. Parameters such as the electrode impedance and capacitance, interface electrochemistry, surface structuring and long term in vivo stability have been thoroughly studied. However, in many applications, especially clinical ones, only trivial electrode geometries are used, resulting in increased charge density thresholds. Using optimized electrode geometries and stimulation protocols may overall be more effective, especially in the case of implanted bioelectronic devices with limited current generation capabilities.
For highly localized target specific electrostimulation, electrode design and stimulation protocol are crucial parameters to consider. We consider multiple planar and 3D electrode configurations for stimulating excitable cells and tissues, and different stimulation protocols using pulsed and modulated current. A comprehensive finite element method (FEM) model encompassing realistic capacitive photo-electrode (organic electrolytic photocapacitor – OEPC) and tissue model is made in COMSOL Multiphysics® software. Electrodes are characterized by their contact electrical properties, contact capacitance and contact resistance, while the OEPC is characterized by its equivalent circuit model. Realistic cell membranes and action potential propagation are implemented using the Hodgkin–Huxley model which can be tailored to a specific cell type.
We show that using the optimized electrode configuration enables multifold current density enhancement at the targeted stimulation area which enables effective cell and tissue excitation while minimising the residual effect on the surrounding tissue. Our numerical findings are validated in vitro using cortical neuron cell cultures and mouse brain slices.

SB08.08.02
Passivation Strategies for Enhanced BioFET Performance and Stability in Ionic Solutions Faris M. Albarghouthi, Nicholas Williams, Joseph Andrews, Shiheng Lu, Jay Doherty, Steven Noyce and Aaron D. Franklin; Duke University, United States

Increasing demand for personalized medicine has led to a surge of research into electronic biosensing approaches, particularly those involving the use of a field-effect transistor (FET) as the transduction element in ion-sensitive FET-like structures. While electrical biosensors adhere to many of the tenets of the so-called “ideal biosensor,” one limitation that could hinder their success in a solution-gated setup is gate leakage. As electrical devices become immersed in solution (such as physiological liquid), improper passivation of the components results in electrical current leaking between the BioFET and the solution, thus compromising the transduction signal and preventing sensitive biological detection. Focus in the field has been on singular demonstration of BioFET applications, yet there is no consensus on device design and passivation strategy, which leads to difficulty comparing results between reports that ostensibly investigate similar phenomena, particularly with regards to gate leakage.
In this work, we investigate various passivation strategies for printed, solution-gated carbon nanotube (CNT) BioFETs. Contact-only photoresist passivation is investigated alongside whole-device dielectric passivation, particularly in the context of gate leakage reduction, long-term device stability, and wafer-scale device yield. We find that while optimized photoresist-only and dielectric-only passivation both result in high-quality BioFETs, the combination of the two – coating the contacts with a photoresist then the entire device with a dielectric – results in highly consistent performance, with more than 90% of tested devices displaying nA-level gate leakage with on/off-current ratios greater than 10^3 in solution. The photoresist+dielectric strategy also results in the best stability over 500 testing cycles, demonstrating robust performance on a timescale exceeding that required for most biomolecular binding reactions to occur. Finally, we show that the addition of a polyethylene glycol (PEG) polymer layer, which reduces non-specific protein adsorption and increases Debye length, has no significant impact on device performance both in initial device metrics and after long-term cycling when polymerized on these passivation structures. Ultimately, these results help pave the path toward the development of a truly high-yield, sensitive, stable, and robust electrical biosensing platform.

SB08.08.03
Electrical Transduction of Prothrombin Time Using Printed Nanoparticle-Based Sensors Brittani L. Carroll, Nicholas X. Williams, Jay Doherty, Steven Noyce and Aaron D. Franklin; Duke University, United States

Heart failure affects over 6.4 million people in the United States alone, with over 550,000 new cases emerging annually. Ventricular assist devices (VADs) have become a popular means of long-term care; yet, due to their thrombogenic nature, patients are frequently prescribed anticoagulation medication (e.g., warfarin). To ensure dosages remain in the therapeutic window for this strong anticoagulation drug, periodic blood-based testing (every 1-4 weeks) is required to measure patients’ prothrombin time/international normalized ratio (PT/INR), which reflect the clotting tendency of blood and hence the extent of anticoagulation. This frequent, clinic-based monitoring of PT/INR is cumbersome and costly; thus, an at-home monitoring system to ensure adequate coagulation times would be transformative for those on warfarin therapy.
Although point-of-care (POC) coagulometers are commercially available and have been demonstrated to reduce the burden on both patients and the healthcare system, only a small percentage of VAD patients perform POC self-testing. Current POC coagulometers and reagent cartridges are high cost, which limits insurance coverage, and are inconsistent in device performance. Therefore, there is a need for an alternative device that offers an at-home and portable measurement of PT/INR that is low-cost, accurate, and user friendly. In this work, a fully printed POC PT/INR test using electrical transduction is demonstrated. In order to create a low-cost device, an inexpensive testing platform was designed, which consists of aerosol jet printed silver nanoparticle electrodes. The functionality of the device was demonstrated in whole blood derived from both animal and human subjects. Given the necessity of a robust sensor, identical clotting times were measured on both a ridged and a flexible substrate tested under bending strain. In addition, a handheld sensor with low-cost electronics was designed and shown to have a measurement accurate to within a standard deviation of the costly, stationary, computer-based testing system. Finally, to improve upon the accuracy of developed handheld devices, multiple sensing modalities were combined to incorporate on-chip calibration for the impedimetric coagulometer. Taken together, these results lay the groundwork for fully printed impedimetric sensors, which address the unmet need for a low-cost, robust, POC device, potentially improving outcomes for VAD patients by early detection of aberrations in PT/INR.

SB08.08.04
Detecting Cancer Biomarkers Electrically Using Single-Molecule Techniques for Future Liquid Biopsy Applications—Understanding Bioelectronics Fingerprints at the Nucleic Acid Bioelectronic Interface Keshani G. Pattiya Arachchillage, Subrata Chandra, Jordan Ventura, Sarah Currier, Steven Ayoub and Juan Artes Vivancos; University of Massachusetts Lowell, United States

Cancer is one of the most frequent causes of death globally and kills more than 8 million people per year.[1] Early diagnosed cancers are relatively easier to treat and cure. Cancer biomarkers, such as circulating free tumor nucleic acids (ctNA), are promising for detecting cancers early.[2,3] There are various techniques to screen cancers and liquid biopsy is one of them.[2] This is a promising approach since it is used to diagnose tumor-specific biomarkers non-invasively.[2] Detecting ctNA in body fluids is challenging, because of the low ctNA concentration and the low frequency of mutations compared to wild-type sequences.[2] Nanotechnology bioelectronics methods can help to address this challenge. In particular, the Scanning Tunneling Microscopic (STM)-assisted break junctions method (STM-BJ)[4] has recently allowed the first demonstration of detection and identification of RNA from E.Coli via single-molecule conductance.[5] This is an ideal new method for liquid biopsy bioelectronics since it is non-invasive, highly sensitive, and specific.

This work focuses on characterizing ctNAs and investigating an effective method for their ultra-sensitive detection in complex samples using STM-BJ. The study's main hypothesis is that the sequences of ctNAs can be used to detect cancers electrically, by finding their unique electronic fingerprints. We focus the study on KRAS, BRAF, and Nras as effective cancer biomarkers, in agreement with data from the Pan-Cancer Analysis of Whole Genomes (PCAWG) Consortium of the International Cancer Genome Consortium (ICGC) and The Cancer Genome Atlas (TCGA).[6,7] We already have obtained some preliminary data for RNA sequences for KRAS biomarker and we expect to understand the bioelectronics interface between genetic material(ctNA) and nanostructured electrodes. Our initial analysis and the results pave the way for the early detection of bioelectronic fingerprints from biomarkers, such as ctDNA and ctRNA, through liquid biopsy using nanotechnology. This new bioelectronics method may allow beginning treatments early, potentially saving many lives from cancer patients in the future.

Degradation Mechanisms in Organic Electrochemical Transistors Emily Schafer, Ruiheng Wu, Dilara Meli, Bryan D. Paulsen and Jonathan Rivnay; Northwestern University, United States

Organic electrochemical transistors (OECTs) leverage the volumetric capacitance of mixed conducting conjugated polymers to enable efficient signal transduction and amplification at the biotic/abiotic interface, which is advantageous for applications such as electrophysiology and biosensing. The specific properties of conducting polymer OECT channel materials can be synthetically tailored to meet a variety of application and device requirements, such as biocompatibility, high degree of amplification, fast switching times, processability, and more. However, issues of OECT stability must be addressed in order to realize long-term biological interfacing. First and foremost, the mechanisms of OECT degradation have yet to be directly assessed. Further, a common standard for quantifying OECT stability has yet to be adopted across the field, limiting the general utility of published OECT stability results. Without addressing the fundamental issues of OECT stability and degradation, the translational potential of OECTs is unlikely to be realized.

We therefore have quantified OECT degradation during cycling with a suite of electrical, electrochemical, and *in situ* spectroscopic measurements which enable the separate investigation of OECT channel degradation near the source and drain electrodes, and allow the deconvolution of bias and current stress effects. Employing a prototypical P-Type polythiophene based polymer with oligoethylene glycol side chains, we find OECT degradation to be a complex phenomenon, exacerbated by the coexistence of oxidating and reducing potential environments arising near the source and drain electrodes during device operation. These environments depend on both the mass transport of electrochemically produced reactive species and the residence time of electronic charge carriers in the channel. Interestingly, device implementations that avoid the coexistence of oxidating and reducing potential environments drastically improve device stability. To test the universality of these results we have extended our studies to N-type and other P-type conjugated polymers.

Our results identify clear material properties targets (highest occupied and lowest unoccupied molecular orbital level positions) for directing the rational design of next generation OECT channel materials to maximize device stability. Further, we elucidate the most stable OECT biasing schemes and circuit implementations to maximize device stability, particularly for long-term biological sensing. Finally, we present suggestions for straightforward and rigorous OECT stability evaluation and discuss key caveats to consider when interpreting OECT stability results in the literature.

SB08.08.08
Late News: Modeling Quantum Transport in Bacterial Nanowires for Nanoelectronics William Livernois and M.P. Anantram; University of Washington, United States

Heme-based nanowires found in the pili of Geobacter sulfurreducens bacteria show great promise as a biomaterial for sensors and nanodevices. These nanowires, which consist of stacked cytochromes in a protein scaffold, have been shown to have high metallic-like conductivity. The structure was only recently determined using cryo-EM techniques, showing alternating perpendicular and parallel coordinated heme porphyrins with a repeating six heme subunit that forms a helical wire. Previous studies have modeled charge transport in cytochromes using Marcus theory, which combines modeling methods with a semi-classical electron hopping model that uses transition states to determine rate kinetics. While this has yielded models that match some cytochrome systems, the electronic behavior of the pili nanowires indicates that coherent and decoherent transport contribute significantly to overall conductivity.

The electronic properties of these nanowires were investigated using density functional theory (DFT) with a localized atomic orbital basis in Gaussian 16. Terminated sub-units of the nanowire structure were investigated, looking at the dependency of quantum transmission on spin states and iron oxidation states. The generated Hamiltonian was used with the non-equilibrium Green's function method to calculate quantum transmission and determine the single molecule conductance. The results show that the Fe (II) neutral structure has a moderate band gap (2.3-2.7eV) that drops significantly with a single oxidized heme site, and further oxidation restoring the original band gap. The quantum transmission was similarly affected, with resulting conductances matching experimental results. This demonstrates the nanowire sensitivity to oxidation state, which can be modulated chemically to change conductivity.

SB08.08.09
Late News: Biosynthetic Electronics with Encoded Functionalities Yixin Zhang; Tufts University, United States

Living electronics that converge the unique functioning modality of biological and electrical circuits has the potential to transform both fundamental biophysical/biochemical inquiries and translational biomedical/engineering applications. The intrinsic mismatches in physiochemical properties and signaling modality at biotic/abiotic interfaces, however, have made the seamless integration challenging. Here we demonstrate the effective hybridization of living and artificial components through a bottom-up approach, where electrochemically active bacteria (such as Shewanella) initiate the interaction and drive the assembly of electronic building blocks to design and formulate new functions across multiple length scales. In particular, by exploiting graphene

oxide (GO) as the solid-state electron acceptors, the bacterial metabolism leads to the construction of fully integrated 3-D living hydrogel material with significantly reduced interfacial charge transfer barrier. Combining desirable material and signaling attributes from both biotic and abiotic components, as assembled biohybrids feature mechanical integrity, optimal mass/charge transport, and bioactive performance. In particular, the electrical conductivity and morphology/shape of the living hydrogel can be simply tunned by changing ratios of two precursor solutions: bacteria and GO and using culture reactors with different shapes, respectively. With minimized charge transfer barrier between biological and electrical centers in our living system, it also enables us to quantitatively "read" intrinsic biological functions/activities based on detected electrical signals. Here we proved this possibility by translating bacteria's metabolism towards heavy metal ions into the measurable electrical signals with both shape and magnitude being linked to specific bio activities. Lastly, we also proved that our hydrogel system is compatible to be interfaced with other biological machineries and therefore, could introduce more advanced functions to our system, such as photosynthetic function. In summary, these works describe by forging the structural and functional synergy between biological and electrical circuits, the as-formed "living electronics" is expected to open-up new opportunities for many cross-disciplinary applications in biosynthesis, sensing, energy transduction, and hybrid information processing.

SB08.08.10

The Influence of Regiochemistry on the Performance of Organic Mixed Ionic and Electronic Conductors Roman Halaksa[1], Ji Hwan Kim[2], Peter A. Finn[1], Hyungju Ahn[3], Myung-Han Yoon[2] and Christian Nielsen[1]; [1]Queen Mary University of London, United Kingdom; [2]Gwangju Institute of Science and Technology, Korea (the Republic of); [3]Pohang Accelerator Laboratory, Korea (the Republic of)

The field of organic bioelectronics has experienced a dramatic development in recent years and during its existence has shown a number of applications such as metabolite sensing, drug delivery, fabrication of neuromorphic devices, and many more.
The organic electrochemical transistor (OECT), which combines both a sensor and a signal amplifier in its structure, is an ideal tool for the interface between biological and artificial systems. Currently, the OECT research is dominated by commercial PEDOT:PSS, which, however, has a number of disadvantages, such as operation in depletion mode, the difficulty of its chemical modification, and very high acidity. Therefore, it is necessary to focus development on other materials as well to remedy these unwanted properties. Both ionic and electrical conductivity are required for OECTs to function properly. It is therefore beneficial to functionalize the OECT active materials with hydrophilic moieties (such as glycol chains), but also to pay attention to their position so that the resulting material can remain structurally organised in order to preserve its electrical conductivity.
In this study, a series of four p-type polymer materials with a high density of glycol side chains were designed, synthesized, and subsequently fully characterized. By choosing different comonomer units, both straight and bent polymer geometries were achieved, with each polymer having been synthesized in two regioisomeric variants depending on the exact positioning of the glycol side chains. All polymers were found to operate efficiently in OECT accumulation mode. Subsequent detailed research revealed that even a small positioning change of side chains can have a major effect on molecular packing and electrochemical properties and can lead to nearly 6-fold increasement of the OECT figure of merit.

SB08.08.12

The Pyroelectricity of M13 Virus Han Kim[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Pyroelectricity is a physical phenomenon of polarization change under temperature fluctuation in the environment. Biological building blocks, such as amino acids, nucleic acids (DNA and RNA), proteins, and biomaterials such as soft and hard tissues with hierarchical structures are composed of polar molecules and are also known to induce pyroelectric properties. However, the understanding of the biological pyroelectric effect is still lacking due to the configurational complexity and few model system. Here, we present the M13 virus as a novel model system to demonstrate the structure-and-function relationship of biological pyroelectricity at the molecular level. M13 virus is a benign and non-harmful virus to infect only bacterial host cells. It has a filamentous shape with 880 nm in length and 6.6 nm in diameter. The M13 virus is assembled with 2700 copies of major pVIII coat protein hierarchically with spontaneous polarization. We observe that the pyroelectricity of the M13 is induced by the non-centrosymmetric structure and spontaneous polarization of the major coat protein (pVIII). With molecular dynamics simulations and circular dichroism spectroscopy, we demonstrate that the alpha-helical structure of pVIII changes to a random coil upon heating, resulting in the change in polar characteristics of M13. By fabricating unidirectionally polarized M13 film, we characterize the macroscopic pyroelectric potential of the M13 surface under various temperature fluctuations using Kelvin probe force microscopy. Further, we measure the pyroelectric voltage and current generated by pulse-modulated near-infrared laser under various frequencies and intensities. Our bioengineering approach shows how the hierarchical assembled polar molecules contribute to the pyroelectricity in a biological system and how we can develop novel virus-based self-powered systems and biomedical applications in the future.

SB08.08.13

Effects of the Doping Elements (Co, Mn, Mg) on Ultrasonic Spray Deposited NiO Thin Films and Their H_2O_2/Glucose Sensing Behavior Yusuf Tutel, Serkan Koylan, Sensu Tunca and Husnu E. Unalan; Middle East Technical University (METU), Turkey

Due to their low cost, wide band gap semiconducting nature, high chemical stability and admirable durability, nickel oxide (NiO) thin films were frequently utilized in electrochromic smart windows, p-type transparent conducting electrodes, photovoltaics (PVs), organic light-emitting diodes (OLEDs), gas sensors and functional layers for chemical sensors [1]. Chemical sensors used in healthcare have utmost importance, hydrogen peroxide (H_2O_2) and glucose being the two typical analytes. Excess H_2O_2 in the environment may lead to serious health problems as diabetes, cardiovascular disorders, cancer, and concerning neurodegenerative diseases so that an accurate, rapid and reliable method to detect H_2O_2 is of great importance [2]. Likewise, measurement of glucose concentration is also highly critical for clinical diagnosis of diabetes, fermentation and food quality control [3]. To date, many methods for determining H_2O_2 and glucose have been developed, but these methods are often time-consuming and expensive. On the other hand, electrochemical detection of H_2O_2 and glucose can be performed in a cost-effective manner, on-site with high sensitivity, using simple instrumentation. Electrochemical detection with enzyme-free electrodes has superior pH and temperature stability performance compared to that of enzyme-based sensors. Transition metals, metal oxides and their alloys are suitable candidates for the determination of H_2O_2 and glucose sensors owing to their electrocatalytic properties. And the sensor characteristics can simply be tuned via doping the electrochemically active thin films. In this work, NiO and doped NiO (cobalt, manganese and magnesium) thin films were deposited via ultrasonic spray deposition (USD) method. Then, deposited thin films were annealed to crystallize. The addition of different dopant atoms on the morphological, optical and electrochemical sensing properties of NiO thin films have been systematically investigated. Significant decrease in the crystallite sizes was observed upon doping NiO thin films. Likewise, the bandgap of doped NiO thin films decreased drastically compared to undoped NiO thin films (3.74 eV). Detection of H_2O_2 and glucose was performed using a 3-electrode setup where 0.1 M sodium hydroxide was used as an electrolyte, the fabricated thin film electrodes acted as working electrodes and Ag/AgCl and Pt wire were used as a reference and counter electrodes, respectively. The addition of interferences with different concentrations was monitored through the change in the current response at an applied potential of +0.65V (vs. Ag/AgCl). The NiO thin film H_2O_2 sensor showed a sensitivity of 1.5 µA/µM with a limit of detection of 3.8 µA. The response time was calculated as 5 seconds using 90% of initial step change in the current. These results showed the promise of ultrasonic spray deposited NiO thin films for amperometric detection of H_2O_2 and glucose.

SESSION SB08.09: Biosensors I

10:30 AM SB08.09.01
Three-Dimensional Graphene Microelectrode Arrays for Detection of Wound Healing Biomarkers Daniel J. San Roman[1], Yingqiao Wang[1], Raghav Garg[1], Mangesh Kulkarni[2], Bryan Brown[2], Stephen Badylak[2] and Tzahi Cohen-Karni[1]; [1]Carnegie Mellon University, United States; [2]University of Pittsburgh, United States

Volumetric muscle loss (VML) injuries that result in fibrotic tissue formation and degradation of skeletomuscular function represent a significant hurdle for affected patients and clinicians. Upon wound formation, macrophages and neutrophils are recruited to the site to release cytokines and growth factors for proliferation and innervation. To understand the state of the wound and thus plot an optimal trajectory for rapid regeneration, one must track the wound healing process by spatially mapping key regulatory wound biomarkers, such as nitric oxide (NO). While single-point NO probes for acute measurements have been demonstrated, improvements in device stability and the number of sensing nodes are needed to achieve smart biointerfaces for in vivo applications. Here we leverage novel nanomaterials and their exceptional electrochemical properties to construct three-dimensional fuzzy graphene (3DFG) microelectrode arrays (MEAs) for the multiplexed electrochemical sensing of NO. We report in vitro results for 3DFG MEAs capable of detecting NO at physiological concentrations in the nanomolar regime. We investigate the effects of sensor size and semipermeable selective coatings to optimize the performance of our sensor arrays and benchmark performance against conventional Pt-based sensor arrays. Finally, we demonstrate our devices on a flexible platform for in vivo NO detection (rodent model) to aid in monitoring inflammatory wound states.

10:45 AM SB08.09.02
All-Printed Organic Electrochemical Transistors for Detecting Macronutrients in Raw Plant Sap Elliot Strand[1], Eloise Bihar[1], Sanggil Han[2], Sean Gleason[3], Megan Renny[1], George G. Malliaras[2], Robert McLeod[1] and Gregory L. Whiting[1]; [1]University of Colorado, United States; [2]University of Cambridge, United Kingdom; [3]United States Department of Agriculture, United States

Conscious cultivation of plants has sustained human civilization for millennia. Maintaining optimal levels of macronutrients like potassium (K^+) and calcium (Ca^{2+}) is critical for promoting healthy plant growth and development. However, there remains no technical solution for monitoring these vital nutrients in plants in real-time. Existing nutrient detection methods typically require the excavation and transportation of plant samples to off-site laboratories for characterization, which is labor intensive and time consuming. Organic electrochemical transistors (OECTs) are devices that can monitor plant chemical levels in real-time due to their high sensitivity, low voltage and power requirements, and compatibility with living tissue. Additionally, OECTs can be fabricated using readily scalable additive manufacturing techniques (e.g., inkjet and screen printing) making them suitable for applications where many sensors are required under capital constraints.

This presentation will describe the development of fully printed, mechanically flexible, and ion selective OECTs that can accurately detect macronutrient concentrations in raw whole plant sap in real-time. The performance of these devices is drastically improved by doping PEDOT:PSS with common sugar alcohols to generate “internal ion reservoirs” within the OECT channel. The all-printed OECTs show maximum transconductances over 5 mS, which, as far as we are aware, is the highest reported for a fully printed OECT. By utilizing ion selective membranes (ISMs), OECT-based ion sensors are fabricated that show super-Nernstian sensitivity, selectivity to the target ion against similar ions over five orders of magnitude in concentration, and a limit of detection (LOD) as low as 10 µM. This work provides a potential path to high-throughput, low-cost, high spatiotemporal assessment of plant nutrition, enabling correlation of sap chemical composition to overall plant and soil health, and the potential for massive efficiency gains in agriculture.

Novel Materials and Devices for Bioelectronic Medicine George G. Malliaras; University of Cambridge, United Kingdom

As the discovery of new drugs becomes slower and more expensive with time, there is an urgent need for a new approach to treating disease. Bioelectronic medicine, which uses electrical stimulation to influence neural behaviour, has emerged as a powerful technology to that end: Deep brain stimulation, for example, has shown exceptional promise in the treatment of neurological and neuropsychiatric disorders, while stimulation of peripheral nerves is being explored to treat autoimmune disorders. To bring these technologies to patients at scale, however, significant challenges remain to be addressed. Key among these is our ability to establish stable and efficient interfaces between electronics and the human body. I will show examples of how this can be achieved using new electronic materials and devices engineered to communicate with the body and evolve with it.

2:00 PM SB08.10.02
On-Body Seismology for Continuous Monitoring of Tissue Mechanics Changsheng Wu[1], Chenhang Li[2], Heling Wang[1], Mengdi Han[1], Ziwu Song[3], Zihao Zhao[3], Jiahong Li[1], Lin Shu[1], Haixu Shen[4], Tzu-Li Liu[1], Wenbo Ding[3], Yonggang Huang[1], John A. Rogers[1] and Xiaoyue Ni[2]; [1]Northwestern University, United States; [2]Duke University, United States; [3]Tsinghua University, China; [4]California Institute of Technology, United States

Recent progress in wearable devices provides new opportunities for precise, non-invasive, long-term recording of body mechanics. The soft device incorporating a single MEMS accelerometer captures subtle vibration of the skin with a resolution of 1×10^{-4} g/sqrt(Hz) in frequency range 0 to 800 Hz. In this study, we introduce an on-body mechano-acoustic sensing technology based on a skin-mounted accelerometer array to assess the mechanical profiles of subdermal tissues in-vivo, similar to seismology. A system-level wearable device construction, optimized for a comfortable skin interface and high precision, incorporates a broadband dual-accelerometer sensor, an audio actuator, and a Bluetooth System-on-Chip and enables a wireless, automated operation. An automated algorithm, leveraging the spectral analysis of surface waves (SASW) methods, computes the depth-sensitive, elastic modulus information of the propagation media from the mechanical dispersion relationship. Comprehensive theoretical and experimental investigation verifies that the device, together with the automated data-processing platform, provides a precise, robust, and non-invasive evaluation of the elasticity with a resolution

of ~5 kPa and depth information in the range of ~1-140 mm of various phantom materials (Young's modulus E= ~10-1500 kPa). The device also identifies the softening of pork tissues with increasing injected water content and the changes of modulus of brachioradialis muscle under different levels of tension. The results are in agreement with the in-parallel Ultrasound Elastography measurements. A quantitative assessment of the stiffness profile of the rectus femoris muscle during leg-press exercise demonstrates the continuous monitoring capability in the ambulant environment that can support long-term clinical assessment of different tissues and disease states in a large population.

2:15 PM SB08.10.03
Topological Supramolecular Network Enabled Highly Conductive and Stretchable Organic Bioelectronics Yuanwen Jiang and Zhenan Bao; Stanford University, United States

Intrinsically stretchable bioelectronic devices based on soft and conducting organic materials have been regarded as the ideal interface for seamless and biocompatible integration with the human body. However, the grand challenge remains for the conducting polymer to possess both high mechanical ductility and good electrical conduction at cellular level feature sizes. This longstanding material limitation in organic bioelectronics has impeded the full exploitation of its unique benefits.

Here, we introduce a new molecular engineering strategy based on rationally designed topological supramolecular networks, which allows effective decoupling of competing effects from multiple molecular building blocks to meet complex requirements. We achieve two orders of magnitude improvement in the conductivity under 100% strain in physiological environment, along with the capability for direct photopatterning down to 2 µm.

These unprecedented capabilities allow us to realize previously inaccessible bioelectronic applications including high-resolution monitoring of 'soft and malleable' creatures, e.g., octopus, and localized neuromodulation down to single nucleus precision for controlling organ-specific activities through delicate tissues, e.g., brainstem.

2:30 PM SB08.10.04
Bimetallic Nanocatalysts Immobilized in Nanoporous Hydrogels for Long-Term Robust Continuous Glucose Monitoring of Smart Contact Lens Su-Kyoung Kim and Sei Kwang Hahn; POSTECH, Korea (the Republic of)

Smart contact lenses for continuous glucose monitoring (CGM) have great potential for huge clinical impact . To date, their development has been limited by challenges in rapid detection of glucose without hysteresis for tear glucose monitoring to track the blood glucose levels. Here, we demonstrate that bimetallic nanocatalysts immobilized in nanoporous hydrogels in smart contact lenses enable reliable CGM in diabetic rabbits. After redox reaction of glucose oxidase, the nanocatalysts facilitate rapid decomposition of hydrogen peroxide and nanoparticle-mediated charge transfer with drastically improved diffusion via rapid swelling of nanoporous hydrogels. The ocular glucose sensors result in high sensitivity, fast response time, low detection limit, low hysteresis, and rapid sensor warming-up time. In diabetic rabbits, smart contact lens can detect tear glucose levels consistent with blood glucose levels measured by a glucometer and a CGM device, reflecting rapid concentration changes without hysteresis. The CGM in a human demonstrates the feasibility of smart contact lenses for further clinical applications.

4:00 PM *SB08.11.01
Tuning the Functionality of Mixed Ionic-Electronic Conductors Using Block Copolymers Laure V. Kayser; University of Delaware, United States

The development of bioelectronic devices for sensing or actuation requires materials that have properties similar to that of biological entities. In particular, a strong emphasis has recently been placed on minimizing the mechanical mismatch between 'hard' electronics and 'soft' biological tissues to reduce tissue scaring and increase device longevity. This mismatch can be partially addressed by using conductive polymers instead of inorganic materials. Not only do polymers have a lower Young's modulus, but they can also behave as mixed ionic-electronic conductors. This mixed conduction is essential to transduce electronic to biological (ionic) signals (e.g., in neurological electrodes) and vice versa (e.g., in organic electrochemical transistors). Amongst organic mixed conductors, the polyelectrolyte complex poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) is probably the most commonly used. While some properties of PEDOT:PSS are highly desirable for bioelectronics such as its high conductivity and biocompatibility, it remains difficult to access new functionality without using a composite approach. A major challenge stems from the lack of control over the molecular structure of PEDOT:PSS, which leads to a highly disordered morphology in the solid state. Instead of taking a blending approach toward functionalizing PEDOT:PSS, we have developed a method to direct its solid-state assembly using block copolymers. Our approach uses block copolymers of PSS with neutral polymers to drive the self-assembly of PEDOT particles in solution while imparting additional functionality. In this presentation, I will share some of our results showing the importance of controlling the molecular structure of PEDOT:PSS to access properties relevant to bioelectronics, such as volumetric capacitance and reversible self-assembly.

4:30 PM SB08.11.02
Ambipolar Organic Electrochemical Transistors Based on the Bulk Heterojunction Morphology Eyal Stein[1], Oded Nahor[1], Iuliana P. Maria[2], Jonathan Rivnay[3], Iain McCulloch[4,2] and Gitti L. Frey[1]; [1]Technion--Israel Institute of Technology, Israel; [2]University of Oxford, United Kingdom; [3]Northwestern University, United States; [4]KAUST, Saudi Arabia

Organic Electrochemical Transistors (OECTs) offer transduction and high amplification of biological signals. Both p-type and n-type mixed ionic and electronic conductors and their corresponding OECT devices are gaining significant interest. Ambipolar OECTs, however, offer additional advantages including simplifying the design and fabrication of OECT-based complementary circuits, detecting biological multifunctional analytes, enabling versatile device architectures such as vertical OECTs, reducing device footprint and increasing the density of elements, etc. Still, ambipolar OECTs are scarce because it is difficult to balance the performance and stability of the device when operating under the negative and the positive conditions. Here we show that the bulk-heterojunction approach, borrowed from organic solar cells, can be harnessed to achieve ambipolarity in an OECT device. More specifically,

a semiconducting polymer and small molecule are judiciously selected, blended at suitable ratios and annealed to yield the morphology optimal for mixed conductivity and ionic-electronic coupling. We demonstrate the approach using a common OECT p-type polymer and an n-type fullerene derivative and show, for the first time, a truly balanced ambipolar OECT device. Electrical and electrochemical techniques are used to follow the physical processes under bias, while the morphology is studied using Xray techniques and VPI. Device stability as a function of time and temperature are also investigated. Changes in the morphology induced by time and temperature are associated with device performance to realize structure-property relationships in bulk-heterojunction-based OECTs.

4:45 PM SB08.11.03
Role of Molecular Mass and Processing on the Performance of an Oligoethylene Glycol-Substituted Polythiophene Based Organic Electrochemical Transistor Lucas Flagg[1], Ulyana S. Cubeta[1], Jonathan W. Onorato[2], Christine Luscombe[2], Chad R. Snyder[1] and Lee Richter[1]; [1]National Institute of Standards and Technology, United States; [2]University of Washington, United States

Organic electrochemical transistors (OECTs) are a novel device architecture, emerging as a potential platform for biosensors and neuromorphic computing. In an OECT, volumetric doping (gating) of the active semiconductor is achieved through ingress of electrolyte ions, under potential control. This opens unique transduction modalities, due to the mixed (ionic and electronic) modes of conduction. This also challenges established paradigms for the operation of traditional, organic field-effect transistors as operation involves the dynamic swelling of the active layer by both solvent and ion. Poly(3-(methoxyethoxyethoxymethyl)thiophene) (P3MEEMT) has emerged as an interesting, prototypical OECT material, differing from the classic OFET material, regioregular poly(3- hexyl)thiophene (P3HT), by the replacement of the non-polar alkyl side chains with oligoethylene glycol (OEG). In an early study of P3MEEMT,[1] is was observed to exhibit the counter-intuitive behavior of degraded charge transport upon thermal processing. We have conducted a detailed study of the variation of the structure and OECT performance of P3MEEMT with thermal processing. In the study we compare polymers with number average molecular mass, Mn, varying from (13 to 87) kg/mol. Using GIWAXS to characterize the degree of crystallinity and crystal orientation distribution, we find the OEG side chains introduce rich thermal processing behavior. All polymers exhibit only moderate and nearly isotropic order when coated from chlorobenzene. Low Mn material adopts an edge-on structure, with monotonically increasing degree of crystallinity with increasing anneal temperature. In contrast, high Mn material first adopts a face-on orientation when annealed at (115 to 125) ° C, and then a nearly isotropic crystal distribution when annealed above the last crystal melt transition near 145 ° C. Remarkably, the OECT device behavior (C*m) is nominally independent of the severe differences in orientation distribution across Mn at anneal temperatures below 120 ° C. Consistent with the earlier report,[1] 13 kg/mol Mn material exhibits a degradation in C*mu when melt-annealed (at T ≥145 ° C), in striking contrast to the higher Mn (≥ 23 kg/mol) material that exhibits anneal T independent performance. In accord with recent studies for the Mn dependence of transport in P3HT[2] we attribute the drop in performance of annealed, low Mn P3MEEMT to the phenomena of tie-chain-pullout and ripening of the crystalline domains.

Controlling Morphology, Adhesion and Electrochromic Behaviour of PEDOT Films Through Molecular Design and Processing Christina J. Kousseff, Fani E. Taifakou, William G. Neal, Matteo Palma and Christian Nielsen; Queen Mary University of London, United Kingdom

The structure-based tuneability of the electronic and optical properties of conjugated polymers has enabled their application across a range of fields, including energy harvesting and optoelectronics. However, in the context of biological sensing, the use of conjugated polymers has thus far incorporated little specificity in terms of covalent modification.

Developing robust, highly selective, biologically compatible sensing platforms is of critical importance because the measurement of analyte concentrations in biological samples is crucial for the management or detection of many diseases. Currently, many devices which function for this purpose are complex, multi-component systems. However, directed synthetic strategy with conjugated polymers enables the fine-tuning of analyte specificity, electroactive or optical functionality, and physical and morphological properties, within a single multi-purpose material. In addition, these entirely organic systems offer affordability, biocompatibility, and simple design and fabrication.

I will present my work on a novel covalently-modified PEDOT polymer featuring a 15-crown-5 moiety. The introduction of such a group is shown to enhance a diverse range of characteristics in comparison to regular PEDOT, including: adhesion to ITO substrates, physical and electrochemical integrity, film uniformity, and spectroelectrochemical properties. Furthermore, we find that the long-term electrochromic behaviour of PEDOT-Crown is altered in the presence of its chelating ion, sodium, compared to unmodified and analyte-free controls, which may open the door to its application as a sensor material. The adaptable nature of the synthetic pathway also unlocks access to range of potential sensor materials, featuring differently modified PEDOTs specific to other biomarkers, a space we have begun to explore.

5:15 PM SB08.11.05
Role of Side Chain Redistribution on the Morphology of Hydrated Organic Mixed Ionic-Electronic Conductors Lucas Flagg[1], Maximilian Moser[2], Iain McCulloch[2,3], Dean DeLongchamp[1] and Lee Richter[1]; [1]National Institute of Standards and Technology, United States; [2]University of Oxford, United Kingdom; [3]KAUST Solar Center (KSC), Saudi Arabia

Organic mixed ionic-electronic conductors (OMIECs) are a class of materials that have recently drawn interest as materials for next generation biosensors. For these applications, cycling stability is an important parameter that is not yet well understood. Recent work has shown that redistributing the ethylene glycol side chain units along the backbone, while maintaining a constant number of ethylene glycol units, can be used to optimize the cyclability of polythiophenes. In this system the polymers with unevenly distributed sidechains showed a greatly suppressed active (in response to bias) swelling as measured by quartz crystal gravimetry. This reduced swelling in response to electrochemical bias correlated with increased cycling stability.[1] Here we investigate this side chain redistribution series using grazing incidence x-ray scattering (GIWAXS) with *in-situ* potential control to examine the passive and active swelling of the polymer crystallites in addition to the bulk film. We find that when the side chain is evenly distributed, the polymer crystallites swell minimally upon contact with electrolyte, implying that most of the swelling occurs in the amorphous regions of the film. However, in polymers with highly uneven side chain distribution, contact with electrolyte causes the formation of a hydrated crystal lattice that is ~ 50 percent expanded relative to the dry lattice. We hypothesize that this hydrated crystal lattice minimizes mechanical strain caused by cycling and helps explain the greater cycling stability of these polymers. Additionally, we examine the role of different anions in swelling both the hydrated state and the dry state of the polymer films to further understand electrochemically induced swelling of these films. Overall, this work provides insights into the synthetic design of highly cyclable OMIEC materials.

Electrical Characteristics of Solution-Gated Ultrathin Channel ITO-Based Transistor Fabricated by One-Step Procedure and Biomolecular Recognition Based on Its Chemical Modification Xianqi Dong, Akiko Saito and Toshiya Sakata; The University of Tokyo, Japan

We previously proposed a one-step procedure for fabricating a solution-gated ultrathin channel indium tin oxide (ITO)-based field-effect transistor (FET) biosensor.[1] A thin-film sheet was placed on both ends of a metal shadow mask, which were contacted with a glass substrate. The bottom of the metal shadow mask corresponding to the channel was slightly raised from the substrate, resulting in the creeping of some particles into the gap during sputtering. Owing to this modified metal shadow mask, a thin ITO channel (< 30–40 nm) and thick ITO source/drain electrodes (ca. 100 nm) were simultaneously fabricated during the one-step sputtering. The thickness of ITO films was critical for them to be semiconductive, depending on the maximum depletion width, similarly to 2D materials. The ultrathin ITO channel worked as an ion-sensitive membrane as well, owing to the intrinsic oxidated surface directly contacting with an electrolyte solution. The solution-gated 20-nm-thick channel ITO-based FET, with a steep subthreshold slope (SS) of 55 mV per decade (pH 7.41) attributable to the electric double-layer capacitance at the electrolyte solution/channel interface and the absence of interfacial traps among electrodes formed in one step, demonstrated an ideal pH responsivity (~56 mV/pH). Therefore, the chemical modification of the ITO channel surface is expected to contribute to biomolecular recognition with ultrahigh sensitivity owing to the remarkably steep SS. In this study, we fabricate the solution-gated ultrathin channel ITO-based FET on glass substrate by one-step sputtering, then modify it with an aptamer, which binds to a specific target biomolecule (e.g., dopamine). Moreover, the fundamental electrical properties of the solution-gated ultrathin channel ITO-based FET with and without aptamer are investigated.
The ITO device was prepared on a glass substrate by sputtering. The ITO channel was immersed in 0.2% 3-aminopropyltrimethoxysilane (APTMS) solutions for 30 min. After the surface was washed by deionized (DI) water, the ITO transistor was heated for 10 min at 120°C. Then, the ITO channel was immersed in the mixed solution of 10% dimethyl sulfoxide (DMSO) and 90% phosphate buffered salts (PBS), containing 1 mM *N*-succinimidyl 3-maleimidobenzoate (MBS) for 1 h, and then the surface was washed with DI water. Finally, 5 mM dopamine aptamer solution (pH 7.4) was dropped on the ITO channel surface overnight. Using the prepared device, the fundamental electrical properties such as transfer characteristics (I_D-V_G), output characteristics (I_D-V_D), and real-time monitoring (I/V-t) were collected.
The solution-gated ultrathin channel ITO-based FET showed a good sensitivity near the Nernstian response to pH. Besides, by setting a gate potential in the subthreshold regime, the ITO device, which is modified by aptamer, should be capable of detecting dopamine with high sensitivity.

Bioelectronic Single-Molecule Label-Free Sensing with Large-Area Transducing Interfaces Luisa Torsi; University of Bari A. Moro, Italy

Nanosized bioelectronic detecting interfaces seem the privileged pathway to single-molecule detections. However, while giving access to rarer events, this *near-field* approach is unsuited to detect at concentrations lower than nanomolar because of the diffusion-barrier issue. *Large-area* (μm^2 - mm^2 wide) bioelectronic transistors are perceived as unsuited due to the irrelevant footprint of a single molecule on a much larger detecting interface. *Indeed, detecting such an event would be like spotting the wave generated by a single droplet of water falling on a one-kilometer-wide pond*. However, many field-effect large-area biosensors have been shown to detect at limit-of-detection below femtomolar, being also naturally suited for point-of-care applications. Here the field is reviewed, illustrating device architectures, materials used, and target analytes that can be selectively detected. The sensing mechanisms and the amplification effects enabling the large-area bioelectronic sensor to detect at the physical limit are also detailed

8:45 AM SB08.12.04
A Wearable Microneedle-based Potentiometric Sensing System for Continuous Monitoring of Multiple Electrolytes in Skin Interstitial Fluid Huijie Li and Yi Zhang; University of Connecticut, United States

Electrolytes play a pivotal role in regulating cardiovascular functions, hydration, and muscle activation. The current standards for monitoring electrolytes involve periodic sampling of blood and measurements using laboratory techniques, which are often uncomfortable/inconvenient to the subjects and add considerable expense to the management of their conditions. The wide range of electrolytes in skin interstitial fluids (ISF) and their correlations with plasma create exciting opportunities for applications such as electrolyte and circadian metabolism monitoring. However, it has been challenging to monitor these electrolytes in the skin ISF. In this study, we report a minimally invasive microneedle-based potentiometric sensing system for multiplexed and continuous monitoring of Na^+ and K^+ in the skin ISF. The potentiometric sensing system consists of a miniaturized stainless-steel hollow-microneedle to prevent the sensor delamination and a set of modified microneedle electrodes for multiplex monitoring. We demonstrate the measurement of Na^+ and K^+ in artificial ISF with a fast response time, excellent reversibility and repeatability, adequate selectivity and negligible potential interferences upon the addition of physiologically relevant concentration of metabolites, dietary biomarker and nutrients. In addition, the sensor maintains the sensitivity after multiple insertions into the chicken skin model. Furthermore, the measurements in artificial ISF using calibrated sensors confirms the accurate measurements of physiological electrolytes in artificial ISF. Finally, the agarose gel model and chicken skin model experiments demonstrate sensor's potential for minimally invasive monitoring of electrolytes in skin ISF. The developed sensor platform can be adapted for a wide range of other applications, including real-time monitoring of nutrients, metabolites and proteins.

Late News: The Role of Oxygen in the Operation of Organic Enzymatic Metabolite Sensors Victor Druet[1], Anil Koklu[1], David Ohayon[1], Prem Nayak[1], Xingxing Chen[1], Iain McCulloch[1,2] and Sahika Inal[1]; [1]KAUST, Saudi Arabia; [2]University of Oxford, United Kingdom

When combined with oxidase enzymes, the NDI-T2 based electron transporting polymer led to high performance metabolite sensors, yet their working mechanism has been poorly understood.[1,2] Here using in-situ oxygen, hydrogen peroxide, and pH analysis during device operation, we shed light into the biocatalysis at the semiconducting polymer interface. We demonstrate the significant role that oxygen plays during the operation of glucose sensors made

of n-type organic electrochemical transistors (OECTs). We show that the oxygen reduction capability of our polymer is mainly responsible for the observed sensing performance, where a strong correlation has been seen in the amount of solution oxygen and the charge carrier density of the n-type film in the OECT channel. Our results show the importance of in operando analysis for understanding polymer-catalytic enzyme activity, as well as the importance of ambient oxygen in the operation of n-type devices.

Self-Powered, Ultraflexible Photonic Skin for Continuous Bio-Signal Detection Takao Someya[1], Tomoyuki Yokota[1], Hiroaki Jinno[1] and Kenjiro Fukuda[2]; [1]The University of Tokyo, Japan; [2]RIKEN, Japan

Organic semiconductor devices are actively being applied to the next generation of wearable electronics, taking advantage of their lightweight, thinness, and flexibility. Flexible displays based on organic light-emitting diodes (LEDs) are being used in smartwatches and wristband applications to help reduce power consumption. Pulse oximetry has also been realized by combining organic LEDs with organic photodetectors. By making these organic optical sensors flexible, they can be attached directly to a human's skin with little discomfort and enable long-term health monitoring.
However, it is still difficult to integrate such thin organic optical sensors with power sources at the system level. In addition, ultra-thin organic LEDs are not stable enough to operate in air, which hinders long-term monitoring of biological signals.
Here, we present an ultra-thin, self-powered organic optical system for monitoring photoplethysmogram (PPG). The system consists of three ultra-thin electronic devices: a polymer LED (PLED), an organic solar cell, and an organic photodetector. By adopting an inverted structure and a polyethyleneimine ethoxylate (PEIE) layer doped with 8-quinolinolathritium (Liq) as the electron transport layer (ETL), organic light-emitting diodes exhibit improved operation stability under ambient air conditions. Because of the intrinsic air operational stability of inverted PLED with PEIE:Liq electron injection layers, the ultra-flexible OLED fabricated without passivation shows 70% of the initial brightness lifetime of 11.3 hours in air, which is more than three times the lifetime of conventional ultra-flexible OLEDs. In addition, the built-in light sensor showed high linearity with respect to the output of 0.98 of the PLED light sources. Such a self-powered ultra-flexible PPG sensor can stably monitor the blood flow pulse signal of human hands.

7:00 PM SB08.13.02
Wireless Human-AI Collaborative System for Enhancing Machine Decision-Making Using Tattoo-Like Electronics Joohwan Shin; Sungkyunkwan University, Korea (the Republic of)

"A.I. Artificial Intelligence" (2001), Steven Spielberg's film, features a robot that tries to understand human emotions via communication. However, human sentiments, which are nonverbal communication tools, are very ambiguous in terms of interpretation and are difficult for machines or artificial intelligence (AI) to translate technically. If AI understands a user's mental state, AI will learn the right decisions from humans in unclear situations that have been difficult to judge. Here, we introduce a wirelessly operative, neuroadaptable (adaptable in relation to his/her mindset), communicable “Human-AI Collaborative System” (HACS) based on the earbud-like wireless EEG device (e-EEGd) composed of tattoo-like electrodes, connectors, and a wireless EEG earbud. The HACS can make up for AI-based machines’ incorrect decisions to revise and reinforce its decision accuracies according to P300 event-related potential (ERP) in volunteers’ brain signals. It is based on the P300 EEG signal, one of ERP components, positive rises around 300 msec after an unexpected external stimulus is applied due to the human decision-making process[37]. In the case of the HACS, an unexpected behavior of the AI-based machine causes the P300. Since the intensity of P300 is small and the frequency range overlaps with the range of motion artifact, it is vital to measure high-quality EEG and accurately classify only P300 among various noises and components. We proposed an integration strategy based on gradually increasing thickness from ultra-thin electrodes (900 nm) to rigid earbud measurement system that enables lower motion artifacts. The e-EEGd conformally adheres to the skin on the head, minimizes volunteer motion artifacts, and continuously records EEG even while the volunteer is walking, driving, etc, which expands the variety of situations in which this technology can be used. The device weighs only 8.24 g, which is several times lighter than other available EEG devices, and generates 8.5-times less artifactual noise. The e-EEGd enables the achievement of high signal-to-noise ratio (SNR) EEG signals and transmits EEG signals wirelessly with minimal delay (up to 15 ms). We measured the P300 component with 12 subjects using e-EEGd by sensory stimulation and controlling the unexpected behavior of the autonomous machines. In addition, based on the measured P300, we conducted a signal processing and classifier optimizing study for efficient and fast real-time classification to be performed on an AI-based machine. The HACS can immediately correct unexpected working of AI-based machines or reinforce the system choices based on the presence/absence of the P300 in the user’s EEG. We demonstrated potential applications of the HACS and the e-EEGd with embedded real-time classification on AI-based machines, including virtual assistants, maze solvers, and autonomous remote-controlled (RC) cars.

7:15 PM SB08.13.03
Patch Type Glucose Sensor for Prediabetes Based on Microneedle and Self-Powered Supercapacitor Hyejun Kil and Jin-Woo Park; Yonsei University, Korea (the Republic of)

Pre-diabetic patients with glucose levels between diabetes and normal can recover to normal levels without medication if their blood glucose management is well done. However, unlike diabetics who keep blood glucose levels with medication prescribed by doctors, pre-diabetes patients should make significant efforts to control blood glucose through diet and regular exercise. The basis of blood glucose management is blood glucose measurement. A commonly used blood glucometer is a one-time measurement through blood collection by a sharp needle, which is an invasive method. Hence, patients feel pain at each measurement. Recently, continuous blood glucometers using microneedles have been commercialized, allowing patients to continuously measure and manage blood glucose without pain. However, there are several drawbacks such as that medical staff has to help attach the blood glucose meter, and side effects such as inflammatory reactions can be caused by the use of metal needles. In this work, we present a painless, lightweight, and small

patch-type wearable glucometer made of polydimethylsiloxane (PDMS) microneedle and a self-powered supercapacitor. The principle of self-powering of this patch-type glucose sensor is to charge the supercapacitor by generating a potential difference of the supercapacitor with electrons generated by the oxidation reaction of glucose. Due to this potential difference, ions present in the electrolyte are adsorbed on the surface of each electrode, and charging begins. Herein, the supercapacitor consists of polymeric thin films, which makes it mechanically flexible. We coated the electrode layer and enzyme layer by dip-coating method to form the glucose sensor on the uneven microneedle surface. The PDMS microneedle-type blood glucose sensor can penetrate the skin without pain and detect the blood glucose in the interstitial fluid (ISF). The experimental verification of the glucose-sensing by the microneedle-type sensor was done with an artificial skin immersed in the solution with glucose. The glucose concentration varies from the pre-diabetes level to diabetes, and the levels between the two. As glucose concentration increases, more electrons are produced by glucose oxidation. The potential difference between the supercapacitor electrodes increases, which gives the driving force for more electrolyte ions to move towards the electrodes. As a result, we confirmed that the supercapacitor was charged with more energy as the glucose concentration was increased through cyclic voltammetry. Finally, the self-powered patch-type glucose sensor is combined with a light-emitting diode (LED) on-off system to inform users of blood glucose levels easily and quickly. When the glucose concentration increased from the pre-diabetic to the diabetic level, the light turned on because enough energy was delivered to the connected LED.

Self-Folding Graphene-Based Electrode Array for Long-Term Monitoring of Interconnected 3D Neuronal Culture Koji Sakai, Tetsuhiko F. Teshima, Toichiro Goto, Hiroshi Nakashima and Masumi Yamaguchi; NTT Corporation, Japan

Single-layer graphene (SLG) is an ideal material for neuronal interfaces such as electrodes and cell scaffolds thanks to its high biocompatibility, transparency, and electro-conductivity. Despite these useful properties, conventional SLG-based neuronal interfaces involve constrains related to a mismatch between the 2D SLG surface and the complex structure of 3D neuronal tissues. Self-folding with SLG-based film has recently emerged as a method to encapsulate cells for both constructing 3D-shaped tissues and sensing molecules from the encapsulated cells. This suggests it could be applied for electrophysiology from a 3D-shaped neuronal construct. The approach with a foldable electrode has recently attracted a great deal of interest in 3D-spatio electrophysiology of single neural spheroids. However, it is still challenging to investigate the firing dynamics exhibited by networks of interconnected neuronal constructs because the multiple neuronal constructs need to be in contact with each electrode. In this work, we propose a foldable SLG-based electrode array that allows for producing 3D-shaped neuronal constructs within the folded electrodes while recoding firing dynamics from neuronal constructs simultaneously.
To encapsulate cultured cells within an SLG surface, we modified our previous method to induce self-folding with SLG-based film. A previous report showed that this method causes a SLG/parylene-C bilayer to spontaneously roll up into a folded cylindrical structure (micro-roll), with the SLG formed on the outer face, so we need to modify it such that the SLG forms on the inner face. We transferred another SLG to the opposite side of the parylene-C layer, and the SLG-sandwiched parylene-C film formed a micro-roll that allowed us to encapsulate cells within the inner SLG surface. We applied the self-folding to an electrode array by incorporating the SLG-sandwiched parylene-C film as an electrode. To investigate whether the electrode allows for both creating cellular constructs and electrophysiology, dissociated hippocampal neurons were encapsulated by the self-folding electrodes. Immunocytochemical images indicated that the encapsulated neurons formed a neuronal construct within the folded SLG and interconnected between each neuronal construct via axons. Spontaneous activities of neurons were continuously recorded for 70 days from the folded electrodes, whereas the signals disappeared at 28 days in recordings of an aggregated culture by unfolded electrodes. These long-term recordings were possible because the confined structure provides a firm contact between the neuronal construct and the electrode. To take advantage of the long-term recording, we further investigated a development of functional networks in the interconnected neuronal constructs (clustered culture). The clustered culture exhibited synchronous bursting activities from nine days in culture, which is consistent with a homogenous culture. On the other hand, fewer electrodes participated in the synchronized activities in the clustered culture (40% of all electrodes) than in the homogenous culture (>90%), suggesting that the clustered culture contained the rich pattern repertories of smaller networks. These results demonstrate that our method for self-folding graphene-based electrode arrays allows us to characterize the firing dynamics exhibited by interconnected neuronal constructs for a long culture period.

Organic Mixed Ionic-Electronic Conductor-Based Sub-1V Signal Rectifying Electrochemical Device Operated with Aqueous Electrolytes Youngseok Kim[1], Gunwoo Kim[1], Bowen Ding[2], Martin Heeney[2] and Myung-Han Yoon[1]; [1]Gwangju Institute of Science and Technology, Korea (the Republic of); [2]Imperial College London, United Kingdom

Owing to outstanding electrical/electrochemical performance, device operational stability and solution processability, organic mixed ionic–electronic conductors (OMIECs) have been researched for their applications to flexible biosensors, bioelectronics interfaces, neuromorphic devices, etc. Considering essential device modalities in the modern electrical circuit architecture, not only transistors but also diodes are needed for many purposes such as signal processing and device protection. Herein, we report OMIEC-based electrochemical diodes operated with aqueous electrolytes. By designing an active layer asymmetrically patterned on source and drain electrodes, the channel could be electrochemically doped/dedoped under opposite bias polarity of the applied signal, and the unprecedented current density over 30 $kAcm^{-2}$ could be achieved by using high-transconductance OMIECs. The resultant device architecture was utilized to realize two-terminal rectifying electrochemical devices. Furthermore, not only analog signal rectification but also digital logic processing could be demonstrated by employing a simple circuitry based on the multiple number of organic electrochemical diodes.

8:00 PM SB08.13.06
Flexible, Stretchable and Self-Adhesive Biopotential Electrodes Using Silver Nanorods Embedded PDMS Microstructures Yogita Maithani[1], Bijit Choudhuri[2], Bodh Raj Mehta[1] and Jitendra P. Singh[1]; [1]Indian Institute of Technology Delhi, India; [2]NIT Silchar, India

Biopotential signals are extremely useful in assessing organ function and diagnosing diseases. In order to measure and record biopotentials, biopotential electrodes act as an interface between the biological tissue and the electronic circuit. The electrical and mechanical characteristics of the electrodes used for biopotential measurements significantly influence the measured signal quality.
This work proposes a highly flexible, conductive, antibacterial, and self-adhesive silver nanorods (AgNRs) embedded polydimethylsiloxane (PDMS) based dry electrode for biopotential measurements. We have used a unique glancing angle deposition method to fabricate aligned AgNRs and embedded them in a biocompatible PDMS matrix. These electrodes do not cause skin irritation even after several hours of use and work efficiently even without prior skin preparation. These AgNRs-PDMS electrodes have an electrical resistivity of 10^{-7} Ω-m and a skin contact impedance of 93.9 ± 0.7 kΩ to 6.2 ± 3.7 kΩ for frequencies ranging from 40 Hz to 1 kHz, which is comparable to the most conventional Ag/AgCl wet electrodes. Furthermore, it maintains its conductivity across various mechanical stress, including bending, twisting, and stretching, as illustrated by a light-emitting diode circuit. Nanoindentation was used to measure the mechanical properties of fabricated AgNRs-PDMS electrodes, which shows the elastic modulus and hardness of the AgNRs-PDMS are increased by 167.6 and 93.3 %, respectively, compared to PDMS film, due to the strong interfacial adhesion of AgNRs embedded in the PDMS matrix.
The proposed AgNRs-PDMS dry electrodes are expected to give greater comfort for use over time due to their flexible nature and a better match to the skin's modulus. Simultaneously, the antibacterial properties of silver make it an attractive candidate for wearable electronics. The fabrication method is simple, cost-effective, and scalable, thus permitting the production of arbitrary-shaped flexible electrodes for long-term biopotential monitoring.

8:15 PM SB08.13.07
Electrical Properties of Free-Standing Conductive Hydrogel Electrode for Autonomous Mobile Biosensors Shogo Himori and Toshiya Sakata; The University of Tokyo, Japan

Electrochemical biosensors directly detect electrical signals based on biomolecular charges or electrical changes in biomolecular recognition events, regardless of their molecular sizes; therefore, such electrochemical methods are suitable for the detection of small biomolecules. In general, carbon and metals such as gold and platinum are used for the electrodes of electrochemical biosensors. On the other hand, considering the development of a novel biosensor in the future, a conductive polymer, which shows a flexibility and then reduces the burden to a body, is a strong candidate for the electrode in an autonomous mobile biosensing system, whereby targeted biomolecules and ions are collected and detected all over in a biological fluid or a sample solution. However, the lack of mechanical strength for the conductive polymer prevents it from maintaining a free-standing state, even when it is coated on a supporting electrode, which is a concern of the conductive polymer for the practical use [1]. That is, the development of free-standing conductive polymer is expected for the autonomous mobile biosensor without the supporting electrode. In this study, we have developed the free-standing conductive hydrogel with a functional monomer that allows biomolecular recognition, and evaluated the electrical properties with the electrochemical setup. In particular, we would like to discuss about the possibility of the functionalized free-standing conductive hydrogel for its application to the autonomous mobile electrochemical biosensor.
As the conductive hydrogel used in this study, polyaniline (PAni) was prepared with self-oxidation of aniline (Ani) monomers in an ammonium persulfate solution. In particular, aminophenylboronic acid (APBA) was copolymerized to obtain the PAni-PBA hydrogel electrode; that is, diol compounds such as glucose bind to PBA on the basis of the equilibrium reaction, which allows the detection of glucose molecules. Furthermore, by adding polyvinyl alcohol (PVA) into the PAni-PBA polymer gel network, the obtained hydrogel showed the free-standing property [1]. This is because PVA also has diol groups and is cross-linked in the PAni-PBA polymer based on the diol binding. The PAni-PBA-PVA free-standing conductive hydrogel was connected to the gate electrode of field-effect transistor (FET) through a platinum wire, and then the change in the surface potential of the hydrogel was measured with varying the glucose concentrations.
As a result, the gate potential of the FET sensor with the PAni-PBA-PVA free-standing conductive hydrogel increased with increasing the glucose concentrations. Because the binding constant of PBA to glucose was higher than that to PVA, the binding of PBA to PVA was replaced by that to glucose in the hydrogel [2]. Therefore, the crosslink density based on PVA decreased with increasing the glucose concentrations in the hydrogel and then the negative charge of PBA was induced by the diol binding with glucose; as a result, the capacitance of the hydrogel increased, which contributed to the FET signals. In this study, we have found the electrical properties of the PAni-PBA-PVA free-standing conductive hydrogel for the glucose detection with the electrochemical setup. Moreover, we would like to discuss about the possibility of the fabricated free-standing conductive hydrogel for the autonomous mobile electrochemical biosensor.

8:00 AM SB08.14.01
Multifunctional Polymer Scaffolds for Human Stem Cell Cultures Achilleas Savva and Roisin Owens; University of Cambridge, United Kingdom

Stem cell research has benefitted enormously from a variety of different materials used to create scaffolds to grow stem cells in 3D, however, only few studies report the development of structures that are able to recapitulate 3D tissue-like environments and exhibit multifunctional properties (i.e. electrical and optical). Three-dimensional organic bioelectronic devices proposed to bridge the dimensionality mismatch between 2D/static electronics and 3D/dynamic biology, comprising a versatile platform for hosting and monitoring cells. These devices take advantage of the mixed conduction properties of conjugated polymers (CPs) and enabled the realization of highly biomimetic, electro-active interfaces. Here we show the development of 3D, multifunctional polymer composite structures that exhibit good electrical and optical properties. Water-based solution mixtures of PEDOT:PSS, polythiophene and a polyethylene glycol-based crosslinker are freeze dried, and 3D scaffolds with an average pores size of 50 μm are realized. These structures exhibit lower Young's modulus and higher water swelling capacity compared with pure PEDOT:PSS scaffolds cross-linked with GOPS. Scaffold slices with different thicknesses between 100 μm - 400 μm are attached on flat ITO substrates and their photo-electrochemical properties are measured with electrochemical impedance spectroscopy (EIS) and photo-amperometry. These multifunctional platforms are used to host human adipose derived stem cells (hADCs) and to monitor their proliferation in situ with both EIS and fluorescence microscopy.

***In Vitro* Biosensing Enhanced by Optically Responsive Nanostructures and Novel Electro-Optical Transduction Approaches** Michele Dipalo[1], Sahil Rastogi[2], Raghav Garg[2], Andrea Barbaglia[1], Giulia Bruno[1], Rustamzhon Melikov[1], Giuseppina Iachetta[1], Laura Matino[1], Francesco Tantussi[1], Francesca Santoro[1], Tzahi Cohen-Karni[2] and Francesco De Angelis[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Carnegie Mellon University, United States

Over the past decade, nanostructured materials have substantially improved the performance and the capabilities of in-vitro biosensors for cellular analyses. On the one hand, materials with ordered nanostructures or with randomly nanostructured morphology improve adhesion and coupling of cells. On the other hand, these materials enable new effects that are beyond the capabilities of planar interfaces, such as electrical and optical enhancements.
In this talk, I will focus on two recent nanotechnologies: (i) ultrashort pulsed lasers on nanostructured materials for enhancing detection capabilities of electrophysiological sensors, and (ii) novel strategies for electro-optical transduction of action potentials.
The key-enabling factor of ultrashort pulsed lasers in biosensing is the squeezing of high energy in short and sparsely distributed photon packages. Lasers with pulse duration in the picosecond range may reach extremely high peak powers for activating threshold phenomena while maintaining low average irradiation intensities and thus low photocytotoxicity. By proper irradiation with ultrashort pulsed lasers, nanostructured materials immersed in water can emit hot-electrons, which are highly energetic charges that can produce redox reactions and lead to useful effects on adhering cells. In particular, the emission of hot-charges from nanomaterials may result in the non-invasive poration of the cellular membrane or in the photostimulation of action potentials. I will show that such effects can be exploited for enabling intracellular recordings or stimulation of action potentials in electrogenic cells on microelectrode arrays (MEA) decorated with nanomaterials[1,2].
In the second part of the talk, I will describe the novel concept of "VIrtual mirror CEll" (VICE)[3] for monitoring non-invasively the action potentials of

electrogenic cells in-vitro with high spatial resolution. The approach relies on the “mirror charge” effect to transduce transmembrane ionic currents into the motion of fluorophores in a separated microfluidic compartment. The VICE biosensor consists in a thin silicon nitride (Si_3N_4) membrane (thickness 100 - 500 nm) decorated with pass-through gold nanoelectrodes in floating configuration. Electrogenic cells such as neurons or cardiomyocytes are cultivated on the Si_3N_4 membrane and adhere strongly on the gold nanoelectrodes. The other side of the Si_3N_4 membrane is in contact with a microfluidic chamber loaded with charged fluorescent dyes. When cells fire action potentials, the gold nanoelectrodes become polarized and the fluorescent dyes in the microfluidic compartment move according to the generated electric field. Thus, the fluorescent optical intensity under each gold nanoelectrode is directly proportional to variations of the membrane potential of the adhering cell above. By employing high resolution cameras to detect variations of fluorescence intensities under each gold nanoelectrode, the action potentials of thousands of cells can be monitored accurately and non-invasively. In fact, the key advantage of the VICE concept is that the fluorescence dyes are completely separated by the cells thanks to the Si_3N_4 membrane. Thus, cells remain in physiological conditions and can be measured in long-term experiments.

Crosstalk Studies of Thin Polymer Microelectrode Arrays Yi Qiang and Hui Fang; Dartmouth College, United States

Thin-film polymer microelectrode array (MEA) has emerged as an increasingly significant tool for neuroscience by enabling the measurement of neuronal activities through a more mechanically compliant substrate. The miniaturization of the MEA, which includes high electrode densities and thin encapsulation/substrate layers, is essential for achieving the desired spatial resolution and mechanical compliance. However, the miniaturized MEA sizes, along with the interest of recording neuronal signals in a wide frequency band, lead to the potential frequency-dependent crosstalk among the densely packed microelectrode and interconnects, which can cause severe interference in the signal recording, especially for polymer MEAs. To date, how device parameters affect this crosstalk in polymer MEAs remain poorly studies. In this work, the crosstalk between two adjacent microelectrodes in a thin Kapton thread is modelled using equivalent circuits, then validated with experimental results. Experimentally, crosstalks are measured between two microelectrodes distanced with a different gap, encapsulated by a SU8 layer of different thicknesses and fabricated when placed in different environments (dry, wet, vs. wet with different load resistances). Finite element analysis (FEA) simulation are then utilized to explore the crosstalk in more aggressively scaled polymer electrode threads. This study sheds light on the dependence of the crosstalk in polymer MEAs on a variety of important device parameters and provides the guidelines to the design of thin polymer MEAs for high-quality neural signal recording.

A Look at Resorbable Polymers for Flexible Electronics Kaitlyn E. Crawford; University of Central Florida, United States

Over 200 million wearables were shipped in 2020 with the number of shipped devices likely to increase to over 700 million by 2026 [1]. Wearables are being used for a range of applications from human health monitoring, to lifestyle organizing. The rapidly increasing demand for wearable devices come at a time when environmental and interplanetary pollution are at an all-time high. It is becoming ever-more necessary to consider the sustainability and life-cycle of emerging wearables. To this end, the amount of electronic waste (e-waste) produced in 2020 was ~50 million tons with up to 80% of that waste expected to reach landfills [2]. Other devices such as medical implants remain in patients or require risky second surgeries to remove when their use is complete. The development and integration of degradable materials for wearables can facilitate the decomposition of electronic devices when they are no longer needed. This talk focuses on the use of bioresorbable materials to achieve transient flexible electronics for medical applications, including devices for use underwater and as implants. The talk will include a discussion about the use of natural materials, and resorbable conductive materials for transient electronics. An evaluation of their biocompatibility, moisture permeability, and biodegradation pathways will be presented.

Late News: Rapid Single-Molecule Detection of COVID-19 and MERS Antigens via Nanobody-Functionalized Organic Electrochemical Transistors Keying Guo[1], Shofarul Wustoni[1], Anil Koklu[1], Escarlet Díaz-Galicia[1,1], Maximilian Moser[2], Iain McCulloch[2,1], Stefan T. Arold[1,1,3], Raik Grünberg[1,1] and Sahika Inal[1]; [1]King Abdullah University of Science and Technology, Saudi Arabia; [2]University of Oxford, United Kingdom; [3]Université de Montpellier, France

The COVID-19 pandemic has highlighted the need for rapid and sensitive protein detection and quantification in simple and robust formats for widespread point-of-care applications. We here introduce a modular nanobody-functionalized organic electrochemical transistors (OECT) architecture that enables rapid quantification of single-molecule-to-nanomolar levels of specific antigens in complex bodily fluids.[1] The sensors combine a new solution-processable organic semiconductor material in the transistor channel and the high-density and orientation-controlled bioconjugation of nanobody–SpyCatcher fusion proteins on disposable gate electrodes. They provide results after 10-min of exposure to 5 µL of unprocessed samples, maintain high specificity and single-molecule sensitivity in human saliva and serum, and can be reprogrammed to detect any protein antigen for which nanobodies exist. We demonstrate the use of this highly modular platform to detect green fluorescent protein (GFP), SARS-CoV-2 and MERS-CoV spike proteins, and for the COVID-19 screening of unprocessed clinical nasopharyngeal swab and saliva samples with a wide range of viral loads.

S-Layer Protein Coated Carbon Nanotubes Dietmar Pum, Andreas Breitwieser and Uwe Sleytr; University of Natural Resources and Life Sciences Vienna, Austria

S-layer proteins form the outermost cell envelope component in a wide range of bacteria and archaea [1]. They can be considered one of the most abundant biopolymers on Earth. In addition to the surface of bacterial cells, S-layer proteins have the natural ability to reassemble into crystalline monomolecular arrays on solid supports, at the air-water interface, on planar lipid films and liposomes. Recently, we have shown that the S-layer protein SbpA from *Lysinibacillus sphaericus* CCM2177 can be used to disperse and functionalize pristine or oxidized multi-walled carbon nanotubes (MWNTs) by fully coating them [2,3].
This presentation summarizes the covalent and non-covalent modification of MWNTs, characterizes the highly ordered helical arrangement of the S-layer proteins, but also lattice defects at kinks and describes the formation of caps on closed nanotubes. In addition, using the recombinant fusion protein $rSbpA_{31\text{-}1068}GG$ (consisting of the SbpA S-layer protein and two copies of the IgG binding region of protein G) as a proof-of-concept, the introduced functionality could be confirmed by visualizing bound gold-labelled antibodies following a helical path around the nanotubes. Moreover, SbpA coated MWNTs were silicified with tetramethoxysilane (TMOS) in a mild biogenic approach. As expected, the thickness of the silica layer could be controlled by the reaction time. Since S-layer proteins have already demonstrated their capability to bind (bio)molecules in dense packing or to act as catalytic sites in biomineralization processes the successful coating of pristine or oxidized MWNTs has the potential for the development of new materials, such as biosensor surfaces. Key to such developments are S-layer fusion proteins, which - as shown here too - have retained the natural self-assembly properties of wild-type proteins, but are additionally equipped with specially tailored bio-reactive domains that enable a highly specific and sensitive functionalization of surfaces.

Late News: Quantitative Understanding of Amplification in Organic Electrochemical Transistor-Based Impedance Sensors Filippo Bonafè, Tobias Cramer, Isabella Zironi, Francesco Decataldo and Beatrice Fraboni; University of Bologna, Italy

Organic electrochemical transistors (OECTs) based on the conducting polymer poly(3,4 ethylenedioxythiophene) doped with poly(styrene sulfonate) (PEDOT:PSS) allow for highly efficient bioelectronic interfaces which can transduce biological signals with high gain.[1] Due to their low operation voltage, high transconductance and biocompatibility, [2] OECTs have been successfully employed for the detection of biochemical analytes and the impedance sensing of living tissue.[3] Despite these promising applications, different studies demonstrate that the OECT gain is limited to the low frequency regime, [4] and a quantitative study on the transistor amplification in the frequency spectrum relevant for biosensing is still lacking.
To overcome the issue, we introduce a model experiment where we simulate the detection of a single cell by the impedance sensing of a dielectric microparticle. The microparticle is attached to an atomic force microscopy cantilever to have a refined control of its positioning on the device channel. Measurements are performed with both an OECT and a PEDOT:PSS microelectrode to study the impact of the transistor amplification on the device sensitivity. We interpret the experimental results with a mathematical model which relates the OECT gain to the applied frequency and the device geometry. We use this model as a guideline for the design of an optimized device, and we perform an *in vitro* experiment where we sense the impedance of a single cell with both an OECT and a PEDOT:PSS microelectrode.
By comparing the experimental sensitivities, we observe a significant gain for the transistor structure, thereby demonstrating the advantages arising from the OECT amplification in high precision bioelectronic impedance sensing.

4:05 PM SB08.17.02
Nernst-Planck-Poisson Modelling of EGOFET Biosensors Larissa Huetter[1], Adrica Kyndiah[2] and Gabriel Gomila[1]; [1]Institute for Bioengineering of Catalonia (IBEC), Spain; [2]Italiano Istituto di Technologia (IIT), Italy

Electrolyte-gated organic field-Effect transistors (EGOFETs) are promising electronic devices for application as biosensors. Using organic semiconductors as active materials enables developing biocompatible, low-cost and highly sensitive devices for biorecognition events. Biosensing events modify the charge and/or specific capacitance of the biolayer/electrolyte interface at the gate electrode or semiconductor interfaces, resulting in the alteration of the semiconductor's conductivity, hence the electric current flowing through the device. EGOFETs can also be used to record the electrical activity of excitable cells since a slight potential variation at the gate electrode or semiconductor surface can lead to a shift into the current flowing through the transistor[1,2].
Despite their wide use and potential, the theoretical modelling of the EGOFET biosensor still lacks a proper understanding of several of the experimental features observed. The main reason is the use of theoretical models borrowed from the analysis of solid-state devices like MOSFETs and TFTs, which lack the physics of liquid electrolytes present in EGOFETs.

In the current work, we present the theoretical modelling of EGOFET biosensors in the Nernst-Planck-Poisson and drift-diffusion framework. In the present approach, we offer a physical description of the coupling of the electrolyte and the semiconductor through its interface, retaining the entire physics of the formation and evolution of the electrical double layers. We analyze the voltage and charge distributions across the EGOFET devices and explore how the variations of the interfacial charge or the specific capacitances at the electrolyte interfaces during a biorecognition effect affect them. Moreover, we investigate the current-voltage characteristics of the devices predicted in this framework and propose a generalized phenomenological model for its description. Finally, and based on the phenomenological model proposed, we propose an interpretation technique of experimental biosensor data based on the analysis of the conductivity vs gate voltage function, which offer significant advantages with respect to the analysis of current-voltage transfer curves, common in the field at present.

4:10 PM SB08.17.03
Development of a Wearable, Ultra-Sensitive and Highly Stable Electrospun Strain Sensor Incorporating Graphene-MXene-CNC Nanohybrids Sara Mohseni Taromsari, Chul B. Park and Hani E. Naguib; University of Toronto, Canada

Wearable strain sensors have long been a prominent member of the biomedical sensing devices, however, their applications are mostly hindered by their low sensitivity (gauge factor of at most 32 at subtle strains as caused by most of the physiological motions), as well as insufficient stability. In order to overcome such shortcomings, we have focused on development of a nanoporous, highly stretchable styrene-butadiene-styrene (SBS) substrate via electrospinning, to provide nanofibrous, interconnected pathway for a conductive network. Further, a novel approach consisting of simultaneous ultrasonic-assisted atomization and vacuum-assisted filtration was taken to carefully deposit suspensions of two types of conductive 2D materials, graphene and MXene with varying ratios, onto the surface of each fiber within the interlocked network. Such approach managed to guarantee fiber decoration, instead of forming a blanket coating on the whole surface of electrospun membranes, and to preserve the nanofibrous network that contributes to both high sensitivity and ultra stretchability. Cellulose nanocrystals (CNC) were used both as a surfactant in the liquid phase to assist 2D materials dispersion and as a compatibilizer in solid phase to act as nano-stitches, consequently enhancing the interfacial bonding between the fillers and the SBS substrate, and providing long-term stability. In the meanwhile, in an optimal concentrations which includes equal contents of graphene and MXene, each of the conductive fillers play a vital role in formation of the conductive network and its ultimate reversible disconnection when exposed to subtle motions; graphene's larger flakes provide mechanical strength by supporting the conductive framework, develop conductive interconnections for smaller MXene flakes, while they contribute to stability and easy slippage of the fillers over one another due to their inborn lubricity effect. On the other hand, smaller, yet metallic conductive MXene flakes form the conductive network at much lower filler contents (3.9 wt.% in total), while their irregular, more brittle nanoparticles with random morphologies contribute to the formation of small brittle structures that can respond to smallest of strains. The chemical, interfacial bonding between CNC, SBS and the conductive fillers were studied and verified by Fourier-transform infrared spectroscopy (FTIR), x-ray photoelectron spectroscopy (XPS) and thermogravimetric analysis (TGA) analyses, while the scanning electron microscopy (SEM) micrographs could prove the formation of a uniform, agglomerate-free, hybrid conductive network on each fiber of the interlocked network. Results of the tensile and dynamic mechanical analysis (DMA) tests, indicated the successful effect of both CNC and graphene in providing a mechanically robust conductive network with up to 171% and 167% increase in yield strength and elastic modulus, respectively. Moreover, the hybrid sensors, especially the one containing the optimal concentrations of fillers, showed the highest reported gauge factor of 68 for small strain regions, while the same factor went up to even 430 for higher strain regions, which is over 50% higher than the best value reported in the literature. Cyclic loading/unloading tests were carried out on the samples, the results of which indicated the effectiveness of CNC and graphene's role in providing low hysteresis and stabilizing the conductive network over the long run. Results of the actual sensing performance of the samples indicated highly sensitive and repeatable detection of phonations, respiration patterns and muscle movement as physiological motions, thanks to the formation of the robust, reversibly disconnectable conductive network and the stabilization provided by the compatibilizer and the processing technique.

4:15 PM SB08.17.04
Automated High Throughput Testing of Organic Electrochemical Transistors (OECT) Ulyana S. Cubeta[1], Lucas Flagg[1], Austin L. Jones[2], John R. Reynolds[2] and Lee Richter[1]; [1]National Institute of Standards and Technology, United States; [2]Georgia Institute of Technology, United States

Because biosensors can be designed with a wide array of materials, device architectures, and used in a wide array of sensing environments, the rapid development and optimization of a biosensors is particularly amenable to automated high throughput testing. We have devised a screening system to rapidly perform electrochemical device testing in an array of sensing environments. Organic mixed electronic/ion conductors are emerging as an important material platform for applications diverse as energy storage, neuromorphic computing and organic electrochemical (OECT) biosensors. Unlike the related organic semiconductors, OECTs typically operate as bulk devices, in intimate contact with electrolyte. Therefore, their electronic and ionic conductivity is intimately linked to their swelling by both electrolyte and compensating ions. Insight into the impact of swelling on the fundamental operation of OECTs can be obtained by varying the polarity or dielectric constant of the solvent and by selecting a different ion from the Hofmeister series; however, these studies are rarely done due to their tedium. As a proof-of-concept we have deployed our automated measurement system to rapidly test OECT devices in multiple electrolytes. We compare the solvent and ion sensitivity of the prototypical PEDOT:PSS polymer semiconductor to a novel oligo(ether)-functionalized propylenedioxythiophene (ProDOT)-based copolymer[1] in a standard OECT architecture. When applied to complete sensors, the system enables testing against multiple analyte concentrations with varied interfering species. When combined with automated device fabrication, automated testing will enable machine-guided optimization of complete sensor architectures.

Investigation of the Effects of Prednisone on Normal Epithelial Cell and Cancer Cell Attachment Using Electric Impedance Characterization Steffi Kong, Alejandra Martinez and Maddy Behravan; Converse College, United States

This research investigates the effects of Prednisone on the attachment of normal epithelial cells (HaCAT) and cancerous cells (A431) by electric impedance measurement. An alternating signal is applied to a series of electrodes on the bottom of cultureware on which cells were seeded. The impedance (resistance and capacitance) is recorded in real-time and corelated to cell spreading, cell-to-cell, and cell-to-substrate attachment. The real-time resistance and the capacitance were examined to infer the effects of prednisone on HaCAT and A431 cells. In harmony with prior work on these cells, it was observed the resistance increases with time and the capacitance decreases with time for both cell types. And consistently, a larger resistance and smaller capacitance

were measured for A431 cell compared with HaCAT cells. The impedance data analysis indicates that Prednisone at applied doses does not have a significant effect on the impedance of HaCAT cells over a long time. The impedance data exhibits that Prednisone may result in partial detachment and reattachment of A431 cell-to-cell bonds, indicating cellular matrix restructuring.

4:25 PM SB08.17.06
Late News: Understanding the Role of Voltage-Dependent Ion Movement in Organic Electrochemical Transistor Using Equivalent Circuit Modeling Jaspreet Kaur Pawa[1,2], Rachel Owyeung[1,1] and Sameer Sonkusale[1,1]; [1]Tufts University, United States; [2]Birla Institute of Technology and Science, India

Organic electrochemical transistors (OECTs) are promising devices for a wide variety of biological applications, as they exhibit a high transconductance at low operational regimes, and can mimic ion doping profiles of biochemical signals for artificial synapse applications. However, to our knowledge, the asymmetric nature of an OECTs transient drain current response to a uniform gate voltage pulse has not been addressed adequately, although it is apparent across devices shown in literature. In this work, we seek to analyze this asymmetric transient response, as well as hysteresis in the transistor's characteristic curves, to gain a better understanding of the device physics of OECTs. We fabricated PEDOT:PSS-based OECTs with different configurations and dimensions, and took transfer and output characteristics, as well as tested the transient behavior of the device. The OECT under consideration showed a pinch off voltage of 0.54V, and a process transconductance parameter of 0.89 mA/V^2. A uniform pulse of 100mHz frequency, alternating between voltages -0.5V and +0.5V was applied to the gate terminal of the OECT with a source-drain voltage of 0.8V. The resulting drain current response was seen to have an asymmetric shape, i.e. for the falling edge of input gate voltage pulse, we witnessed a gradual increase in drain current magnitude (3.0 s), whereas we observed an abrupt decrease in drain current magnitude for the rising edge (0.4 s). This is a landmark observation in most OECTs published in literature, though not thoroughly explored.

We hypothesize that the interplay between concentration gradient (electrolyte to channel) and influence of applied voltage on the dedoping cations, alters the rate of cation movement in and out of the semiconductor channel. This consequently affects the rise and fall time in drain current response, ultimately giving rise to hysteresis in the characteristic curves and an asymmetric transient response. We model the components of the OECT, namely the gate electrolyte, its interface with the active channel (in this case, PEDOT:PSS), and the channel itself using resistances, capacitances, and a diode. Using device equations, characteristics, and dimensions of the devices, we can accurately predict the drain current response for any voltage input or shape (absolute error of 5.35% in simulated output characteristics). We argue this model can be applied to OECTs with different geometries and materials. Further, using discrete electrical elements in the model allows us to isolate how the OECT components affect the overall device performance. This can be a powerful tool for better design of future OECTs, and for more facile implementation of OECTs into more complex, higher order circuitry, which requires knowledge of device behavior at all points of operation.

4:30 PM SB08.17.07
Tailoring the Physicochemistry of SU-8 Polymers to Modulate Bacteria-Surface Interaction Silambarasan Anbumani[1], Aldeliane M. Silva[1], Andrei Alaferdov[1], Marcos Puydinger[1], Mariana S. Silva[2], Stanislav Moshkalev[1], Hernandes F. Carvalho[1], Alessandra A. de Souza[2] and Monica A. Cotta[1]; [1]University of Campinas, Brazil; [2]Agronomic Institute of Campinas, Brazil

An epoxy polymer, SU-8 shows important potential for fabrication of high aspect ratio of micro/nanostructures scaffolds for lab-on-a-chip devices. In particular, this polymer has been used as an impressive platform for the development of various smart biomedical devices owing to its excellent optical and mechanical properties, as well as chemical stability. Whilst SU-8 properties combined with its biocompatibility facilitate its application in bio-related material interfaces, still, how SU-8 physicochemical properties affect bacteria-surface interaction has not been properly evaluated so far.
In this work, we tailor SU-8 surface properties to investigate single cell motility and adhesion of *Xylella fastidiosa* bacteria. Different SU-8 samples have been prepared using UV illumination, thermal processing and oxygen plasma treatment. Atomic Force Microscopy and X-Ray Photoelectron Spectroscopy were used to determine nanoscale surface properties; in vitro studies at the level from single cell to biofilm formation were carried out with Confocal Laser Scanning Microscopy (CLSM). The mean velocity and displacement of single cells have been extracted from CLSM tracking information data and the architecture of biofilms as well as surface coverage are compared for different samples. We observed significant differences in bacterial cell motility, for both speed and direction, as well as adhesion and biofilm architecture on SU-8 as nanoscale surface property changes. Larger density of carboxyl groups in SU-8 plasma-treated surfaces provide enhanced cell motility, while denser biofilms are found in untreated SU-8. Our results can be interpreted based on how bacterial pili interaction with the surface takes place, therefore providing different bacterial motility and cluster assemby regimes.
These results advance our understanding of the role of surface functional groups and wettability on bacteria-surface interaction for biosensing and bioelectronics applications; additionally, they might indicate new strategies to prevent microbial adhesion and, consequently, biofilm development of pathogenic species.

4:35 PM SB08.17.08
Optogenetic Behaviour Control of *Drosophila melanogaster* Using Smartphone Displays Ilenia Meloni[1], Divya Sachidanandan[2,3], Andreas S. Thum[2,3], Robert J. Kittel[2] and Caroline Murawski[1]; [1]Kurt-Schwabe-Institut für Mess- und Sensortechnik Meinsberg e.V, Germany; [2]Institute of Biology, Universität Leipzig, Germany; [3]Carl-Ludwig-Institute for Physiology, Universität Leipzig, Germany

Optogenetics is a powerful method to modulate neuronal activity with light[1]. Currently used optogenetic light sources such as lasers, LEDs, and projectors are limited in spatial resolution and typically require sophisticated, bulky and expensive experimental setups. Here, we propose using smartphone displays as simple, low-cost light sources that provide high spatial resolution for optogenetic stimulation of larval and adult stages of *Drosophila melanogaster* (fruit fly)[2].
We developed a smartphone app that allows spectral, spatial, and temporal control over the light emitted by the display and used this to deliver light patterns to induce activation and inhibition of several sets of neurons, including motoneurons, muscles, all sensory and class IV multidendritic neurons using different light-sensitive proteins (*UAS-CsChrimson, UAS-ChR2^{XXL}, UAS-GtACR1 and UAS-GtACR2*). Using, e.g., the green/red light-sensitive CsChrimson expressed in the muscles of *Drosophila* larvae, we detected a strong muscle contraction in response to stimulation with green, red, and white light of around 2-6 $\mu W/mm^2$ intensity. We also used fine patterns of light to constrain larval movement within a maze pattern or guide larvae through a disk of light. We demonstrate the suitability of smartphones as a simple testbench for a wide range of standard optogenetic experiments in both flies and larvae. In order to precisely determine the optical power density of the display also for complex light patterns, we developed a routine to simulate the spatial light distribution. This tool improves our understanding of the larvae's light-induced behaviour and leads to enhanced targeting of both individual and groups of larvae. We expect this low-cost test environment may be extended to other invertebrate species or adopted for use in teaching labs.

Multi-Mechanism Pressure Sensor—Simulation and Fabrication Azmal H. Chowdhury, Borzooye Jafarizadeh, Iman Khakpour, Nezih Pala and Chunlei Wang; Florida International University, United States

Recently, skin mountable wearable devices have gained much attention due to their non-invasive usage and wearer comfort for health care monitoring. These devices are generally used for applications such as pulse detection and e-skin application. For instance, monitoring pulse waveform detected from the wrist or neck artery can provide information on cardiovascular abnormalities such as arterial fibrosis or hypertension. The requirement for a high-performance flexible pressure sensor is good sensitivity, low power consumption, and instantaneous response for effective human-machine interfacing. In general, pressure sensors can be categorized by types of operations into piezoresistive, capacitive, piezoelectric, triboelectric, etc. Since all of these mechanisms require one flexible substrate, merging different sensing mechanisms into one multi-mechanism sensor can compound the advantages and minimize the shortcomings of these various modes of operation.
In this study, the design parameters were optimized to realize a breathable, multimodal pressure sensor consisting of piezoresistive, capacitive, and strain gauge sensing elements for precise monitoring of arterial pulse waveform. Using finite element analysis (commercial software COMSOL), simulation studies were carried out on micro-feature design parameters, such as pyramid angle, base size, and number density to find the design rules to achieve high sensitivity for the piezoresistive mode of the sensor. Also, based on finite element analysis of structural deformation, the rule for a micropatterned dielectric layer for the capacitive sensor has also been studied. These design rules yield a compact multi-mechanism sensing platform where each part has been fabricated separately. Moreover, fabrication of breathable polymeric substrate has been accomplished by methods such as electrospinning, sacrificial template, and electrostatic spray deposition to ensure long term comfortable wearability of the device. Finally, the conductive sensing material was realized via bi-polar electrochemistry to deposit porous graphene on the polymeric foundation for the piezoresistive sensor. The simulation results state that lower number density, smaller feature size, and an angle of about 50 degrees of microfeatures achieve the highest sensitivity. Furthermore, the fabrication of the multi-mechanism sensor followed the standard microfabrication techniques including photolithography and transfer printing method to integrate heterogeneous elements into the sensor. The detailed results will be discussed during the presentation.

Keywords: Wearable pressure sensor, pulse, simulation, bipolar electrochemistry, graphene, photolithography, transfer printing, finite element analysis, modeling.

Late News: Microelectrode Arrays for Simultaneous Electrophysiology and Advanced Brain Imaging Sagnik Middya, Alejandro Carnicer Lombarte, Stephen Sawiak, Sam Hilton, Vincenzo F. Curto, Gabriele Kaminski Schierle and George G. Malliaras; University of Cambridge, United Kingdom

Advanced brain imaging techniques are crucial in neuroscience research as well as in clinical diagnosis. Optical microscopy enables the targeting of specific molecules in the brain and provides a high spatial resolution. On the other hand, spectroscopic techniques like magnetic resonance imaging (MRI) can access deep regions of the brain over a large area and identify their functions. Additionally, electrical readout through neural electrodes is indispensable in measuring their activity. It is important in several applications, for example, in mapping different functions to different regions of the brain. Clinically, it is utilised in studying the initiation and spreading of seizure like activities. Unfortunately, simultaneous brain imaging and electrophysiology is challenging. Firstly, conventional electrodes are non-transparent, thus inhibiting optical imaging. In case of MRI, this is further compounded by the possibility of heating caused by eddy currents in metal electrodes. Mismatch between the magnetic susceptibilities of common electrode materials and the surrounding tissue also results in significant artefacts due to loss of signal. In this regard, conducting polymer electrodes are prospective alternatives since their compositions are closer to biological tissues. PEDOT:PSS, one of the most widely used conducting polymers, has been used in neural electrodes to improve their signal to noise ratio. This can be achieved by virtue of the volumetric capacitance effect in the conducting polymer which significantly reduces the electrode impedance. Here, we present PEDOT:PSS based versatile transparent microelectrode arrays (MEA). The glass substrate-based MEAs are immune to laser-induced artefacts and enable simultaneous Ca^{2+} imaging with electrophysiology in vitro. They are also compatible with the state-of-the-art optical imaging as well as super resolution microscopy techniques. Further, in the form of conformable electrocorticography arrays, the PEDOT:PSS electrodes can be coupled with optical brain imaging techniques. They allow MRI along with simultaneous electrical interrogation through stimulation and recording.

SESSION SB08.19: Poster Session III: Bioelectronics—Materials and Interfaces

9:00 PM SB08.18.01
Electropolymerized pHEMA coating on Flexible Multichannel Neural Probe for Localized Sensing and Stimulation Gary Kwok Ki Chik[1,2], Na Xiao[3,2], Jianni Deng[2], Chung Tin[3] and Paddy K. L. Chan[1,2]; [1]The University of Hong Kong, Hong Kong; [2]Advanced Biomedical Instrumentation Centre, Hong Kong; [3]City University of Hong Kong, Hong Kong

Miniaturization and minimization of mechanical mismatch in neural probes have been two well-proven directions in suppressing immune response and improving spatial resolution for neural stimulations and recordings. While the high impedance brought by the miniaturization of electrodes have been addressed by using conductive polymers (CPs) coatings in multiple reports, the stiffness of such coatings remains orders of magnitude from the brain tissue. In this study, we present a highly flexible microelectrode array neural probe of 8 gold electrodes with electrodeposited hydrogel coatings poly(2-hydroxyethyl methacrylate) (pHEMA) and conductive polymer poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS), with a cross-section area at only 300 μm x 2.5 μm. The porous and sponge-like pHEMA provided excellent cell adhesion properties and bridged the mechanical mismatch between the probe and the brain tissues. Besides, the PEDOT:PSS coating provides a low interfacial impedance that enhance the signal-to-noise ratio and allow the microelectrodes array to be engineered for both recording and stimulation purposes. The signal-to-noise ratio increases 70% while comparing with bare gold electrodes, and the charge injection capacity of the probe achieved 2.2 mC/cm^2. In vivo testing of microelectrode arrays implanted in rat hippocampus revealed that the microelectrodes show high signal-to-noise ratio and excellent charge injection capacity, providing a robust and low-cost solution in the brain interfaces problem.

9:05 PM SB08.18.02
Monitoring Cells After Low-Voltage Electroporation Using a Small-Size Multiple-Pulse Framework Denise Lee[1], Sophia Chan[1], Nemanja Aksic[1], J Shamita Naiker[1,2], Natasa Bajalovic[1] and Desmond K. Loke[1,2]; [1]Singapore University of Technology and Design, Singapore; [2]Changi General Hospital, Singapore

A long-term, nondestructive monitoring of cells is significant for understanding different cellular processes and functions. However, traditional methods are limited to a certain range of testing conditions and may reduce cell viability. Furthermore, the ability to demonstrate cell recovery and pore resealing after electroporation for long periods remains elusive due to difficulties in cell maintenance. Here, we develop a small-size, multiple-pulse electroporation system for monitoring cell recovery for an extended period of time with the use of low bias voltage pulses. We demonstrate that our system is able to preserve cell viability during the electroporation of cells and achieve real-time cell monitoring during the recovery period. Theoretical studies elucidate the origin of the pulsing-facilitated change in recovery time. Additionally, our method does not require specialized equipment, which allows for easy access across laboratories and medical facilities.

9:10 PM SB08.18.03
Flexible Semi-Transparent Top-Contact Organic Electrochemical Transistors Based on Ultra-Thin Gold-PEDOT:PSS Hybrid Electrode for Human Skin Interfaces Il-Young Jo, Gunwoo Kim, Youngseok Kim and Myung-Han Yoon; Gwangju Institute of Science and Technology, Korea (the Republic of)

In this research, we report ultra-thin gold-conducting polymer hybrid electrodes and their applications to flexible semi-transparent human skin interfaces. Ultra-thin hybrid electrodes were fabricated by thermal evaporation of a very thin gold layer on crystalline poly(3,4 ethylene dioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) film, leading to low sheet resistance (39.13 Ω/sq) as well as substantial optical transparency (56%) at the visible light range. Subsequently, semi-transparent electrodes were realized on flexible top-contact OECT devices which exhibited decent optical transparency, high transconductance (1 mS), and operational stability even at the highly bent state. Finally, it was successfully demonstrated that these semi-transparent flexible OECTs were mounted on human skin for electromyography recording.

9:15 PM SB08.18.04
Doubly Crosslinked Microgel-Based Electrodes Enable Electrically-Controlled Drug Delivery and Biochemical Sensing Applied for Smart Wound Dressing Chi-Yao Ku, Ting-Heng Lu, Liang-Jie Lu, Wei-Chen Huang and Yu-Te Liao; National Yang Ming Chiao Tung University, Taiwan

Smart Wound dressings with electrically controlled drug release and real-time monitoring can accelerate wound healing. Flexible electronics integrated with structurally and mechanically tissue-mimicked electrodes can not only provide high filling space for drug loading, but also can permit a seamless and biocompliant contact with skin to reduce the resistance for drug delivery and electrical signal transduction. Herein, an antibacterial hydrogel electrode is designed and integrated into a wireless system composed of a multimodality readout IC and an electrical current stimulator for electrically-controllable anti-inflammatroy drug release and uric acid (UA) detection. The doubly crosslinked microcapsules composed of carboxymethyl-hexanoyl chitosan-doped poly(3,4-ethylenedioxythiophene) and silk, called PEDOT:CHC/silk, are served as hydrogel electrodes to demonstrate tissue-like mechanical properties, electrochemical activity, and antibacterial ability. Active loading of ibuprofen (Ibu) in the PEDOT:CHC microgels allows large amount of drug loading, whereas the incorporation of silk leads to densely crosslinking of the microgels, in turns resulting in a precisely electrically-controlled release under the application of both DC (1-5V) and cyclic voltametric (CV) electrical stimulation. With the integration of hydrogel electrodes into a wireless multimodality chip fabricated in a 0.18um CMOS process, a repeated burst-to-zero-to-burst and UA detection through CA/CV is demonstrated. This smart wound dressing with highly biological and electrical compatibility is expected to provide more precise wound care.

9:20 PM SB08.18.05
Biocompatible Performance Enhancer for Organic Electrochemical Transistors Ting Li, Wei Lin Leong, Xihu Wu and Shuai Chen; Nanyang Technological University, Singapore

Organic electrochemical transistors (OECTs) have attracted attention in recent years due to their high transconductance, low operating voltage, and compatibility with aqueous solutions for broad biosensing applications. Especially, OECT-based biocompatible electronic devices enable the monitoring of physiological signals on human skin. Poly-3,4-ethylenedioxythiophene:poly-4-styrenesulfonate (PEDOT:PSS) is a typical material acting as the active channel layer in OECTs. However, the poor electrical conductivity of pristine PEDOT:PSS diminish the lifetime and restrict the application scope of the electronic device systems. Although some additives in PEDOT:PSS have been proposed to enhance the conductivity, those additives are not proved to be non-toxic or biocompatible. Besides, 4-dodecylbenzenesulfonic acid (DBSA), glycerol, dimethyl sulfoxide (DMSO), and ethylene glycol (EG) have been claimed to be biocompatible and reported to obtain PEDOT:PSS based OECTs with higher performance, however, their contribution to the enhancement of OECT performance is limited. It is worth investigating whether there is any intrinsically biocompatible additive that is more effective. Herein, a biocompatible ionic liquid [MTEOA][$MeOSO_3$] is proposed as a biocompatible additive to enhance the performance of PEDOT:PSS based OECTs. The influence of [MTEOA][$MeOSO_3$] on the morphology, conductivity, and the redox process of PEDOT:PSS during electrochemical doping/de-doping processes are explored. The biocompatible P+[MTEOA][$MeOSO_3$] (PEDOT:PSS mixed with [MTEOA][$MeOSO_3$]) film as OECT channel layer exhibits enhanced transistor characteristics, including higher transconductance, excellent switching cycling stability, and low energy consumption. The electrophysiological (ECG) signals recording ability of the P+[MTEOA][$MeOSO_3$] based OECT is explored, ECG signals from the hand and heart of a volunteer are recorded successfully. Further, the P+[MTEOA][$MeOSO_3$] film is employed as the sensing component of a pressure sensor, and the integration of the pressure sensor with the OECT shows interesting tunable pressure sensitivity by gate bias and is demonstrated to monitor physiological signals on human skin as a wearable electronic device. In addition, the P+[MTEOA][$MeOSO_3$] film also shows robust resistance to physical deformation and desired compatibility with flexible substrates as the active channel layer of the flexible OECT.

9:25 PM SB08.18.06
Late News: Effect of Additives on the Performance of a p-type Organic Semiconductor Tania C. Hidalgo Castillo[1], Maximilian Moser[2], Camila Cendra[3], Prem Nayak[1], Alberto Salleo[3], Iain McCulloch[2] and Sahika Inal[1]; [1]King Abdullah University of Science and Technology, Saudi Arabia; [2]University of Oxford, United Kingdom; [3]Stanford University, United States

Organic electrochemical transistors (OECTs) transduce ionic fluxes into electronic signals with exceptional performance.[1] It has been shown that OECTs comprising channels made of poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS) show stable operation up to ~21 days.[2] These transistors, however, operate in depletion mode, which show inferior ON/OFF ratios at low bias and are always ON, having adverse influence on power consumption. These are drawbacks hindering the practical use of these devices for long-term, biological sensing applications.
On the contrary, semiconducting polymers give rise to accumulation (enhancement) mode OECTs with inherently high ON/OFF ratios and low power consumption, and, as such, they are highly sought after. These polymers should however be stable at ambient and aqueous conditions, typical for biological sensing applications.

A good measure for OECT stability is switching the gate between ON and OFF states while biasing the drain electrode. As such, current degradation, and therefore transconductance loss, is probed. Nonetheless, longer term stability measurements, such as shelf-life stability, have often been overlooked. Recently, a p-type diketopyrrolopyrrole-based organic semiconducting polymer was reported to retain more than 85% its initial transconductance value

over ~75 hours exposed to electrolyte.[3] However, this value was reported for a large radius anion, which is not biologically relevant.
We show that by tuning the solvent mixture composition used to cast a thiophene-based p-type semiconducting polymer film, not only the OECT performance is enhanced but also the device shelf-life stability is significantly improved. The same effect is obtained by the use of a strong Lewis acid in the polymer solution. We find that the solvent additive and the acid both change the film morphology and microstructure, leading to such significant improvements in OECT performance and stability. As such, our work provides insights into structure-property relations of semiconducting polymers for applications in bioelectronics that require high performance alongside long shelf-life.

Soft, Flexible Cryogel-Based Neurostimulation Electrodes to Promote Neuroplasticity in the Brain Tianhao Chen[1], Kylie Lau[1], Mary Jiaxi Chen[1], Sung Hwa Hong[1], Stephanie Iwasa[2], HaoTian Shi[3], Taylor Morrison[1], Suneil Kalia[1], Milos Popovic[1], Cindi M. Morshead[1] and Hani E. Naguib[1]; [1]University of Toronto, Canada; [2]University Health Network, Canada; [3]University of Cambridge, United Kingdom

Deep brain stimulation (DBS) involves the delivery of electrical pulses to the brain via penetrating electrodes. While the mechanism is not well understood, DBS has proven to be a successful clinical approach to treat a variety of neurological disorders. Most recently, it has been shown that resident neural precursor cells in the brain are electrosensitive cells that expand in number, migrate and differentiate in response to stimulation. As such, the potential for electrical stimulation to promote brain repair by harnessing the regenerative properties of neural precursor cells (NPCs) is an exciting area of research. We have shown that metal-based electrodes with optimized electrical stimulation parameters can activate resident NPCs however, conventional rigid, metal-based materials are suboptimal for clinical application. This is due to the mechanical mismatch with brain tissue, poor biocompatibility and high electrode-tissue impedance that can cause damage to both electrodes and tissue during stimulation. Currently, there are numerous soft electrodes designs with good stimulating capacity and similar modulus with neural tissue in the kilopascal range but these are mostly surface electrodes that require sophisticated fabrication and additional implantation techniques due to low modulus. Here, we report a conductive and biocompatible cryogel electrode that has a simple modulus switching mechanism – high stiffness for penetration to brain tissue when dry, then softening to the kilopascal range in response to the wet environment of brain tissue. The material also exhibits high charge storage and injection capacities in brain electrolyte, reducing the interfacial impedance to deliver the required electrical field with ~7 times lower voltage under charge-balanced current controlled stimulation. We have demonstrated successful NPC stimulation using cryogel electrodes resulting in significant NPC expansion and migration of NPCs in ex-vivo brain tissue models. The cryogel material combined with optimized stimulation parameters is a promising approach to be used in DBS to promote endogenous neural repair.

Flexible Adhesive Electronics for Electrophysiological Monitoring Chenchen Mou[1], Jiwoo Song[1], Charles Horn[2], Scott Halbreiner[3] and Christopher J. Bettinger[1]; [1]Carnegie Mellon University, United States; [2]University of Pittsburgh, United States; [3]Allegheny General Hospital, United States

Reliable recording and modulation of excitable tissue using implantable electronic devices have implications in diagnosing and treating many types of diseases. The advent of flexible electronics has enabled new concepts in interfacing devices with soft tissues. However, to date, most flexible electronics achieve mechanical compliance by using substrates composed of thin curable resins or elastomers. These materials are suboptimal for tissue interfacing because they: (1) exhibit Young's moduli that are orders of magnitude larger than many excitable tissues, such as peripheral nerves and vascular structures; (2) are difficult to integrate with hydrated tissue in vivo. Here we present recent advances in materials and fabrication from our lab to address current limitations in flexible electronics. Specifically, the synthesis and formulation of flexible adhesive hydrogels and transfer printing to create ultracompliant devices to interface with peripheral nerves and cardiac tissues will be described. Details regarding the in vitro and in vivo performance of peripheral nerve interfaces and cardiac monitoring devices will be presented. Future prospective applications for this concept will also be highlighted, too.

11:45 AM *SB08.20.04
3D Artificial Dendritic Spines for Engineering Bioelectronic Interfaces Chiara Ausilio, Sara Grasselli, Anna Mariano, Valeria Criscuolo and Francesca Santoro; Istituto Italiano di Tecnologia, Italy

The interface between biological cells and non-biological materials has profound influences on cellular activities, chronic tissue responses, and ultimately the success of medical implants and bioelectronic devices. The optimal coupling between cells, i.e. neurons, and materials is mainly based on surface interaction, electrical communication and sensing.
In the last years, many efforts have been devoted to the engineering of materials to recapitulate both the environment (i.e. dimensionality, curvature, dynamicity)[1] and the functionalities (i.e. long and short term plasticity)[2] of the neuronal tissue to ensure a better integration of the bioelectronic platform and cells.
Here, we present how dendritic spine-like structures can be engineered by means of two-photon polymerization in 2.5 and 3D architectures[3]. In particular, these structures can be functionalized with ECM proteins and artificial lipid bilayers to emulate the composition of living spines in the neuronal tissue. Moreover, the topographical cues at the spine-neuron interface trigger different cell response in terms of neuronal polarization, network development and synaptic formation in primary and differentiated neuronal cultures.

In this way, both the topology and the material functionalities can be exploited for achieving in vitro biohybrid platforms for neuronal network interfacing.

Chronic and Minimally Invasive Subdermally Implantable Neuromodulation and Recording Tools in Freely Moving Subjects Philipp Gutruf; University of Arizona, United States

Materials and fabrication concepts for the creation of soft electronics coupled with miniaturization of wireless energy harvesting schemes enable the construction of high-performance electronic and optoelectronic systems with sizes, shapes and physical properties matched its biological host[1]. Applications range from continuous monitors for health diagnosis to minimally invasive exploratory tools for neuroscience[2]. This talk presents science and engineering approaches for the creation of soft devices with near field power transfer and data communication capabilities[3] and discusses application in devices for the stimulation of the brain and the peripherals in a range of complex 3D environments and contexts (e.g. social interactions) that cannot be explored with conventional technologies. We introduce a series of advances in subdermally implantable device technologies that follow from developments in materials, electronics and operational concepts that enable digitally controllable subdermal platforms with multimodal optogenetic and electrical stimulation capabilities[4][5] with the ability to provide stimulus without the physical penetration of the blood brain barrier. Additional to these stimulation capabilities new developments in low power electronics allow for capabilities in recording genetically encoded calcium indicators and physiological states of organs to enable neuronal modulation with high precision and direct feedback in freely moving subjects.[6] Because of the minimally invasive nature of these tools we show chronic neuromodulation capabilities over months in freely moving subjects. Combined these capabilities elevate device functionality substantially over current tethered platforms enabling fundamentally new approaches in experimental design to uncover the working principle of the central and peripheral nervous system and show promise to advance digital medicine approaches.

Organic Electronic Ion Pump for Flow-Free Ions Delivery for Controlling Water Transpiration in Intact Arabidopsis and Kalanchoe Plant Models Towards Better Understanding of Drought Tolerance Iwona A. Bernacka-Wojcik[1], Alexandra Sandéhn[1], Loïc Talide[2], Daniel Cowan-Turner[3], Ilaria Abdel Aziz[1], Abdul Manan Dar[1], Totte Niittylä[2] and Eleni Stavrinidou[1]; [1]Linkoping University, Sweden; [2]Umeå Plant Science Centre, Sweden; [3]Newcastle University, United Kingdom

Developments in imaging techniques accounted for unravelling insights in plant signaling at the molecular level, elucidating the role of transporters, proteins and ions during plant growth, development and stress. However, the imaging technological improvements did not go hand in hand with stimulation approaches, as important molecular compounds are currently delivered through low resolution approaches, as foliar spraying or soaking. Therefore, the need of precise and controllable delivery techniques is evident. In this context, we have developed Organic Electronic Ion Pump (OEIP) that enables electrophoretic delivery of ions in a flow-free manner greatly reducing the imposed shear stress. The delivery channel is based on polyelectrolyte of high fixed charge concentration that prevents backflow of ions minimizing the disturbance of the ionic concentrations in the targeted tissue. Previously, we have demonstrated that miniaturized, capillary-based OEIP can be inserted in intact plant with low invasiveness allowing hormone ions delivery at cellular resolution, demonstrating local and precise electronic control of plant physiology. Here, we report the development of OEIP for implantation in hard tissue of plants, such as stem, hypocotyl or succulent leaves. The mechanical properties of the capillary-based OEIPs have been significantly enhanced thanks to the use of thin polyimide coating. These devices were applied in the model plant species Arabidopsis to deliver abscisic acid that controls plant response to environmental stresses. The device targeted the plant vascular tissue for systemic control of plant transpiration. Furthermore, OEIPs were used to gain insight on the high drought tolerance of the tropical plant *Kalanchoe Blossfeldiana*.

Plant Bioelectronics for Real Time Monitoring and dYnamic Regulation of Plant Physiology Eleni Stavrinidou; Linköping University, Sweden

The development of bioelectronic technologies is driven by biomedical applications for new therapeutic and diagnostic tools. However, there are many important questions in plant biology that remain unanswered due to lack of sophisticate tools. Furthermore, the climate change and growing population calls for plants with increased tolerance to biotic and abiotic stress and plants with higher productivity. In my group we are developing organic bioelectronic technologies for sensing and actuation in plants that overcome limitations of conventional methods used in plant science. In my talk I will present our recent advancements of interfacing bioelectronic tools with plant model systems. We demonstrate enchanced plant resistance to drought via

electronically controlled delivery of biomolecules with the organic electronic ion pump. Furthermore, with OECT implantable sensors we reveal previously uncharacterized sugars dynamics in trees and finally we present a novel bioelectronic platform for stimulation of plant growth. Our results highlight the potential of bioelectronics in elucidating and enhancing plant processes but also for their application in agriculture.

Electrochemical Detection of Glucose with Highly Conductive PEDOT:PSS:Poly(acrylamide)-Based Hydrogels Containing Phenylboronic Acid Alex C. Tseng and Toshiya Sakata; The University of Tokyo, Japan

Sensors built on smart, functional materials pave the way for democratized health care by providing high quality personal health data at the point-of-care. In the aftermath of the novel coronavirus pandemic, the need for such technologies is salient. The required materials must be mediators of electronic and ionic transport, mechanically compliant and flexible, and crucially, chemically stable and biocompatible. Hydrogels of semiconducting conjugated polymers (CPs) fit this profile exceptionally well.
PEDOT:PSS (poly(3,4-ethylenedioxythiophene) polymerized with poly(styrene sulfonate)) may be readily gelated by various means [1]; however, so-called interpenetrating networks (IPNs), whereby separate conducting and structural polymers form a homogenous phase, are interesting because of the possibility for orthogonal design of electrical and mechanical properties. This allows for the use of optimized CP formulations with sensor functionality governed by the selection of hydrogel monomers, for instance, by including phenylboronic acid moieties to give selective binding towards diol-containing biomolecules [2].
In this study, we take a simple approach of polymerizing acrylamide monomers mixed with equal parts by weight of PEDOT:PSS from ready-made suspensions. Specifically, we took acrylamide (AAm) as the backbone, 2-acrylamido-2-methylpropanesulfonic acid (AMPS) as a polyelectrolytic mediator, 3-(acrylamido)phenylboronic acid (AAPBA) as a complexing site, and *N-N'*-methylenebisacrylamide (MBA) as cross-linker. The resulting PEDOT:PSS:P(AAm-*co*-AMPS-*co*-AAPBA) hydrogels, prepared as sheets tens of micrometers thick, (de)swelled reversibly in thickness by a factor of ~5 in phosphate-buffered saline (pH 7.4). Conductivities of ca. 50 (dry) and 10 S/cm (swelled, accumulating) were typical. These results indicate that the formation of IPN did not hinder electrical transport in the CP, and their high values compare favorably with previously reported pure PEDOT:PSS hydrogels [3] considering our CP loading.
Cyclic voltammetry revealed the effect of AAPBA as a secondary dopant, evidenced by the appearance of a redox peak that delayed the onset of PEDOT reduction and hastened its re-oxidation. This extended the range of pseudo-capacitance, giving a value of 2.2 F/cm^3. Upon exposure to glucose, AAPBA redox activity is suppressed, suggesting that boronic acid is preferentially reduced to boronate by applied potentials, until the formation of boronate esters with addition of glucose shifts the equilibrium back towards boronic acid. Thanks to the high conductivity of our hydrogels, direct use as the channel of an organic electrochemical transistor is possible and an amplified signal from AAPBA-glucose binding was observed. These results indicate the possibility of using PEDOT:PSS:P(AAm-*co*-AMPS-*co*-AAPBA) hydrogels for the direct electrochemical detection of glucose concentration at physiologically-relevant levels.

Surface Characteristics of Polyserotonin Thin Film for Molecularly Imprinted Polymer-Based Electrochemical Biosensors Kanako Ishino, Shoichi Nishitani and Toshiya Sakata; The University of Tokyo, Japan

In developing an electrochemical biosensor, the design and fabrication of the bioelectrical interface is important for transducing the adsorption of a target biomolecule on an electrode to an electrical signal. Recently, a poly-dopamine (pDA) film has been attractive for the bioelectrical interface, because it can be easily synthesized with self-oxidation of DA monomers on an electrode;[1] thus, it has been used for many purposes.[2] Similarly to the pDA film, serotonin (ST) monomers are simply polymerized on the electrode with its self-oxidation in an alkaline solution; as a result, the pST film shows a good biocompatibility and adhesiveness.[3] In particular, pST has been reported to be more slowly polymerized than pDA, which can expectedly lead to a smoother and thinner film formation on the electrode. On the other hand, the pDA film is utilized for a molecularly imprinted polymer (MIP)-based biosensor to detect biomarkers as one of the applications.[2] Also, considering our previous works,[4] the MIP-based biosensor can detect target biomolecules with high binding affinities by measuring the change in the molecular charges. However, the surface roughness of pDA film may be too large to properly control the thickness and surface roughness of MIP films suitable for biomolecular sizes; therefore, the thin and smooth surface characteristics of pST film are expected as one of the bioelectrical interfaces for the MIP-based biosensor. In this paper, we show the fundamental surface and electrochemical characteristics of pST film for its application to the MIP-based electrochemical biosensor.
The pST film was coated on a gold electrode or a silicon substrate by the electrochemical deposition or the self-oxidation of ST monomers in the alkaline solution (pH 8.5). After that, the thickness and roughness of pST film were measured by atomic force microscopy (AFM), and cyclic voltammetry (CV) was performed to evaluate electrical properties in buffer solutions containing a redox couple. These fundamental characteristics of pST film were strictly controlled by the CV cycles for the electrochemical deposition or the polymerization time for the self-oxidation.
Not only was the thickness of pST film linearly controlled within 5 to 15 nm, according to the CV cycles or the polymerization time, but also the roughness of pST film was much smaller than that of pDA film. Moreover, the pST film was found to be insulative from the CV curve, the surface charge of which varied with the change in pH of the measurement solutions. The insulative film on the electrode was suitable for the bioelectrical interface to control the electrical conductivities, when including cavities like MIP films. Considering the above, the thinner and smoother pST insulative film, compared to the pDA film, is applied to the MIP-based electrochemical biosensor. In the conference we are going to introduce the results about the detection of biomarkers such as peptides with the pST-MIP-based electrochemical biosensor as well.

4:15 PM SB08.22.03

Development of the Au-Au Flexible Bonding Without Any Adhesive Masahito Takakuwa[1,2], Kenjiro Fukuda[2], Tomoyuki Yokota[3], Daishi Inoue[2], Daisuke Hashizume[2], Shinjiro Umezu[1] and Takao Someya[2,3]; [1]Waseda University, Japan; [2]RIKEN, Japan; [3]The University of Tokyo, Japan

By using flexible and lightweight electronics such as sensors and energy harvester fabricated on the μm-thick polymer film, developing the next-generation wearable electronics with the excellent conformability of human skin is expected[1]. One of the important challenges for fabricating the practical electronics device is how to integrate each electronic such sensor, energy harvester, and control unit. Conductive adhesive such as anisotropic conductive film (ACF) is mainly used as a conventional conductive bonding method for the integration of each ultra-thin electronics now. However, such conventional conductive bonding lost flexibility at the bonding area because flexural rigidity gets large along with an increasing thickness.
This research shows the Au-Au direct bonding method by water vapor plasma activation. In this research, evaporated gold electrodes on 2 μm-thick of parylene substrate were used as a bonding target. A gold surface of a thin-film sample had a rough surface (root-mean roughness of 6.3 nm) compare with metal on a Si wafer. There is a simple bonding procedure: firstly, the gold surface was treated by water vapor plasma treatment. Secondly, treated gold surfaces contacted together, and keeping left several time. Then, we achieved direct bonding in the air at room temperature without any adhesive and post-treatment such as annealing and pressing.
The cross-sections of a bonded gold thin film were observed by scanning electron microscope. In the case of a sample bonded by using water vapor plasma, the bonding interface had disappeared and the gold deposited on the separate films had become one. On the other hand, thin-film samples bonded using conventional Ar plasma bonding[2,3], which is used to bond Si wafers, were clearly separated at the interface, and direct bonding of thin-film gold could not be achieved. Therefore, only water vapor plasma bonding achieved direct bonding of gold on thin film.
Moreover, the bonding area maintained excellent flexibility since there is no increase in thickness by the adhesive. In the flexibility test, two kinds of bonding samples were prepared, thin-film samples bonded by using the water vapor plasma and ACF tape. And each bonded sample placed on the plate having a bump of several bending radius. A bonded thin-film sample by water vapor plasma was exhibited excellent conformation even at a 0.5 mm radius, whereas bonded thin-film sample by ACF tape was not conformed at a less than 1 mm radius.
By using a new conductive bonding method using water vapor plasma, we have succeeded in flexibly bonding gold electrodes on a thin film without adhesives. It can be applied to fabricate the integration electronics using the ultra-thin sensor and energy harvester through investigation of the bonding of other metal materials by using water vapor plasma bonding.

4:30 PM SB08.22.04
Highly Flexible Magnetic-Elastomeric Composite Film—Experiments and Modelling Zhi LI[1,2], Erwin Alles[1,2], Ivan P. Parkin[1], Adrien Desjardins[1,2] and Sacha Noimark[1,2]; [1]University College London, United Kingdom; [2]Wellcome/ EPSRC Centre for Interventional and Surgical Sciences, United Kingdom

Soft magnetic-elastomeric composites are a class of smart materials formed by embedding magnetic particles into non-magnetic elastomer matrix host materials and curing in the presence or absence of a magnetic field. When fabricated into films, magnetic-elastomeric composites can be readily integrated with micro-scale structures to achieve flexible and compact smart sensors. With respect to their magnetic/mechanical properties, magnetic-elastomeric composite films can exhibit rapid and robust mechanical responses to external magnetic fields, which are enabling for wide biomedical applications such as wireless soft robotics, remotely stimulated magnetic actuators, and medical localisation sensors.

One of the key technical challenges in the development of the magnetic-elastomeric materials is to achieve a strong and reversible magnetic response whilst maintaining high and long-lasting mechanical flexibility. The magnetic response is governed by intrinsic material properties, such as B-H behavior and the Young's elastic modulus. Recent efforts have been centred on the fundamental mechanisms of magneto-mechanical coupling effects (dipole-dipole interactions of isolated magnetic particles) accounting for the static responses subject to external magnetic field, and magnetorheological effects that allow for dynamic changes to the elasticity of the composite material by applying an external magnetic field. It appears that multiple factors could all play vital but sometimes conflicting roles in the material performances, including: (i) the initial properties of magnetic particles and elastomers, (ii) the magnetic conditions for composite curing, (iii) the loading ratio of each component, and (iv) the film thickness. There is a significant need to understand and balance the trade-off effects of each factor to optimize the overall material properties.

Here, we report on the development of a simple, cost-effective, and scalable fabrication method to achieve centimetre-scale, highly flexible magnetic-elastomeric composite films with readily controllable magnetic particle loadings (0- 70 wt%) and film thickness (micron-scale). The composition-dependent magnetic and mechanical properties were explored by investigating a wide range of parameters including magnetic particle loading and film thickness. As a demonstration of their practical value in different applications, the magnetically induced mechanical deformations of the films with different particle loadings, field thickness and external magnetic field were simulated using a computational framework (Ansys Mechanical). Benefitting from their extremely high magnetization and maintained low Young's moduli, magnetic-elastomeric composite films show large deformation and excellent stability in response to magnetic stimuli. We conclude that soft magnetic-elastomeric composites are very promising for a wide range of biomedical devices.

How to See Without Eyes—Lessons Learned from Dissecting Cephalopod Skin Leila Deravi; Northeastern University, United States

Cephalopods, including squid, octopus, and cuttlefish, can rapidly camouflage in different underwater environments by employing multiple optical effects including light scattering, absorption, reflection, and refraction. They can do so with exquisite control and within a fraction of a second—two features that indicate distributed, intra-dermal sensory and signaling components. However, the fundamental biochemical, electrical, and mechanical controls that regulate color and color change, from discrete elements to interconnected modules, are still not fully understood despite decades of research in this space. This talk highlights key advancements in the biochemical and structural analysis of cephalopod skin and discusses compositional connections between cephalopod ocular lenses and skin with features that may also facilitate signal transduction during camouflage.

11:00 AM SB09.01.02
Crystallization Pathways of Biogenic Guanine Crystals Avital Wagner, Gan Zhang and Benjamin A. Palmer; Ben-Gurion University of the Negev, Israel

Guanine crystals are responsible for an extraordinary variety of optical phenomena in animals. The crystals are formed from stacked, planar layers of H-bonded molecules. The optical utility of guanine derives from its extreme refractive index (n=1.83) within the H-bonded plane. Little is known about how these crystals form and how the organisms precisely control crystal morphology. Key questions include whether crystallization proceeds via an amorphous precursor phase or whether physical confinement by de-limiting membranes dictates morphology. To illuminate pathways governing the crystallization, we studied model guanine-producing organisms during development, including spiders, lizards, and scallops. The onset of crystallization was determined by the emergence of birefringence in the crystal-forming cells. the tissues were then examined by cryogenic scanning electron microscopy (cryo-SEM) and transmission electron microscopy (TEM). In all three models, crystallization occurs within a spherical, double-membrane delimited vesicle. In white widow spiders, which produce prismatic guanine crystals, the crystals are progressively laid down along the H-bonded direction on parallel fibers which stretch across the length of the vesicle. As crystallization proceeds these 2D sheets of crystals merge along the π-stacking direction to form a single crystal. In lizard tails, vesicles containing very small crystals are observed and grow in all directions to form the final crystal. Evidence of a layered structure is sometimes observed in the side faces of mature guanine crystals in all three models. Though we cannot yet fully describe the crystallization pathway of biogenic guanine, initial observations are consistent with a classical 2D growth model where H-bonded layers of guanine molecules are deposited epitaxially on lipid membranes. Biological crystallization pathways can inspire new ways to synthetically control morphologies of organic crystals which then can be utilized in many optical systems.

11:15 AM SB09.01.03
Cephalopod Protein-Based Materials—Structure, Self-Assembly and Applications Preeta Pratakshya, Nadia Tolouei and Alon Gorodetsky; University of California, Irvine, United States

The study of protein-based materials has enabled the development of several optical, electronic, and medical technologies. Within this context, cephalopod structural proteins called reflectins have recently gained attention due to their demonstrated potential for the development of biophotonic and bioelectronic devices. Moreover, reflectins make up the subcellular structures found in optically active cephalopod skin cells that play a critical role in cephalopods' remarkable camouflage abilities. Given reflectins' significance from both technological applications and fundamental biology perspectives, these proteins have recently emerged as a desirable target for the design of functional biomaterials. However, the development of such materials has been hindered by a lack of complete understanding of their structures and properties. Here we highlight the structure, self-assembly, and multi-faceted applications of reflectin-based materials within the context of biophotonic and bioelectronic platforms. Specifically, we discuss how the structure and assembly of these biomaterials enable their optical and electrical functionalities. Our findings not only underscore the potential of these unique cephalopod proteins as functional biomaterials but also hold relevance for the development of cephalopod-inspired optical and electronic technologies.

11:30 AM SB09.01.04
Crack-Resistant Layered Structure in Coralline Red Algae—Formation Mechanism via Periodic Spinodal Decomposition Alexander Katsman, Nuphar Bianco-Stein and Boaz Pokroy; Technion - Israel Institute of Technology, Israel

*A*rticulated coralline red alga is abundant in the shallow waters of oceans worldwide. Its structure exhibits hierarchical organization from the macro to the nano-scale. We revealed that the high-Mg calcite cell wall nanocrystals of *Jania* sp. are arranged in layers with alternating Mg contents. This non-

homogenous elemental distribution assists the alga in preventing fracture caused by crack propagation. The mechanism of the layered structure formation was proposed as a periodic spinodal decomposition (SD) of the Mg-ACC matrix.
The crystallization in the coralline red algae occurs on an organic template via an amorphous precursor. SD of amorphous precursor to Mg-rich ACC nanoparticles and subcritical Mg-ACC matrix is activated near the cell wall/organic interface and advances to the internal regions. Following crystallization of the subcritical Mg-ACC to Mg-calcite is accompanied by an exclusion of excess Mg ions to the adjacent ACC layer. After a certain time, Mg concentration in this layer exceeds the critical value, and a secondary SD occurs, thus a layer of Mg-ACC with increased density of Mg-rich nanoparticles forms. Parameters of the layered structure were calculated based on the diffusional model developed. Using reasonable values for diffusion coefficient of Mg in gel/liquid ACC, $D \approx 10^{-15} m^2/s$, and crystallization rate $V \approx 10^{-9} m/s$, the typical layer thickness ~0.3 μm was obtained, which corresponds rather well to experimental data.

11:45 AM SB09.01.05
Functional Biopigment Xanthommatin—Bio-Inspiration and Squid Skin Optics Richard M. Osgood[1], Sean Dinneen[1], Zhuangsheng Lin[2], Steven Kooi[3] and Leila Deravi[2]; [1]DEVCOM SC, United States; [2]Northeastern University, United States; [3]Massachusetts Institute of Technology, United States

Biomaterials and bio-inspired materials like biopigments (xanthommatin (Xa), melanin, etc.) are of increasing interest for photonics applications and for basic science to understand how some species create an impressive array of photonic effects, ranging from bright color due to structural coloration or photonic crystals in tropical birds to stunning visible camouflage in underwater animals like the cephalopods, which still partially defies understanding (how can they blend into the background so well?).

Small-molecule biopigments dissolve in polymer hosts and are robust against ultraviolet light and toxicologically benign, and could form optical thin films (e.g., anti-reflective coatings). The chromatophores in squid skin, which contain the biopigment Xa in nanostructured bioparticles (granules) (100-500 nm dia.), influence light scattering and color; they achieve both pancake-like, expanded and spherical, punctate states. The granules are well-sized for nanophotonic scattering of visible light, especially blue-green wavelengths, instead of absorbing it, even in sub-monolayer arrays [1]. Recently, researchers have succeeded in mimicking chromatophore color and the light scattering granules within them, using artificial materials in the laboratory and chemically synthesizing Xa; the latter was produced in large (hundreds of mg) quantities via a straightforward, scalable process, and spraycoated onto surfaces [2]. The chromatophore could be approximated as containing multiple layer of sub-monolayers. Under the chromatophores lie iridocytes; multilayered Bragg reflectors that reflect color iridescently. By understanding how the color of the chromatophore plus iridocyte changes, artificial and novel material platforms will enable more efficient control of light at the nanoscale.

We have discovered that the Xa pigment in cephalopod chromatophores has a high refractive index (RI) ($n > 1.55$) at fixed wavelengths [3]. Recently, we have carried out comprehensive broadband (300 nm – 3200 nm) ellipsometric spectroscopy to determine the UV-to-infrared optical indices (n and k) of Xa pigment, using natural Xa from the squid's chromatophores and forming smooth, high-quality films using a novel method. These broadband measurements of Xa's fundamental optical properties allow the design of new lightweight optical components, such as lenses, that can adaptively change in response to external stimuli.

In this presentation, we will use our new experimental data for a 4-flux model (forward and backwards-propagating specular and diffuse light), to better understand squid skin optics, improving on an earlier analytical model (Kubelka-Munk). An optical model [4] made important discoveries on the optics of combined squid skin organs, but lacked separate experimental data on Xa. We improve this model analytically, coupling the chromatophore and iridocyte and not ignoring the background reflectivity and scattering. Armed with experimental n and k, our model will better assess the optical response (e.g. scattering, reflectivity) of the combined chromatophore-iridocyte to best understand the squid skin optical system. This will enable biopigments and bio-inspired pigments to serve as optically and sensing functional materials (perhaps even with electrical functionality [2]). Such a high-RI material will demonstrate strong and interesting new scattering and coloration functionalities and, when synthesized in large scale in an environmentally-friendly way, may enable new lightweight optical systems that can adapt and change shape, that may aid in underwater detection or imaging. We discuss possible new functional and optical nanophotonic systems, using the interesting biopigments and bio-inspired pigments, and possible applications in optical sensing.

SESSION SB09.02: Novel Biomaterials
Session Chairs: Mathias Kolle and Admir Masic
Tuesday Afternoon, November 30, 2021
Sheraton, 2nd Floor, Republic B

2:00 PM *SB09.02.01
Molecular Crystals in Animal Coloration and Vision Keshet Shavit[1], Avital Wagner[1], Gan Zhang[1], Jayasurya Yallapragada[2] and Benjamin Palmer[1]; [1]Ben-Gurion University of the Negev, Israel; [2]Weizmann Institute of Science, Israel

Organic crystals are widely used as the reflective materials in animal coloration and vision [1]. Guanine crystals, for example, have been studied for over 100 years and their role in structural coloration is well-established. Here we focus mainly on the less-studied pteridine molecules which are used, in crystalline form, as colorants and as reflectors in vision. Isoxanthopterin crystals form reflectors in the eyes of decapod crustaceans which are used in image-formation, enhancing photon-capture and camouflage [2]. The isoxanthopterin crystals are arranged in nanoparticles, constructed from a shell of plate-like isoxanthopterin crystals arranged in concentric lamellae around an aqueous core. The reflectors are formed from dense assemblies of nanoparticles. Isoxanthopterin crystals are characterized by layers of planer H-bonded molecules, and the reflectivity of the material derives from the extreme refractive index (n=1.96) parallel to these layers. The reflectivity and scattering of the particles are enhanced by the alignment of the crystals and an optimized core-shell ratio [3]. We also present recent insights on the formation of biogenic crystals from cryo-SEM studies of developing organisms. This includes the formation of guanine-based photonic structures in lizards and spiders and the formation of isoxanthopterin crystals in larval crustaceans. The exquisite control organisms exert over formation of these materials provides a wealth of inspiration for the design of new optical materials.

2:30 PM SB09.02.03
Biomineralization by Design—Application of *de novo* Proteins for Nanocrystal Synthesis Leah Spangler, Sarangan Chari, Michael Hecht and Gregory Scholes; Princeton University, United States

Biomineralization – the synthesis of inorganic materials using proteins – has recently gained interest as a low cost, green route for the production of metal chalcogenide semiconductor nanocrystals. Typically, biomineralized nanocrystals are synthesized using proteins or biomolecules identified from organisms which possess a native biomineralization response. Natural biomineralization pathways utilize proteins which either catalyze or template mineralization, but rarely possess a single biomolecule capable of both functions. Here, we demonstrate an alternative biomineralization approach which uses the artificially designed *de novo* protein, Construct K (ConK), to both catalyze and template metal chalcogenide nanocrystals. ConK was found to catalyze a PLP-dependent reaction which produces H_2S from L-cysteine. In the presence of metal precursors, such as Cd, enzymatically produced H_2S then reacts to form metal sulfide quantum dots in solution. In addition to having enzymatic activity, ConK is also structurally stable and highly tolerant to mutations in amino acid sequence, allowing for facile addition of new functionalities and properties. Using site directed mutagenesis, we selectively modified ConK to contain strong metal binding amino acids, such as histidine and cysteine, which act as stabilizing capping ligands to template nanocrystal populations of various controllable sizes. We characterized the optical properties of the resultant nanocrystal populations using absorbance and fluorescence spectroscopy, and verified the crystal structure using XRD and TEM measurements. Semiconductor nanocrystals synthesized using ConK demonstrate well-controlled growth and high stability when compared to naturally derived biomineralization pathways, making them ideal for commercial implementation and use.

Asymmetric Polymer/Lipid Vesicles Yuting Huang[1], Arash Manafirad[2], Simon Matoori[1], David Weitz[1], Anthony Dinsmore[2] and David Mooney[1]; [1]Harvard University, United States; [2]University of Massachusetts Amherst, United States

Lipid vesicles are aqueous volumes surrounded by a bilayer of lipid molecules, which are amphiphilic molecules with their head groups facing water and tail groups facing oil. These vesicles are simple models for cell membranes and can be used for drug delivery. Similarly, block copolymers are amphiphilic molecules that form vesicles by themselves or with lipids. Like lipid vesicles, polymer vesicles can also be used for drug delivery and cell membrane mimicry. One interesting type of lipid/polymer vesicle is the asymmetric vesicle, in which its bilayer is composed of two dissimilar lipid monolayers or a lipid monolayer and a polymer monolayer. Importantly, all eukaryotic cell membranes exhibit this type of asymmetry and asymmetry is also proposed to enhance mechanical properties of the membrane. Here, we use microfluidics to fabricate mono disperse and highly controllable asymmetric vesicles, which unlike the conventional methods that often end up wit
h highly poly disperse samples. To achieve this, asymmetric vesicles are produced using water/oil1/oil2/water emulsions in a glass capillary device, with different lipids/polymers immersed in two different volatile oil phases. In future, we envision asymmetric lipid/polymer vesicles could open a new door in the drug delivery field.

Effects of Lignin on Bacterial Cellulose Nanocomposite Materials Andrew Jimenez[1], Esther Law[1], Mallory Parker[1], Jeremy Fredricks[1], Hareesh Iyer[1], Marissa Nelsen[1], Bichlien H. Nguyen[1,2], Karin Strauss[1,2] and Eleftheria Roumeli[1]; [1]University of Washington, United States; [2]Microsoft, United States

In recent years, there has been a significant thrust towards the creation of sustainable green polymers and polymer composites [1,2]. Reductions in manufacturing resources, synthetic polymer waste, and greenhouse emissions are all driving forces for advancements in this area. Cellulose, the world's most abundant polymer, is not only derived from renewable resources, but also combines remarkable specific mechanical properties (comparable to steel wire, Kevlar and carbon fibers [3,4]) with biodegradability, biocompatibility, and a molecular structure that allows for easy functionalization [4–6]. Compared to cellulose extracted from wood, nanocellulose secreted from bacterial cultures (also referred to as bacterial cellulose, 'BC') is matrix-free, has high aspect ratio and crystallinity, and can be obtained with minimal processing [3,4]. Emerging applications of BC include nanopapers and microfibers showing remarkable Young's modulus (~66 GPa[3]), strength (~1GPa[3]) and toughness (16.9 MJ/m^3 [7]) for binder-free, pure nanocellulose materials. The incredible mechanical properties and ability to self-bind without additives stem from the combination of high aspect ratio nanofibrils, vast hydrogen bonding network, high degree of crystallinity, and for the mentioned cases arise from fiber alignment effects that enhance further the hydrogen bonding interactions between the cellulose nanofibrils[7,8]. However, BC-based materials are naturally brittle and hydrophilic due to the molecular structure of cellulose. In natural wood, phenolic molecules forming large lignin networks, serve, together with other biopolymers, as a binder to the cellulose matrix, tuning mechanical properties, conferring hydrophobicity, and protecting against pathogens[4]. In fact, recent research into sustainable biocomposites has shown significant increases of mechanical properties, thermal stability and hydrophobicity on wood-extracted cellulose-lignin composite papers with hot press treatment, compared to conventional cellulose paper[9].
In this work, we present an exploration into the development of BC-lignin nanocomposites through a design of experiments approach which allows the systematic investigation of the governing structure-processing-property relationships in these nanocomposites. Specifically, we explore a matrix of hot press processing conditions including time (10-30 minutes), temperature (120-160 °C), and pressure (5-15 MPa) and correlate the performance of those nanocomposites in response to the processing conditions. Our characterization includes scanning electron microscopy, thermogravimetric analysis, X-ray diffraction and nanoindentation tests. Additionally, the effects of lignin binding the cellulose matrix are further examined through contact angle analysis and Fourier-transform infrared spectroscopy.

AquaPlastic—A Novel Water-Processable, Coatable and Biodegradable Bioplastic Produced from Genetically Engineered Microbial Biofilms Avinash Manjula Basavanna[1,2,3], Anna Duraj-Thatte[1,2,3], Noemie-Manuelle Dorval Courchesne[1], Giorgia Cannici[1], Antoni Sanchez-Ferrer[4],

Benjamin Frank[5], Leonie van't Hag[4], Sarah Cotts[6], Howard Fairbrother[5], Raffaele Mezzenga[4] and Neel Joshi[3]; [1]Wyss Institute Harvard University, United States; [2]Massachusetts Institute of Technology, United States; [3]Northeastern University, United States; [4]ETH Zürich, Switzerland; [5]Johns Hopkins University, United States; [6]TA Instruments, United States

The non-biodegradability of petrochemical-based plastics has led to its pollution in almost all parts of the globe causing severe damages to our ecosystems, while the recent discovery of microplastics in human gut and lungs, shows alarming signs of the potential health problems. One promising long-term solution to this global problem of plastic pollution is to design and develop novel biodegradable bioplastics that can replace the conventional plastics. In this regard, we have engineered E. coli biofilms to produce the world's first water-processable protein nanofiber-based bioplastic termed as AquaPlastic, which biodegrades to ~90% in just 45 days.[1] AquaPlastic is resistant to organic solvents, strong acid, and base, which can be further utilized to form the protective coatings on various 1D and 2D substrates. Remarkably, AquaPlastic can also be molded, healed, and welded by using water. This work on AquaPlastic paves the way for packaging and coating applications, and to build a sustainable world.

Contribution of Crystallographic Texture to the Mechanical Properties of Biomineralized Composite Materials Admir Masic; Massachusetts Institute of Technology, United States

Most of the structural materials found in nature are characterized by a complex multi-scale hierarchy, which ultimately contributes to their multiple functions and mechanical properties1. Recent studies have shown that crystal orientation is yet another element of hierarchical structure that affects the mechanical properties of mineralized biological materials 2,3. In this talk I will describe how correlative chemical, mechanical, and crystallographic characterization tools can be used to explore structure-property relationships in crystallographically anisotropic biological minerals. I will show how the combination of polarized piezo-Raman and micro-indentation can be used to quantify the residual strain energy in nacreous material. Nacre's work of fracture is approximately 3,000 times that of monolithic aragonite, and its high toughness has been attributed to various chemo-mechanical mechanisms generally related to its hierarchical structure. We show that the cooperative movement of the co-oriented aragonite stacks contributes to the strain hardening of the nacre, defining a new length scale of nacre toughening[4]. In a similar fashion we studied the contributions of the chemical and crystallographic texture in the enameloid and dentin layers to mechanical properties of the drumfish teeth material. We show that the chemical doping of fluoride and zinc on the outer surface, the high crystallinity, and the crystallographic misalignment all contribute to the superior stiffness, hardness, and fracture resistance of the enameloid. The incorporation of these features into the design strategies paves the road for crystal orientation-driven mechanical enhancement of bio-inspired composite materials.

Silk Fibroin—A Fundamental Spin to Biomaterials Fabrication Rafael O. Moreno Tortolero[1], Nick Skaer[2], Robert Walker[2] and Sean A. Davis[1]; [1]University of Bristol, United Kingdom; [2]Orthox LTD, United Kingdom

Our current understanding about the seemingly broad range of self-assembly mechanisms involved in natural silk production has been developed predominantly from studies of dragline spider silk. Protein monomeric units (spidroins) polymerize via terminal interactions and allow the material to undergo an orchestrated liquid-to-solid transformation, ultimately resulting in the silk thread. However, despite its widespread availability, there have been limited mechanistic investigations on the analogous protein fibroin, which is the main component in silkworm silk. This is attributed to both its complexity and perceived inferior mechanical properties. Paradoxically, silkworm silks are the most commercially exploited of the natural silks. The inherent biocompatibility has driven applications in biomedicine, where a liquid precursor form of fibroin can be processed into a myriad of materials, from vesicles, nano and microparticles, films, hydrogels, and sponges. To obtain liquid fibroin from the solid fibre, it must first endure a process termed regeneration, where the protein is considered to be returned to a state similar to its pre-spun condition. This work explores fundamental aspects of silkworm silk fabrication that encompasses, simultaneously, a fundamental biophysical understanding of the regeneration process at the molecular scale and its effects. We use the acquired knowledge to exploit the delicate and metastable equilibrium between protein self-assembly and aggregation in a more controlled manner to fabricate complex materials with a special focus on the regeneration of hard tissue.

4:45 PM SB09.03.03
The Rose Petal Surface, a Wonder of Nature—Complexity on the Nanoscaleab Lisa Almonte[1], Carlos Pimentel[2], Enrique Rodríguez-Cañas[3], Jose Abad[4], Victoria Fernandez[5] and Jaime Colchero[1]; [1]University de Murcia, Spain; [2]Instituto Andaluz de Ciencias de la Tierra, Spain; [3]Universidad Miguel Hernández, Spain; [4]Technical University of Cartagena, Saint Pierre and Miquelon; [5]Universidad Politécnica de Madrid, Spain

Biological organisms are covered with a cuticle as outermost extracellular material and interface between organs and the environment. A precise understanding of the structure-function relation of these interfaces is still an open issue. In particular for the case of wetting, it is far from clear how nanoscale chemistry and structure determine macroscopic wetting. In our opinion, Nature is still ahead of "first principles calculations": if surfaces with well-defined and robust wetting properties are to be designed, it is still more effective to "look" at what Nature offers, than to rely on theoretical modeling. The Lotus and Rose Petal effect are two striking examples of how Nature fine-tunes nanoscale physics to obtain an appropriate (biological) function on the

macro-scale.
We use Atomic Force Microscopy (AFM) to simultaneously measure nanoscale topography and chemistry of (natural!) Rose Petals. We found two extraordinary features linked to their peculiar wetting properties, namely: (i) surface roughness is concentrated on the nanoscale and fractal-like, and (ii) the surface has an extreme nanoscale chemical variability. While high roughness is generally accepted to be the origin of peculiar wetting (super-hydrophobicity) the role of nanoscale chemical variability is usually not really a topic of discussion; most probably because -up to now- it could not be "seen".
An extreme roughness on the scale from 5 nm to 25 µm was measured. Although the total roughness is very different (25 µm vs. 3 µm), the Power Spectral Density of surface roughness of the upper and lower side are very similar, both surfaces being fractal with $df \approx 2.45$. For water, the contact angle on both surfaces is similar, which proves that rather than total roughness, other parameters -and in particular fractal dimension- are relevant for their wetting behavior. In addition, we find an extreme chemical heterogeneity of the surfaces, with very hydrophilic and very hydrophobic patches being close together. In our opinion, both, extreme roughness and chemical variability are the basis for the Rose Petal Effect.
From our data, we conclude that a liquid drop will strongly adhere to nanoscale hydrophilic patches, and detach from all the other hydrophobic parts of the surface, since the combined effect of roughness and chemical (nanoscale) wetting properties will induce a high effective local contact angle (=nanoscale wetting parameter). This explains the surprising and in principle antagonistic properties associated with the Rose Petal Effect, i.e., high contact angle and high drop adhesion. We are convinced that, although this work has focused on rose petals, the fundamental mechanism by which Nature is able to generate high contact angle and drop adhesion will apply to other surfaces with similar characteristics. In addition, the application of this fundamental mechanism will trigger the development of new functional surfaces by "learning from Nature".

5:00 PM SB09.03.04
Magnetic Nacre—Superior Mechanical and Magnetic Performance of Highly Anisotropic Sendust–Flake Composites Freeze Cast in a Uniform Magnetic Field Kaiyang Yin[1,2,3], Bradley A. Reese[2], Charles R. Sullivan[2] and Ulrike G. Wegst[1,2]; [1]Northeastern University, United States; [2]Dartmouth College, United States; [3]University of Freiburg, Germany

Despite extensive research, the manufacture in the bulk of high–performance flake–based magnetic composites with a highly aligned, nacre–like structure remains challenging. Many challenges can be overcome by freeze casting in an externally applied, uniform magnetic field, which causes both the flakes and the composite walls of the cellular solid to align parallel to the B–field lines. When appropriately sized, the flakes experience a second alignment parallel to the freezing direction because of a shear flow that occurs due to both the volumetric expansion of the ice phase and mold contraction during the directional solidification. The resulting orthotropic structure of the freeze–cast magnetic composite is reflected in orthotropic mechanical and magnetic properties of the material. The magnetic composites manufactured by magnetic–field assisted freeze casting outperform by a factor of 2–4 in terms of stiffness, strength, and toughness materials that are processed in the absence of a magnetic field and do not exhibit a monodomain architecture. Additionally, the anisotropic freeze–cast magnetic composites achieve lower losses in two directions of flux excitation so that they can be used without an additional high permeability flux return path in applications like power transformation. Because of the highly aligned microstructure, it is possible to compact the initially lamellar composite with 90% porosity to at least 80% strain. The results presented in this study illustrate the tremendous potential for magnetic freeze casting of nacre–like magnetic composites for use in power conversion.

Light-Adapted Photosynthetic Membranes from Marine Bacteria and Diatoms for Bio-Electronic and Bio-Photovoltaic Applications Constantinos A. Varotsis, Marios Papageorgiou, Konstantinos Yiannakkos, Charalambos Andreou and Charambos Tselios; Cyprus University of Technology, Cyprus

The high quantum efficiency of photosynthetic reaction centers (RCs) makes them attractive for bioelectronics and biophotovoltaic applications. In the bacterial species *Roseobacter denitrificans*, *Roseobacter lotoralis* and *Erythrobacter litoralis* the photovoltaic machinery which is located within few nm diameter transmembrane protein can be removed from the cells and interfaced with electrodes. Cytochrome *c* (cyt *c*) has been utilized as an electron-transfer (ET) element between electrodes and RCs. Diatoms are a major group of microalgae ubiquitous in the oceans. They have developed a unique light-harvesting apparatus, the Fucoxantin Chl *a*/*c* binding protein (FCP) which shows a sequence similarity to light harvesting complex (LHC II) of higher plants but with pigment composition significantly different. In FCP, Chl *b* is replaced by Chl c_2 and Fucoxanthin (Fx) is the major carotenoid instead of lutein in LH II.
In the present work the photodynamics and spectroscopic characterization, including Resonance Raman, FTIR, Fluorescence, light induced adaptations, and Electrochemistry, of membranes from *Roseobacter denitrificans*, *Roseobacter litoralis* and *Erythrobacter litoralis* and from the diatoms *Thalassiosira pseudonan*, *Chaetoceros ceratosporus* and *Chaetoceros sp* will be presented.

Multi-Lamellar Structured Ceramide Microparticles Enveloped with a Thin Layer of Bacterial Cellulose Nanofibers Kyounghee Shin, Boryeong Lee and Jin Woong Kim; Sungkyunkwan University, Korea (the Republic of)

Ceramides are the main component of the stratum corneum, the outermost layer of the skin, providing an epidermal barrier against dehydration or external microorganisms. However, much wider application of ceramides has been limited since molecular crystallization readily occurs in aqueous formulations. To solve this problem, this study introduces a practically useful approach to encapsulate ceramide molecules, in which hydrophobically modified bacterial cellulose nanofibers (BCNFs) were employed as a thin film-forming fiber surfactant. We confirmed that the ceramide microparticle core with a multi-lamellar structure could be enveloped with a BCNF wall of which thickness is about hundreds of nanometers. The multi-lamellar structure was

characterized by analyzing the inter-layer distance through small-angle x-ray scattering. The inter-layer distance could be manipulated by using fatty alcohols with different alkyl chain length; 4.3 nm, 4.9 nm, and 5.9 nm for 1-tetradecanol, 1-octadecanol, and 1-docosanol, respectively. Wide-angle x-ray scattering showed that the ceramide exhibited hexagonal lateral packing with 1-tetradecanol and orthorhombic lateral packing with 1-octadecanol and 1-docosanol. These results suggest that the chain length of fatty alcohols critically involved in the process of ceramide molecules forming the multi-lamellar structure. Furthermore, we demonstrated that the longer chain length of fatty alcohols prevented more effectively the microcrystalline phase from penetrating the capsule wall and protruding out due to the formation of thicker hydrophobic lamellar phase. The results obtained in this study highlight that BCNF-based encapsulation technology provides a practical methodology to control the crystallization behavior of ceramide molecules, thus enabling the development of various types of skin-friendly formulations that can strengthen the skin barrier function.

SB09.04.05
***Euglena gracilis*-Derived Exosomal Nanovesicles as Cell Activating Therapeutic Agents** Hwira Baek, Yuri Ko and Jin Woong Kim; Sungkyunkwan University, Korea (the Republic of)

Exosomes, a class of extracellular vesicles secreted by almost eukaryotic cells, are known as an important mediator for signaling in cell-cell communication and cellular processes including immune response and antigen presentation. Since exosomes contain therapeutic proteins, a variety of cell therapeutic strategies are developing while avoiding side effects such as low survival rate and immune rejection response associated with direct use of cells as a therapeutic agent. Most of the exosome studies conducted so far are based on animal-originated cells. Recently, there are challenging attempts to extract exosomes from other types of raw materials such as plant cells and microalgae. The approach to obtain exosomes from microalgae is of special interest, because they have abundant biomolecules such as proteins, vitamins, minerals, and amino acids. Herein, we first propose a microalgae-derived exosomal nanovesicle (ExoNV) system for cellular drug delivery. Our ExoNVs were extracted from *euglena gracilis*, representative microalgae, containing b-glucans, vitamins, and minerals, via cell-extrusion. Extruding *euglena gracilis* through a series of polycarbonate membrane from 5μm to 0.2μm pores allowed us to produce ExoNVs with a particle size of ~190 nm and the number of $6.55x10^9$ particles/ml. The ExoNVs produced by using this approach encapsulated 14% of β-glucans, which was confirmed by aniline blue fluorescence analysis. In our continued studies, we also confirmed through *in vitro* cellular ROS detection and cell proliferation assays that β-glucans-containing ExoNVs not only exert improved cellular antioxidation activity but also aid dramatically in cell proliferation. These results highlight that our ExoNV system has great potential as an exosome-mimetic therapeutic agent that can activate cells or deliver drugs to cells.

SB09.04.06
A Biomimetic Approach to Improve the Tribological Performance of PVD Coated Surfaces for Automotive Applications SangYul Lee[1] and Jungwan Kim[2]; [1]Korea Aerospace University, Korea (the Republic of); [2]InCheon National University, Korea (the Republic of)

Improvement of tribological properties with the enhancement of lubrication by applying surface texturing has been paid much attention recently in wide ranges of applications. The laser texturing, a surface texturing using a laser has been received lots of attention to improve the tribological performance of various surfaces and this laser surface texturing could be considered in a large extent as one of various biomimetic approaches to improve surface performance. In this work, the surface engineering using bio-inspired patterns had been introduced and the results from the laser texturing on the PVD coated steel substrate were illuminated so that the feasibility of combining surface texturing and hard coating to further improve the tribological properties could be examined. The tribological properties of the surface were evaluated using a ball on disk type tribometer with a 9.25 mm diameter Al_2O_3 ball as a counterpart material. The tests were performed at room temperature in air environment with oil lubrication under an applied normal load of 5.0 N. Our results indicated that laser texturing affected the tribological performance of the surfaces extensively and the size as well as pattern type of laser texturing were critical factors affecting the tribological performance of the coatings. For CrZrSiN coatings applied on the laser textured steel specimens, much improvement of the friction coefficient at room temperature, nearly 10 times depending upon the type of the bio-inspired pattern could be obtained under lubrication condition.

SB09.04.10
Color Pattern Variation with the Control of Multiply Scattered Light in Birds Deok-Jin Jeon[1], Seungmuk Ji[1], Eunok Lee[2], Jihun Kang[1] and Jong-Souk Yeo[1]; [1]Yonsei University, Korea (the Republic of); [2]National Institute of Ecology, Korea (the Republic of)

Coloration in nature has evolved for a long time to become biologically diversified for camouflage, predation, signal communication, and mate choice. Birds are representative examples of nature's coloration. More than 10,000 bird species have amazing diversity of colors in their feathers. Nature's coloration methods are mainly divided into two parts: pigments and structural colors. Structural colors are produced by selective light reflection of certain wavelengths from nanostructures, not by light absorption in contrast to pigment-based colors. Birds also show the colors not only with pigments but also with optical nanostructures. The optical nanostructures are highly organized with keratin, melanin, and air in varying refractive indices, thus producing the most brilliant colors in nature through structural coloration. In birds, structural colors are mainly observed in feather barbules and feather barbs.

Avian structural colors are produced by constructive interference of coherent backscattering of light. Although this single-scattering model helps to analyze reflectance peaks, color pattern variations are not well understood due to the limitations of single-scattering model to analyze real structural colors of blue birds. So, we use the theoretical model based on transport length, which provides improved understanding on the multiply scattered light in birds. The transport length in a strongly diffusing medium is the length over which the direction of the photon’s propagation is randomized. We select Eurasian jay and Oriental dollarbird as the target species and analyzed the transport length based on the thickness of spongy layer. Eurasian jay and Oriental dollarbird show color pattern variations from white to sky blue, blue, and dark, and the thickness of disordered medium could be defined as thickness of spongy layer in this transport system. We calculate transport length by energy-density coherent-potential approximation (ECPA). From the results, we also observe that light propagation regime is in intermediate state between ballistic and diffusive transport. Therefore, we need to consider color pattern or spectrum variation by the relationship between transport length and thickness of spongy layer. For blue bards with thin spongy layer, red light that could not be scattered through the layer will be absorbed by basal melanin layer. In the case of white barbs, the spongy layer is sufficiently thick so the multiply scattered light spans from blue to red light, resulting in white. Our results also suggest that the peak broadening by multiple scattering could only occur when spongy layer is sufficiently thick. Based on this knowledge, we develop thickness-dependent bio-inspired structural colors via self-assembly. This enhanced understanding on the nature's coloration has a potential for various biomimetic application to reflective colors such as pigment-free coating materials to digital signage, and deformable display.

SB09.04.12
Photoreactivity and Enhanced Toughness and Stability in Polysaccharide-Based Films Using Vanadium Ion Coordination Carina Haddad, Alexis D. Ostrowski, Kalani D. Edirisinghe and Hope Brown; Bowling Green State University, United States

Strategies such as covalent cross-linking, chemical modification and blending of polymers or nanotechnology can be used to enhance the physicochemical and mechanical properties of soft polysaccharides-based materials. In an alternative approach, we used metal coordination bonding of vanadium ions to

polysaccharides tocreate strong, and water-stable bio-based films. Two naturally occurring polymers, pectin and chitosan were combined with glycerol to impart stretchability. Vanadium ions were incorporated into the films and the formation of ionic interactions as well as hydrogen bonding and coordinate bonding was confirmed via FT-IR. Scanning electron microscopy showed laminated sheets with intermolecular distance of ~0.16 µm for V(V) containing films as compared to a much larger~ 0.75 µm for films without vanadium. Moreover, we showed that V(V) coordinated films possessed higher storage modulus, water and thermal stability than films without vanadium. More interestingly, we observed striking changes in color from yellow to blue inside the V(V)-containing films upon irradiation with blue light. This corresponds to reduction of V(V) to V(IV) according to previous studies. A small change in modulus was observed with light stimulus, with no significant changes in the structure of the film. Based on these results, we can conclude that it is possible to create robust, water-stable and photoresponsive polysaccharides-based materials through the strong supramolecular metal-coordination interactions between metals and polysaccharides.

SB09.04.13
Bioinspired Guanine-Based Photonic Structures—Synthesis and Magnetic Alignment Natalie Nicolas and Joanna Aizenberg; Harvard University, United States

Guanine crystals are a common natural material used in biological photonic crystals and photonically active structures. Layered guanine crystals produce the characteristic structural colors of iridophores in cephalopods and tree frogs, as well as producing complex optical structures such as the concave mirrors in the eyes of scallops. They can also produce dynamic structural color, as some species of frogs can change the shape and alignment of layered guanine in their iridophores to produce skin colors ranging from yellow-green to dark gray. The production of β phase guanine platelets with various morphologies was achieved by recrystallizing guanine in formamide in the presence of poly(1-vinylpyrrolidone-co-vinyl-acetate) and small organic molecules such as uric acid. The diamagnetic anisotropy of guanine crystals created the opportunity to both align guanine crystals and to affect their morphology to create interesting photonic structures, such as C-shaped crystal stacks, by applying a magnetic field. Magnetically aligned guanine platelets and platelet stacks were then embedded inside a hydrogel or elastomer matrix to create bioinspired photonic crystals with dynamic photonic properties, taking inspiration from the iridophores of tree frogs. By examining the effect of magnetic fields on guanine crystal structure and assembly, we can better understand how magnetic fields affect the crystallization dynamics of diamagnetic molecules and better utilize guanine crystals in applications where alignment is a critical factor, including in the assembly of bioinspired photonic structures.

Harnessing Microstructures for Tunable Structural Color Lauren Zarzar; The Pennsylvania State University, United States

A variety of physical phenomena create color, such as selective absorption by dyes or pigments, optical dispersion, and structural color from light interference. Nature has exquisitely harnessed structural color, with examples including opals, butterfly wings, and iridescent bird feathers, which traditionally exploit nanoscale periodic geometries to create optical interference. Here, we explore an optical mechanism for creating iridescent structural color that is accessible in larger, microscale geometries. In this mechanism, light traveling by different trajectories of total internal reflection along a concave interface interferes to generate patterns of color. The effect is generated at interfaces with dimensions that are orders of magnitude larger than the wavelength of visible light and is readily observed in materials as simple as sessile water droplets. We further exploit this phenomenon in more complex systems, including multiphase droplets, solid micro-particles, and 3D patterned polymer surfaces to create patterns of iridescent color that are consistent with theoretical predictions. Given the ease by which controllable structural coloration is generated at microscale interfaces, we expect that the design principles and predictive theory outlined here will be of interest for fundamental exploration in optics and application in functional colloidal inks and paints, displays, and sensors.

11:15 AM SB09.05.03
Structural Color Production in Melanin-Based Colloidal Assemblies in Spherical Confinement Anvay A. Patil[1], Christian Heil[2], Arthi Jayaraman[2,2] and Ali Dhinojwala[1]; [1]The University of Akron, United States; [2]University of Delaware, United States

Melanin, a ubiquitous dark pigment present in various living organisms, is well-known for its two unique optical properties - high refractive index (RI) and broadband absorption, that contribute to structural coloration, photoprotection, and thermoregulation in many biological systems. These dark melanin particles self-assemble strategically in many organisms including avian species to produce a wide gamut of structural colors ranging from vibrant iridescent to earthy colors. Nevertheless, little is discussed about how absorbing species like melanin participate in color production. In this work, we perform optical modeling using the finite-difference time-domain (FDTD) method on melanin particle supraballs and binary melanin and silica particle supraballs to elucidate the role of melanin in structural color generation. By filling this void in the literature, we can open exciting avenues to tune structural colors, and these insights are of interest for many applications including cosmetics, paints, inks, and food colorings.

Engineering the Self-Assembly of Large Colloidal Crystals With DNA-Programmed Interactions Alexander Hensley[1], William Jacobs[2] and Benjamin Rogers[1]; [1]Brandeis University, United States; [2]Princeton University, United States

Self-assembly is one of the cornerstones of the development of nanometer-scale functional materials in living systems. Inspired by nature, researchers have developed methods that use specific short-range interactions between building blocks made possible by DNA to self-assemble prescribed structures. For example, grafting single-stranded DNA to the surfaces of micrometer-scale particles can direct the particles to self-assemble into a diverse set of crystal structures. However, a relatively poor understanding of the dynamic pathways that lead to crystallization has made it difficult to assemble the types of large, defect-free crystals that are required for practical applications in plasmonics or photonics. In this talk I will present a detailed study of the nucleation and growth of DNA-coated particles. I will show an experiment that uses several droplets containing DNA-coated particles that under specific conditions nucleate and grow a single crystal per droplet due to the crystal's growth depleting monomers from the solution, quickly lowering the supersaturation below where further crystals are likely to form. I will also describe the development of a model, grounded in classical nucleation theory, that predicts the absolute nucleation and growth rates that we observe in experiments. Finally, we apply this knowledge to develop protocols that create colloidal crystals that are large, mono-disperse, faceted, and exhibit pronounced structural coloration using a combination of microfluidics and commercial temperature-

control hardware. These advancements in understanding and controlling the dynamic pathways to crystallization with DNA-coated micrometer-scale particles is a firm foundation for future experiments involving the creation of large crystals of the wide variety of structures that thus far have only been self-assembled in small amounts which is a significant step towards approaching the impressive resourcefulness of the natural world.

11:45 AM SB09.05.05
Reflectin-Based Optical Structures in Human Cells Georgii Bogdanov, Atrouli Chatterjee, Preeta Pratakshya, Nikhil Kaimal and Alon Gorodetsky; University of California, Irvine, United States

Over the last few decades, the camouflage capabilities of cephalopods were extensively studied and shown to be enabled by their unique skin morphology. These capabilities are achieved via the complex optical phenomena that occur within the multiple layers of cephalopod skin. The layers may contain one or more types of cells: pigment-based organs called chromatophores that act like color filters; reflective cells called iridophores that act like Bragg stacks; and scattering cells called leucophores that act like broadband diffusers. Iridophores and leucophores possess reflective and scattering properties due to the presence of unusual proteins known as reflectins, which assemble into high refractive index subcellular ultrastructures. We show that such high refractive index structures can be produced in human cells as well. We discuss optical properties of the human cells with and without high refractive index structures, associated challenges, and future potential. The reproduction of the optical elements within the human cells holds a potential for the development of bio-derived optical living materials.

Butterfly Scale Morphogenesis: Wrinkling on the Micron Scale Jan F. Totz; Massachusetts Institute of Technology, United States

Micron-scale surface modulations such as wrinkles or folds underly a number of modern engineering applications, such as photonic structures in photovoltaics and flexible metasurfaces. Controlled and precise fabrication of these modulations is a challenge for human manufacturing techniques. In stark contrast, biological systems robustly utilize morphological changes in their developmental program to create multi-germ bodies, hairs and scales on spatial scales which would be costly to replicate with human manufacturing. In this talk I will present recent measurements of in-vivo butterfly scale development exhibiting wrinkling. The observations are rationalized with a parsimonious continuum mechanics model.

2:00 PM SB09.06.02
A Geometrical Theory for Edge-Driven Growth of Thin-Walled Materials C. N. Kaplan[1] and L. Mahadevan[2]; [1]Virginia Tech, United States; [2]Harvard University, United States

Accretion of mineralized thin wall-like structures via localized growth along their edges is observed in a range of physical and biological systems ranging from molluscan and brachiopod shells to carbonate-silica composite precipitates. Controlled self-assembly drawing inspiration from these systems holds great potential for fabrication of functional materials with complex geometries. To understand the shape of these mineralized structures, we develop a mathematical framework that treats the thin walls as a smooth surface left behind an evolving space curve which corresponds to the growth front. Our theory that takes an explicit geometric form indicates that in addition to prescribing the interfacial growth speed, the growth of a non-planar 2D pattern in a 3D domain requires a closure equation related to the nature of surface curling, unlike the growth of a bulk crystal in 3D that solely requires a condition for the surface growth rate. The result is a set of equations for the geometrical dynamics of a curve that leaves behind a compatible surface. Solutions of these equations capture a range of shapes such as those of clam shells, rippled chemical garden tubes, and other curled precipitate patterns. Overall, our theory provides a versatile framework for the practical realization of intricate functional morphologies that harness accretive mineralization.

2:15 PM SB09.06.03
Soft Materials Surface and Interface Characterization Through Multi-Scale Simulations Francesco M. Bellussi, Annalisa Cardellini, Pietro Asinari and Matteo Fasano; Politecnico di Torino, Italy

The surface free energy of soft coatings determines the adhesion, friction, and wettability response of solid surfaces in several applications of engineering and biomedical interest. However, the multiscale nature of these phenomena limits a bottom-up prediction of the resulting surface properties.

In this work we use computational experiments to characterize the surface and solid-fluid interface of low-surface-free-energy coatings and materials [1,2]. In particular, the free energy perturbation approach is first used to evaluate the work of adhesion between polymer surfaces and fluids; then, the Young-Dupré equation is adopted to compute the ideal contact angle [3]. Such molecular dynamics and coarse-grained simulations allow to explore the interfacial properties of soft materials, enabling a more comprehensive understanding of their effect on the adhesion, friction, and wettability of solid surfaces. Differently from standardized experimental approaches, numerical experiments allow to understand and decouple the different mechanisms regulating the wetting properties of soft coatings with atomistic precision. The aim is to propose a first step towards a multiscale standard framework for the computational characterization of surfaces, required for the optimal design of materials with tailored surface properties.

The results obtained in this work are validated against experiments and then used as input parameters for materials modelling at higher scales, such as finite elements simulations, to investigate the contribution of surface topology on wettability, in terms of nano- and micro-roughness or patterning. In perspective, multiscale models linking the chemical and topological characteristics of soft surfaces with their effective response will allow predictive in silico testing of new materials with tunable functionalities.

Bioinspired Materials with Dynamically Adaptable Mechanical Properties and Damage Mitigation Santiago Orrego[1,2], Mostafa Omar[1], Bohan Sun[1] and Sung Hoon Kang[1]; [1]Johns Hopkins University, United States; [2]Temple University, United States

Nature provides inspiration for next-generation materials that can dynamically adapt to the changing environments by modulating their properties such as color, adhesion, and stiffness. Inspired by natural examples, there have been many impressive progresses in synthesizing tunable materials that can either actively or passively switch their properties. However, they usually allow a finite number of (usually two) pre-determined configurations, there are few material systems that can "sense" and adapt their properties in response to a dynamically changing environment.

Inspired by bone mineralization mechanisms, we have investigated a multifunctional material system that "senses" mechanical loading and proportionally triggers mineral formation from media with mineral ions so that the material can adaptably change its mechanical property and mitigate damages. The mineralization rate is autonomously modulated in response to changing loading conditions, for example, resulting in a 30-180% increase in the modulus of the material upon 1 to 5 N cyclic loadings (frequency: 2 Hz). Moreover, the material adds more minerals to the region of high stress and vice versa for that of low stress so that the material can mitigate the damage and enhance its fatigue life. We envision that our findings can open new strategies for synthesizing multifunctional materials with dynamically adaptable mechanical properties and damage mitigation.

Mechanical Properties and Deformation Behavior of Self-Assembled Nanoparticle Superlattices Daryl W. Yee, Somayajulu Dhulipala, Margaret S. Lee, Carlos Portela and Robert J. Macfarlane; Massachusetts Institute of Technology, United States

Natural materials often exhibit complex material properties due to hierarchically organized structural motifs at the molecular, nano, micro, and macroscopic size regimes. They have inspired a whole generation of advanced multifunctional synthetic materials that utilize structural hierarchy to reach new property spaces. Self-assembly approaches have been heavily utilized to fabricate these hierarchical materials as its ability to build materials via weak, dynamic interactions between nanometer-sized build blocks provides great control over material structure from the molecular to the micro-scale.

In particular, self-assembled nanoparticle superlattices — three-dimensional ordered arrays of nanoparticles — have been the subject of significant interest due to their emergent properties that arise from the ordering of their nanoparticle building blocks. As a result, these nanoparticles superlattices are promising materials for a variety of applications, from optoelectronics to energy storage. While significant efforts have been made on understanding and controlling the formation of these nanoparticle superlattices, investigations on their mechanical properties are scarce. As the mechanical properties of a material impacts its processing and its suitability for a given application, it is critical that we understand the mechanical behavior of these self-assembled nanoparticle superlattices and develop chemistries to control them.

Here, we discuss how the self-assembly chemistry and superlattice structure impacts the mechanical behavior of these nanoparticle superlattices. Nanocomposite tectons (NCTs), a recently developed nanoparticle superlattice system that uses polymer brush particles functionalized with supramolecular binding groups to drive assembly, are ideal for exploring these parameters as the strength of the supramolecular interactions and the superlattice structure can be easily tuned. In-situ uniaxial compression of substrate-grown hydrogen-bonded nanoparticle superlattices show that these materials undergo significant plastic deformation with an associated loss of nanoparticle ordering. Our systematic nanomechanical experiments, performed to various compression states (up to 50% strain), shed light on the mechanisms of deformation as well as the evolution of properties such as Young's modulus and yield strength. By modulating the strength of the nanoparticle interactions, via the use of different supramolecular binding groups or covalent bonds, we show that the mechanical properties and deformation behavior of these nanoparticle superlattices can be controlled. The impact of superlattice crystal structure on the mechanical properties are also discussed. These observations provide a more general understanding of how self-assembly chemistry and superlattice structure can be used to control the mechanical properties of these nanoparticle superlattices.

4:00 PM SB09.07.01
Nanopatterning Surface with a Self-Assemble Protein Depicting a Honeycomb Structure with Tunable Pores—A New Biomaterial for Nanotechnological Field Elise Jacquier[1,2], Grégory Si Larbi[2], Renaud Dumas[2] and Pierre-Henri Elchinger[1]; [1]Univ. Grenoble Alpes, CEA, CNRS, IRIG-DIESE-SYMMES, France; [2]Univ. Grenoble Alpes, CEA, CNRS, INRAE, IRIG-DBSCI-LPCV, France

Achieving nanopatterning of a surface is a key point in fields covering microelectronics, photovoltaic, biomedial and biosensors. The purpose of nanopatterning a surface is to increase the surface specificity to improve, for example, nanotechnological devices sensitivity. As cutting-edge technics (*e.g.* top down methods) are reaching physical limitations and become more and more expensive, light has been put on bottom up methods. This approach relies on the organization of small building blocks to create supramolecular 2D lattices. Nowadays, constructing 2D lattices for nanopatterning is mainly

based on self-assembly process with an emphasis on biological self-assembled building blocks. However, these 2D lattices depict thin height which limits their grafting capability and thereby their wider use in nanotechnological field.
In this work, we present a self-assembled protein oligomerization domain able to create large 3D honeycomb lattice based on the natural ability of the protein to self-assemble through head-tail interaction. With electron microscopy analysis, we showed that the orientation of the honeycomb structure on carbon or SiO_2 surface can be modulated. Atomic force microscopy measurements revealed a height of 30 nm corresponding to 40-stacked protein for one pore of the honeycomb. Furthermore, we showed that the amino acid sequence of the protein can be modulate without altering the honeycomb structure. Noteworthy, depending on the amino acid present inside the honeycomb pores, we also showed a specific metal chelation inside the pore.
Altogether, these characteristics make this protein-based 3D lattice a grafting platform never described until now paving the way to design adaptive self-assembled structure for nanotechnological purpose.

4:15 PM SB09.07.02
Microscopic Actuation for Macroscopic Aggregation Mustafa K. Abdelrahman, Lindy Jang, Suitu Wang, Mahjabeen Javed and Taylor H. Ware; Texas A&M University, United States

An important area of materials research is the development of adaptive structures capable of sensing, reconfiguring, and self-healing with minimal intervention. Such structures will enable the realization of a new class of materials capable of on-demand assembly, reorganization, and disassembly. Inspiration for the development of such structures is found in the survival strategies demonstrated by many insects. For example, fire ants quickly organize themselves into a buoyant raft in the presence of floods, and honey bees aggregate to form bivouacs during turbulent weather conditions. Notably, the structures formed demonstrate viscoelastic behavior with one remarkable feature which distinguishes these aggregations from their synthetic polymer counterparts: the aggregate's ability to morph from a fluid-like swarm to a global solid-like material. This dynamic behavior is achieved through each insect's ability to attach and detach to its neighbors. In order to mimic this behavior, liquid crystal elastomer (LCE) rectangular films (strips) (250 μm x 6 mm x 50 μm in cross-section) are programmed to reversibly actuate from a straight to a coiled configuration. By heating these LCE strips and allowing them to aggregate and mechanically interlock with each other, structures capable of reversibly transitioning from a liquid-like state to a solid-like state are achieved. Rheological data of these structures demonstrate an increase in yield stress from 23 Pa at 50 °C to 329 Pa at 150 °C. Along with this increase in yield stress, a reversible negative thermal expansion of 30% is observed. Notably, mechanical properties of the aggregate structure are controlled by tuning individual strip properties. By increasing the length of the individual strips from 3 mm to 12 mm, yield stress increases from 200 Pa to 725 Pa, and by increasing the cutting angle from 0° to 45°, a decrease in yield stress from 459 Pa to 38 Pa is observed. This synthetic aggregate's ability to reversibly transition from low yield stress to high yield stress on-demand enables various functionalities such as clogging, targeting, and self-healing.

4:30 PM SB09.07.03
Photo-Driven Fabrication of Bioinspired Surface Textures with Programmable Anisotropy Marcella Salvatore, Stefano Luigi Oscurato and Pasqualino Maddalena; University of Naples Federico II, Italy

The realization of artificial complex surface pattern, inspired by nature or driven by specific technological needs, requires the use of lithographic techniques which have brought to prominent progress in several fields. However, the standard lithographic techniques are often costly and time-consuming, and do not allow further modification of the pattern once fabricated. The fabrication of superficial micro-textures, in simple and cost-effective way, is high desirable in this framework. A versatile technique for surface micropatterning is based on surface reconfiguration of photosensitive materials, such as light-responsive polymers containing azobenzene molecules.
Azopolymers are material systems able to be directly structured in a reversible way over large scale in simple fabrication schemes without any further development step. Spatially structured UV/visible light fields generate topographic modulations on the free surface of films of such materials by activating cyclic structural transitions between *trans* and *cis* isomerization states of the azomolecules. The final surface geometry depends on the irradiated intensity pattern and the light polarization state over the sample, which control the degree of the surface deformation and its directionality, respectively.
Here we demonstrate several large-scale surface textures, with different degrees of complexity and anisotropy, realized by means of simple illumination schemes based on interference lithography and light-induced reconfiguration of pre-structured azopolymer microtextures. In particular, periodic and aperiodic complex surface textures are obtained by means of multiple exposures steps or multiple beam interference. Furthermore, surfaces with programmable directionality and degree of anisotropy have been achieved by reconfiguring symmetric prepatterned azopolymer films, exploiting the peculiar anisotropic response of the material motion to the polarization distribution of the optical field.
The techniques described here allow the all-optical tailoring of surface functionalities directly affected by relief geometry, including anisotropic wetting effects (such as controlled directionality or unidirectional spreading) and substrate-influenced cell growth that opens to the design of new biomaterials generation with improved functionalities and bioactive properties.

4:45 PM SB09.07.04
Droplet-Assited Growth and Shaping (DAGS)—A Straightforward Process to Synthesize Bioinspired Nano- and Microstructures with Complex Geometrical Shape and Subnanometer-Confined Reactive Sites Stefan Seeger, Georg Artus, Sandro Olveira and Kangwei Chen; University of Zurich, Switzerland

The control of shape and intraparticle heterogneity of nano and microstructures in some cases is extremely complex and often even impossible. However, it is important for practical applications, since complex shapes may have influence on rheology, wetting, coating stability, and mechanical properties of bulk composites. Recently, we described a simple and low-cost approach to synthesize nanoparticles applying a delicate composition of monomer, water, and surface properties. We call this synthesis approach Droplet assisted growth and shaping (DAGS). It has been applied in many variants to synthesize various nano- and microstructures based on polysiloxanes which are applied in industrial products, e.g. filters, insulation materials, etc. Beside the different shapes, e.g. filaments, rods, spirals, stars, and others, subsequently, we have been able to extend the range of structures to other materials, e.g. Germaniumoxide, Aluminum oxide and Al-Si-based structures. These structures are useful as coatings for luminescence and/or wetting control of surfaces. In this presentation we will show that further nano- and micromaterials can easily be created: Ceramic structures with defined shapes as well as nano and microstructres with incorprated ultrasmall reactive sites and other heterogeneities which show new properties and can be used for building highly anisotropic and complex coatings. The sequential use of different chemical entities during the synthesis of the nano and microstructures allows for completly new and highly sophisticated shapes. Using those structures as coatings, a precise tuning of surface properties, i.e. wetting, loading with reactive particles and nanocatalysts, adsorption properties and others more, becomes possible.

Beyond these structural properties and performance tuning, this DAGS chemical synthesis strategy is of interest also because of its simple execution: The process can be executed at room temperature, normal pressure, and with simple equipment and low-cost chemicals. The process execution in gas phase of liquid phase both is possible. We also demonstrate potantial for industrial applications.

5:00 PM SB09.07.05
Late News: Electric Field Induced Macroscopic Cellular Phase of Nanoparticles Abigail L. Rendos[1], Wenhan Cao[1], Margaret Chern[1], Marco Lauricella[2], Sauro Succi[2], Joerg Werner[1], Allison M. Dennis[1] and Keith A. Brown[1]; [1]Boston University, United States; [2]Center for Life Nano Science, Italy

Electric fields provide a flexible means to manipulate soft matter, however, they interact with polarizable materials in electrolytic solutions through numerous distinct phenomena making the outcome of field-directed assembly difficult to predict. In this work, a suspension of nanoparticles is found to assemble into a macroscopic cellular phase with particle-rich walls and particle-free voids under the collective influence of AC and DC voltages. This unique, porous structure is observed here at a volume fraction and particle size an order of magnitude smaller than previous examples. Systematic variation of the applied field revealed that the onset of the cellular phase is determined by the volume fraction of the particles, the AC voltage, and the DC voltage. Additionally, a series of control experiments revealed that the complex interactions required to produce a cellular phase in this system include (1) electrochemistry to generate a DC current, (2) electrophoresis to aggregate particles into a 2D arrangement on one electrode, and (3) an instability driven by the long-ranged repulsive and short-ranged attractive electrohydrodynamic interaction that is nucleated at regions on the electrode with high local field enhancement. This mechanistic understanding, along with comparison to prior work, reveals two characteristics needed to observe a cellular phase: a system that is considered two-dimensional and short-range attractive, long-range repulsive interparticle interactions. Furthermore, photolithography was used to localize assembly thus proving the potential to tune the location of the pores in the cellular structure. This understanding paves the way towards electrically-driven assembly of hierarchical porous structures that may impact fields including energy storage and filtration.

5:15 PM SB09.07.06
Late News: Inorganic Phototropism–Biomimetic Mesostructure Growth via Light-Mediated Electrodeposition Azhar I. Carim and Nathan S. Lewis; California Institute of Technology, United States

Plants exhibit a phototropic growth response and direct the addition of new biomass to optimize collection of solar insolation. Analogous inorganic phototropic growth has been demonstrated via the light-mediated electrodeposition of chalcogen semiconductor materials and can generate highly ordered mesostructures with anisotropic nanoscale features conformally over macroscopic length scales. This process mirrors the phenotypic plasticity exhibited by plants, wherein despite a fixed genotype a wide range of different morphologiess can be displayed depending on the environmental conditions: the precise structure produced is determined by the characteristics of the growth illumination and wide array of structures can be despite a consistent material composition and phase. No structured light field (no photomask) and no physical or chemical templates are utilized. The structure pitch is dependent on the spectral distribution of the input light with shorter wavelengths effecting higher feature densities, similar to how blue light effects branching in many shade-intolerant plants. The out-of-plane growth direction is related to the propagation direction of the input light, mirroring the way in which palm trees develop an observable tilt toward the average position of the solar azimuth. In-plane anisotropy is a function of the input polarization. Modeling of the growth using a combination of full-wave electromagnetic simulations of light absorption and scattering coupled with Monte Carlo simulations of mass addition successfully reproduced the experimentally observed morphologies and indicated that morphology development was directed by evolution of the growth interface to maximize anisotropic light collection. The growth process was observed to be a highly emergent phenomenon involving optical communication between neighboring features including cooperative scattering and synergistic absorption and thus is similar to the manner in which neighboring plants exchange information and avoid competition for light resources.

Nanomechanics of Actin Filaments—A Steered Molecular Dynamics Approach Sharad V. Jaswandkar, Kalpana Katti and Dinesh R. Katti; North Dakota State University, United States

Biological systems commonly use complex multiscale and multiphasic structures to provide functions that surpass those of artificial systems. Although knowing the chemical makeup of these systems is essential, understanding the passive and active mechanics inside biological systems is critical when examining the various natural systems that reach advanced features like high strength and stimuli-responsive adaptability. Finding out how and why biological systems achieve these desirable mechanical functions frequently exposes concepts that can be used to inform future synthetic designs based on biological systems. In eukaryotic cells, the cytoskeleton is a three-dimensional dynamic structure that helps cells retain their form, internal organization, and mechanical rigidity. The polymer biomolecules in eukaryotic cells that function as structural elements of the cytoskeleton are the actin microfilaments, microtubules, and intermediate filaments. The diseases like cancer transform the cell's cytoskeletal structure. Altered cytoskeletal structures modify cancer cell's ability to contract or stretch by affecting their deformation mechanics. The abnormal cellular motility is a signature characteristic of metastatic cancer cells, promoting tumor cells' spread to both local and distant locations in the body. The dynamic reorganization of the actin cytoskeleton is a fundamental requirement of this process. We have also shown that the cancer cells' altered mechanical properties during disease progression are connected with the actin reorganization. In actin assembly dynamics, actin filaments are severed constitutively by an essential regulatory protein, ADF/Cofilin. Therefore, Several studies were performed to examine the mechanical properties of F-actins. However, the fundamental mechanism that controls F-actin's response to deformation is not understood. In the present study, steered molecular dynamics (SMD) simulation approach has been utilized to understand actin filament mechanics. The work was performed in four computational sets of experiments, namely bending, compression, tension, and torsion simulations. Our findings demonstrate that F-actin's deformation response is regulated by the pattern of dissociation of conformational locks at intra-strand and inter-strand G-actin interfaces. F-actin elongation enabled salt bridge formation at the inter-strand interfaces improving the G-actin-G-actin bond strength. Furthermore,

we noticed an inter-strand serrated locking pattern connecting G-actin subunits, restricting their relative movement, thus enabling F-actin's ability to resist deformation. Additionally, we found ADF/Cofilin to cause structural transmutations in f-actin, thus altering their physical properties. The F-actin mechanics described here are vital for constructing a mechanobiological eukaryotic cell model that mimics cell mechanics with disease progression.

Directing Macromolecular Self-Assembly of Graphene Oxide and Silk Fibroin Towards Mesoscale Architectures Catherine Machnicki, Megan Fay, Eric DuBois and Ian Wong; Brown University, United States

Mesoporous, anisotropic architectures that integrate two-dimensional nanomaterials with protein-based polymers are highly promising as biologically-inspired functional materials. In particular, ice-templated freeze-casting offers a facile and economical process to create aligned, nacre-like architectures. Here, we investigated freeze-casting of biologically-inspired composites that incorporate graphene oxide (GO). Silk fibroin, a naturally-occurring polypeptide, forms crystalline β-sheets as a result of hydrogen bonding between repetitive subunits. However, in mesoporous structures, natural polymers like silk fibroin often exhibit limited chemical stability and mechanical strength. We hypothesized that silk fibroin could be reinforced by leveraging the inherent structural stiffness and surface functionalization of GO, a nanomaterial that would readily form hydrogen bonds between silk subunits. By studying the physical, chemical and mechanical properties, we were able to gain insight into the nature of self-assembly of this composite meso-structure.

Our work optimized the freeze-casting process by tuning the pH and freezing direction which resulted in aligned and porous microstructures. Next, we varied the ratio of GO to silk content by weight. We found alterations to the micro-porous structure, mechanical stiffness and uptake of both water and oil with the addition of GO. Moreover, with increasing amounts of GO, there is an increase of stability in water, ionic solutions and oil over relatively long periods of time. Using analytical techniques including FTIR-ATR, Raman, contact angle, compression and other mechanical tests, we were able to deduce structural information and interactions of GO with silk sub-units. Overall, these self-assembled mesoporous materials exhibit outstanding physicochemical properties for extreme mechanics, environmental remediation, and energy storage.

Modulating Nanoparticle Size to Understand Factors Affecting Hemostatic Efficacy and Maximize Survival in a Lethal Inferior Vena Cava Injury Model Celestine Hong[1,1], Osaid Alser[2], Anthony Gebran[2], Yanpu He[1,1], Wontae Joo[1], Nikolaos Kokoroskos[2], George Velmahos[2], Bradley Olsen[1] and Paula Hammond[1]; [1]Massachusetts Institute of Technology, United States; [2]Harvard Medical School, United States

Polymeric particle-based hemostats have been demonstrated to be an attractive technology to halt bleeding through extensive testing in animal models, ranging from arterial injury to blast trauma. While the results of these *in vivo* experiments have been well documented and utilized to develop subsequent generations of hemostats, the details of particle-target interactions *in vitro* and their predictive capabilities for *in vivo* performance has yet to be fully explored. In this work, the size of GRGDS-conjugated PEG-b-PLGA nanoparticles was tuned and its effect on platelet binding, particle adherence to wound-mimetic surfaces, aggregation capability, biodistribution, and circulation lifetime were systematically assessed using various *in vitro* and *in vivo* experiments. Smaller and intermediate-sized nanoparticles were all found to specifically bind a larger number of activated platelets when compared to larger (>250 nm) particles, while incubation of these larger particles on collagen and activated platelet-coated surfaces led to a higher total mass of polymer bound. Intermediate particle diameters led to the greatest number of platelets aggregated on a surface relative to agonist-only positive controls. Finally, larger particles experienced faster clearance and higher pulmonary accumulation per organ mass in an uninjured murine model, whereas smaller particles exhibited longer circulation and retention times and increased accumulation in the liver. To assess hemostatic efficacy, these three distinct sizes were challenged with a lethal inferior vena cava (IVC) puncture model. The intermediate nanoparticle size was observed to result in the most significant increase in survival over the course of two hours ($P = 0.0060$), as well as the greatest accumulation at the injury site relative to uninjured vessel controls. These results indicate that tuning particle size provides a key handle for engineering the performance of particle-based hemostat systems, and may influence its efficacy in treating various types of lethal internal hemorrhage.

Changes in the Magnetic Properties of Manganese (II) Carbonate Using a Bio-Inspired Route Arad Lang[1], Iryna Polishchuk[1], Ariel Maniv[2], Elad Caspi[2] and Boaz Pokroy[1]; [1]Technion - Israel Institute of Technology, Israel; [2]Nuclear Research Centre, Israel

The creation of inter-crystalline organic inclusions is one of Nature’s strategies to enhance the mechanical properties of biominerals. As was shown synthetically for calcite, the most abundant marine biomineral, incorporated pinned organic species act as barriers for dislocations movement. Thus, they increase the hardness of the single-crystalline calcite host.
Inspired by this phenomenon, we showed in the past that a variety of semiconductors, both fully inorganic and hybrid organic-inorganic, are able to incorporate single amino acids. This incorporation induces a measurable increase in the optical band gap of the semiconducting host, which results from charge localization created by the incorporated amino acids.
Here, we decided to study the influence of amino acids incorporation on yet another set of properties, namely the magnetic properties of manganese (II) carbonate ($MnCO_3$). Similarly to the isostructural calcite, we discovered that certain amino acids can be incorporated into the crystalline structure of the host. Using high-resolution powder X-ray diffraction (HR-PXRD, using synchrotron source), we measured an anisotropic lattice expansion, of both *a*- and *c*-parameters, resulting from amino acids incorporation. These induced lattice distortions can be relaxed upon heating and organics decomposition.
When we measured the magnetic properties of amino acid-incorporated $MnCO_3$, we observed the predicted paramagnetic behavior, namely, a positive and linear relation between the magnetization, M, and the applied magnetic field, H. Nevertheless, the magnetic susceptibility (which was taken as the slope of the M-H curve), was observed to decrease with the increase of incorporated amino acids concentration. This decrease follows the simple rule of mixtures, indicating the creation of a $MnCO_3$-amino acid composite.
$MnCO_3$ is known to possess a Néel temperature of about 32 K. At this temperature, it undergoes a magnetic phase transition, from a paramagnetic to a canted antiferromagnetic phase. When we repeated our M-H measurement at 2 K, we discovered the opposite trend: the increase in magnetic susceptibility upon the increasing amount of incorporated amino acid. Moreover, the Néel temperature itself decreases. During amino acids incorporation, the inter-atomic distances inside $MnCO_3$ increases. This results in a weakening of the magnetic interaction, which makes the $MnCO_3$ crystal more sensitive to external changes, such as the applied magnetic field and the changes in temperature.

SB09.08.08
Bioinspired Ion Conducting Membranes for Next-Generation Batteries Ahmet Emre, Emine S. Turali-Emre, Ji-Young Kim, Jinchen Fan, Volkan Cecen and Nicholas Kotov; University of Michigan, United States

Bioinspired ion transport membranes have been widely investigated for energy storage applications. The high theoretical specific energy density (2600Wh/kg) and high specific capacity (1675mA/g) along with the natural abundance and low toxicity of sulfur have been attracting significant attention for the development of an alternative battery system to replace traditional lithium-ion batteries which suffer from safety and capacity/energy density limitations in various applications. However, challenges such as polysulfide dissolution and shuttling prevent the mass commercialization of metal sulfur

batteries. Inspired by biological ion transport mechanisms, we show a practical yet comprehensive approach for the development of high-performance metal sulfur batteries. Aramid nanofiber (ANF) based composite ion transport membranes not only prevent dendrite formation but also confine polysulfides on the cathode side. ANF composite battery separators provide diverse and opposing properties including high mechanical properties, high ionic conductivity, and high thermal/chemical stability. The highly selective ion sieving properties of these biomimetic separators provide safe and high-performance batteries. Fabrication of such biocompatible, affordable, flexible, and high energy density battery is quite crucial in powering next-generation electronics including but not limited to portable, wearable, and implantable biomedical devices.

SB09.08.12
Late News: RNA Chemistry in Multiphase Complex Coacervates as Bioinspired Protocell Models Saehyun Choi, Philip C. Bevilacqua and Christine D. Keating; The Pennsylvania State University, United States

Compartment systems encapsulating RNAs have gained significant interests as artificial cells and drug delivery systems. Cells form liquid membraneless organelles to localize and control RNAs' activities. Specifically, multiphasic biomolecular condensates are appealing as material systems to have an impact on functional control of RNA and other biomolecular processes. However, the understanding of the relationship between RNA chemistry and multiphasic biomolecular condensates is still lacking that limits the development of such RNA compartments for various applications. Therefore, inspired by these multiphasic biomolecular condensates, we investigated complex coacervates composed of simple biomolecules, such as oligopeptides, and their impact on RNA partitioning and hybridization. Complex coacervates are organic-rich phases or droplets, formed by spontaneous liquid-liquid phase separation of mixed oppositely charged molecules. Complex coacervates share similarities to liquid biomolecular condensates in cells and have great encapsulation efficiency of RNAs. Here, we present that coacervates can have different levels of RNA partitioning and hybridization depending upon the length and identity of oligopeptides. We recently found that multiphase complex coacervate droplets can have different RNA partitioning and hybridization levels in each phase due to local differences in RNA-peptide interactions without specific RNA binding motifs. This study aids fundamental understanding of how biocondensates influence RNA localization and function, and points to design strategies for artificial cells construction using coacervate droplets.

SB09.08.13
Functional Active and Adaptive Janus Particles Templated from Responsive Complex Emulsions Lukas Zeininger; Max Planck Institute of Colloids and Interfaces, Germany

Responsive materials capable to autonomously and reversibly adapt to their chemical environment hold great promise in the design of artificial chemo-intelligent life-like soft material platforms. In this context, we are using active complex emulsions, kinetically stabilized multiphase dispersions of fluids, as an intrinsically out-of-equilibrium material platform that can act as structural controlling elements for the generation of a variety of functional intricate, responsive and adaptive, precision objects. The dynamic multiphase emulsion droplets are formed from two or more immiscible fluids that are immiscible at room temperature but exhibit a lower (LCST) or upper critical solution temperature (UCST). Emulsification of the mixture below LCST or above UCST enables a simple one-step generation of complex multicomponent emulsions with highly uniform internal droplet morphologies. The internal droplet geometry of these dynamic liquid colloids is exclusively controlled by the force-balance of interfacial tensions acting at the individual interfaces, which allows altering the droplet geometries also after emulsification.
The complex emulsions can be hardened or gelled, e.g. by using photo-crosslinkable acrylate monomers as the constituent droplet phases. Upon polymerization, the shape of the droplet molds is essentially retained and a compartmentalization of designer surfactants, biologicals, polymer, and nanoparticle solutes enables their use as functional "cytoskeletons" for the generation of Janus particles with tunable shape, functionality and wettability profiles, functional thin-films as well as defined 3D objects and meso- and macroscale assemblies. In addition, as a result of the refractive index contrast of the individual phases, the particles can manipulate the pathway of light passing through these micro-scale colloids. Examples on how an associated understanding of the unique chemical-morphological-optical coupling inside these chemically functionalized active soft matter colloids give rise to a variety of new and improved application concepts, including in biomimicry, (photo-)catalysis, optical imaging platforms, as structural templates for the generation of precision objects, and as chemo-intelligent transducers in chemo- and biosensing applications will be presented.

Physical Hydrogels from Entropy-Driven Non-Covalent Interactions and Their Applications Eric A. Appel; Stanford University, United States

Physically-crosslinked hydrogels exhibit highly useful properties that are impossible with traditional hydrogels but crucial for a wide variety of emerging applications in industry or biomedicine. Yet, these materials typically employ enthalpy-dominated crosslinking interactions that become more dynamic at elevated temperatures, leading to network softening. Indeed, standard mathematical frameworks typically assume network softening and faster dynamics at elevated temperatures. Yet, deriving a mathematical framework connecting the crosslinking thermodynamics to the temperature-dependent viscoelasticity of physical networks suggests the possibility for entropy-driven crosslinking interactions to provide alternative temperature dependencies. Herein, we will discuss the investigation of a physical hydrogel platform exploiting dynamic multivalent interactions between biopolymers and nanoparticles that are strongly entropically driven. We will discuss the implications of these crosslinking thermodynamics on the observed mechanical properties, demonstrating that tuning the thermodynamics and kinetics of these crosslinking interactions enable broad modulation of the mechanical properties of these materials, including their shear-dependent viscosities, temperature responsiveness, self-healing, and cargo encapsulation and controlled release. In particular, these materials exhibit viscous flow under shear stress (shear-thinning) and rapid recovery of mechanical properties when the applied stress is relaxed (self-healing), affording facile processing though direct injection or spraying approaches, making then well served for applications ranging from wildfire prevention to biomedicine. Overall, this talk will illustrate our recent efforts exploiting dynamic and multivalent interactions between polymers and nanoparticles to generate hydrogel materials exhibiting properties not previously observed in physical hydrogels and affording unique opportunities in industry and biomedicine.

11:00 AM SB09.09.02
Amphiphilic Copolymer Excipients to Enable an Ultrafast Monomeric Insulin Formulation and Ultrastable Insulin Formulation Caitlin L. Maikawa, Joseph Mann and Eric A. Appel; Stanford University, United States

Insulin was first isolated a century ago, yet commercial formulations of insulin and its analogues for hormone replacement therapy falls short of mimicking the endogenous glycemic control that occurs in non-diabetic individuals. Insulin formulations that better mimic secretion from the beta-cells, by enabling more rapid insulin absorption kinetics and/or co-delivering complementary hormones (i.e. amylin), are needed to reduce patient burden and improve glucose management. However, formulation innovation is complicated by the poor stability of insulin monomers and amylin. We have developed a polymeric excipient platform using amphiphilic acrylamide copolymers that can be used to increase the stability of insulin in formulation. Here I will present on the use of these designer excipients, to develop an ultrafast monomeric insulin lispro and an ultra-stable insulin for improved global access.

A formulation of insulin monomers would more closely mimic endogenous postprandial insulin secretion, but monomeric insulin is unstable in solution using present formulation strategies and rapidly aggregates into amyloid fibrils. Amphiphilic acrylamide copolymer (AC/DC) excipients preferentially adsorb to the air-water interface and disrupt interfacial insulin-insulin aggregation events. Combining a AC/DC excipient with monomeric insulin lispro enables stable formulation under stressed-aging conditions for up to 25 hours compared to only 5 hours for commercial fast-acting insulin lispro formulations (Humalog). In a diabetic pig model, our ultrafast monomeric lispro formulation demonstrated unprecedented ultrafast absorption kinetics, exhibiting peak action at 9 minutes, whereas commercial Humalog exhibited peak action at 25 minutes. The more rapid onset and shorter duration of action observed in our monomeric lispro formulation has the potential to better control mealtime glucose excursions.

Moreover, the prevalence of diabetes is rising in middle and low-income countries. Current commercial insulin formulations require costly refrigerated transport and storage to prevent loss of insulin integrity. Our AC/DC excipients can be used as a simple additive to current standard commercial insulin formulations and demonstrated we can extend stability, while maintaining formulation integrity, bioactivity, pharmacokinetics and pharmacodynamics, for over 2 months in stressed aging conditions that cause current formulations to fail in under 2 days. These enhanced insulin formulations are promising candidates for improving glucose control and reducing burden for patients with diabetes.

11:15 AM SB09.09.03
Bioinspired Enzyme-Powered Nano/Nicromotors for Smart Healthcare Applications Hyunsik Choi, Jeeyoon Yi and Sei Kwang Hahn; Pohang University of Science and Technology, Korea (the Republic of)

Self-propelling micro- and nano-motors (MNMs) have been extensively investigated as an emerging oral drug delivery carrier for gastrointestinal (GI) tract diseases. However, the propulsion of current MNMs reported so far is mostly based on the redox reaction of metals (such as Zn and Mg) with severe propulsion gas generation, remaining non-degradable residue in the GI tract. Here, we develop a bioinspired enzyme-powered biopolymer micromotor mimicking the mucin penetrating behavior of Helicobacter pylori in the stomach. It converts urea to ammonia and the subsequent increase of pH induces local gel-sol transition of the mucin layer facilitating the penetration into the stomach tissue layer. The successful fabrication of micromotors is confirmed by high-resolution transmission electron microscopy, electron energy loss spectroscopy, dynamic light scattering analysis, zeta-potential analysis. In acidic condition, the immobilized urease could efficiently converted urea to ammonia, comparable with that of neutral condition because of the increase of surrounding pH during propulsion. After administration into the stomach, the micromotors show enhanced penetration and prolonged retention in the stomach for 24 h. Furthermore, histological analysis shows that the micromotors are cleared within 3 days without causing any toxicity in the GI tract. The enhanced penetration and retention of the micromotors as an active oral delivery carrier in the stomach would be successfully harnessed for the treatment of various GI tract diseases.

11:30 AM SB09.09.04
Microstructured Hydrogels via Phase Separation of Elastomeric Resilin-Like Polypeptides Sai Patkar, Cristobal Garcia and Kristi Kiick; University of Delaware, United States

Resilin-like polypeptides (RLPs), bioinspired protein-engineered polymers derived from the elastomeric insect protein resilin undergo phase separation upon cooling below their Upper Critical Solution Temperature (UCST), which can be precisely controlled by altering their amino acid composition. The native extracellular matrix (ECM) is characterized by structural and compositional heterogeneity across varying length scales. Current state-of-the-art soft matter patterning techniques for generating sophisticated ECM mimics are limited due to their reliance on expensive equipment and multiple time- and energy-intensive steps. Therefore, photocrosslinking distinct morphologies of multicomponent RLP solutions undergoing phase separation offers a relatively simple alternative for the fabrication of microstructured hydrogels. RLPs enriched in select aromatic and aliphatic residues were recombinantly produced in bacterial expression hosts and purified via immobilized metal affinity chromatography. Gel electrophoresis and mass spectrometry were used to confirm their composition and purity. The thermal response of distinct RLPs and their multicomponent solutions was investigated via turbidimetry. The RLPs reported in this study fall into two main categories based on their physicochemical properties. Molecules in the first category, defined as phase separating RLPs (psRLPs) demonstrate robust UCST-type behavior, and function as cell-friendly porogens/templating agents. Lysine residues along the polypeptide backbone of the molecules in the second category were modified to produce photocrosslinkable RLP-acrylamide (pcRLP-Ac), which upon UV irradiation in the presence of photoinitiator and psRLPs result in the formation of microporous hydrogels. Confocal microscopy data indicate that harnessing the interplay of inter-and intramolecular interactions between distinct psRLP and pcRLP-Ac molecules allows further control over pore size. The average pore size observed in hydrogels enriched in aliphatic residues was approximately 10 μm, an order of magnitude lower than the average pore size observed in hydrogels enriched in aromatic residues (ca. 100 μm). We report a simple biofabrication method to produce microstructured hydrogels for use as cell-instructive materials to support regenerative medicine applications.

11:45 AM SB09.09.05
High Water-Responsiveness of Peptidoglycan from Gram-Positive *Staphylococcus aureus* and *Saccharomyces cerevisiae* Haozhen Wang, Zhi-Lun Liu, Seungri Kim, Tai-De Li and Xi Chen; ASRC, CUNY, United States

In nature, plants use water-responsive (WR) materials that deform in response to humidity changes to drive their essential movements. Recent studies have shown that such kind of WR actuation could be extremely powerful and hold great potential to be used as actuating components for robotics, shape-morphing, and energy harvesting. Here, we present that peptidoglycan (PG) extracted from gram-positive bacteria *Saccharomyces cerevisiae* and *Staphylococcus aureus* show significant water-responsiveness such that their WR actuation energy density and efficiency reach 39.6 MJ m^{-3} and 38.4%, respectively, surpassing those of frequently used actuator materials. PG is the primary component of gram-positive bacterial cell walls, and it shows distinct architectures and molecular structures across different bacteria species. For example, peptidoglycan extracted from *Saccharomyces cerevisiae* (~2000 nm) is thicker than that from *Staphylococcus aureus* (~500 nm). Moreover, PG of *Staphylococcus aureus* have polysaccharides of alternating N-acetyl-glucosamine and N-acetyl-muramic acid crosslinked by peptide stems, whereas PG of *Saccharomyces cerevisiae* consists of two types of polysaccharides: β-1,3 and β-1,6 linked glucose and β-1,4 linked NAG. Meanwhile, *Saccharomyces cerevisiae* PG is not crosslinked by peptide stems but by the alkali-sensitive bond to mannoproteins or disulfide link to the PIR protein. By using a liquid AFM, we also showed that these PG consist of nanoscale pores with different porosities, pore sizes, and geometries. Using a customized AFM, we characterized WR strain and energy density of *Staphylococcus aureus* PG and *Saccharomyces cerevisiae* PG, and found that *Staphylococcus aureus* PG, with a lower WR strain (11.2 %), exhibits a much higher WR energy density (39.6 MJ m^{-3}) than that of *Saccharomyces cerevisiae* PG (6.0 MJ m^{-3}). By introducing pressure disturbance on PG's

surface using the AFM, we also measured these two PGs' relaxation dynamics, and found that *Staphylococcus aureus* PG's higher WR energy density strongly correlates to its super viscous nanoconfined water. Our findings suggest that highly viscous confined water resulted from nanoporous *Staphylococcus aureus* PG' plays an important role in the energy conversion from water's chemical potential to PG's mechanical deformations, which could be serving as general criteria for high-efficiency WR structures.

SESSION SB09.10: Wetting Properties and Application of Biological and Bioinspired Materials

Thursday Afternoon, December 2, 2021
Sheraton, 2nd Floor, Republic B

2:00 PM SB09.10.02
Bioinspired Self-Cleaning Broadband Antireflection Coatings Peng Jiang; University of Florida, United States

Millions of years before people began to generate functional nanostructures, biological systems were using nanometer-scale architectures to produce unique functionalities. Some nocturnal moths use hexagonal arrays of subwavelength nipples as antireflection coatings to reduce reflection from their compound eyes. Similar periodic arrays of nanopillars have also been observed on the wings of cicada to render superhydrophobic surfaces for self-cleaning functionality. Inspired by these natural nanostructures, we have developed various bottom-up nanofabrication technologies for producing wafer-scale, self-cleaning, broadband antireflection coatings on a large variety of technologically important optical substrates, such as crystalline silicon, GaAs, polymer, and glass. These techniques combine the simplicity and cost benefits of bottom-up self-assembly with the scalability and compatibility of standard top-down microfabrication. The resulting subwavelength-structured antireflection coatings can greatly suppress light reflection, promising for a spectrum of applications ranging from highly efficient photovoltaics and light emitting diodes to smart optical devices. By integrating this biomimetic design with smart shape memory polymers, we have demonstrated tunable antireflection coatings with multi-stimuli-responsive optical properties.

2:15 PM SB09.10.03
Bioinspired Translation of Classical Music into *de novo* Protein Structures Markus J. Buehler, Mario Milazzo and Grace I. Anderson; Massachusetts Institute of Technology, United States

Architected biomaterials, as well as sound and music, are constructed from small building blocks that are assembled across time- and length-scales. Here we present a novel deep learning-enabled integrated algorithmic workflow to merge the two concepts for radical discovery of *de novo* protein materials, exploiting musical creativity as the foundation, and extrapolating through a recursive method to increase protein complexity by successively injecting protein chemistry into the process. Indeed, music is able to overcome differences among people and nations, creating bridges between cultures, and to find associations between seemingly unrelated concepts, and can form a novel way to generate bio-inspired designs that derive functions from the imaginations of the creative mind. Earlier work (Buehler et al., ACS Nano, 2019) has offered a pathway to concert proteins into sound, and sound into proteins. Here we build on this paradigm and translate a piece of classical music into matter. Based on a sytematic analysis of different pieces including J.S. Bach's Goldberg variations and Leonard Bernstein's Chichester Psalms, we offer a series of case studies to convert the musical data imagined by the composer into protein design, and folded into a 3D structure using deep learning. The quest we seek to address is to identify semblances, or deep-time memories, or information content in such musical creation, that offers new insights into pattern relationships between distinct manifestations of information. The resulting protein forms the basis for iterative musical composition, and an evolutionary paradigm that defines a variational pathway for melodic development, complementing conventional creative or mathematical methods. This paper broadens the concept of what is understood as bio-inspiration to include a broad array of signals and designs created by humans, animals, or complex physical mechanisms.

2:30 PM SB09.10.04
Wafer-Scale Heterostructured Piezoelectric Bio-Organic Thin Films Jun Li; University of Wisconsin--Madison, United States

Piezoelectric biomaterials are intrinsically suitable for coupling mechanical and electrical energy in biological systems to achieve in vivo real-time sensing, actuation, and electricity generation. However, the inability to synthesize and align the piezoelectric phase on a large scale remains a roadblock toward practical applications. We present a wafer-scale approach to creating piezoelectric biomaterial thin films based on γ glycine crystals. The thin film had a sandwich structure, where a crystalline glycine layer self-assembles and automatically aligns between two polyvinyl alcohol (PVA) thin films. The heterostructured glycine-PVA films exhibited piezoelectric coefficients of 5.3 pC/N or 157.5×10−3 Vm/N, and nearly an order of magnitude enhancement of the mechanical flexibility compared to pure glycine crystals. With its natural compatibility and degradability in physiological environments, glycine-PVA film may enable the development of transient implantable electromechanical devices

2:45 PM SB09.10.05
A Wearable UV Sensor Based on Unique Features of a Natural Biochrome Daniel Wilson and Leila Deravi; Northeastern University Chemistry & Chemical Biology, United States

The optical properties of the primary pigment that facilitates rapid and precise appearance changes in cephalopods, xanthommatin, have been evaluated for a variety of applications including electrochromic displays and photoprotective films. However, the fundamental mechanisms underlying the optical performance of xanthommatin upon irradiation with solar light remain incompletely characterized. We investigated irradiation-induced color changes of xanthommatin that could be controlled by manipulating the pH of the surrounding environment. Photoreduction of the pigment in acidic conditions was enhanced by incorporating additional ultraviolet (UV)-responsive materials (e.g., disulfides) to generate redox agents upon irradiation. We leveraged these dose-dependent optical changes to create colorimetric UV light sensors, which can be incorporated into a user-friendly microfluidic architecture that can be worn or surface-mounted. These devices provide radiation-driven responses that may be useful for personal solar monitoring, tracking exposure of perishable goods, or verifying UV dose thresholds for germicidal sterilization.

3:00 PM SB09.10.06
Late News: Self-Organized Mycelium Nanocomposites for Sustainable Buildings—From Bioprocessing to Structure and Mechanical Properties Precious O. Etinosa[1], Ali Salifu[1,1], Salifu Tahiru Azeko[2] and Winston W. Soboyejo[1,1,3]; [1]Worcester Polytechnic Institute, United States; [2]Tamale Technical University, Ghana; [3]African University of Science and Technology, Nigeria

This work presents the results of a combined experimental and analytical study of the mechanical properties of bioprocessed mycelium nanocomposites

that are reinforced with self-organized cellulosic fibers. The bioprocessed mycelium nanocomposite blocks were composed of cellulose/hemicellulose hemp-duct with varying laterite percentage compositions. The mycelium functions as a supportive matrix holding the reinforcing hemp-duct particles within its filamentous structural network. In-situ studies of the mechanical properties of the composites were conducted to determine the hardness, compression/flexural properties, and fracture toughness/resistance-curve behaviors. For supportive evidence and to gain further insight into the failure mechanism, the microstructure and strain mapping of the resulting composites at relevant stages of compression was characterized using SEM and DIC, respectively. The observed deformation and fracture mechanisms are then used to provide insights for the prediction of the composite strength and resistance-curve behavior. The implications of the results are discussed for the bioprocessing of mycelium-nanocomposite for sustainable building materials.

SESSION SB09.11: Bioinspired Materials I
Session Chairs: Guillaume Gomard and Silvia Vignolini
Tuesday Morning, December 7, 2021
SB09-Virtual

8:00 AM *SB09.11.01
Bioinspired Fabrication of Strong and Tough Hydrogels Esther Amstad; Ecole Polytechnique Federale de Lausanne, Switzerland

Nature produces soft materials possessing exceptional mechanical properties. These properties are to a large extent related to the well-defined structures and locally varying compositions of these natural materials. Key to the excellent control nature possesses over the structure and local composition of its materials is their fabrication: Many of these materials are formed from compartmentalized reagents that are transported to the desired locations where they are released locally. Inspired by nature, we use emulsion drops as compartments to build macroscopic granular hydrogels. In this talk, I will demonstrate how we convert individually dispersed emulsion drops into selectively permeable viscoelastic capsules that enable controlled localized release of reagents. These capsules are most frequently employed as individually dispersed delivery vehicles. In the second part of this talk, I will demonstrate how we go a step beyond the current use of capsules by converting them into inks that can be 3D printed into strong and tough double network granular hydrogels.

8:30 AM SB09.11.02
Multi-Scale Characterisation of the Load-Bearing Shells of the Brachiopod Discinisca Tenuis Johannes Ihli[1], Anna Schenk[2], Sabine Rosenfeldt[2], Klaus Wakonig[1], Mirko Holler[1], Giuseppe Falini[3], Eugenia Delacou[4], Jim Buckman[5], Thomas Kress[6], Esther Tsai[7], David Reid[6], Melinda Duer[6], Maggie Cusack[8] and Fabio Nudelman[4]; [1]Paul Scherrer Institute, Switzerland; [2]Universität Bayreuth, Germany; [3]Università di Bologna, Italy; [4]University of Edinburgh, United Kingdom; [5]Heriot-Watt University, United Kingdom; [6]University of Cambridge, United Kingdom; [7]Brookhaven National Laboratory, United States; [8]University of Stirling, United Kingdom

Biominerals are a class of inorganic-organic composite materials that exhibit function-optimized properties. These properties arise from a hierarchical organization of primary building blocks. While some biomineral producing organisms can alter these properties in response to environmental stresses, this generally involves a time-intensive process of resorption and reprecipitation. In this presentation, we show that the load-bearing shells of the brachiopod *Discinisca tenuis* can dynamically modulate their mechanical properties in response to environmental changes. They gradually transition from hard and stiff to fully malleable as a function of water content in the environment/ their structure. Using a combination of Cryo ptychographic X-ray computed tomography, electron microscopy, spectroscopy, in-situ wide-angle X-ray scattering and mechanical testing, we describe the hierarchical structure and composition of these shells to reveal the structural motifs and deformation mechanism that endow the shells with this adaptability.

8:45 AM SB09.11.03
From Nature to Applications—Self Healing and Breathable Multilayer Composit Materials Thorsten Neumann; Continental SSL / Benecke Kaliko AG, Germany

Continental is widely known as the tire company. However, the company has a wide product range for multiple applications in the automotive industry as well as beyond.
Contitech Business Unit Surface Solutions specializes in innovative and functional films and multilayer textile laminates which are applied in the automotive industry, transportation, and many other business fields e.g. cruise ships, stadiums, and hotels.
In this presentation we describe smart and functional materials that exhibit self-healing properties and breathability for seating applications in the field of artificial leather materials. These materials must fulfill a wide range of specific tests, ranging from flame retardant behavior, stain-, flexibility- and abrasion- resistance as well as decent haptic touch and environmental impact resistance. The breathable material is made by several layers and pores that are generated in situ, allowing the penetration of air and humidity. Furthermore, the hybrid approach of soft PVC and polyurethane allows the free passage of water vapor through the material depending on the relative humidity level. This technology may allow a reduction of energy use (for example by reducing the need for air conditioning), especially in seating applications. Use of upcycling raw materials such as used coffee grounds reduce the CO_2 footprint of the material.
The second topic of self-healing materials is an in situ generated polyurethane system based on a solid phase reaction of a diamine. A chemically controlled reaction allows production of a defined polymer chain length range, which leads to a self-healing coated fabric. Material cuts heal within minutes by the adhesion of small fast migration molecules which tend to concentrate on the surface of the cut material, leading to an initial adhesion similar to the healing process of human skin. Longer chain polymers migrate and stabilize the cut to its full strength. Mechanical tests show no reduction of performance of the healed materials.

9:00 AM SB09.11.04
When and How Self-Cleaning of Superhydrophobic Surfaces Works Doris Vollmer, Florian Geyer, Rüdiger Berger and Hans-Jürgen Butt; Max Planck Institute for Polymer Research, Germany

Self-cleaning is the most prominent feature of superhydrophobic surfaces [1]. Macroscopic contamination such as dust is indeed easily cleaned away by water drops rolling across the superhydrophobic surface. A lot of research went into exploring different strategies to achieve long-lasting and highly liquid-repellent surfaces [2]. Despite the enormous interest in superhydrophobicity, it is still unclear when microscopic and in particular nanoscopic contamination (soot, aerosols, etc.) influences superhydrophobicity and how self-cleaning works in detail.

To gain an in-depth insight into self-cleaning, we monitored self-cleaning at the micron scale using laser scanning confocal microscopy [3]. Aiming to correlate self-cleaning, surface topography and particle size and hydrophilicity, we contaminated different surfaces with particles varying four orders of magnitude and having different polarities. When the drop is moved over the contaminated surface, individual particles were picked up at the advancing edge. Upon further movement of the drop, these particles accumulated at the lower air-water interface of the drop. To design superhydrophobic surfaces that are resistant to hydrophobic as well as hydrophilic particle contamination, the pore size of the superhydrophobic surface needs to be smaller than the contamination particle size. Even smaller nanoscopic contaminants do not necessarily degrade superhydrophobicity.

While the ability to withstand various kinds of contamination is essential, the ease of self-cleaning is equally crucial. To remove particles from a superhydrophobic surface, the capillary force acting on the particle at the rear side of the drop needs to overcome the adhesion force between the particle and the surface. We quantified the forces involved in the self-cleaning process and compared the experimental results with quantitative calculations.

To compare the results based on model contamination to real-world outdoor exposure, we fixed several coated fabrics on a car. These fabrics repelled water and organic liquids and were chosen because of their robustness. They were obtained by coating polyester fabrics silicone filaments. These superhydrophobic surfaces having a nanoscale pore size surfaces are capable of resisting long-term real-world exposure and industrial contamintion tests.

9:15 AM SB09.11.05
Focusing and Camouflage Mirrors in the Eyes of Decapod Crustaceans Qiang Wen; Ben-Gurion University of the Negev, Israel

Many aquatic animals use reflective optics in their eyes. The nature of the reflective materials underling these systems is often unknown. A fascinating example is the reflecting superposition compound eye of decapod crustaceans. This eye contains a distal mirror which focusses light across onto the retina and a photon-enhancing tapetum reflector. Previous reports[1] suggested that both the tapetum and distal mirror were formed from high refractive index crystals of isoxanthopterin. We present a comparative study of reflecting optics in the eyes of several decapods to reveal that: **(i)** the distal mirror is formed from xanthopterin crystals, not isoxanthopterin and **(ii)** many species contain a third reflector – the 'reflective cap' which underlies the cornea and which appears to function as a camouflage device. Cryo-SEM, TEM in-situ X-ray diffraction studies showed that the distal mirror in the eyes of decapods is formed from polycrystalline rods of xanthopterin crystals. These rods are aligned in a 3-tiered multilayer reflector surrounding the distal portion of the ommatidia. The mirror boosts the reflection of off-axis light at the walls of the ommatidia, enhancing the amount of light of focused on the retina. In several species a third reflector – the reflecting cap resides immediately above the distal mirror. The reflective cap is formed from a dense array of crystalline isoxanthopterin nano-spheres identical to those found in the tapetum[2]. Optical ray-tracing and comparative anatomy of decapods from diverse habitats shows that the reflecting cap is a camouflage device, which deflects light away from the underling conspicuous screening pigments.

9:30 AM *SB09.11.06
Structural Colour from Plant Waxes Rox Middleton, Sverre A. Tunstad and Heather Whitney; University of Bristol, United Kingdom

Structural colour is a widespread phenomenon in nature, especially well-known in its production of brilliant high intensity hues in insects and feather. More recent developments have demonstrated the sometimes more subtle effects of structural colour in plants, for example fruits [1], leaves [2] and flowers [3]. Epicuticular waxes are well known for their striking hydrophobic qualities [4], and many other potential functions across plant organs. We discuss a previously unreported phenomenon of coloration from natural epicuticular wax crystal surface coatings. Widespread in nature, these offer a new self-assembled avenue to alternative coloration for artificial application without dye molecules. We report on the chemical and mechanical composition of these materials, and their in vitro recrystallisation for use as colorants.

Tuesday Morning, December 7, 2021
SB09-Virtual

10:30 AM *SB09.12.01
Control over Chitin Fiber Orientation in the Insect Cuticle Yael Politi[1], Luca Bertinetti[1], Peter Fratzl[2], Jan-Henning Dirks[3] and Bernard Moussian[4]; [1]Technische Universität Dresden, Germany; [2]Max Planck Institute of Colloids and Interfaces, Germany; [3]Hochschule Bremen, Germany; [4]Eberhard-Karls Universität Tübingen, Germany

The orientation of fibers in the arthropod cuticle, made of chitin and proteins, strongly affects its physical properties, which in turn determines morphogenesis and functionality. Fiber orientation therefore needs to be spatially and temporally controlled by the animal. The arthropod cuticle is often described as liquid crystal (LC) analogues as it exhibits structural similarity to LC but are solid in its functional state. Using focused ion beam/scanning electron microscopy (FIB/SEM) volume imaging and scanning X-ray scattering, we show that the epidermal cells depositing the cuticle, determine an initial fiber orientation, from which the final architecture emerges by the self-organized co-assembly of chitin and proteins. Fiber orientation in the locust cuticle is therefore determined by both active and passive processes.

11:00 AM SB09.12.02
Spatiotemporal Control of Melanin Synthesis in Liquid Droplets Ayala Lampel; Tel Aviv University, Israel

Melanins are natural biopolymers that have remarkable properties including UV-protection, coloration and antioxidant activity. Their biosynthesis is regulated both spatially and temporally and involves supramolecular templating and compartmentalization of enzymes and reactants within specialized organelles called melanosomes. In contrast, the laboratory-based bulk synthesis of melanin by tyrosine or dopamine oxidation is a poorly controlled process, resulting in materials with undefined properties. Inspired by the pigment's biosynthesis, we developed a methodology to spatiotemporally regulate melanin formation in liquid droplets. The spatial control is achieved by sequestration of the reaction in dextran-rich droplets of a polyethylene glycol/dextran aqueous two-phase system, where the use of a photocleavable protected tyrosine provides a temporal control over its enzymatic oxidation-polymerization. This methodology opens tremendous opportunities for applications in skincare and biomedicine.

11:15 AM SB09.12.03
Extracting Meaningful Structural Information on the Nanometer Scale from Highly Hydrated Materials Irene U. Wacker[1], Ernest R. Curticean[2], Willi Wagner[2], Christine Arndt[1], Christine Selhuber-Unkel[1], Steven J. Mentzer[3] and Rasmus R. Schröder[2,1]; [1]Universität Heidelberg, Germany; [2]University Hospital Heidelberg, Germany; [3]Brigham & Women's Hospital, Harvard Medical School, United States

Ultrastructural analysis of morphological features of highly hydrated biomaterials is still a difficult task. In structural biology, specifically protein structure determination, cryo-preparation and cryo-imaging have led to a "resolution revolution" [1]. While vitrification – the embedding in amorphous ice – is routinely achievable for concentrated protein solutions, the situation is different for carbohydrates or bio-inspired hydrogels. Their water content can be so high that conventionally used freezing methods – e.g. "flash freezing" followed by lyophilization – may not provide accurate ultrastructural features such as the exact size of pores [2]. For alginate hydrogels the effects on matrix morphology of different freezing techniques - including high-pressure freezing, the gold standard for cellular material – were analyzed in detail using cryo-SEM [3]. Pore sizes varied by two orders of magnitude from micropores in the range of tens of nanometers to macropores in the micrometer range, depending on the freezing method used. Although high pressure freezing was found in this study to be the most suitable freezing method it cannot be applied to large or more complex systems, because sample size is limited to roughly 2x2x0.2 mm. Analyzing e.g. the interaction of a pectin-based pleural sealant with the outer surface of the mammalian lung [4] is not possible with this approach.

Another important aspect when imaging low atomic number Z materials in an electron microscope is the lack of contrast – conventionally this is solved by "staining" materials with high Z metal (Ru, Os, U) compounds. For carbohydrates and many hydrogel materials without reactive groups this procedure is not straightforward.

Due to these numerous limitations and the need for rather sophisticated machinery for cryo-preparation and cryo-imaging we were looking for alternative, more easily accessible methods.
One approach, which has been used in the early days of cryo-preparation, is the replacement of freely diffusible water in a sample by a number of reagents, which either directly dehydrate the sample in a gentle way or help prevent formation of ice-crystals during a sub-optimal freezing regime. We tested partial dehydration with ethanol or tannic acid, and infiltration with trehalose to reduce the amount of free water, which would otherwise be available for crystallization. In combination with osmium tetroxide alone or together with ruthenium red we were able to introduce sufficient contrast to image bulk samples or thin sections from resin-embedded hydrated carbohydrates in an SEM at highest resolution.
For biomaterial films fabricated with pectins from different plant sources we could demonstrate different morphologies – from a more globular aspect for potato pectin to a highly branched network of interconnected carbohydrate chains for lemon and orange pectin. Controlling the degree of dehydration during the initial preparation step allowed us to visualize carbohydrate networks with different pore sizes.
We are currently investigating how to apply our preparation protocols to a number of different hydrogel classes with different pores sizes and validating the effects of the different reagents used on water content and morphology.

Bioinspired Multifunctional Glass Surfaces Through Regenerative Secondary Mask Lithography Martyna Michalska, Sophia K. Laney, Tao Li, Mark Portnoi, Nicola Mordan, Elaine Allan, Manish K. Tiwari, Ivan P. Parkin and Ioannis Papakonstantinou; University College London, United Kingdom

Nature-inspired nanopatterning offers exciting multifunctionality spanning antireflectance and the ability to repel water/fog, oils, and bacteria; strongly dependent upon nanofeature size and morphology [1,2]. Broadly, this multifunctionality is inherent to and bridged by the nanocone structure, yet such patterning in glass (SiO_2) – a material of great practical importance – remains a bottleneck due to its high chemical stability alongside structuring at the nanoscale itself, which becomes increasingly challenging to manage as the pattern resolution advances (pitch <100 nm).
Here, we demonstrate a novel Regenerative Secondary Mask Lithography process which enables customized glass nanopillars through dynamic nanoscale tunability of the side-wall profile and aspect ratio (>7). Our method is facile and versatile, comprising just two steps. Firstly, we generate sub-wavelength scalable soft etch-masks (55-350 nm) through an example of block copolymer micelles or nanoimprinted photoresist. Secondly, we overcome their inherent durability problem – typically addressed by metal/metal oxide incorporation which adds time and complexity – through our innovative cyclic etching. During this etching, the original mask becomes embedded within a protective secondary organic mask, which is tuned and regenerated, permitting dynamic nanofeature profiling with etching selectivity >1:32.
We envision that such structuring in glass will facilitate fundamental studies and be useful for myriad of practical applications – from displays to architectural windows. Providing the highly-tunable nature of our method (size/shape/pitch), we tailor glass features and present excellent broadband omnidirectional antireflectivity, self-cleaning, and unique antibacterial activity towards *Staphylococcus aureus*.

11:45 AM SB09.12.05
Droplet Dynamics on Asymmetric Wettability Patterns on Superbiphilic Surfaces David Feldmann and Bat-El Pinchasik; Tel Aviv University, Israel

A little beetle (*Stenocara Gracilipes*) living in the desert collects water from early morning mist. Nature has equipped its back with a biphilic wettability pattern: small hydrophilic patches embedded into a hydrophobic matrix made of wax. Since the discovery of this wettability pattern, extensive research was conducted to analyze and create biphilic surfaces for various purposes such as boiling heat transfer, and freezing or defreezing, and water collection from air. Hydrophilic surfaces favor nucleation, whereas hydrophobic surfaces favor water transport. The role of surface design is not well elaborated. In most cases, the patches are randomly or circularly shaped. We investigate the effect of patch asymmetry, size, distribution, and surface direction on droplet growth and droplet transport. To achieve efficient water collection, asymmetric patches can induce directional transport in capillary regime, and thus, fast water removal from the surface. Nucleation favors droplet growth in hydrophilic patches, however, for roll-off droplets need to overcome strong adhesion forces due to hysteresis hindering water removal. The influence of area fraction, distribution, and size of asymmetric patches on growth dynamics such as coalescence and droplet motion has been studied. We developed superbiphilic surfaces with isosceles triangular patches with a varying length to width ratio (l/w) from 2.0 to 10 and sizes between l = 200 microns and 4 mm. Droplets grow favorably in patches with accumulation on the base of the triangle. Experiments have been conducted in a controlled environment (T, RH) under a tilting angle (0° - 90°). A top-down camera records details about droplet distribution and area coverage. A quantitative image analysis reveals droplet dynamics, in which we identify various phases of droplet growth until roll-off. Adhesion forces have been determined depending on the direction of the triangles.

Biomimetic Nano- and Microstructured Polymeric Surfaces Hendrik Hoelscher; Karlsruhe Institute of Technology, Germany

Many nano- and microstructured surfaces found in nature can serve as an inspiration for improving technical applications. Although most biomimetic archetypes can be replicated with advanced techniques on a lab-scale, it remains a challenge to develop processes for large-scale fabrication techniques appropriate for commercial applications. Here, I review recent approaches with high potential for up-scaling.
The super-hydrophobic surfaces of water ferns like *Salvinia* and *Pistia* can be mimicked with nanofur, a dense fur of nanoscale hair hot pulled from polymer surfaces. This fractal surface is super-hydrophobic and oleophilic at the same time. With these properties it is the perfect material to separate oil and water and to clean up oil spills [1, 2].
White beetles of the genus *Cyphochilus* are well-known for their scales producing a nearly perfect whiteness in a very efficient way with an astonishing low amount of material. Inspired by this biological architecture, we developed two techniques allowing for the fabrication of ultra-thin, yet highly scattering, white polymer films [3,4]. Both approaches can be utilized for various applications ranging from extremely white but ultra-thin coatings to scattering particles as potential replacements for titanium dioxide.
Many snakes feature nano-scale fibril structures on their scales which are only some 10 nm high and feature a periodicity of some µm. Although they cannot be observed in the visible range and the surfaces appear smooth, these nano-steps cause significant anisotropic frictional properties which are helpful for the locomotion of snakes. These nano-step structures can be copied to artificial polymeric surfaces which can be utilized for the self-cleaning of photo-voltaic modules.

SESSION SB09.13: Bioinspired Materials III
Session Chairs: Guillaume Gomard and Mathias Kolle
Tuesday Afternoon, December 7, 2021
SB09-Virtual

1:00 PM SB09.13.01
Bioinspired Synthesis of Thermally Stable and Mechanically Strong Nanocomposite Coatings Guangping Xu, Hongyou Fan, Chad A. McCoy, Melissa M. Mills, Jens Schwarz, Tuan A. Ho and Justin Rosenthal; Sandia National Laboratories, United States

The demand for materials with strong thermal and mechanical properties that can withstand harsh environments, such as pulsed power facilities, magnetic fusion reactors and space environments, is rapidly increasing. The ideal materials need to survive a range of individual and combined threats such as mechanical, shock, and x-ray insults. However, such materials are presently not available.
An innovative biomimetic method has been developed to synthesize layered nanocomposite coatings using silica and sugar-derived carbon to mimic the formation of natural seashell structure. The layered nanocomposites are fabricated through alternate coatings of condensed silicate and sugar. Sugar-derived carbon is a cost-effective material due to sugar being abundantly available, making it a relatively inexpensive chemical, as well as environmentally friendly. Pyrolysis of sugar will form polycyclic aromatic carbon sheets, i.e., carbon black.
Each layer is thermally pretreated at ~ 200 °C for 3-5 minutes in order to solidify the composite before coating the next layer. The final nanocomposite coatings are then thermally treated at temperatures higher than 800 °C which converts the sugar into carbon black and condenses silicate to form a silica network through cross-linking of carbon with silica. Infrared spectra show chemical crosslinking of Si-O with carbon ring and Si- with carbon ring. Chemical crosslinking between silica and carbon contributes to the enhanced mechanical properties, and thermal pretreatment plays the important role in solidification of the composite coatings while initiating crosslinking. Without this step, the hardness and modulus of the nanocomposite is not enhanced. Molecular dynamics models, incorporating the crosslinking between silica and carbon layers, are conducted to simulate the interfacial bonding energy and shear strength.
The resulting final nanocomposite coatings can survive temperatures of more than 1150 °C and potentially up to 1700 °C. These coatings have strong mechanical properties, with hardness of more than 23 GPa, elastic modulus of 240 GPa, and yield stress of more than 20 GPa, which are 62 – 94% greater than those of pure silica. The layered coatings have more than 80% transmission for >10keV x-rays and have many applications besides use in pulsed power facilities, such as shielding in the form of mechanical barriers, body armors, and space debris shields.
SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525

1:15 PM SB09.13.02
Coupled Oscillatory Motion of Photothermal Particles Driven by Marangoni Forces Hyunki Kim[1,2], Subramanian Sundaram[3,4], Todd Emrick[1] and Ryan Hayward[5]; [1]University of Massachusetts Amherst, United States; [2]3M, United States; [3]Boston University, United States; [4]Harvard University, United States; [5]University of Colorado Boulder, United States

Coupled motions are frequently observed in living systems, such as oscillatory gait patterns of terrestrial animals, flocking behaviors of birds, and oscillatory motion of bacterial flagella. These motions are dynamically reconfigurable, with the possibility to select from multiple oscillatory patterns from a single system. Here, we describe an oscillatory material system, which relies on optically-defined boundary conditions to guide photothermal Marangoni propulsion and coordinate multiple particles. Hydrogel nanocomposite particles containing plasmonic gold nanoparticles are illuminated by patterned light at an air-water interface, leading to coupled oscillatory motions with on-demand reconfiguration through variations in light patterns. This experimental platform may prove useful in understanding oscillatory dynamics in natural and synthetic systems.

1:30 PM SB09.13.04
Bioinspired Oil-Infused Elastomers with Excellent Water and Ion Barrier Properties for Flexible Bioelectronic Implants He Sun and Yi Zhang; University of Connecticut, United States

Implantable bioelectronics have a wide range of applications in basic biomedical research and clinical medicine. The encapsulation of these systems represents a key challenge as they demand perfect isolation of electronics from surrounding biofluids to prevent current leakage and the degradation of underlying devices. To date, all the barrier materials for flexible bioelectronics, including polymer layers, inorganic coatings, and transferred barriers, are *solid* materials. These solid materials suffer from limited barrier lifetime due to pinholes, cracks, and nanopores or from complicated fabrication processes and limited stretchability for interfacing with complex biological tissues. This paper reports a solution to this materials challenge by introducing an bioinspired oil-infused rough silicone elastomer as a transparent, flexible, stretchable, slippery, and damage-tolerant biofluid barrier material. Accelerated lifetime tests suggest robust water barrier characteristics that approach 226 days at 37 degrees, even under severe mechanical damage using a knife. A combination of temperature- and thickness-dependent experimental measurements and reaction-diffusion modeling reveal the key water-proof property. In addition to serving as a barrier to water, oil-infused rough elastomer demonstrates an attractive ion prevention property. All these exceptional properties suggest the potential applications in flexible bioelectronics implants for emerging applications ranging from chronic neural recording to bioelectronic medicine.

1:45 PM *SB09.13.05
Bioceramic Cellular Solids—Structure, Mechanics and Formation Ling Li; Virginia Polytechnic Institute and State University, United States

Cellular solids, or foams, are an important class of structural materials for packaging, transportation, sports, and infrastructure due to their mechanical efficiency. While many current foams are primarily based on metallic and polymeric materials, ceramic foams are usually used for non-mechanical applications, such as filtration, catalysis, thermal insulation, etc. The major limitation of using ceramic cellular solids as structural components are their brittleness and flaw sensitivity. Overcoming the fragile nature of ceramic foams, making them lighter while reaching higher stiffness, strength and energy absorption capability is challenging but critical toward many applications. In this talk, I will present our ongoing work in elucidating the structural design principles in natural ceramic cellular solids from a variety of model systems, particularly echinoderm stereom, cuttlefish bone, and sponges. These structures are characterized by their highly mineralized porous morphology, yet exhibiting remarkable damage tolerance, which is in stark contrast to synthetic ceramic foams. We utilize a combinatorial approach by integrating quantitative 3D structural analysis, 4D in-situ mechanical analysis, theoretical and mechanical modeling in order to establish the structure-property relationship for this unique group of biological materials. In this talk, we demonstrate important microstructural design strategies to overcome the intrinsic brittleness of porous ceramics learned from these model systems, which could inspire novel lightweight ceramic cellular solids. In addition, the formation mechanisms of these complex biomineralized structures will also be briefly discussed.

2:15 PM SB09.13.06
A Camouflage Reflector in the Eyes of Decapod Crustaceans Larvae Keshet Shavit[1], Avital Wagner[1], Venkata Jayasurya Yallapragada[2], Bracha V. Farstey[3], Amir Sagi[1] and Benjamin A. Palmer[1]; [1]Ben-Gurion University of the Negev, Israel; [2]Weizmann Institute of Science, Israel; [3]The Interuniversity Institute for Marine Sciences in Eilat, Israel

Larval crustaceans use transparency to camouflage themselves in rivers and the open ocean. Many of these animals have evolved an ingenious optical device to conceal the conspicuous screening pigments in their eyes – an 'eyeshine' reflector that deflects light away from the opaque pigments [1]. Using cryo-SEM and TEM we show that the eyeshine reflection of larval shrimp is produced by light-scattering from dense arrays of high refractive index, core-shell nanoparticles of crystalline isoxanthopterin. The same nanoparticles were recently found in the tapetum of adult shrimp where they are used in image-formation and enhancing photon-capture [2]. The reflectivity and scattering of the particles are enhanced by their birefringence, which results from the anisotropic arrangement of refractive indexes within the particle shell [3]. These particles are located in specialized cells overlaying the screening pigment and extending down the sides of the rhabdoms. The location of the particles indicates that the reflector has a dual function: camouflaging retinal pigment and preserving visual acuity by preventing crosstalk between neighboring rhabdoms. Reflectivity measurements and optical modeling demonstrate that the color of the scattering is determined by the size of the particles and their degree of short-range ordering. The eyeshine color is spectrally-matched to the watercolor in the native habitat of the shrimp and also changes upon light-dark adaptation. This enables the crustaceans to remain inconspicuous against the background. For example, the prawn *M. rosenbergii* which inhabits yellow/green rivers in the Indo-Pacific exhibits yellow/green eyeshine, produced by 400 nm particles. While Marine shrimp from the gulf of Eilat have blue eyeshine, produced by 220 – 330 nm particles.

2:20 PM SB09.13.07
USAXS Study of High Aspect Ratio 2D Clay Nanolayer Suspended in sAline Water—Nematic Self-Assembly in the Photonic Range of Interlayer Spacings Osvaldo Trigueiro Neto[1], Paulo H. Michels Brito[1], Tomás S. Plivelic[2], Daniel Wagner[3], Josef Breu[3], Barbara Pacakova[1], Kenneth Knudsen[4] and Jon O. Fossum[1]; [1]Norwegian University of Science and Technology, Norway; [2]MAX IV Laboratory, Lund University, Sweden; [3]University of Bayreuth, Germany; [4]Institute for Energy Technology (IFE), Norway

Systems of high aspect ratio of 2D nanolayers of fluorohectorite clay mineral, suspended in saline solutions of various clay and salt concentrations, exhibit a rich nematic phase behavior. This system is studied here using Ultra Small-Angle X-ray Scattering (USAXS): the anisotropy of the obtained images is quantified, and, together with reflective spectrophotometric measurements, this provides a precise determination of the nematic organization and inter-particle distance. In addition, the USAXS analysis provides information about nematic phase order such as misalignment or turbostratic organization. We find that the inter-nanolayer distances can be related to electrostatic interactions combined with osmotic pressure effects.

2:25 PM SB09.13.08
Role of Zn2+ Ions in the Folding of Nereis Virens Nvjp-1 Folding Jaden Luo[1], Eesha Khare[1], Patrick Dennis[2], Rajesh Naik[2] and Markus J. Buehler[1]; [1]Massachusetts Institute of Technology, United States; [2]Air Force Research Laboratory, United States

Metal-coordination bonds are dative chemical bonds that arise when a ligand donates a lone pair of electrons to a metal ion. These bonds are dynamic, reversible, and easily tunable, allowing them to span a large range of different strengths and timescales. Several biological organisms have been found to utilize metal-coordination bonds to synthesize a wealth of bioinspired materials. One such organism, the *Nereis virens*, is a species of marine worm with a remarkably strong and stiff jaw that owes its strength not to bones or minerals, but to metal-coordination bonds. Understanding how metal-coordination bonds affect the structure and properties of the *Nereis virens* worm jaw Nvjp-1 protein would enable the understanding and design of new metal-coordinated materials with complex and optimized mechanical properties.

Nvjp-1 contains over 25 mol % of histidine, which is believed to play a key role in the metal-coordinated crosslinking that gives the worm jaw its strength. To understand the understand the nanoscale mechanism behind the crosslinking and its pathway to macroscopic mechanical behavior, we analyze the effect of Zn^{2+} on the form and structure of the Nvjp-1 protein. To gain insight into the behavior of the Nvjp-1 protein in the presence of metal ions, replica-exchange molecular dynamics (REMD) simulations are run with explicit solvent conditions to investigate the formation of the protein structures in various environments. REMD enables an efficient computational search of likely protein structures by overcoming kinetic trapping in local energy minima during the protein folding simulation of Nvjp-1. Metal ions are initiated in different positions of the Nvjp-1 protein, previously solved by REMD in Chou et. al (ACS Nano, 2017) to understand how the protein folds in the presence of metal ions and how differing conditions of metal ions impact the strength of the metal-coordination bonds that the Nvjp-1 protein forms. We find that the initial location of metal ions has an effect on the resulting protein structure.

Largely, this work helps elucidate further details on the roles of metal-coordination binding in protein structures to lend better insight into how the bonds affect macroscopic mechanical properties. Further, information about Nvjp-1 binding with metal ions will enable its broader use in mechanomutable engineering materials. With this information, optimized bioinspired materials could be created for a variety of practical applications.

2:30 PM SB09.13.10
Identifying New Strategies to Promoted Polymer Adhesion via Bacterial Surface Display Mark T. Kozlowski, Joshua A. Orlicki, Randall A. Hughes, Rebecca L. Renberg, Randi M. Pullen and Jimmy Gollihar; U.S. Army Research Laboratory, United States

Modern polymers have a wide range of surface characteristics, from polar plastics such as polycarbonate, to highly non-polar plastics such as polystyrene and polypropylene. The poor reactivity of many polymers makes adhesion an ongoing challenge. This challenge is particularly pronounced in hydrophobic polymers, which require extensive pre-treatment, priming, solvent plasticization, or high temperatures to adhere. While adhesion of more-polar polymers is typically easier to achieve, these polymers are susceptible to water infiltration, which can lessen the strength of the adhesive contact in humid environments. New strategies to enable good adhesive bonding would allow for facile repair in the field, and the creation of new types of composites.

The large diversity of peptides in both sequence and functional groups makes them potentially useful to search for strong interactions with polymer substrates. Furthermore, the insights provided by peptide binding may eventually allow the design of more-effective synthetic adhesives. Screening the chemical compositional space afforded by peptides and the natural amino acids would be nearly impossible if undertaken in a serial fashion. Recently, the Army Research Laboratory developed a peptide surface display and high-throughput library screening system to find candidate peptides capable of adhering to polylactic acid [1], and to gold nanoparticles [2]. The on-cell peptide screening has the advantages of easy recoverability, the ability to propagate and sequence the genetic code of the adhesive peptides, and possible further improvements of the peptides by directed evolution. In this presentation, we will provide updates on peptide library construction, screening methods, and initial results of screens against substrates with a range of polarities.

Direct, Real-Time Visualization of Self-Assembly of Lipid Bilayers into Liposomes by Graphene Liquid Cell-Transmission Electron Microscopy Vahid Jabbari and Reza Shahbazian-Yassar; University of Illinois at Chicago, United States

Liposomes, vesicles formed by self-assembly of lipid bilayers, have a similar structure to biological membranes, making them a model system for biotechnological and biomedical purposes. Liposomes are composed of one or more lamellae, consisting of a phospholipid bilayer and enclosing a small volume of aqueous liquid. Liposomes diameter can vary (from tens of nanometers up to tens of micrometers) depending on amphiphilic lipid structure, synthetic procedure and solution properties. Biodegradability, biocompatibility, and ability to encapsulate different substances, to isolate and permit controlled release of drugs make these lipid vesicles attractive drug carriers. Indeed, development of lipid-based formulations to enhance recombinant vaccine antigens immunogenicity is of high interest to modern vaccine research [1].
With a growing interest in high precision drug therapies, it is critical to assess microemulsions in a liquid environment similar to living systems. However, fragile structures and susceptibility to electron beam damage, imaging liposome delivery vehicles is challenging with transmission electron microscope (TEM). Low contrast between lipid-based species and aqueous environment causing liposomes imaging particularly challenging without contrast reagents or staining. Emergence of graphene liquid cell-transmission electron microscopy (GLC-TEM) with ability to attain the lowest possible solvent thickness, mitigation of the electron radiation-induced damage by conductive graphene layers, significantly contributed to attain high-resolution TEM images of dynamic processes in real time [2,3].
In this work, and for the first time, in-situ GLC-TEM is employed to observe liposomes dynamics (nucleation and evolution) in real time. Liposomes are synthesized by using phosphatidylcholine and cholesterol in PBS buffer solution. We were able to visualize some of fundamental and important steps in the formation of liposomes. Based on our observations, liposome formation mechanism can be described by initial amphiphilic lipids assembly into micelles followed by turning into small vesicles (liposomes). Coalescence of small liposomes results in the formation of larger liposomes.

Bright, Non-Iridescent Structural Coloration from Clay Mineral Nanosheet Suspensions Paulo H. Michels Brito[1], Volodymyr Dudko[2], Daniel Wagner[2], Josef Breu[2] and Jon O. Fossum[1]; [1]Norwegian University of Science and Technology, Norway; [2]University of Bayreuth, Germany

Structural colors originate from the constructive interference by reflection and scattering of light from structures with length scales in the visible region of wavelengths. Structural colors can be iridescent or non-iridescent depending on the degree of disorder in the structures. Bright and non-iridescent structural coloration could not yet be achieved for the most abundant two-dimensional (2D) sustainable material, clay minerals. Recently we have demonstrated that bright non-iridescence structural coloration easily and rapidly can be achieved from nematics of suspended clay mineral nanolayers. We demonstrated how brightness can be enormously improved in this system, and moreover that non-iridescence is readily obtained. The clay nanolayer distances, and thus the structural colors are precisely controlled by clay concentration and water salinity.

SESSION SB09.14: Bioinspired Materials IV
Session Chairs: Mathias Kolle and Radwanul Siddique

SB09-Virtual

4:00 PM SB09.14.01
Sustained Enzymatic Activity and Flow in Crowded Protein Droplets Andrea Testa[1], Mirco Dindo[2], Aleksander Rebane[1], Robert Style[1], Paola Laurino[2] and Eric Dufresne[1]; [1]ETH Zürich, Switzerland; [2]Okinawa Institute of Science and Technology, Japan

Living cellular systems are active materials typically consisting of an extremely crowded environment, in which millions of different enzyme-catalysed reactions happen any second. The complexity and out-of-equilibrium nature of these systems makes it very hard to comprehend the underlying mechanisms governing their behaviour.
In this work, we present a model system consisting of protein droplets that are driven out of equilibrium by enzymatically catalysed reactions, at activity and crowding levels comparable to the cellular cytoplasm, yet retaining compositional simplicity. The droplets possess remarkable stability, and show a plethora of interesting biomimetic activity driven behaviours. We hope our findings can provide an effective framework to design active systems, study biological and biochemical phenomena in a controllable yet biologically relevant environment, and ultimately design active materials that possess superior properties.

4:03 PM SB09.14.03
Bio-Hybrid White Light-Emitting Devices Using Elastic Fluorescent Proteins Jinyeong Kim[1], Butaek Lim[2] and Seung Wuk Lee[2,3]; [1]Sansung Display, Korea (the Republic of); [2]University of California, Berkeley, United States; [3]Lawrence Berkeley National Laboratory, United States

Fluorescent proteins (FPs) provide a novel opportunity to design highly efficient and eco-friendly display devices and technology. Current organic and inorganic display materials (i.e., fluorescent dyes and quantum dots) are toxic and environmentally harmful. In contrast, nature evolves proteins to produce highly efficient and photostability chromophore, FPs together with intrinsic eco-friendly and biocompatibility features. The integration of FPs into light-emitting devices, however, presents several scientific and technical challenges including stability of chromophores and mechanical rigidity in harsh manufacturing conditions. In this study, we designed a novel bio-inspired functional optical material by combining fluorescent proteins as color down-converters conjugated with elastin-like polypeptide (ELP) to enhance mechanical processability. ELPs are naturally evolved biopolymers in nature to endow the flexibility and rigidity of our body in blood vessels and muscles. Using recombinant DNA technique, we fused FPs and ELP genes and synthesized novel functional proteins, and fabricated a composite material of FP/ELP as a thin film to integrate into a blue-emitting LED chip. The resulting thin FP/ ELP film exhibited excellent optical properties as well as mechanical properties such as elasticity, stiffness, and tensile strength. We anticipate that biocompatible and eco-friendly elastic biopolymer coating of FP/ELP onto LED would pave a new way to create robust, biocompatible, and environment friendly display technology and its applications in human-machine interfacing materials in the future.

4:06 PM SB09.14.04
Influence of Carbon Source and Concentration on Microbial Cellulose Biofabrication Romare Antrobus[1], Yueh-Ting Chui[1], Theanne Schiros[1,2] and Helen H. Lu[1]; [1]Columbia University, United States; [2]Fashion Institute of Technology, United States

Introduction: The textile industry's linear model of production and reliance upon nonrenewable resources to manufacture synthetic fibers, dyes, and finishing agents make it one of the most polluting industries globally, and the leading source of carbon emissions, global waste water, and microplastic pollution. Similarly, medical textiles fabricated in the tissue engineering field also utilize harsh solvents during development, not only limiting their biocompatibility and scalability, but also creating environmental concern in large, industrial volumes. Consequently, new fabrication strategies are required to design functional biomaterials that support a sustainable and circular material economy. Inspired by the complexity of nature and its robust regenerative potential, we harness microbial biosynthesis of nanocellulose using *Gluconacetobacter xylinus* (*G. xylinus*) bacteria for the synthesis and production of regenerative, high performance biotextiles. A variety of carbon sources can be metabolized by *G. xylinus* to tailor microbial cellulose (MC) for different textile applications, in which changes in bioavailability and molecular weight affect biochemical pathways, production rates and ultimately, structural properties. Here, we evaluate the effect of several carbon sources (mannitol, dextrose, and sucrose) and concentration (2% and 8% w/v), on the production of microbial cellulose. It is hypothesized that both sugar type and dose will regulate cellulose yield, crystallinity, and tensile properties.

Methods: *Fabrication:* Microbial cellulose pellicles were biofabricated by culturing *G. xylinus* (ATCC 31174, Manassas, VA) in Hestrin–Schramm (HS) medium with varying carbon sources. Culture medium pH was adjusted to 4.5 using citric acid (Fisher Scientific, Chicago, IL). Prior to investigating the effects of carbon source and concentration, *G. xylinus* was pre-cultured in HS medium (2% w/v sucrose) at 30^{o}C for 72 hours under static conditions.

Medium prepared with various carbon sources were inoculated with 5% v/v preculture. All cultures were held under static conditions at 30 oC for 14 days. *Media and Cellulose Production Analyses:* pH was assessed at each timepoint with a pH meter (n=3/group). MC samples were weighed before and after freeze drying to obtain wet and dry weights, respectively (n=3/group). Morphology was assessed with electron microscopy (Zeiss Sigma VP, Oberkochen, Germany; 3 kV; n=5/group). The fiber diameter of each sample was measured by analyzing randomly selected fiber segments in SEM images using NIH ImageJ software (Bethesda, MD; n=50/group). For mechanical testing, samples (1 x 5 cm) were mounted in a uniaxial tensile testing machine (Instron, Norwood, MA, USA; n=5/group), equipped with a 100N load cell. Samples were maintained to have a gauge length of 30 mm and were tested to failure. MC Young's modulus, toughness, and ultimate tensile strength were determined from stress-strain curves.

Results/Discussion: Electron microscopy revealed that MC produced from either mannitol, dextrose, or sucrose as carbon sources exhibited a nanofibrous morphology and are comparable in fiber diameter. However, use of dextrose (2% and 8% w/v) resulted in a significant decrease in medium pH, indicative of gluconic acid formation, and is associated with a lower cellulose yield. In contrast, mannitol, a sugar alcohol, added at 2% w/v resulted in significantly higher cellulose production by day 7. Although differences in yield between carbon sources was minimized at higher sugar concentrations, the overall increase in production led to an increase in Young's modulus and ultimate tensile strength. The ability to tailor mechanical properties of MC by altering carbon sources, offers a versatile platform for tailoring material properties during synthesis. Clearly, biofabrication of MC can be readily engineered to meet target material properties, with broad applicability for the production of both medical or non-medical biotextiles.

4:09 PM SB09.14.05
Characterization of Covalently Crosslinked Cellulose Nanocrystals for Multifunctional Materials with Tunable Physicochemical Properties Joseph Batta-Mpouma[1,2,2], Joshua Sakon[2] and Jin-Woo Kim[1,2,2]; [1]Institute for Nanoscience & Engineering, University of Arkansas, United States; [2]University of Arkansas, United States

Biologically extracted cellulose nanocrystals (CNCs) have drawn significant attention for the development of multifunctional materials for many research communities, ranging from bioresource engineering to materials science and engineering. CNCs are rod-like materials that exhibit unique physicochemical properties such as high surface area, high mechanical strength, high aspect ratio, and unique self-assembly with a rheological and liquid crystalline nature. CNCs not only offer hydroxyl (OH) group-rich surfaces that are amenable and suitable for surface functionalization, but their ability to phase change is also triggered by the formation of self-assembled networks, which are held together by hydrogen (H) bonds. While the intramolecular H-bond interactions in CNCs are responsible for their observed relative stiffness and rigidity, the intermolecular H-bond interactions are the major contributors to the organization of CNC networks, holding the interactions among pristine CNCs as the predominant factor responsible for their assembly through packed units into films or gel-like forms, and leading to a preferential tendency to form ordered structures. However, accessible OH groups of colloidal CNCs at the (10)β/(100)α and (110)β/(010)α facets and their intermolecular H-bonds account for the good water molecule adsorption at their surface, making them structurally instable in moist environment.
In this work, exposed OH groups of CNCs were crosslinked with adjacent ones to develop a hydrogel (crosslinked (x) CNC). The intermolecular H-bond was controlled by the type and concentration of cross-linkers, as well as CNC concentrations. Rheological analyses showed tunable viscoelasticity of formed hydrogels, using loss tangent for the determination of the degree of crosslinking. Fourier transform infrared spectroscopy demonstrated that H-bond intensity (HBI) was inversely proportional to increasing crosslinking degree when using an acid-reactive (i.e., pH<7) crosslinker, but proportional for a base-reactive (i.e., pH>7) crosslinker. Wettability showed that water contact angle (CA) increased with degree of crosslinking by an acidic crosslinker, indicating tunable water stability of CNC network structures from hydrophilic to hydrophobic surfaces. While the diffraction intensity of the crosslinked CNC network varied, the diffraction patterns, as shown by X-ray diffraction, remained identical to that of pristine CNCs, suggesting the interface modification process did not alter the intrinsic molecular crystal structure, and confirming crosslinking was solely achieved from the exposed OH groups. Atomic force microscopy showed images with varied CNC organization and surface roughness inversely proportional to increasing CA when an acidic crosslinker was used, as opposed to a basic one, suggesting cross-linking is related to degree of intermolecular regularity of cellulose chains, which were consistent with observations made with HBI. The technology of crosslinking CNCs does not only generate a potential pathway to fabricate water-stable network of colloidal CNCs, but also provide an alternate approach to integrate CNCs in biological and synthetic nanomaterials, as well as polymer matrices for the development of cutting-edge multifunctional materials. The non-toxic, renewable, and biocompatible nature of x-CNCs could see potential use as building blocks to produce advanced 3D printed scaffolds, beads, and nanofibers for their related functions.

This project is supported by the Center for Advanced Surface Engineering (CASE), under the National Science Foundation (NSF) Grant No. IIA-1457888 and the Arkansas EPSCoR Program, ASSET III.

Anisometric Microgels for All-Aqueous Liquid-Liquid Phase Separation Studies Yufan Xu[1], Yi Shen[1,2] and Tuomas P. Knowles[1,1]; [1]University of Cambridge, United Kingdom; [2]The University of Sydney, Australia

Liquid-liquid phase separation of protein is a burgeoning area that is thought to be related to functional and aberrant biology, and can inspire the conceptualisation and processing of smart and multifunctional materials. Conventionally, fluorescence recovery after photobleaching, the fusion of liquid droplets, and rheology were used to characterise the liquid nature of the phases in liquid-liquid phase-separated systems. Other simple methods can also realise the above-mentioned characterisation, and are expected to be developed.
Recently, we demonstrated that protein microgels, from droplet microfluidics, could function as the precursors of the formation of all-aqueous liquid-liquid phase-separated systems that were two-phase or multiphase. We developed oil-free anisometric protein microgels, such as elongated microgels, hole-shell microgels, and buckled core-shell microgels. More interestingly, we demonstrated that these three forms of anisometric microgels could undergo gel-sol transition and convert into isometric droplets or isometric core-shell droplets. In summary, the microgels can be the consequences and the outcomes of liquid-liquid phase separation. The protein microgels and all-aqueous liquid-liquid phase-separated systems are promising candidates for extracellular matrix analogues, tissue engineering scaffolds, as well as implantable or injectable biosensors.

The Effect of Chemical Composition on the Morphology and Structure of Biogenic Guanine Crystals Noam Pinsk and Benjamin A. Palmer; Ben-Gurion University of the Negev, Israel

Animals use guanine crystals to manipulate light, producing a variety of plate-like habits in which the reflective (100) face is preferentially expressed. These habits differ from the stable prismatic growth-form produced synthetically. How does biology so precisely control crystal morphology? One

hypothesis is that the biogenic guanine contains additives that inhibit crystal growth along certain directions. In the 1960s hypoxanthine was found in guanine-containing tissues in fish but it could not be determined whether this molecule was included within the crystal lattice or was simply a solute in the crystal-forming cells. Our study aims to determine the chemical composition of biogenic guanine in order to support or refute the 'additive hypothesis'. Here we report nine unique guanine crystal morphologies from different animals, characterized by SEM and TEM. These include prisms, regular hexagonal and square plates, irregular hexagonal plates and a variety of irregular polygonal plate habits. We developed an enzymatic/centrifugation method for extracting and purifying the crystals from their surrounding- a key weakness in previous studies. Solid-state Raman spectroscopy and MALDI-TOF analysis on the purified crystals showed that hypoxanthine was present in plate-like crystals but was absent from prismatic crystals. UV-vis analysis of dissolved crystal solutions showed that fish guanine contains approximately 16 mol% hypoxanthine. UV-vis and NMR studies are ongoing to quantify the chemical compositions of the remaining crystal morphologies. Preliminary analysis of synchrotron PXRD data reveals only minute differences in the lattice parameters of guanine crystals with differing compositions, but substantial differences in crystal strain.
We show for the first time that 'guanine' crystals are, much like inorganic biominerals, composites. The impact that additives have on crystal structure and morphology remains an intriguing open question we are actively pursuing.

4:18 PM SB09.14.08
Sustainable Anti-Icing on Cilia-Inspired Quasi-Liquid Surface Jyotirmoy Sarma and Xianming Dai; The University of Texas at Dallas, United States

Each year icing significantly impacts energy production, transportation, and human activities. For example, the entire state of Texas came to a standstill in February 2021 due to the unexpected freeze. Typically, active strategies (e.g., electrical heating elements, infrared hangars) and passive strategies (e.g., surface coatings) are used for fighting against icing. However, most of the active approaches are complex and costly. Consequently, passive anti-icing strategies relying on durable surface coatings are highly desired. The current state-of-the-art anti-icing technologies, such as liquid-infused surfaces and superhydrophobic surfaces, dramatically reduce ice adhesion strength. Nevertheless, severe durability challenges of lubricant depletion and coating damage during the ice removal process hinder their practical applications. Taking inspirations from how the mobile cilia in the bronchus of human lungs remove microbes and debris, we developed a quasi-liquid surface (QLS) coating that can effectively reduce the ice adhesion strength. QLS is made by chemically grafting flexible polymer of polydimethylsiloxane on a substrate where one end of the molecular chain is tethered to the solid substrate and the other end is mobile. These highly mobile chains of the flexible polymer with nanometer thickness serve as persistent interfacial lubrication and transfer the steady ice/solid interface to a non-sticky ice/quasi-liquid interface. This dramatically reduces the interfacial shear strength between ice and the substrate as well as provide long-term de-icing even after harsh chemical rinsing when state-of-the-art anti-icing surfaces fail. We envision that the robust QLS with sustainable ultralow shear strength to ice will provide design guidelines to the next generation anti-icing technologies that can be potentially applied on wind turbine blades, aircrafts, power lines, and vehicles.
Keywords: Anti-icing, ultralow ice adhesion, cilia-inspired, quasi-liquid surface, sustainable

4:33 PM SB09.14.09
Microbial Biotextiles for a Circular Materials Economy Theanne Schiros[1,2], Romare Antrobus[1], Delfina Farias[2], Christian Joseph[1], Shanece Esdaille[1], Yueh-Ting Chui[1], Dong An[1], Sebastian T. Russell[3], Adrian Chitu[1], Susanne Goetz[2], Anne Marika Verploegh Chassé[2], Colin Nuckolls[1], Sanat Kumar[1] and Helen H. Lu[1]; [1]Columbia University, United States; [2]Fashion Institute of Technology, United States; [3]Brookhaven National Laboratory, United States

A circular materials economy can disrupt linear production models while mitigating environmental threats. The linear economy that has been the dominant production model since the Industrial Revolution presents serious ecological and human health concerns and threatens potentially catastrophic climate instability. In particular, the textile industry is reliant on industrial agriculture for cellulosic fibers, and nonrenewable resources and petrochemicals to produce synthetic fibers, dyes, tanning and finishing agents, as well as chemically and energy intensive processing, making it one of the most polluting industries globally. We harness extracellular biosynthesis of microbial nanocellulose (MC), coupled to a protocol inspired by a serendipitous intersection between ancient textile techniques and biobased processing as a route to high-performance bioleather with a circular life cycle. Specifically, we used lecithin phosphocholine as a plasticizer to modify MC's crystallinity and cross-linking, to create a material with excellent mechanical properties and outstanding flame retardance, without introducing toxicity or compromising end of life biodegradability. A broad color palette and controlled color modulation was achieved with cultural heritage dyes and waste-to-resource strategies. Life cycle impact assessment shows up to an order of magnitude reduction in environmental impacts relative to conventional textiles, making MC relevant for widespread application in fashion, interiors, construction and insulating materials. The sustainable development of regenerative, high performance biotextiles shown here highlights how biofabrication and green chemistry can strategically address the most damaging impacts of a linear economy, as encapsulated by the fashion industry.

4:48 PM SB09.14.10
Coarsening Droplet—Hydrophilic Slippery Surface Enabled Coarsening Effect for Rapid Water Harvesting Zongqi Guo[1], Deepak Monga[1], Lei Zhang[1], Howard Stone[2] and Xianming Dai[1]; [1]The University of Texas at Dallas, United States; [2]Princeton University, United States

Water harvesting through condensation of water vapor in air has the potential to alleviate water scarcity in arid regions around the globe. When water vapor is condensed on a cooled surface, tiny water droplets are formed on the condensing surface and act as thermal barriers for further vapor condensation. Thus, water droplets must be removed rapidly for efficient water harvesting. State-of-the-art passive technologies for droplet removal rely on in-site growth and direct contact of densely distributed droplets, such as coalescence-induced jumping droplets. However, it is challenging to remove submicrometer droplets that lead to a large area of water coverage and poor water harvesting. There exists a scientific gap of droplet size evolution from nucleated droplet to shedding droplet. Here, we present a meniscus-mediated spontaneous droplet climbing and coalescence, namely a coarsening effect, to rapidly remove water droplets with diameters below 20 μm from the hydrophilic slippery liquid-infused porous surface (SLIPS). The self-propelled microdroplets move along the oil meniscus to approach and coalesce with larger water droplets. This passive droplet movement rapidly reduces the number of droplets below 20 μm and simultaneously increases the number of droplets with diameters above 150 μm. We quantitatively study the driving and drag forces for droplet movement and provide important design rationales to enhance the coarsening effect-enabled rapid droplet size evolution. The self-propelled climbing droplet on hydrophilic SLIPS shows rapid removal of droplets below 20 μm and growth of droplets above 150 μm, showing a promising mechanism compared to hydrophobic SLIPS, PEGylated hydrophilic surface, and superhydrophobic surface in water harvesting.

5:03 PM SB09.14.11
Broadband and Pixelated Camouflage by Pneumatic Actuation of Main-Chain Chiral Nematic Liquid Crystalline Elastomers with Large Poisson Effect Shu Yang, Se-Um Kim, YoungJoo Lee, Jiaqi Liu, Dae Seok Kim and Haihuan Wang; University of Pennsylvania, United States

Fishes, cephalopods, and clams can dynamically change their appearances with a wide range of hues and patterns, closely matching their respective environments for camouflage, signaling, or energy regulation. Structural colors offer many advantages over dye or pigment colors, such as brighter color, longer lifetime, and environmental friendliness. However, their tunable range is often limited by the sample's physical size and geometric constraints, making it difficult to achieve broadband, pixelated color switching. Here, we fabricate thin membranes from the main-chain chiral nematic liquid crystalline elastomers (MCLCEs) with large elasticity anisotropy and Poisson's ratio (> 0.5). We demonstrate pneumatic inflation of the thin membranes

with geometrically patterned air channels to achieve broadband color shift from near-infrared to ultraviolet wavelengths with less than 20 % equi-biaxial transverse strain. Each channel could be individually programmed as a color “pixel” to match with surroundings for on-demand camouflage.

5:18 PM SB09.14.12
Mechanical Function and Multiscale Modeling of Mycelium Based Bio-Composites Libin Yang and Zhao Qin; Syracuse University, United States

Mycelium-based bio-composites materials have been invented and widely applied to different areas including the construction industry, manufacturing industry, agriculture, and biomedical. As the vegetative part of a fungus, mycelium has the unique capability to utilize agricultural crop waste (e.g., sugarcane bagasse, rice husks, cotton stalks, straw, and stover) as substrates for the growth of its network, which integrates the wastes from pieces to continuous composites without energy input nor generating extra waste. Their low-cost and environmentally friendly features attract interest in its research and commercialization. For example, mycelium-based foam and sandwich composites are commonly used for construction structures. We are working toward combining computational simulation and experimental methods to synthesize and optimize the mechanics of lightweight mycelium composites. Our result shows that by growing mycelium in a humid environment and using the heat-press process, we can turn the mixture of hardwood and straws into a lightweight synthetic plate with a strength higher than 10 MPa, the same order as that of medium density fiberboard. It is shown that the material function of these composites can be further tuned by controlling the species of fungus, the growing conditions, and the post-growth processing methods. Our multiscale computational simulations help to explore the interface between mycelium and wood fibers and reveal that the entanglement and binding from mycelium fibers can enhance the composite mechanics and thus yield maximum strength and toughness through structural optimization.

5:33 PM SB09.14.13
Polymorphism in Hierarchical Assemblies of Coiled-Coil Building Blocks Adam Grosvirt-Dramen[1], Zachary J. Urbach[1], Fengbin Wang[2], Michal Wierzbicki[1], Paul Hurst[1], Wyeth Gibson[1], Joseph Patterson[1], Edward Egelman[2] and Allon Hochbaum[1]; [1]University of California, Irvine, United States; [2]University of Virginia School of Medicine, United States

Nature’s vast array of multifunctional proteins and peptides provides inspiration for synthetic stimuli-responsive nanomaterials. Both amino acid sequence and solution environment are key to dynamic protein folding/assembly into these multifunctional materials. Building on this foundation, novel pH-sensitive peptide-based assemblies were designed and synthesized. In this work, the assembly mechanism of a *de novo* class of Phe-Ile zipper coiled-coil peptides were studied through point mutations of the amino acid sequence and varying assembly solution conditions. The resulting structures represent polymorphic assemblies ranging from β-sheet amyloid-like fibers to highly ordered, hierarchical fibers of α-helical peptides in coiled-coil building blocks as analyzed by their cryo-electron microscopy structure. Buffer concentration and pH affect multi-scale aspects of supramolecular assembly, including peptide monomer secondary structure and interactions between hexamer building blocks. Here, the library of self-assembling peptide sequences has been expanded to include new sequences and structures that can be used to create amino acid-based biomaterials that mimic the complexity and stimuli-responsiveness of their natural counterparts.

5:48 PM SB09.14.14
Bioinspired Color-Changing and Morphing Structures with Stiffness Heterogeneity Yi Li and Xueju Wang; University of Connecticut, United States

Three-dimensional (3D) structures that can mimic the characteristics of biological systems such as camouflage, adaptivity to environment, and material heterogeneity are desired for a lot of applications. In this talk, I will discuss our recent effort in designing and fabricating bioinspired multifunctional structures by using liquid crystal elastomers (LCEs) as a platform. Color-changing and adaptive capabilities will be incorporated into LCEs that are capable of large, reversible shape changes. In addition, stiffness heterogeneity in the material will be created by utilizing the different domains of the material. Structures that resemble the shape and the functionality of a butterfly and a chameleon will be presented. The studies would provide important insights for the development of intelligent bioinspired systems.

5:51 PM SB09.14.15
Stimulus-Responsive Microphase-Separation of Resilin/Elastin Block-Copolypeptides in Solution and on Surfaces Luis Navarro[1], Justin Ryan[2], Michael Dzuricky[1], Ashutosh Chilkoti[1] and Stefan Zauscher[1]; [1]Duke University, United States; [2]U.S. Naval Research Laboratory, United States

We investigated the self-assembly of a series of stimulus-responsive block copolypeptides (BCPs) composed of a hydrophobic, resilin-like domain and a hydrophilic, elastin-like domain in the bulk and on surfaces using small-angle X-ray scattering (SAXS) and atomic force microscopy (AFM). We observed classical, microphase-separated nanostructures, such as hexagonally-packed cylinders and alternating lamella, in concentrated solutions of the block copolypeptides. The emergence of these nanostructures was strongly dependent on copolymer composition and temperature. Discrete order-order transitions were observed for higher molecular weight species, and order-disorder transitions were observed with increasing temperature for all species due to the lower-critical solution behavior of the elastin-like block. BCP thin-films also exhibited microphase-separated nanostructures that resembled those in solution and could be further refined by annealing in a high humidity environment, resulting in long-range, periodic nanostructures. Structures that form via microphase-separation of distinct polypeptide blocks can display linear peptide motifs that serve as sites for protein / peptide recognition, or enable the selective and ordered presentation of functional proteins with high spatial density.

5:54 PM SB09.14.16
Facile and Cost-Effective Fabrication of Bio-Inspired Patterned Surfaces for Multiple Applications Ravi Kant Upadhyay and Chander S. Sharma; Indian Institute of Technology (IIT) Ropar, India

The introduction of bio-inspired patterned surfaces exhibiting wettability gradient has presented a new approach towards enhancing environmental water harvesting from fog and dew. A wide range of multifunctional patterned surfaces has been designed by drawing inspiration from different natural surfaces to outperform conventional surfaces in terms of atmospheric water harvesting capacity. However, intricate and expensive fabrication is a major bottleneck that discourages the large-scale implementation of these surfaces. Therefore, efforts are ongoing to address these challenges to make the use of bio-inspired patterned surfaces more viable for practical applications. In this direction, herein, we introduce a novel facile and cost-effective fabrication approach capable of delivering multipurpose patterned surfaces with millimeter to micrometer-level precision.
Our method involves the controlled deposition of superhydrophobic carbon nanoparticles onto the masked hydrophilic or moderately hydrophobic surface for printing a predefined array of adjacent superhydrophobic and hydrophilic patterns. Unlike conventional methods such as laser engraving and photolithography, the developed method does not require any sophisticated instrumentation or costly masks. Steel mesh and PDMS sheets having carved patterns of desired shapes are successfully used as masks. To demonstrate the flexibility and wide-scale applicability of the method, we have successfully created biomimetic patterns on a wide range of substrates, including polymers and metals. These include surfaces with patterns mimicking the surface textures of Namib Desert beetle, rice leaf, and pitcher plant which have inspired many of the recent studies on water harvesting. Subsequently, we test these patterned surfaces for fog harvesting in a controlled environment to investigate the underlying mechanism of water collection and the influence of the size and shape of the patterns. Through judicious tailoring of the shapes of patterns and careful optimization of their dimensions, we are able to achieve

significantly higher fog harvesting performance compared to several state-of-the-art interfaces.
Apart from fog harvesting, we also demonstrate that the developed method can be utilized for creating channels exhibiting sharp wettability contrast for surface microfluidics applications. We show that these channels can be used for water drop manipulation, storage, and guided fluid transport. Overall, the current study not only reports a versatile method for the fabrication of bio-inspired patterned surfaces but also demonstrates the use of these surfaces for multiple applications.

SESSION SB09.15: Bioinspired Materials V

6:30 PM *SB09.15.01
Bio-Inspired Multifunctional Metaphotonic Devices for Sensing and Imaging Applications Radwanul H. Siddique, Vinayak Narasimhan, Daniel Assumpcao and Hyuck Choo; Samsung Electronics, United States

Recent progress in mobile optoelectronics and machine vision has increased the demand for advanced image acquisition and sensing technologies. Conventional optical imaging and sensing devices require bulky and sophisticated optical systems to obtain high-quality information. Over the last decades, photonic metamaterials have attracted considerable interest in various imaging and sensing applications due to their compactness and on-chip processing capabilities. However, millions of years of evolution in the biological world has developed a plethora of unique micro- and nanoscopic photonic structures to perform versatile vision and sensory functions.

In this talk, I will discuss how the development of metaphotonic devices harnessing bioinspired attributes can provide novel yet highly practical solutions for novel imaging and sensing applications. First, I will present our studies on biophotonic nanostructures found in butterfly wings that show unique optical properties with tailored structural disorder, and their successful replication in laboratories using a self-assembly based scalable nanofabrication technique. We utilize this approach to pattern Si_3N_4-based metasurfaces onto a Fabry-Perot-resonator-based intraocular pressure (IOP) sensor for glaucoma management. The metasurface integration onto the IOP sensor led to a 2.5-fold improvement in readout angle allowing easy handheld monitoring and in a one-month in vivo study conducted in rabbits, showed a 3-fold reduction in IOP error and 12-fold reduction in tissue encapsulation and inflammation, compared to an IOP sensor without nanostructures.

We will further show its application in optical wearables and contact lenses where, we developed a nanostructured scleral lens with enhanced optical, bactericidal, and sensing capabilities. The bioinspired nanostructures, made on biocompatible parylene thin-films are mounted on the anterior and posterior side of a traditional scleral lens. Compared to a traditional scleral lens, the nanostructured scleral lens minimizes glare at large viewing angles of 80^o by 4.3-fold, and block UVA light while offering greater transmission in the visible regime. Furthermore, they display potent bactericidal activity against Escherichia coli, killing 89% of tested bacteria within 4 hr in vitro. The same nanostructures conformally coated with gold are used to perform simple, rapid, and label-free multiplex detection of lysozyme and lactoferrin (protein biomarkers of chronic dry eye disease) in artificial and whole human tears using drop coating deposition Raman spectroscopy within their physiological and pathological concentration range of 0-6 mg/mL, each.

I will conclude the talk showing our recent progress on developing an ultracompact optical spectrometer for smartphones using bioinspired tricks with high angular tolerance, resolution and throughput, suitable for realization of high-performance point-of-care biosensing. Using the smartphone spectrometer, we demonstrated sub-5 nm spectral resolution, 30^o FOV, and high throughput sensing and detection.

7:00 PM SB09.15.02
A Novel Multi-Function Cylindrical Structure with Donut-Shaped Tips Hyunjung Kim and Seongmin Kang; Chungnam National University, Korea (the Republic of)

In this paper, a novel multi-functions cylindrical structure with donut-shaped tips was produced inspired from teacup-shaped mushrooms (*Nidula niveotomentosa*) which has a seed carrier function with concave structure and a chamber function with a roof. With unique structural characteristics, a cylindrical column having donut-shaped tips inside and outside the top of it was fabricated using a simple yet robust lithography method. Due to the structural properties of its donut-shaped tips, the surface on which this unique structure was formed has remarkable omniphobic properties without additional chemical surface treatment. By applying the micro-dewetting phenomenon on micro/nano structure surfaces with omniphobic properties, the NOA polymer roof was covered. The stable polymer roof formation was proved in that it has omniphobic properties without additional chemical surface treatment and its micro-chamber function was demonstrated by inserting an average of 1.5μm nanoparticles into the structure and covering with polymer roof. Consequently, this work introduces a matchless fabrication method for fabricating cylindrical structure with donut-shaped tips and proves its multi-functions of omniphobic properties and particles storage function.

A Bioinspired Solar Evaporator for Continuous and Efficient Desalination by Salt Dilution and Secretion Shuqian Zhang; Shanghai Jiao Tong University, China

In recent years, solar interfacial evaporation has been one of the most promising techniques to alleviate freshwater scarcity. However, the salt deposition on the evaporation surface limits the long-term operation of evaporators. Herein, inspired by the salt dilution and secretion mechanisms in halophytes, a solar evaporator with a bundle-cross-layer structured absorber and salt secretion bundles is reported. The unique bundle-cross-layer structure realizes the salt dilution by enhancing the water storage and transport, which enables the absorber a high and stable evaporation efficiency of 90.2% over 60 h in brine. More importantly, the salt secretion bundles can completely separate salt crystallization from the absorber by a humidity-controlled salt creeping mechanism. The solar desalination prototype equipped with this evaporator exhibited a stable water collection rate over 600 h of continuous operation, realizing zero liquid discharge in desalination. The study provides new insights into the solar evaporator design and advances other applications such as sea-salt extract, wastewater treatment, and resource recovery.

Energy Dissipation in Composites with Hybrid Nacre-Like Helicoidal Microstructures Hortense Le Ferrand; Nanyang Technological University, Singapore

Natural ceramic composites present complex microstructures that lead to tortuous crack path and confer them high toughness. Current microreinforced composites do not yet reach the level of complexity found in natural microstructures. To achieve this, we developed an automated set up for controlling 2D microplatelet orientation using magnetic fields. The setup has 4 degrees of freedom and allows fine control of platelet angles in 3D as well as position. With our setup, we can thus build microstructured porous ceramic materials (alumina) with local orientation of microplatelets, at a concentration of about 40 vol%. Other work in our group has shown that the same setup can be used to process microstructured ceramics up to 95 vol%.
Among the infinite possible microstructures, a nacre-like helicoidal arrangement was selected due to its ability to tilt and twist the crack path. Indeed, we used an analytical model based on the laminate theory to compare energy dissipation due to mixed modes of failure. Nacre-like helicoidal arrangement was predicted to exhibit the highest energy dissipation. Then, we fabricated the hybrid microstructured porous specimen fabricated and infiltrated them with a silicone matrix. Using compression tests, our hybrid dissipated 1.6 times more energy as compared to nacre-like samples of same composition. The fabrication strategy proposed here could thus be a simple route to increase the toughness of microplatelet reinforced composites.

Biomimetic Printing of Thermo-Responsive Shape Memory Polymer via Digital Light Processing (DLP) Hyun Lee and Hyun-do Jung; The Catholic University of Korea, Korea (the Republic of)

Shape memory polymers (SMPs) have been utilized for versatile applications due to their stimuli responsive behavior which recovers its original shape after deformation. Compared to shape memory metals, shape memory polymers have exhibited light weight, larger elastic region, and biocompatibility. However, the fabrication method of shape memory polymers mainly dependent on traditional strategies like molding, casting, and extrusion. Those traditional methods are limited to generate customer specific structure rapidly since additional constraint to hold the shape during hardening process of polymer solution. Regarding that, researches adopted 3D printing techniques such as direct ink writing, polyjet, and fused filament fabrication (FFF) to produce objects consisting of shape memory polymers. On the other hand, challenges in acquiring higher resolution and characteristics of usable material are still remained. Alternatively, researches have considered the utilization photopolymerizable raw materials to digital light processing (DLP) technique. Through DLP technique, layer-by-layer stacking of raw materials are possible with excellent precision and resolution. In this study, we aimed to fabricate shape memory polymers which could be facilitated to biomedical applications with biomimetic structure. Mixture of photopolymerizable soft branching material and hard branching material was cured in the aid of photoinitiator. The systematic analyses of the produced objects were carried out in terms of light power, exposure time, layer thickness, and composition. Printability was firstly assessed to determine possible candidates for printing. And degree of precision, compressive properties, tensile properties, and recovering ability were further examined using produced photopolymerized objects. Additionally, bioinspired design of certain seed was applied to SMP and its biomimetic functions was observed. *In vitro* cell tests using pre-osteoblast cells were carried out to assess feasibility of SMPs to biomedical applications.

7:49 PM SB09.15.07
Magnetic Stepwise-Organization of Periodically Arranged Micropillar Arrays Jeong Eun Park[1], Sei Jin Park[2], Augustine Urbas[3], Zahyun Ku[3] and Jeong Jae Wie[1]; [1]Inha University, Korea (the Republic of); [2]Lawrence Berkeley National Laboratory, United States; [3]Air Force Research Laboratory, United States

Self-organization of magnetic composites that mimic the collective swarming of natural living creatures has been explored as potential means of accomplishing more complicated tasks. Micron/submicron-scale composite particles can organize into chain-like morphology which allows for directionality of the magnetic response. However, organized shapes and positions could not be reproduced due to unfixed positions of the composite particles. To develop the programmable and reproducible magnetic organization of microscale objects, we introduce periodically arranged micropillar arrays consisting of elastomeric polymer/magnetic particle composites. The magnetic polarities of embedded particles are arranged from S to N pole when an external magnetic field is applied using two permanent magnets. Accordingly, the micropillars act as individual micromagnets where quadrupolar magnetic interactions occur between two vicinal micropillars. As magnetic flux density increases, two vicinal pillar-tops assemble as a pair. At higher magnetic flux density, the two pairwise-assembled micropillars further assemble into a quad-body, and long-range connectivity is ultimately accomplished. We will delve into the mechanisms and governing parameters of this stepwise magnetic-organization via a thorough look into these micropillars consisting of isotropic/anisotropic cross-sections with the directionality of an external magnetic field relative to the geometry of the micropillars.

7:53 PM SB09.15.08
Agile and Adaptable Swimming of Biomimetic Modular Magnetic Soft Robots Sukyoung Won[1], Hee Eun Lee[1], Young Shik Cho[2], Jeong Eun Park[1], Seung Jae Yang[1] and Jeong Jae Wie[1]; [1]Inha University, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

In soft robotics, agile and adaptable collective motion has been challenged due to sophisticated path programming of individual soft robots. Herein, we present multimodal collective swimming of musculoskeletal system-mimetic soft robots which can control vorticity of fluids. For agile locomotion with lightweight body, the architecture of soft robot consists of nanoporous carbon nanotube yarn (CNTY) filled with magnetic polymer composites, mimicking spongy bone and surrounding skeletal muscle. Under a pulsed rotating electromagnetic field, single magnetic soft robots swim with rectilinear translational motility or rotational motility according to the rotational frequency of the magnetic field. Multiple soft robots articulate with other soft robots owing to magnetic attraction, enabling the assembled swimming. The multiple soft robots are adaptably organized and competition between magnetic attractive force and fluid drag results in trimodal assembly: assembled rectilinear translational swimming, assembled rotational swimming, and interactive vibrational swimming. We will discuss collective swimming of the modular soft robots which can clean hundreds of microbeads and transport multiple semi-submerged millimeter-scale beads.

7:57 PM SB09.04.11
3D Liquid Collecting Surface Decorated with Hierarchically-Structured TiO_2 –Al Flakes Inspired from Plant Tissue System Sun Mi Yoon and Myoung-Woon Moon; Korea Institute of Science and Technology, Korea (the Republic of)

Numerous studies have been conducted on the functional structures of living organisms due to their unique properties derived from their intrinsic topological structures and chemistry, which apply to various applications, including nano-micro robotics, self-cleaning surfaces, and water harvesting.For example, all plants have optimized cellular structures and tissue systems for protective function and water absorption. Additionally, among plants with functional surfaces or structures, some, such as Mimosa pudica, exhibit extreme wettability, allowing for a strong self-cleaning against water drops to protect their tiny leaves, which is attributed to the well-distributed microscale clusters composed of nanoscale wax flake.
In this study, we proposed a hybrid nanocomposite of TiO_2 nanoparticle encapsulated Aluminum (Al) flake clusters by mimicking the hierarchically grown flake clusters on the leaf of Mimosa pudica. These flake clusters could be produced not only on Al and TiO_2 but also on the various surface including 3D structures such as 3D printed polymer surface. When Al substrate is immersed in a heated TiO_2 nanofluid with a three-dimensional substrate, it reacts with the hydroxyl ion decomposed water in the nanofluid to form a flake-like Al nanostructure, with TiO_2nanoparticles serving as the nucleus of the Al flakes. Due to the dual scale roughness of hierarchical Al flake clusters and the TiO_2 effect, the TiO_2-Al based flakes exhibit long-term stability (more than 90

days) in superhydrophilicity and underwater oleophobicity, whereas the Al base substrate alone exhibited mild hydrophilicity but did not last as long. Since the method to fabricate the durable superhydrophilicity and anti-oil fouling surface is simple and easy to scale up, it would have a broad range of applications in numerous industrial fields. We were able to apply hierarchical structures with long-lasting superwetting to water-transport structures and oil-collecting systems by developing multi-scale functional structures inspired by plant tissue systems such as leaf vein and xylem.

Imaging of Biological Bicontinuous Membranes—A New Tool to Learn from Nature's Versatile Membrane Forms Gerd E. Schroeder-Turk[1,2], Tobias M. Hain[3,1], Michal K. Bykowski[4], Matthias Saba[5], Myfanwy E. Evans[3] and Lucja M. Kowalewska[4]; [1]Murdoch University, Australia; [2]The Australian National University, Australia; [3]University of Potsdam, Germany; [4]University of Warsaw, Poland; [5]University of Fribourg, Switzerland

Bicontinuous membranes in cell organelles epitomise nature's ability to create complex functional nanostructures. Like their synthetic counterparts, these membranes are characterised by continuous membrane sheets draped onto topologically complex saddle-shaped surfaces with a periodic network-like structure. In cell organelles, their structure sizes around 50–500 nm and fluid nature make Transmission Electron Microscopy (TEM) the analysis method of choice to decipher nanostructural features. Here we present a tool to identify bicontinuous structures from TEM sections by comparison to mathematical "nodal surface" models, including the hexagonal lonsdaleite geometry. Our approach, following pioneering work by Deng and Mieczkowski (1998), creates synthetic TEM images of known bicontinuous geometries for interactive structure identification. We apply the method to the inner membrane network in plant cell chloroplast precursors and achieve a robust identification of the bicontinuous diamond surface as the dominant geometry in several plant species. This represents an important step in understanding their as yet elusive structure-function relationship.

9:30 PM SB09.16.02
Late News: Bioinspired Interfacial Design to Regulate the Electrical and Mechanical Properties of Inorganic Fibers and Their Applications Jing Ren; ShanghaiTech University, China

High-performance polymeric fibers with merit of lightweight, strong and tough are of great interest for various applications from functional textiles to structural composites. Carbon nanotubes (CNTs) fibers have an inherently hierarchical structure with high internal surface area approaching 100 $m^2 g^{-1}$ and provide good thermal and electrical conductivity. However, difficulties remain in the exploitation of these nanomaterials' exceptional properties on a macroscopic length scale. CNTs in a CNT fiber are interconnected by "weak link", Van der Waals forces, the properties of bare CNT fiber are far below single CNTs. In practice, the imbalance between strength and toughness not only exist in CNT fibers but also widely occurs in engineering materials. The high-strength materials, such as high-performance Kevlar and carbon fibers, are often brittle, whereas the elastic materials, such as rubbers and elastomers, possess low strength. However, certain exceptions can be observed in nature. The alternating organic-inorganic nanostructures of bone, nacre and other biological structures, are the secret to achieve an elegant balance between strength and toughness. The organic-inorganic interfaces, on the other hand, play a crucial role in improving fracture toughness and fracture resistance through energy dissipation due to breaking of mineral bridges, inelastic shear of nano-biominerals and presence of interlocking nanobuilding blocks during sliding.

Ductile and damage-tolerant CNT fibers were produced at large scale by utilizing conductive ionic silk fibroin (ISF) glue to regulate the CNTs' interface. Benefiting from the low energy barrier of solvent molecules within CNTs, the ISF glue can intercalate between CNTs interfaces and, thereby, form an alternating soft and hard interface. Consequently, the inorganic-organic cooperative interactions enhanced the performance of CNT-ISF fiber, rendering an elongation at break of 14%, toughness of 22 MJ m^{-3} and electrical conductivity of 4.4×10^4 S m^{-1}. Similar to other biological nanocomposites, the CNT-ISF fibers exhibit remarkable damage tolerance behavior due to confined CNT sliding and shearing during tensile fracture, supported by TR-SAXS characterization and MD simulations.

Besides mechanical and electric features, the composite fibers can also achieve fog collecting functions. Similar as the cactus, which uses structures and composites to collect fog and retain the water in the body. The fog first deposits on the barb and spine to form water droplets, and the larger droplets are transported along the gradient microchannel. Mucilage is present in the cells of the cactus stem, which is composed of complex polysaccharides including pectin and calcium ions. The existence of calcium ions allows pectin to form hydrogel molecular networks, capable of retaining a large amount of water to meet life activity under arid environmental conditions. The CNT-ISF yarn can capture water molecules from the surrounding foggy environment, and the spine-like microgroove structure was created on the surface of CNT yarn, which provided the driving forces for the directional movement of water droplets. The chemical and structural synergetic effects allow the fog-collecting yarn to absorb the fog, gather water, and directionally transmit the droplets to the ends of yarn.

These structure, mechanical and electric features of CNT-ISF fibers enable them to be used in functional textiles, and flexible and wearable devices.

9:45 PM SB09.16.03
Late News: Direct-Writing of Structural-Color 2D Graphics and 3D Architectures with Colloidal Inks Jong Bin Kim[1], Changju Chae[2], Sang Hoon Han[1], Su Yeon Lee[2] and Shin-Hyun Kim[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Korea Research Institute of Chemical Technology, Korea (the Republic of)

Nature has astonishing nanostructures in which periodicity is highly crystalline or amorphous exhibiting brilliant or matte structural colors, respectively. Humans have used colloids to mimic the structural colors in nature, where the periodicity is manipulated to design photonic crystals or glasses. Many researchers have used various strategies for creating structural-color patterns. However, both structures mostly require colloid-wasting, complicated, and

multistep processes, which is time-consuming especially for colloidal crystals. Inkjet printing is one of the most promising methods to solve those limitations, but it does not make monolithic structures so that it shows poor mechanical and optical properties. Furthermore, 3D architectures with structural colors have been rarely explored.
Here, we report a direct writing of two- and three-dimensional structural-color patterns using highly viscoelastic colloidal dispersions, first making their patterning highly customizable. We disperse silica nanoparticles in acrylate polymers, where the particles are repulsive as the overlap of solvation layers exerts disjoining pressure. For 2D patterns, the particle fraction in the dispersion is set right before the solid transition fraction over which the dispersion becomes solid. The high fraction brings about good printability including fluid resistance to a sudden flow and a high resolution along with a high printing speed. The particles are crystallized by a shear force when the polymer viscosity is moderate in a range of a few tens of cps. In contrast, a high polymer viscosity over 1000 cps frustrates the crystallization of particles as the high viscosity prevents particles from being sheared to find the energetically optimal state and just kinetically captured in the amorphous state.
By choosing the polymer viscosity, we can customize a photonic-crystal or -glass line pattern with the highest speed of 15 mm/s in a width-controllable manner. It is outstanding to print a 2D Eiffel tower with a dimension of 13×7 mm^2 in 10 min, of which color is either iridescent or matte according to the polymer viscosity. The rheological properties of the two kinds of inks are examined for the first time, and the analysis is directly linked to the crystallization aspect and to the final colloidal arrangement that is found to have relations with the shear history. Aside from a line, a face is direct-written by merging individual lines at a rate of 4 cm^2/min and shows the highest reflectance over 80% by thermal annealing for 10 min. Additionally, this strategy facilitates a multicolor patterning as different inks are not mixed even after being dispensed adjacently. Finally, we can target any kinds of substrates—including glass, plastic, metal, paper, and fabric—and any kinds of mechanical properties of final patterns—they can be rigid, foldable, and stretchable. Interestingly, the colloidal inks can be piled up when ethanol inhibits the solvation layer formation so that the colloids are linked in the dispersion. The dispersion loses flow resistance and becomes transparent around optimal ethanol content as ethanol disrupts the solvation layer that requires shear force to make particles slip and matches the two refractive indices. The particle content must be higher than a threshold where the colloids are close enough to be linked entirely after the solvation layer disruption, which is still much lower than the solid-transition fraction defined at an ethanol-free basis. However, a higher particle fraction is better in that printed structures retain their morphology better as the overall linkage between particles is sturdy. The matte colors are shown after ethanol evaporation, first realizing the 3D-printable colloidal glasses. To sum, direct-writing of these colloidal systems opens a new avenue for creating customizable structural-color patterns both in 2D and 3D spaces by fast and local deposition of the dispersion with programmable trajectories.

10:00 PM SB09.16.04
Mechanical Properties and fRacture Behavior of Sierpinski Carpet Fractal Composites Ya-Yun Tsai, Yuan Chiang, Jacqueline Buford, Meng-Lin Tsai, Hsien-Chun Chen and Shu-Wei Chang; National Taiwan University, Taiwan

Fractals are ubiquitous in nature. Examples include snowflakes, lightning, clouds, river networks, mountains, trees, and coastlines. Fractal geometry formed by simple components has long been applied to many fields, from physics and chemistry to electronics and architecture. The Sierpinski carpet (SC) has a two-dimensional space-filling ability and therefore provides many structural applications. However, few studies have investigated its mechanical properties and fracture behaviors. Here, to understand how fractal iterations affect their mechanical properties and crack propagation, we utilize the lattice spring model (LSM) to construct SC composites with two base materials and to simulate uniaxial tensile tests. The results show that, for either the soft-base or stiff-base SC composites, the one with two hierarchies has the optimal mechanical performance in the terms of stiffness, strength, and toughness compared to the others with higher hierarchies. The reason behind this surprising result is that the largest stress intensities occur at the corners of the smallest inclusion squares, which consequently induces crack nucleation. We also find that the main crack tends to deflect locally in SC composites with a soft matrix, but in global main crack behavior, SC composites with a stiff matrix have a large equivalent crack deflection. Furthermore, considering the inherent anisotropy of SC composites, we rotate the SC composites by 45°. The tensile strength and toughness of the rotated SC composites are inferior and the crack propagating behaviors are distinct from the standard SC composites. Moreover, the rotated SC composites have notable different crack behaviors between the soft-base and the stiff-base ones. This finding infers advanced engineering for crack control and deflection by adjusting the orientation of SC composites. Overall, our study opens the door for future engineering applications in stretchable devices, seismic metamaterials, and structural materials with tunable properties and hierarchies.

10:15 PM SB09.16.05
Spatiotemporal Matter in Meniscus Splitting of Viscous Fluids for Mathematical Models Yoshifumi Katsushima[1] and Kosuke Okeyoshi[2]; [1]Aoyama Gakuin University, Japan; [2]Japan Advanced Institute of Science and Technology, Japan

‘Viscous fingering’ is an example of fluidic flow, an unstable situation that is widely known as tears of wine. This has been explained through the Marangoni effect, coffee ring effect, Saffman-Taylor instability, etc. However, because of the transitional nature of these phenomena, there are difficulties to utilize such fluidically regulated interfaces for preparation of materials. The interfacial instability is comparable to the mechanical instability of gels at the phase transition or to the skin layer of gel surfaces during shrinking. For establishing a universal model of dissipative structures in nature, investigation of biopolymer’s behaviors in air-water interface is an important practical challenge. Recently, the phenomena have been successfully developed to an ordered structure by controlling the evaporation of an aqueous mixture of polysacccharides.[1] Furthermore, by introducing crosslinking points into the deposited polymer, it has huge potentials to use for uniaxially swellable hydrogels.
In this study, we present a brief discussion of nonequilibrium phenomenon, ‘meniscus splitting’ through mathematical approaches. As an experimental model, when the mixture is dried from a top open cell with a millimeter-scale gap, the polymer forms deposits at specific positions to split the air-water meniscus by bridging the gap. Because water irreversibly evaporates to the air phase through a gap, the air-water interface is in a nonequilibrium state between polymer deposition and water evaporation. As a result, the air-liquid interface is divided into multiple interfaces to partition a space. Based on such facts, the interface from the cross-sectional view are focused for the mathematical modeling. The interfacial curves at the typical times for the meniscus splitting are ideally expressed using catenary curves. By validating the length of the multiple curves, the area of the evaporative interface would be evaluated. We envision that this mathematical approach will help general understandings for the phenomena and design of advanced materials independent from kind of substances.

10:30 PM SB09.16.06
Space-Filling Open Microfluidic Channels with Two-Dimensional Fractal Wettability Patterning for the Efficient Droplet Collection Hiroyuki Kai; Tohoku University, Japan

Fractal structures are ubiquitous in biology, such as blood vessels, plant leaves and roots, etc. They are designed for the efficient contact with a larger volume by a smaller length and fewer branches as well as the efficient transport. In the field of microfluidics, the open microfluidic channel, which is made of a patterned surface with different wettability properties, has been studied for trapping and unidirectional transport of aqueous droplets by capillary force. We developed open microfluidic channels with fractal branching that densely fill a substrate surface (H. Kai et al., RSC Adv. 2018, 8, 15985; H. KAI, MicroTAS 2020). It can collect water droplets from a wide area of the surface to the center by hierarchically repeated transport and fusion of the droplets.

The developed space-filling open microfluidic channels are reminiscent of fractal biological systems, both of which can efficiently contact a larger volume (or area in the case of two dimensions).

The microfluidic channels were fabricated by coating the substrate surface followed by photolithographic patterning. A film of polyethylene terephthalate was coated with a mixture of titanium oxide nanoparticles and Capstone (R) ST-100 fluoroacrylate copolymer to make the surface superhydrophobic (the contact angle of water droplet > 150°). The coated film was irradiated with 365 nm UV light through a photomask, where the only irradiated area turned superhydrophilic (contact angle ~ 0°), to obtain the open microfluidic channels with wettability patterning.

The droplet collection efficiency of the microfluidic channel was investigated by spraying water droplets into the channel and observing the volume of the water droplets collected in the center of the channel. Various photomasks were designed with the different numbers of branching, and the efficiency of water droplet collection was compared. As the number of repeated branching ("generation number") was increased, the collection efficiency monotonically increased up to the generation number of eight, where the efficiency reached 74%±9%. This indicated the effectiveness of the space-filling structures by fractal branching. In addition to the above experiment, we also conducted the computational fluid dynamics simulation to systematically understand the dynamic behavior. Details of the simulation methods as well as the comparison between the numerical and experimental results will be presented.

SESSION SB09.17: On-Demand

8:00 AM SB09.04.04
Anisotropic Liquid Sliding Velocity Controllable Surfaces with Bioinspired Nanoparticles Composites Joon Hyung An, Jiseong Choi and Seongmin Kang; Chungnam National University, Korea (the Republic of)

In this work, we fabricated omniphobic structural surface with the property of anisotropic droplet sliding using a composite of nano sized ceramic particles and polymers. Inspired by rice leaves, the micro-scale overhang groove structures exhibit omniphobic property and determines the sliding direction of the droplets. The polymer except for the mineral particles on the prepared surface was selectively etched through UV ozone etching treatment, and as a result, nano-bump morphologies were partially exposed. A reliable criterion was presented for the formation of nano-bumps that control the sliding velocity of droplets. It was confirmed that the sliding velocity of various types of liquid droplets with different surface tensions was also controlled according to the exposure level of nanoparticles.

8:05 AM SB09.08.06
Bacterial Pigments as Potential Photosensitizers for Dye-Sensitized Solar Cells Arshi Gupta[1,2], Mukul Dubey[2,1], Wenrong Yang[1], Fred Pfeffer[1], Xavier Conlan[1] and S.V. Eswaran[2]; [1]Deakin University, Australia; [2]TERI Deakin Nanobiotechnology Centre, India

The dye-sensitized solar cells based on synthetic Ruthenium dyes and organic metal-free dyes are widely recognized, however, their toxicity, scarce availability of raw material, high cost, and complex synthesis procedures have been a limitation [1]. This led to the exploration of nature-based dyes. Metabolites from plants such as chlorophyll, carotenoid, flavonoid, and betalains have been tested in dye-sensitized solar cells (DSSC) [2] but their narrow absorption spectrum, absence of functional groups to bind strongly with semiconductor [3], and non-availability of the electron-withdrawing group to achieve efficient intramolecular charge transfer (ICT) [4] resulted in low-efficiency of solar cells, also these metabolites have drawbacks such as low photo and thermal stability [5]. On the other hand, microbial metabolites have additional advantages over plant-based metabolites such as broad sunlight absorption [3], good photostability [6], non-toxic properties [7], and the ability to be produced in bulk through bioreactor approach [8]. There are more than 22000 microbially generated bioactive metabolites reported to date [9] which can be potentially explored for their application in solar cells. However, only a few reports are available on the use of microbial pigments in dye-sensitized solar cells [3] with the highest power conversion efficiency (PCE) of 2.3 % for monascus yellow [10] which is very encouraging. Though this research is in its infancy it shows the promise of these sensitizers for solar cell applications. In our research, purified bacterial cultures were isolated from roots of eggplant, chili, sweet potato, and okra plant, and the extracellular pigments extracted and were characterized for their structural, optical, and electrochemical properties. The initial data showed broad absorption in the range of 350 – 600 nm, presence of functional groups required for binding with the semiconductor, and HOMO-LUMO levels required for favorable charge transport in solar cells. The data clearly indicated the promise of microbial pigment as suitable photosensitizer for solar cell application.

Biomaterial Strategies with Silk Nanoparticles and Nanofibers David L. Kaplan; Tufts University, United States

Silk proteins represent unique protein polymer systems due to their regular peptide repeats with block-copolymer features, along with self-assembly in aqueous, ambient conditions into secondary and higher order structures. In nature, this process leads to unique hierarchically structured and functional fibers with remarkable mechanical properties. Generating insights into the nanoscale features of these systems has generated a new range of material features that can be exploited towards structural and functional biomaterials based on silk. Specific polymer processing paths include exfoliation to generate natural silk nanofibers as building blocks for new materials and generating silk amorphous nanoparticles as feedstocks towards commodity plastics processing using silks. In both cases, the critical features are the silk nanostructures and water content, related to mechanics, processability and functional outcomes. Specific examples will be discussed to highlight these new opportunities with this ancient polymer.

Dual-Crosslinked Alginate-Based Hydrogels as Cell Instructive Scaffolds for Cultured Meat Irfan Tahir and Rachael Oldinski-Floreani; The University of Vermont, United States

Introduction: With the rising harmful effects of climate change, a novel, emerging field of technology called cellular agriculture has arisen to explore 'cultured meat', an artificial meat substitute developed *in vitro* using animal cells and bioengineered cell scaffolds. Cultured meat is an advantageous alternative to traditional animal agriculture, which is not sustainable in a world with a rising human population and growing meat consumption rates. Plant-based alginate scaffolds can be used to support the development of cultured meat due to their high degree of chemical and mechanical tunability, which can be optimized by adjusting the hydrogel's molecular weight, chemical composition, and cross-linking process. In this project, our goal was to create a dual-crosslinked alginate-based scaffold with material properties that supported tissue development of primary bovine muscle cells, with the overall goal of achieving a cultured steak for human consumption. **Methods:** Herein, we synthesized: 1) methacrylated alginate (Alg-MA) using aqueous chemistry to enable covalent crosslinking via visible light exposure, and 2) arginine-glycine-aspartic acid (RGD) conjugates (Alg-MA-RGD) using carbodiimide chemistries to provide cell-binding sites onto the material. Alginate-based hydrogels of different concentrations (1% and 3%, w/v) and cross-linking types were created. Ionically crosslinked hydrogels were made by injecting the hydrogel precursor solutions into custom molds of 8-mm diameter. The molds and solutions were frozen for two hours at -20 °C, and then crosslinking by adding 1M calcium chloride ($CaCl_2$) dropwise onto the mold. Photo-crosslinked alginate-based hydrogels were made by injecting hydrogel precursor solutions premixed with 1mM eosin Y (photo-sensitizer), 125 mM triethanolamine (photo-initiator), and 20 mM 1-vinyl-2-pyrrolidinone (catalyst) in a custom mold and exposed to green light (525 nm, SuperBrightLEDs) for five minutes. Dual cross-linking was achieved by combining the two types where photo-crosslinking preceded ionic crosslinking. The crosslinked alginate scaffolds were characterized using proton nuclear magnetic resonance (^{1}H-NMR), Fourier transform infrared (FTIR) spectroscopy, rheometry, and unconfined uniaxial compression tests. **Results and Discussion:** We demonstrated that modifying the material structure chemically and physically via different crosslinking techniques resulted in differences in the material properties between groups, such as gelation kinetics, viscosity, and scaffold stiffness. For the alginate precursor solution, we were able to obtain low enough viscosity values (0.02 – 0.06 Pa.s) to enable processing via photolithography. The gelation time of the different materials did not vary broadly, although the shear and compression moduli demonstrated significant differences between groups. Ongoing work includes: 1) scaffold structural analysis via scanning electron microscopy (SEM); 2) murine C2C12 and primary bovine muscle cell response and myogenic differentiation on the alginate scaffolds, and investigating the effects of stiffness, pore size, and chemical composition. **Conclusion:** Our unique method of synthesizing alginate hydrogels and the associated pilot data indicates the efficacy of dual-crosslinked alginate-based hydrogels for the production of cultured meat.

Applications of Nanofibers in Building Biological Tissues Kevin K. Parker; Harvard University, United States

The networked architectures that maintain the structural integrity and function of biological tissues are nanofibrous arrays of proteins. We have developed three manufacturing platforms (rotary jet spinning, immersion rotary jet spinning, and pull spinning) as methods of building nanofiber networks of biological and synthetic polymers to mimic the function of the extracellular matrix. We have used these methods to build 3D tissues for in vitro assays, heart valves for implan, wound dressings for skin, cardiac ventricles, and food. This presentation will review the design principles and lessons learned of these works.

Engineering Shape Morphing Biomaterials That Respond to Light Fiorenzo Omenetto; Tufts University, United States

Light and materials interact in natural systems with exquisite precision through a designed interaction between electromagnetic waves and the physical properties of the material, both from the bulk and structural point of view. In particular, structural control over multiple length scales, that span from the nanoscale to the macroscale, defines interesting material responses that enable high-performing functional outcomes in light harvesting, reflection, and thermal management among others. We describe here strategies for light harvesting and optomechanical actuation in hybrid biomaterial-elastomeric composites that leverage rationally designed photonic architectures to obtain wireless, light-responsive material formats. The combination of photonic properties designed at the nanoscale with shaped elastomeric material hosts open opportunities in optomechanical actuators with tunable and complex deformation that respond to simple light illumination. The talk will cover some of the potential opportunities for future development of composite materials that are inspired by Nature's ability to harvest light and explore possible classes of smart optomechanical systems that move with light on demand without the need for external sources of power.

2:00 PM SB10.02.03
Metal Ions Regulated Peptide Self-Assembly as Nanocarriers for Plant Micronutrients Hui Sun, Federica Rigoldi and Benedetto Marelli; Massachusetts Institute of Technology, United States

Metal ions play an essential role in many physiological and pathological processes in living systems. Approximately one-third of all proteins currently known require metal ions as cofactors for their structural integrity and biological function. For example, iron is a cofactor of several metalloproteins involved in chlorophyll synthesis and photosynthetic electron transport. Deficiency in iron therefore induces chlorosis and other plant disorder, lowering crop yields drastically.
Peptides are known to exhibit a variety of interactions with metal ions, due to the wide range of functional groups they possess. Metal-binding peptides then attracted a lot of attention as a potential material platform for nanofabrication of organic-inorganic composites built from the bottom up. Besides, coordination with metal ions may induce peptide association into nanostructures that are conformationally and functionally different from the original peptide assemblies. In this presentation, we show that the self-assembly pathway of a silk fibroin-derived peptide can be regulated through addition of differently charged metal ions. Atomic force microscopy (AFM) in combination with a set of correlative light scattering and spectroscopy techniques are employed to investigate the detailed mechanism of peptide assembly facilitated by different metal ions. Factors including the molar ratio of peptides to metal ions and the charge and type of metal ions are found to largely affect the peptide association kinetics and the size and structure of peptide assemblies at equilibrium. Such understanding can hopefully contribute to the design and development of peptide-based nanocarriers for stabilization and delivery of micronutrients in plants.

Innovating and Characterizing Bioinspired Soft Materials—Multiscale Molecular Modelling and Machine-Learned Metamodels Jingjie Yeo, Chenxi Zhai, Tianjiao Li, Haoyuan Shi and Liming Zhao; Cornell University, United States

Globally, rapidly aging human populations are significantly accelerating the occurrence of non-communicable diseases. Understanding the fundamental mechanisms of tissue damage due to aging can provide predictive capabilities that will inform medical treatments. Coupled with this understanding, nature-inspired dynamically responsive biomedical devices and implants can address this major health crisis due to their excellent environmental adaptability and biocompatibility. Developing such novel biomaterials further necessitates multiscale computational modelling and simulations to fundamentally understand the pertinent physical, chemical, and biological material properties. We apply multiscale molecular modelling and machine-learned metamodels to characterize aging-related diseases and engineer various candidate materials on multiple fronts: (I) collagen-related morbidities, (II) dynamically-responsive silk and silk-elastin-like materials, and (III) viscoelastic mechanical properties of soft polymers. Through this approach, we unveil the myriad material properties of mutant collagens, as well as chemically and physically processed silk-based materials. We also rapidly and efficiently determine the material parameters of constitutive models governing the time-dependent behavior of soft polymers.

2:30 PM SB10.02.05
Compact Peptoid Molecular Brushes for Nanoparticle Passivation Shih-Ting Wang[1], Honghu Zhang[1], Sunting Xuan[2], Dmytro Nykypanchuk[1], Yugang Zhang[1], Guillaume Freychet[1], Benjamin Ocko[1], Ronald N. Zuckermann[2], Nevena Todorova[3] and Oleg Gang[4]; [1]Brookhaven National Laboratory, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]RMIT University, Australia; [4]Columbia University, United States

Controlling the interface of colloidal nanoparticles (NPs) via tethered molecular chains of defined passivation properties is crucial for NP applications in electronics, optoelectronics, catalysis, and nanomedicine. There is an urgent need for a flexible system to vary the chemistry and structure of these interfacial molecules in a systematic and pre-determined way to improve control over NP stability and functionality. Here, we report low molecular weight, bifunctional comb-shaped, and sequence-defined peptoids that effectively passivate gold NPs (AuNPs). Each peptoid (PE) is designed with a multivalent NP-binding domain and a solvation domain consisting of branched oligo-ethylene glycol (EG) and varied in arrangements. We find that a diblock arrangement provides superior colloidal stability in varied salt and ionic aqueous solutions yet form a compact layer on the NP surface only ~1.5 nm thick. We further demonstrate by experiments and molecular dynamics simulations that the PE-coated NPs (PE/NPs) are stable in select organic solvents owing to the strong PE-Au binding and solubility of EG motifs. Finally, the PE/NPs can self-assemble into organized 2D lattices at the air-water interface with small lattice constants (~6 nm) due to the thin PE surface layer. The versatility and designability of peptoid architectures for NP passivation render an

attractive approach for nanomaterial-based (bio)technologies, in which precise control over size, surface property and stability are key.

Dynamic Materials Inspired by Cephalopods Alon Gorodetsky; University of California, Irvine, United States

Cephalopods (e.g., squids, octopuses, and cuttlefish) have captivated the imagination of both the general public and scientists alike due to their sophisticated behavior and stunning camouflage abilities. Given such characteristics, it is not surprising that these marine invertebrates have emerged as exciting models for novel materials and systems. Within this context, our laboratory has focused on the development of cephalopod-inspired biomaterials and platforms with unique electrical and optical properties. Our findings hold implications for next-generation bioelectronic devices and biomedical imaging technologies.

Sustainable Nanotechnology—Bio-Inspired, Nature Derived and Non Toxic Nanomaterials for Agri-Food Applications Philip Demokritou and Tao Xu; Harvard University, United States

Sustainable nanotechnology is an emerging field of interdisciplinary research that focuses on the development of “green” and non toxic nanomaterials and technologies that can be used to tackle major societal challenges in various fields and applications. Maintaining food safety and security for the increasing global population is one of the most important challenges of the 21st century with major societal, environmental and public health implications.
This seminar will present highlights from our current sustainable nanotechnology research in the agriculture and food domain. Projects include among other the development of green, nano-carrier platforms for targeted precision delivery of nature-derived antimicrobials for food safety applications using engineered water nanostructures (EWNS) synthesized using electrospray and ionization processes, EWNS exhibit unique physicochemical properties, are highly mobile due to their nanoscale size and can interact and inactivate food related pathogenic and spoilage microorganisms on surfaces and in the air. In addition, the development of “smart” or stimuli responsive, non toxic and biodegradable antimicrobial packaging materials will be presented. Food packaging plays a key role as it has a great potential to improve food safety and quality and reduce food waste across the “farm to the fork” continuum.

4:30 PM SB10.03.02
Manipulating the Motion of Discretized Droplets with Laser-Microstructured Copper Substrates Decorated with Nanohair-Like Texture Athanasios Milionis, Christos Stamatopoulos, Norbert Ackerl, M. Donati, Paul Leudet de la Vallée, Philipp Rudolf von Rohr and Dimos Poulikakos; ETH Zurich, Switzerland

Transport of small liquid volumes (few and sub droplets) is a desired functionality for a wide range of applications, such as microfluidics, lab-on-chip devices, water collection from the atmosphere, etc. In general, liquid transport is usually achieved through the use of pumping devices, or external fields (electromagnetic, acoustic, optical, etc.) working collaboratively with special fluid or surface properties to enable fluid motion (e.g. ferrofluids or photosensitive substrates). On the other hand, passive droplet transport methods are more attractive compared to the active ones, due to the absence of the need for energy input and their inherent facility.
In addition, another common problem at small scales is the natural liquid adhesion of droplets on surfaces, which deters motion, induces high variation in the transported fluid mass, while the adhered fluid residues also cause surface contamination. Most of the developed passive fluid transport approaches, fail to resolve this issue, as they typically transport fluid in the form of a liquid film rather than discretized droplets. Therefore, still, significant advancements are needed before devices for passive liquid propulsion, without the input of external energy and unwanted contamination, become a reality in applications. In this work, we present an unexplored, bioinspired by the water strider leg surface architecture, scalable, and facile material design approach based on laser micromachining process of copper in the shape of a backgammon-like pattern, followed by chemical growth of copper hydroxide nanoneedles functionalized with a thiol to impart superhydrophobicity. The combined effect of the Laplace-pressure-imbalance and surface superhydrophobicity is able to passively drive droplet motion while maintaining the limited contact of the Cassie-Baxter state on superhydrophobic surfaces. The backgammon-like micro-topography design naturally deforms asymmetrically the menisci formed at the bottom of a spherical droplet and causes a Laplace pressure imbalance that drives droplet motion. We investigate this effect over a range of opening angles (1°, 5°, and 9°) and develop a model to explain and quantify the underlying mechanism of droplet self-propulsion.
We further implement the developed bioinspired topography for applications relevant to microfluidic platform functionalities. In particular, we explore lateral droplet motion and measure the droplet velocity during its self-propulsion (up to 40 mm/s for opening angle 9°), as well as the force acting on the droplet meniscus as it deforms at the solid-liquid interface(up to » 5 μN). Additionally, we achieve controlled rebound angles after droplet impact on the substrates up to $\omega = 8°$, droplet merging, and long-distance droplet transport without mass loss. Furthermore, we demonstrate spontaneous droplet merging of droplets that are released simultaneously. The merging occurs very fast (in a few hundreds of ms) and it is aided by the underlying backgammon-like structures. Finally, we achieve horizontal self-transport to distances up to 65 times the droplet diameter and even show significant uphill motion against gravity, which to our knowledge is the longest traveling distance reported for discretized droplets by using fully passive means.

SESSION SB10.04: Poster Session I: Biomaterials in Medicine, Food and Agriculture

Aptamer-Gold Nanoconstruct Coated with Polymer for Scavenging ROS and Capturing Proinflammatory Cytokine TNF-α Jinseong Kim[1], Hyeongmok Park[1] and Won Jong Kim[1,1,2]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]OmniaMed Co, Ltd., Korea (the Republic of)

In this study, we designed a unique aptamer-gold(Au) nanoconstruct coated with polymer capable of scavenging reactive oxygen species(ROS) and capturing tumor necrosis factor alpha(TNF-α) as anti-inflammatory agent for the treatment of peritonitis. Polymer-coated Au nanoconstruct equipped with TNF-α aptamer and ATP aptamer is constructed by interaction between ATP and both ATP aptamer and polymeric phenylboronic acid (pPBA). The phenylboronic ester formed in the nanoconstruct can scavenge ROS and TNF-α aptamer can capture proinflammatory cytokine TNF-α. ROS-responsive removing of pPBA from nanoconstruct with high ROS scavenging capacity, and high TNF-α capturing ability of nanoconstruct are investigated. Thus, these combined properties enable the nanoconstruct an additive anti-inflammatory effects. We demonstrated the high anti-inflammatory effects of the nanoconstruct in vitro and in vivo peritonitis model by monitoring ROS and pro-inflammatory cytokine levels.

SB10.04.02
Hydrogel-Based Artificial Cell (hAC) for Multipotent Cancer Immunotherapy Yunjin Chae[1], Kang-Gon Lee[2], Yongdoo Park[2] and Jongseong Kim[2]; [1]Scholar Foxtrot, Korea (the Republic of); [2]Korea University, Korea (the Republic of)

Cancer immunotherapy is a clinical strategy that acts on antitumor responses by invigorating the immune system to attack cancer cells. In the treatment of cancer, immune checkpoint inhibitors, i.e. mAbs binding to cytotoxic T lymphocyte antigen 4 (CTLA4), programmed cell death 1 (PD-1), or PD-1 ligand (PD-L1), neutralize the evadability of cancer cells against the immune system. However, this powerful therapy is hampered by expansive cost for the treatment, as well as by limited efficacy only responding to some patients. Here we show the development of hydrogel-based artificial cells (hAC) that potentiate cancer treatment by increasing the efficacy of bispecific immunotherapy targeting to CTLA4 and PD-L1 simultaneously. The conformation of hAC is characterized by a responsive soft hydrogel nanoparticle consisting of *N*-isopropylacrylamide-*co*-acrylic acid, antibody binding protein (protein A), and two immune checkpoint inhibitor mAbs (CTLA4 mAb and PD-L1 mAb, respectively). We demonstrate that the use of hAC significantly decreases the survivability of MCF-7 cancer cells in vitro and suppresses the growth of MCF-7 derived xenografts in vivo in comparison to the mAb treatment by itself. Our result also suggests that the bispecific hAC is more potent to treat cancer cells than monospecific hAC which is conjugated with either CTLA4 mAb or PD-L1 mAb alone. The advantage of hAC over current bispecific antibodies arises from their adaptability to link multiple antibodies in easy and fast, enabling the hAC system for rapid validation of bispecific antibodies in cancer treatment. Our finding has an important implication that hAC-based cancer immunotherapy opens a new paradigm not only to treat cancer but also to evaluate bispecific antibodies.

SB10.04.03
Development of Protein-Based Photo-Electrodes for Retinal Prosthesis Stephanie Monge[1], Ricardo Starbird[2], Juan J. Montero[2], Dariana Aguilar[1], Alexandra Tames[1], Sebastián León[1], Enrique Quiroga-Gonzalez[3], Ashok Mulchandani[4], Renugopalakrishnan Venkatesan[5,6] and Claudia Villarreal[1,7]; [1]Instituto Tecnológico de Costa Rica, Costa Rica; [2]Tecnológico de Costa Rica, Costa Rica; [3]Benemérita Universidad Autónoma de Puebla, Mexico; [4]University of California, Riverside, United States; [5]Harvard Medical School, United States; [6]Northeastern University, United States; [7]University of California, United States

Retinal prostheses are a promising technology in the field of visual restorative medicine for the treatment of patients with severe stages of retinal degenerative diseases. The highly stable light-activated proton pump bacteriorhodopsin (bR) has a great potential to be used in the fabrication of electrodes for artificial retinal implants due to its optical and photoelectric properties. Its usage in the generation of a photoelectrical signal can show remarkable performance in responsivity and quantum efficiency. In the present work, it is shown the development of a bR-sensitized photoelectrode for its future application in a retinal prosthesis. The study is aiming at analyzing the photovoltaic performance of a photoreceptor cell fabricated with a bR photoanode integrated with different low-cost and carbon-based cathodes of 3,4-ethylenedioxythiophene (PEDOT), graphene, carbon nanotubes, and their hybrids. The protein is immobilized on ITO covered by TiO2 by drop-casting and electrophoretic deposition. The cell is tested using a hydroquinone/benzoquinone-based redox electrolyte. Linear sweep voltammetry, open-circuit voltage decay, and electrochemical impedance spectroscopy are measured under dark and illuminated conditions to determine the influence of different parameters in the function of the bR-sensitized photoelectrode. A mathematical model of the bR-cell equivalent circuit is fitted to the experimental data to further elucidate charge transfer resistance and frequency in the different interfaces of the device. The biological photoreceptor could significantly contribute to reduce and replace traditional costly and harmful materials used in conventional photovoltaic technology with renewable carbon-based alternatives; which could decrease the cost, enhance its performance, and improve the device biocompatibility and sustainability.

SB10.04.04
Self-Assembly of Charged Amphiphilic Oligomers at the Liquid-Liquid Interface—Insights from Vibrational Sum Frequency Generation Spectroscopy and Molecular Dynamic Simulation Zening Liu, Lu Lin, Tianyu Li, Jan-Michael Carrillo, Benjamin Doughty, Charles Patrick Collier, Kunlun Hong, John Katsaras and Jesse Labbe; Oak Ridge National Laboratory, United States

Knowing the conformational states of amphiphilic molecules at liquid-liquid interfaces is important for understanding the underlying mechanisms governing interfacial phenomena, including adsorption/desorption dynamics, membrane assembly, and domain formation. Previously, using vibrational sum frequency generation spectroscopy (SFG), we found that a series of simple inorganic anions in aqueous solution at a buried hexadecane-water interface profoundly affected the self-assembly of monolayers of charged, amphiphilic oligomers consisting of ionic liquid (IL) headgroups covalently bonded to hydrophobic tails (oligodimethylsiloxane imidazolium cation (ODMS-MIM$^{(+)}$), *J. Amer. Chem Soc.* **142**, 290-299 (2020)). Elucidating how aqueous counterions alter the interfacial density of the charged IL headgroups will be critical for understanding monolayer formation at the interface. This talk will describe our use of a liquid-liquid Langmuir trough for controlling the interfacial pressure of the ODMS-MIM$^{(+)}$ monolayer at the oil-water interface in conjunction with SFG and molecular dynamic simulations. This enables us to characterize how changes in molecular area correlate with conformational changes of the tails and packing of the oligomers in the membrane during assembly, with and without electrostatic interactions with the counterions. The ability to control the packing of the charged oligomers with compression independently from specific ion effects and ion pairing interactions offers new insight into the mechanisms for amphiphile adsorption, membrane structural changes, and hydrogen bonding at the interface that can inform strategies for controlling chemical reaction dynamics at liquid-liquid interfaces.

SB10.04.05
High-Aspect Ratio Cassettes for Rapid Vitrification of Organisms Justyna Jaskiewicz[1], Derin Sevenler[1], Denise Dayao[2], Anisa Swei[1], Donald Girouard[2], Giovanni Widmer[2], Saul Tzipori[2], Mehmet Toner[1] and Rebecca D. Sandlin[1]; [1]Massachusetts General Hospital/ Harvard Medical School, United States; [2]Tufts University, United States

Infection with protozoa of the genus *Cryptosporidium* is a leading cause of child morbidity and mortality associated with diarrhea in the developing world.

As a zoonotic pathogen transmitted from cattle it is an important threat to public health with its potential for waterborne and foodborne dissemination. Research on this parasite has been impeded by many technical limitations, including the lack of cryopreservation methods. Consequently, laboratory strains of *Cryptosporidium* must be maintained by propagation in susceptible animals every 6–8 weeks, an expensive and time-consuming process. It is parasite sensitivity to formation of ice and limited permeability to cryoprotectants (CPAs) that precludes utilization of classical methods of slow cooling. To address this gap, a vitrification protocol was considered as an ice-free alternative for cryopreservation. Vitrification, unlike slow cooling, utilizes high intracellular concentrations of cryoprotectants combined with rapid cooling rates to achieve formation of an amorphous glassy solid devoid of ice crystals, thus protects cellular systems during cooling. Because of CPA toxicity, the vitrification field has moved toward the development of containers that enable extremely rapid cooling rates and thus vitrify with lower concentrations of intracellular CPA. In consequence of the reduced thermal mass, these containers are restricted to small volumes limiting widespread implementation of vitrification in clinical and research setting. To address this bottleneck, we developed a cryopreservation protocol that enables increased sample volume through the design and manufacture of a novel polycarbonate high aspect ratio specimen container referred to as 'vitrification cassette'. This strategy increases the volume of a single cryopreserved sample by 50-fold up to 100 µL compared to the previously reported methods using 2 µL microcapillaries. The high surface area to volume ratio of vitrification cassettes allows to maintain cooling rate at ~10,000 °C/min and supports vitrification of 30% DMSO/ 0.8 M trehalose extracellular cocktail solution. Due to the increase of CPA concentration required for glass formation, toxic effects were mitigated by application of step-wise CPA addition protocol. These cassettes were shown to support preservation of viable and infectious *Cryptosporidium* oocysts. Oocysts cryopreserved using cassettes exhibit viability at ~75%, maintain in vitro infectivity, and are infectious to interferon-gamma (IFN-γ) knockout mice (*C. parvum*) and gnotobiotic piglets (*C. hominis*). Importantly, the course of the infection is comparable to that observed in animals infected with unfrozen oocysts. Vitrification of *Cryptosporidium* oocysts in larger volumes will expedite progress of research by enabling the sharing of isolates among different laboratories and the standardization of clinical trials. Vitrification cassettes allow to obtain multiple inocula from a single cryopreserved sample thus overcoming a major bottleneck in the development and testing of therapeutics and vaccines for the treatment and prevention of cryptosporidiosis. This technology is readily available for translation to other cellular systems.

SB10.04.06
Late News: Brain Tumor Imaging Using Magnetic Particle Imaging (MPI) Hamed Arami, Chirag Patel, Edwin Chang, Jianghong Rao and Sanjiv Sam Gambhir; Stanford University, United States

Routine glioblastoma multiforme (GBM) imaging in clinics are based on using gadolinium-based magnetic resonance imaging contrast agents. However, using these gadolinium-based contrast agents raises major concerns for GBM patients suffering from chronic kidney disease, which can be resolved by using nanoparticle contrast agents that do not show any renal clearance due to their larger size. Here, we will demonstrate how a new imaging technique, called magnetic particle imaging (MPI) can be used for safer GBM imaging. We have investigated our approach for imaging of several types of brain tumors with different levels of aggressiveness, to identify the feasibility of this method in different brain tumor microenvironments. First, we developed methods for tuning iron oxide nanoparticles (NPs) to generate high resolution (i.e., ~600 µm) MPI images with ultra-high contrast agent mass sensitivity of less than ~550pg Fe/µL. Then, we used MPI for three-dimensional targeted imaging of the orthotopic brain tumors in mice after intravenous injection of these NPs. Iron oxide nanoparticles have been approved by FDA for several clinical applications and we hope that this method will ultimately find clinical applications for safer GBM imaging.

SB10.04.07
Captured the Biophotons to Precisely Activate Chlorin e6 for Photodynamic Therapy Hao Yan[1,2] and Seok-Hyun A. Yun[1,2,3]; [1]Massachusetts General Hospital, United States; [2]Harvard Medical School, United States; [3]Massachusetts Institute of Technology, United States

The clinic utilization of photodynamic therapy (PDT) to treat cancers and malignant diseases has recently gained increasing attention. However, the shallow penetration of activated light, the concern of biosafety for new light delivery methods, and the risks of stimulating invasion and metastasis because of incomplete phototherapy have limited the further applications of PDT in deep tissues. Here we present a bioluminescence (BL) energy-induced PDT (BL-PDT) platform through conjugating sufficient clinic-approved photosensitizer chlorin e6 (Ce6) into the surface of luciferase, which can capture most of the biphotons and precisely activate Ce6 to produce reactive oxygen species (ROS). After largely entering cells, the conjugate (named Luc8-Ce6) produced very considerable intracellular ROS and induced cancer cell death. At the same time, the therapeutic efficiency is comparable to Laser-PDT using the same PS and moderate power. The further *in vivo* studies showed that the conjugate-based BL-PDT resulted in complete tumor remission, prevented the following metastasis in lymph nodes and lungs, and obtained potent neo-adjuvant antitumor efficacy for triple-negative breast cancer tumor after intra-tumoral injection. Our results offer a way to efficiently harness the low energic bioluminescence to achieve noninvasive, depth-independent, and widely applicable phototherapy.

SESSION SB10.05: Nanocarriers and Nanosensors
Session Chair: Benedetto Marelli
Wednesday Morning, December 1, 2021
Sheraton, 2nd Floor, Back Bay C

10:30 AM *SB10.05.01
Applications of Nanomaterials for Agriculture and Plant Biology—Nanocarriers and Nanosensors Michael S. Strano; Massachusetts Institute of Technology, United States

Our laboratory at MIT has been interested in exploring the relatively new interface between living plants and non-biological nanostructures to impart the former with new and enhanced functions, which we call Plant Nanobionics. We have developed a theory of subcellular uptake and kinetic trapping of a wide range of nanoparticles, validated in-vivo in living plants. Confocal visible and near infrared fluorescent microscopy and single particle tracking of Gold-Cystein-AF405 (GNP-Cys-AF405), Streptavidin-Quantum Dot (SA-QD), Dextran and Poly(acrylic acid) nanoceria, and various polymer-wrapped SWCNT, including lipid-PEG-SWCNT, chitosan-SWCNT and $(AT)_{15}$-SWCNT, were used to demonstrate that particle size and the magnitude, but not the sign, of the zeta potential are key in determining whether a particle is spontaneously and kinetically trapped within chloroplasts or the cytosol. We develop a mathematical model of this Lipid Exchange Envelope Penetration (LEEP) mechanism, which agrees well with observations of this size and zeta potential dependence. As an application, we rationally designed a chitosan-complexed single-walled carbon nanotube (SWNT) as nanocarriers to selectively deliver plasmid DNA (pDNA) to chloroplasts of different plant species without external biolistic or chemical aid. We demonstrate chloroplast-targeted transgene delivery and expression in living mature arugula (*Eruca sativa*) and watercress (*Nasturitium officinale*) plants *in planta* and in isolated *Arabidopsis thaliana* mesophyll protoplasts. Another application of nanoparticles and nanotechnology to plant sciences is in the form of

biochemical sensors that operate *in planta* and across diverse species. Using non-destructive optical nanosensors, we find that the spatial and temporal H_2O_2 concentration immediately post-wounding follows a simple logistic waveform for six dicot plant species: lettuce (*Lactuca sativa*), arugula (*Eruca sativa*), spinach (*Spinacia oleracea*), strawberry blite (*Blitum capitatum*), sorrel (*Rumex acetosa*), and *Arabidopsis thaliana*, ranked in order of wave speed from 0.44 to 3.10 cm/min. The H_2O_2 wave tracks the concomitant surface potential wave measured electrochemically for the series of plants. We show that the plant NADPH oxidase RbohD, glutamate receptor-like channels (GLR3.3 and GLR3.6) are all critical to the propagation of the H_2O_2 waveform upon wounding. Our findings highlight the utility of a new type of nanosensor probe that is species-independent and capable of real-time, spatial and temporal biochemical measurements in planta.

11:00 AM SB10.05.03
Precise Payloads Delivery to Multi-Tissues of Plants via Microneedles Fabricated from Silk-Based Biomaterial Yunteng Cao[1,2], Eugene Lim[1], Menglong Xu[3], Jing-Ke Weng[3,1], Pil Joong Chung[4], Nam-Hai Chua[4,2] and Benedetto Marelli[1,2]; [1]Massachusetts Institute of Technology, United States; [2]Singapore-MIT Alliance for Research and Technology, Singapore; [3]Whitehead Institute for Biomedical Research, United States; [4]TLL Temasek Life Sciences Laboratory, Singapore

New challenges to global food security are posed by rapid population growth, limited access to resources, and changes in climate patterns. Plant engineering is of great significance in current efforts by improving yield and/or resistance to abiotic/biotic stresses. The precise deployment of functional payloads to plant tissues is a new approach to help advance fundamental understanding of plant biology and accelerate plant engineering. However, the morphological and physiological barriers in plants (e.g., epidermis, cuticle) hinder efficient delivery of payloads. Here, a novel silk-based biomaterial is designed to function *in planta*. A microneedle-like device (named "phytoinjector"), bio-inspired by the stylet of psyllids fed by xylem/phloem sap, is then fabricated from this material, capable of delivering a variety of payloads ranging from small molecules to large proteins into specific loci of various plant tissues. It is demonstrated that phytoinjector can be used to deliver payloads into plant vasculature to study material transport in xylem and phloem and to perform complex biochemical reactions *in situ*. Furthermore, it is demonstrated *Agrobacterium*-mediated gene transfer to shoot apical meristem (SAM) and leaves at various stages of growth. In addition, tuning of the material composition enables the fabrication of another device, dubbed "phytosampler", which is used to precisely sample plant sap. The design of plant-specific biomaterials to fabricate devices for drug delivery *in planta* opens new avenues to bridge the biotic/abiotic interface with plants, enhances plant resistance to biotic and abiotic stresses, provides new tools for diagnostics, and enables new opportunities in plant engineering.

11:15 AM *SB10.05.04
Designing Multifunctional Nanomaterials for Highly Sensitive Biosensors Antje Baeumner; Universität Regensburg, Germany

Biosensors for the rapid detection of low concentrations of pathogens, toxins, contaminants and metabolites in an on-site fashion is of utmost interest for clinical diagnostics, food safety and environmental monitoring. Albeit many differences in these application fields exists, challenges raised for the detection technology are strikingly similar: Low amounts and numbers of analytes have to be specifically identified and quantified within an immensely complex matrix such as blood, saliva, food stuff and environmental samples to name a few. Our research group addresses challenges arising from this complicated task in part through the development of multifunctional nanomaterials that enable significant improvements in signal transduction and enhancement, immobilization, pre-isolation or in-line purification, respectively. In combination with specific biorecognition and signal read-out, on-site biosensor platform technologies are thus developed that provide significantly lower limits of detection while maintaining a focus on low-cost, ease-of-use and high specificity characteristics.
The presentation will focus on nanomaterials designed as functional transducers, i.e. laser-induced graphene (LIG), and nanofibers. We have recently shown that LIG is a superior transducer in comparison to screen-printed electrodes used in most electrochemical on-site biosensors. Since ease and reproducibility-of-fabrication of such transducers are of utmost importance in the point-of-care and on-site sensor fields, we have investigated strategies to generate LIG and carbon nanofibers using laser-induced pyrolysis. Here, polyimide sheets and electrospun polyimide nanofibers are transformed using a CO2 laser in a simple scribing process under ambient conditions. The resulting 3D LIG structures can be transferred to any other surface or in the case of the nanofibers be used as free-standing transducer, and are therefore very easy to make, to miniaturize, to integrate into sensing platforms including microfluidic systems. In addition, this process also enables straight-forward large-scale production. We will present our most recent work on voltammetric, potentiometric and impedance-based biosensors for medical diagnostics and food safety using these LIG and carbon nanofiber materials. Furthermore, we demonstrate that by doping the nanofiber materials with metal precursors, chemical sensing with most significant sensitivity and specificity can be accomplished. Here, morphological and performance characteristics can be directly influenced by metal content and lasing power and hence can be adapted towards desired performance. Most importantly, we can show that this strategy can be adapted to a whole range of metal precursors and hence provide opportunities for such 3D carbon nanofiber nanocatalyst hybrids.
Nanofibers can also be made out of a variety of other polymers for the purpose of analyte capture, pre-concentration or even as optical transducers. We will hence also discuss nanofibers entrapping upconverting nanoparticles and fluorescent dyes, respectively, to demonstrate unique and intricate characteristics applied to food safety testing.

Aqueous Dispersions of Biodegradable Polymers for Sustainable Crop Protection Tahira Pirzada, Mariam Sohail, Charles H. Opperman and Saad A. Khan; North Carolina State University, United States

Increased awareness of the long-term impacts of agrochemicals has resulted in the hunt for efficient and sustainable delivery platforms. In order to meet the food demands of an exponentially increasing global population, there is a dire need to establish sustainable technologies for targeted and slow release of agrochemicals with minimal environmental footprints. Furthermore, rising concerns of the global community about the accumulation and environmental effects of microplastics have accelerated the search for alternate delivery vehicles developed from biodegradable polymers. We present a sustainable approach to synthesize aqueous dispersions of biodegradable cellulose derivatives *via* anti-solvent precipitation. We propose the utilization of these dispersions as controlled and targeted release formulations for a pesticide as a model active ingredient (AI). While the biodegradable nature of our polymer particles and use of water as the dispersant medium justify the sustainable nature of these formulations, we have investigated dispersion stability, leaf adhesion, rainfastness and AI release profile of the formulations to ensure their efficacy for foliar application. Additionally, we have used Isothermal

Titration Calorimetry (ITC) to investigate the nature of polymer interactions with the AI to provide a comprehensive picture of the performance and tenability of the formulations.

1:45 PM SB10.06.02
Use of Biopolymer-Based Microneedle Technology for the Sustainable Food Supply Chain Doyoon Kim, Yunteng Cao and Benedetto Marelli; Massachusetts Institute of Technology, United States

Ensuring food safety and security requires improvement of the current food quality monitoring system to mitigate risks of foodborne illness and minimize food wastes. Developing a real-time detection platform for bacterial pathogens and spoilage is a compelling goal to achieve this global mission. Incorporating sensors into packaging is a promising approach, but the lack of proper food contacting materials is challenging to enabling all the functionalities required for the smart-sensing sampling. This study presented a platform for detecting pathogenic bacteria in food using a porous microneedle array by utilizing non-toxic and edible silk fibroins extracted from *Bombyx mori* silkworms. The silkworm fibroins have emerged as promising technical materials for food contact applications due to their non-toxic and edible nature, in addition to their tunable mechanical and chemical properties. The porous microneedle structure allows extraction and delivery of internal food fluid to biosensors on the backside of the needle array by capillary action. We demonstrate food contamination by identifying *E. coli* in fish fillets within 16 h of injection through the unique patterns of the polydiacetylene-based colorimetric biosensors. This response by *E. coli* contamination can be distinct from common food spoilage measured via an increase in sample pH. We also show that the microneedle sensor can pierce commercial food packaging, indicating the feasibility of successfully adapting the technology downstream in current food supply chains. This study will contribute to food quality monitoring, ensuring global food safety, and minimizing food loss and waste.

2:00 PM SB10.06.03
Low-Cost Intelligent Food Packaging Systems via Laser-Assisted Synthesis and Microfabrication of Functional Micro/Nanostructures on Metalized Plastic Films Sarath Gopalakrishnan, Sina Nejati, Krish Gupta and Rahim Rahimi; Purdue University, United States

The food packaging market has become an indispensable aspect of our times as it is estimated to reach 450 billion dollars in revenue by 2027. In accordance with the ramping market projections, there has been an increasing demand for improving food quality and guaranteeing food safety. An intelligent and affordable packaging system that can also act as a tracking platform for food quality is the need of the hour. Since the chemical compounds produced inside a package are good indicators of spoilage of non-perishable foods, several active food quality sensors have been developed. However, active sensors are expensive as they need to carry batteries and electronic chips. Battery-less chipless sensors have gained great attention in food packaging and healthcare because of their low cost and wireless sensing capability and are an ideal candidate for pH sensors in food packaging systems. However, the main obstacles along the progress toward commercializing chipless sensors are the shortcomings in their manufacturing process.

Scalable manufacturing techniques such as printing techniques have been widely used for chipless sensors used in item tracking, gas sensors, and healthcare. While scalable manufacturing techniques offer a significant reduction in the number of processes and resources, it introduces tremendous challenges such as the ink formulation for conductive and functional patterns, the need for custom-made screens, and the time required in the drying and sintering processes. We have identified the roll-to-roll laser processing of metalized films as an economically viable low-cost alternative to conventional printing technologies used for chipless sensor development. This approach offers a one-step process that not only patterns the metallic layer to form predefined traces but also leaves remnant nanostructures in the processed region as thin oxide layers which significantly improves the adhesion between the laser ablated region and the functional material.

We propose a novel approach for laser-assisted manufacturing of chipless sensors that can detect the freshness of fish by sensing the levels of hypoxanthine (HX) released by the fish as it undergoes spoilage. A functional material based on xanthine oxidase (XOD), which is sensitive to the HX levels found in fish products, is developed to be coated on the sensor. HX and XOD are optimized to obtain a quick response from the biosensors. The sensor consists of a spiral pattern made of laser ablated Aluminum-based metalized paper that forms an inductor-capacitor tank circuit. The laser ablation of the metalized paper is done to selectively remove aluminum and expose the paper layer underneath. This process also leads to the formation of thin Al_2O_3 layers of the order of nanometers that can provide substantial adhesion to the functional material. The functional material is deposited on the most sensitive region on the inductive coil so that when the functional material dissolves in response to HX, the resonant peak dampens. The sensors are characterized with the help of a portable reader that sends an interrogation signal in the range of 1 MHz to 100 MHz and detects the amplitude of the resonant peak in the spectrum. Since the amplitude of the resonant peak is a function of the dissolution of the functional material, which is concomitant with the HX levels, this wireless sensing approach is employed in the development of a food quality sensor for fish freshness.

2:15 PM *SB10.06.04
Scalable Fabrication of Flexible Graphene Circuits and Fluidics for Multiplexed Electrochemical Sensing for Agriculture Zachary Johnson, Bolin Chen, Cicero Cardoso-Pola, Nate Garland, Carmen L. Gomes and Jonathan Claussen; Iowa State University, United States

This presentation will demonstrate how low-cost printed and flexible graphene circuits can be tailored for agricultural electrochemical biosensing integrated with open microfluidic devices. The use of inkjet and aerosol printing; spin coating; and laser writing (i.e., laser induced graphene) can be used to create such circuits with high resolution (line widths as low as 20 µm). Moreover, the use of laser scribing of the graphene and/or salt porogens added into graphene inks before printing can be used to further improve the electrical conductivity (< 10 ohms/sq.), electroactive surface area (nano/micro structuring), and surface wettability (hydrophilic to superhydrophobic) of the graphene circuits. These printing and laser fabrication techniques are amenable for use on flexible and chemically/thermally sensitive surfaces including polymers and paper.

The graphene-based sensors are subsequently biofunctionalized with enzymes, ion-selective membranes, and antibodies for pesticide and nitrogen sensing in soil/water samples as well as cytokine and histamine monitoring in cattle serum and fish broth. The detection limits of the biosensors so far have achieved 0.6 nM for organophosphate pesticides; 20 mM for ammonium, potassium, and nitrate ions; 25 pg/mL and 46 pg/mL for IL-10 and IFN-g in cattle serum; and 3.41 ppm in tuna broth respectively. Moreover, we demonstrate how the hydrophobicity of the graphene can be tuned to create multifurcating wedge channels with hydrophilic paths surrounded by superhydrophobic walls that transport and split fluid to distinct biosensors *via* Laplace pressure. We demonstrate how such open microfluidics can be used to develop multiplexed fertilizer ion and pesticides sensors for the field. Such sensing results demonstrate that such scalable graphene sensor technology is well-suited for in-field, low-cost biosensing that is needed for large scale mapping of contaminants in watersheds and farm fields as well as monitoring large volumes of food products.

4:00 PM *SB10.07.01
Transitioning Bioactive Excipients from Drug Delivery to Crops Anthony Cartwright and David W. Britt; Utah State University, United States

Pharmaceutical excipients vary widely in function, being used as absorption enhancers, emulsifiers, preservatives, and sustained release matrices. Here the FDA-approved excipient, Poloxamer P188, is explored as a bioactive excipient in the wheat rhizosphere and contrasted with the natural osmolyte, glycine betaine. The P188 triblock copolymer self-assembles into 5.5 ± 0.3 nm micelles whose size does not vary significantly when encapsulating hydrophobic cargo, such as the plant metabolite quercetin. Column transport studies demonstrated loaded P188 micelles delivered cargo intact, supporting assessment in plant studies. Wheat seedlings were grown in a sand matrix for 14 days, subjected to 8 days of simulated drought, and then recovered for 7 days. To better represent wheat grown in drought-prone regions, seeds were inoculated with a model rhizobacterium, *Pseudomonas chlororaphis* O6 (*Pc*O6) which has been shown to improve drought tolerance in winter wheat. Seedlings were treated separately with 0.2 mmol P188 or 10 mmol glycine betaine per kg of sand matrix, or with the combined nano-formulation. The quantum yield of photosystem II, total growth of plant mass, and relative water content under drought were measured. Both P188 and the P188 / betaine nano-formulation increased total above ground plant mass relative to the control, while the inclusion of betaine alone suppressed tissue growth and photosynthetic activity during periods of simulated drought but improved performance during recovery. P188 addition resulted in significantly higher relative water content in wheat under drought, suggesting activity as a synthetic osmolyte that resists sorption to soil components while carrying additional cargo intact through the rhizosphere.

4:30 PM SB10.07.02
Microfabrication of Silk-Based Capsules for Stabilization and Controlled Delivery of Payloads Muchun Liu[1], Pierre-Eric Millard[2], Rupert Konradi[2], Ophelie Zeyons[2], Henning Urch[2] and Benedetto Marelli[1]; [1]Massachusetts Institute of Technology, United States; [2]BASF Corporation, Germany

Microcapsules are used in a wide range of products including certain types of fertilizers, plant protection products, leave-on and rinse-off cosmetic products to adjust release profiles, stabilize actives and control environmental fate such as volatilization or wash off. The development of microencapsulation is targeted to minimize active levels and limit negative impact on the environment. However, plastic materials are generally used in manufacturing. There is an increasing concern about microplastics dissemination by the public and legislators due to their potential impacts on environment and human health. Here we demonstrate an approach to fabricate biodegradable microcapsules using silk protein as a sustainable alternative. Silk fibroin is a known natural, proteinaceous fiber that can be tailored into a water-soluble suspension for solution processing. Two fabrication methods are employed to encapsulate different types of payloads, including water-soluble (Vitamin C) and -insoluble actives (agrochemicals). Ultrasonic spraying and freeze drying produce uniform microspheres with controllable porosity. Spray drying produces crumpled, but dense microparticles. Increased crystallinity of silk component is achieved by ethanol-induced beta-sheet transformation. The effects of morphology, loading and crystallinity on release profiles are discussed. The resulting silk-based microcapsules offer a solution to current microplastic pollution while retaining adequate delivery performance.

4:45 PM *SB10.07.04
Graphene and Stimuli-Responsive Brush Sensors for Foodborne Pathogens Detection in Food and Hydroponic Water Carmen L. Gomes[1], Raquel Soares[1], Daniela A. Oliveira[2], Cicero Cardoso-Pola[1], Robert Hjort[1], Kshama Parate[1], Eric S. McLamore[3] and Jonathan Claussen[1]; [1]Iowa State University, United States; [2]Texas A&M University, United States; [3]Clemson University, United States

Food contamination in processing facilities and during fresh produce cultivation can lead to serious public health problems and costly recalls of millions of food units. Currently, rapid sensing technology is lacking for definitive detection of foodborne pathogen in food-processing plants and irrigation water during fresh produce production, which delays initiation of appropriate control measures and increases the likelihood of spreading contamination and foodborne illnesses outbreaks. Herein, we report the fabrication of user-friendly biosensors capable of rapid (17-22 min), enrichment-free detection of foodborne pathogens in food processing facilities and hydroponic systems at levels comparable to current culture based and PCR methods (detection limits ~5 CFU/mL). The sensors are fabricated using graphene or stimuli-responsive polymers, and subsequently functionalized with pathogen-specific antibodies or aptamers. Unique laser processing induces a 3D nanostructured topology in graphene that becomes electroactive and hydrophilic, and polymer actuation protocol, i.e., brushes on the extended conformation for bacteria capture and the collapsed state for electrochemical signal transduction are desirable for enabling high signal-to-noise ratios and test sensitivity. An example for *Salmonella* Tyhimurium detection is provided. After functionalization with *Salmonella*-antibodies, the graphene-based biosensors were able to detect live *Salmonella* in chicken broth across a wide linear range (25 to 10^5 CFU/mL) and with a low detection limit (13 ± 7 CFU/mL; n = 3). For *Listeria monocytogenes and Escherichia coli* spp. detection the use of stimuli-responsive brush actuation is demonstrated. After functionalization with *Listeria*-aptamer and *E. coli*-antibodies, the stimuli-responsive brush sensors were able to detect live *Listeria monocytogenes* and *E. coli* in vegetable broth and hydroponic water across a wide linear range (10-10^6 CFU/mL) and with a low detection limit (as low as 3.3 ± 0.9 CFU/mL; n = 3). These results were acquired using a potentiostat with an average response time of 17-22 minutes without sample pre-concentration or redox labeling techniques. After analyzing nanobrush actuation in stagnant media, we developed a flow through system using a series of pumps that are triggered by electrochemical events at the surface of the biosensor. Sense-Analyze-Respond-Actuate proof of concept may be viewed as a cyber-physical system that actuates nanomaterials using smartphone-based electroanalytical testing of samples. These graphene and stimuli-responsive sensors displayed high selectivity as demonstrated by non-significant response to other bacteria strains. These results demonstrate how graphene and stimuli-responsive electrodes can be used for electrochemical sensing in general and, more specifically, could be used as a viable option for rapid and selective pathogen detection in food processing facilities and hydroponic farms.

Novel Method for Rapid Detection of Neutralizing Antibodies After COVID-19 Vaccination Using Bioresponsive Microgel Based SPR

Biosensor Su-Kyoung Lee[1], Bora Yim[2], Ara Ko[2], Yongdoo Park[1] and Jongseong Kim[1,2]; [1]Korea University, Korea (the Republic of); [2]Scholar Foxtrot, Korea (the Republic of)

The efficacy of COVID-19 vaccination is closely related with the serum level of the SARS-CoV-2 neutralizing antibodies that bind to the receptor binding domain (RBD) of the SARS-CoV-2 spike protein. Therefore, rapid and quantitative measurement of the SARS-CoV-2 neutralizing antibody (NAb) in the sera of vaccinated people is essential to develop the effective vaccine and further achieve population immunity, i.e., herd immunity. Plaque reduction neutralization test (PRNT), the gold standard of NAb effectiveness in serologic test, is accurate but requiring biosafety facilities due to the use of the virus, which hampers its application for common laboratories and clinical sites. Here, we developed a bioresponsive microgel based surface plasmon resonance (SPR) platform that detects SARS-CoV-2 NAb in clinical samples without complicated pre-treatment. We found that protein multivalent binding (PMB) between microgel conjugated RBD protein and the COVID-19 NA yields significantly enhanced SPR signals than those of nonspecific interference from serum proteins in microgel based SPR assay. The excellence of our microgel based COVID-19 NAb test occurs from its selectivity for the NA only with resistance to all other proteins, allowing rapid detection and quantification of NAbs for each individual. Importantly, our results provide that microgel based SPR assay will be considered as a novel NAb detection platform for COVID-19 vaccination strategy in easy and safely.

SB10.08.02
Understanding the Interface Between Macromolecules and Metal-Organic Frameworks in Water Christopher DelRe, Daniel Erdosy, Malia Wenny, Joy Cho, Ricardo Sanchez and Jarad A. Mason; Harvard University, United States

Metal-organic frameworks (MOFs) are porous crystalline solids with the ability to selectively concentrate large quantities of gases, offering significant promise as building blocks for energy and biomedical technologies. The surfaces of MOFs are frequently modified by polymers to ensure good compatibility or dispersibility in functional materials or liquids; however, the vast majority of current studies focus on MOF-polymer interactions in solid plastic matrices or organic solvents. Here we show that noncovalent complexation with biological or synthetic polymers enables control over the MOF-polymer interface in water. By understanding and manipulating the interface, properties such as MOF dispersibility and structural stability can be finely tuned—for instance, the degradation rate of a hydrolytically unstable MOF in water can be controlled over 2 orders of magnitude depending on the polymer selection. Present studies provide a path toward controlling the properties of MOFs in water and using MOFs as a platform to understand the behavior of macromolecules at porous interfaces in aqueous media, a ubiquitous situation in Nature that is difficult to study given the sensitivity and complexity of biological systems.

SB10.08.04
Reduced Oxidation of PDMS by Microparticles of Natural Polyphenols Yunho Cho and Jonghwi Lee; Chungang University, Korea (the Republic of)

Polydimethylsiloxane (PDMS) could be oxidized by the various stresses of electrical devices, such as heat, ozone, electrical and mechanical stress, leading to loss of elastomeric properties and ultimate failure. To reduce oxidation, various antioxidants could be mixed with PDMS during manufacture processes. Since the effective radius of antioxidant molecules is relatively small, the antioxidants need to be mixed in a molecular level. However, the low surface energy of PDMS makes the mixing in a molecular level difficult. In this study, we mixed tannic acid, naringenin and a commercial antioxidant with PDMS and investigated their characteristic changes after thermo-oxidation. We added microparticles of antioxidants to PDMS precursor, and the particles are retained matrix to reduce oxidation effectively. Although antioxidants are mixed in micron-size, the antioxidants in PDMS effectively reduced oxidation. In thermogravimetric analysis, PDMS showed faster mass losses than the samples containing antioxidants under 400 °C. In the tensile tests of dumbbell shape specimens, the antioxidants provided a 3-fold increase in Young's modulus, while neat PDMS showed an 88-fold increase in Young's modulus at the thermo-oxidative condition of 3 days and 250 °C. Even though both the neat PDMS and the PDMS containing antioxidants showed similar values of strain-at-break within the error range before heat treatment, neat PDMS showed a significantly smaller strain-to-break (only 10.2%) than the PDMS with antioxidants (46.8%) after 1 day oxidation at 250 °C. The FT-IR spectroscopy result of PDMS containing antioxidant showed much smaller changes in the peaks of 1060 and 865 than that of neat PDMS after oxidation, which are assigned to Si-R stretching. The Si peak analysis of XPS showed that the bonding of silicon atoms in neat PDMS is more oxidized from SiO2C2 to SiO4 compared to the PDMS containing naringenin. These results offer the effective and nontoxic ways to widen the service conditions of PDMS.

SESSION SB10.09: Fabrication of Biomaterials for Regenerative Medicine and Tissue Models
Session Chair: Chiara Ghezzi
Thursday Morning, December 2, 2021
Sheraton, 2nd Floor, Back Bay C

10:30 AM *SB10.09.01
Hydrogel Materials to Improve Peripheral Nerve Repair Ryan Koppes[1], Abigail Koppes[1], Jonathan Soucy[2] and Katelyn Neuman[1]; [1]Northeastern University, United States; [2]Schepen's Eye Research Institute, United States

Peripheral nervous system (PNS) injuries often lead to partial or complete loss of sensation, chronic pain, apraxia, and even permanent disability. Current guidelines recommend repairing severed nerves with sutures; however, sutures hinder tissue regeneration and often result in scar tissue formation further preventing functional recovery. To limit the need for sutures, fibrin glue has been proposed as an alternative to reattach severed nerve endings, but current formulations are not mechanically robust to significantly reduce the need for sutures. We have been developing new photocrosslinkable hydrogel systems from bioavailable polymers to be used as a glue for nerve anastomosis. Formulations have been developed to improve mechanical strength, flexibility, biocompatibility, adhesiveness, and electrical conductivity.

Conductive biomaterials can amplify endogenous and exogenous signaling that have been shown to play a crucial role in galvanotropism and galvanotaxis, processes that are crucial for neural repair. However, many of the popular conductive biomaterials are brittle, insoluble, opaque, and non-degradable. Choline acrylate has recently emerged as a biocompatible ionic liquid (IL) that can be incorporated into hydrogels to modify bulk conductivity. This IL is a transparent, degradable alternative to popular conductive materials that are not ideal to be placed as a permanent scaffold in patients. Matching the mechanical properties of the native nerve tissue is a crucial consideration when fabricating a new hydrogel composition. Viscoelastic properties have been demonstrated to play a role in maintaining the extracellular matrix (ECM) and tissue structure during normal movements, as well as cell differentiation. We have investigated the role that the addition of IL has on bulk electrical conductivity, biocompatibility, and dynamic mechanical properties.

Mechanical testing and *in vitro* cell culture demonstrate tunable physicochemical properties of our hydrogel systems, and that these materials support of the

growth of both glial and neuronal cells. Furthermore, results from *in vivo* implantation models demonstrate that the composite is biodegradability and biocompatible. Finally, we have confirmed that a severed nerve anastomosed by this composite has tensile strengths greater than the commercially available fibrin glue. In this talk will discuss our progress and our future work for hydrogel composites for use in nerve repair.

11:00 AM SB10.09.02
***In Vitro* Tissue Models to Study Host-Pathogens Interactions for Preclinical Validation of Medical Devices** Chiara Ghezzi; University of Massachusetts Lowell, United States

Introduction: Upon the recent pandemic, the COVID-19 testing process has been plagued by missing components, including swabs. Multiple companies and researchers have been focusing on the development of new swabs to collect clinical samples for COVID-19 testing. In order to validate new swabs, innovative experimental procedures are needed to streamline this process. Therefore, we have developed an in vitro tissue model to mimic nasopharyngeal (NP) and mid-turbinate (MT) nasal passages to perform pick-up and release of biological samples from a physiologically relevant nasal mucosa on the bench. There are currently no tissue models available for this purpose, as companies validate their new swabs by dipping in saline without mimicking any of the physiological aspects of the nasal passage (i.e., architecture, mechanical and physical structures). The tissue model will be used to validate NP and MT swabs and advance the design and optimization of the prototypes before reaching the clinical study stage.
Materials and Methods: A tissue model was generated to mimic the nasopharyngeal and mid-turbinate nasal cavities for the validation of NP and MT injection molded swabs. The physiological architecture was realized by 3D printing the Carleton-Civic Standardized Human Nasal Geometry (from Carleton University's Aerosol Research Lab), with Acrylonitrile butadiene styrene using a Fused Deposition Modeling 3D printer. The nasal mucosa was recreated by a soft tissue structure saturated with a viscous mucous component, to mimic the native tissue. Specifically, lyophilized silk fibroin sponges from Bombyx Mori formed the inner surface of the model to replicate the nasal passage tissue, and saturated with artificial mucus to mimic both symptomatic and asymptomatic conditions, based on Locust Bean Gum (LBG). Both muci viscosities were measured based on LBG concentration to match previously reported values. The asymptomatic (0.23 w/v%) and symptomatic (0.92 w/v%) muci displayed viscosities at 13 and 1400 cp, respectively. The muci were then spiked with heat inactivated SARS-CoV-2 virus (BEI, NR-52286) to achieve a clinically relevant viral concentration. To quantify swab pick-up, gravimetric analysis was performed by collecting samples from the nasal model following CDC guidelines. Samples were collected using NP and MT injection molded swabs in comparison to FDA-approved flocked swab (Obecare # 20200507). Viral loads were then quantified with a qScript XLT 1-Step RT-qPCR against N1 N2 SARS-CoV-2 probes to quantify swab efficacy.
Results and Discussion: We tested standard flocked NP and MT swabs and novel injection molded NP and MT swab using models saturated with asymptomatic and symptomatic muci containing virus. The gravimetric data indicated that the standard NP, MT swabs with asymptomatic mucus and the standard diseased MT swab picked up significantly more than the injected molded NP and MT swabs for those groups. However, the RT-qPCR data from all swabs demonstrated comparable viral loads.
Conclusions: Despite the reduced pick-up volumes from the injected molded swabs in comparison to standard flocked swabs, the viral detection was comparable. The pick-up and release data from the bench top in vitro model are also in agreement with on-going clinical studies, thus, supporting the validation of the in vitro model for pre-clinical swab validation.

11:15 AM SB10.09.05
Late News: Engineering *In Vitro* Contractile Models of Duchenne's Muscular Dystrophy John Zimmerman, Ziad Al Tanoury, Peyton Nesmith, Jerome Chal, Kevin K. Parker and Olivier Pourquié; Harvard University, United States

Duchenne Muscular Dystrophy (DMD) is a devastating wasting disease that leads to the continual degradation of muscle tissues and eventually premature death. DMD is caused by a rare genetic mutation in the protein dystrophin, which is believed to act as a molecular 'shock absorber', helping stabilize the sarcolemma during muscle contraction. As a rare disease, there are limited curative options available for patients, with current drug trials showing a limited success rate. This is due in part to a lack of viable screening methods, with most pre-clinical testing being done in mdx mouse models, which only partially capture the diseased phenotype. As a result, there is a need for improved model systems using human derived tissues, which can more accurately predict patient outcomes and potentially be used for tailoring individualized treatments. Here we describe how engineered tissue constructs can be used to model the contractile phenotype of diseased and healthy patient cells. Using photolithographically defined muscular thin films, we show that muscle fibers derived from human induced pluripotent stem cell (iPSC) lines exhibit defective contractility when carrying an DMD mutation. This strongly supports the hypothesis that intrinsic contractility defects also contribute to the muscle weakness exhibited in DMD patients, in addition to the classical mechanisms of fibrosis and fatty cell replacement. Additionally, we demonstrate that these contractile defects can be largely rescued using prednisolone treatments, in both patient derived and DMD isogenic cell lines, indicating that prednisolone acts directly on mutant fibers, in addition to its anti-inflammatory or immunosuppressive effects. This work provides an *in vitro* platform for studying the etiology of DMD in human myofibers. Additionally, this study indicates that engineered microphysiological systems can serve as important tools in modeling rare diseases, as these systems are amenable to individualized patient screening and may offer potential insights into the mechanism of pharmaceutical action.

SESSION SB10.10: Biomaterials for Biomedical Nanotechnology
Session Chair: Chiara Ghezzi
Thursday Afternoon, December 2, 2021
Sheraton, 2nd Floor, Back Bay C

1:30 PM SB10.10.01
Inkjet-Patterned Protein Films for Engineering Interactions at the Interface for Size Sorting and Controlled Cell Adhesion Applications Sanjana Gopalakrishnan[1], Shuting Pan[1,2], Li-Sheng Wang[1], Ann Fernandez[1], Bradley Duncan[1], Rui Tang[1], S. T. Thayumanavan[1], Xuexin Duan[2] and Vincent M. Rotello[1]; [1]University of Massachusetts Amherst, United States; [2]Tianjin University, China

Proteins are attractive precursors for the fabrication of biomaterials due to their inherent biocompatibility, biodegradability, and low toxicity. Moreover, fabrication of protein-based materials can be conducted sustainably due to their ready availability and high aqueous solubility. A wide variety of functional proteins are naturally available with unique properties which may be harnessed to design complex multifunctional materials for several applications including tissue engineering, diagnostic tools, and sensors. However, the high solubility of proteins often results in lower aqueous stability and poor mechanical properties. Protein films must therefore be treated to enhance their stability. However, it is challenging to develop treatment strategies that enhance aqueous stability, are widely applicable to different proteins and preserve their native properties. We developed an additive-free thermal treatment strategy in fluorous media (hereafter referred to as fluorous-curing) that enhances aqueous stability of protein films, while preserving native protein

properties such as surface charge and hydrophilicity. In this work, fluorous-curing was utilized in combination with inkjet-printing of proteins to develop patterned protein films with varying surface properties. We investigated the application of these patterned protein films for controlled cellular adhesion and size-based microparticle sorting.

For our study, we utilized two different proteins - anionic bovine serum albumin (BSA) and cationic lysozyme (Lyso). Aqueous protein solutions (protein inks) were loaded into empty cartridges of an inkjet printer to print protein patterns onto a glass surface followed by fluorous-curing. This resulted in patterns of varying charges along the surface. These surface charge patterns were utilized to dictate adhesion of cells on specific regions of the surface with potential applications such as tissue engineering scaffolds and *in vitro* co-culture models.

Charge-patterned protein films were also investigated as a platform to size-sort charged microparticles. Rapid size-based sorting of small volumes of analytes is a crucial first step in biomedical diagnostic tools such as microfluidic devices or point-of-care diagnostic systems. We integrated a hypersound-based acoustic streaming system with our inkjet-patterned protein films to provide efficient sorting of microparticles on the basis of particle charge and size. The hypersonic resonator enabled us to generate microvortices in the fluid that exerts a curvature-dependent drag force on the microparticles adhered to the protein surface. This allowed for the translocation of microparticles based on the strength of their electrostatic interactions with the patterned protein surface and the drag force exerted by the microvortices. As the drag force was curvature-dependent, larger particles experienced stronger forces and translocated further on the patterned protein surface. This difference in translocation allowed for efficient (~95%) sorting of microparticles. The combination of inkjet-patterned protein films and hypersound-based acoustic streaming enables precise manipulation of particle movement at the surface and may be used for sorting a variety of chemical or biological analytes or studying interactions of analytes with protein-based surfaces.

1:45 PM SB10.10.02

Biophysical Properties of Self-Assembled Immune Signals Influence Regulatory Processing and Function Eugene Froimchuk[1], Robert S. Oakes[1,2], Senta M. Kapnick[1], Alexis A. Yanes[1] and Christopher Jewell[1,2,3]; [1]University of Maryland, United States; [2]United States Department of Veteran Affairs, United States; [3]Robert E. Fischell Institute for Biomedical Devices, United States

Introduction: The immune system evolved mechanisms to respond not only to specific molecular signals, but also to biophysical properties such as binding affinity. Unfortunately, the connections between biophysical parameters and immunological outcomes are poorly understood in the context of disease. Understanding this connection would enable better design and translation of new therapies for autoimmune diseases like multiple sclerosis (MS), where the immune system mistakenly attacks myelin in the central nervous system. We posited that inhibiting inflammatory signaling while myelin self-antigen (MOG) is processed by immune cells could reduce autoimmunity and promote immune tolerance during MS. Here we show electrostatically self-assembling complexes formed from an anionic regulatory ligand (GpG) and a cationic MOG peptide improve paralysis in a mouse model of MS. Because efficacy was dependent on antigen-sequence, we probed how antigen sequence and charge impact electrostatic self-assembly of immune signals and how changes in biophysical features of the complexes link to immune tolerance. We ***hypothesized*** increasing cationic charge of MOG peptide sequences would increase the affinity with which MOG peptides adsorb to GpG. We speculated if increased affinity would improve uptake efficiency of signals by immune cells and increase polarization of self-reactive T cells to protective regulatory phenotypes.

Methods: To vary the charge of MOG peptides, we anchored MOG with 2, 3, or 9 cationic residues of lysine (K) or arginine (R). We used surface plasmon resonance to measure how binding affinity between MOG peptides and GpG changed as a function of total peptide charge. We measured signal loading by gel electrophoresis to assess how self-assembly of MOG and GpG changed as a function of charge balance in solution. To probe how GpG impacts signaling in dendritic cells (DCs), we stimulated DCs with the inflammatory signal CpG, treated DCs with MOG/GpG complexes, and then analyzed expression of inflammatory markers CD80/86 by flow cytometry and MyD88 by RT-qPCR. To determine if treated DCs could polarize T cells towards regulatory phenotypes associated with immune tolerance, we cultured DCs with MOG-specific T cells and measured expression of regulatory markers FoxP3 and CD25 by flow cytometry.

Results: When anchoring MOG with K or R, the dissociation rate constant (K_D) decreased as the number of anchored residues was increased from 2 to 3. This observation indicates that the binding affinity between MOG and GpG increased when MOG exhibited a more positive charge. Signals were fully loaded into complexes when the charge balance in solution was neutral. If the charge ratio of cationic MOG to anionic GpG skewed towards GpG, GpG remained in solution. If the charge ratio skewed towards cationic MOG, then GpG was fully loaded but MOG remained in solution. When stimulated with CpG, DCs treated with MOG/GpG complexes or soluble GpG significantly reduced CD80/86 and *Myd88* expression. This result indicates that GpG remained active when delivered in complexes. Intriguingly, DCs treated with $MOGK_9$ and $MOGR_9$ complexes expressed significantly more *Myd88* relative to DCs treated with other complex formulations. GpG may not have been as readily available to inhibit inflammatory signaling when complexed with $MOGK_9$ or $MOGR_9$, possibly due to tighter binding with MOG because of the larger cationic charge per peptide. Furthermore, only $MOGK_2$ and $MOGR_2$ complexes polarized MOG-specific T cells towards regulatory phenotypes.

Conclusions: DCs were most effective in polarizing regulatory T cells when treated with complexes containing peptides of lowest cationic charge. Our results suggest self-antigens designed to self-assemble with tolerizing cues without limiting bioavailability of the signals are most effective in polarizing regulatory T cells. This granular understanding of nanomaterial-immune interactions contributes to more rational immunotherapy design.

Kinetics and Thermodynamics of Fibril Elongation and Dissociation of Oxyntomodulin and Aib2-Oxyntomodulin Alireza Mohammad Karim[1], Ana L. Gomes Dos Santos[2] and Mark E. Welland[1]; [1]University of Cambridge, United Kingdom; [2]AstraZeneca, United Kingdom

Obesity and its implication on type-2 diabetes (T2D) have reached epidemic proportions worldwide. The urgent need to find a safe and effective therapies for treatment of these chronic disorders has gained tremendous attention in scientific community. Recent studies have shown that peptide hormones such as Oxyntomodulin (Oxm) and its analogue 2-aminoisobutyric acid oxyntomodulin (Aib2-Oxm) are extremely safe and effective for body weight loss and regulating the blood glucose level to treat T2D patients. Despite their promising therapeutic effects they exhibit a short *in vivo* bioactivity in serum due to the enzymatic degradation. To address this challenge, it was reported that when these peptides are packed in fibrillar structures they are much less exposed to any degradation and hence their bioactivity is significantly improved. Therefore, it is essential for developing a systematic approach for explore strategies that control the formation of such fibrils and their subsequent controlled dissociation *in vivo* once injected in patients. An understanding of the fibrillation and dissociation processes of such peptides requires a quantitative knowledge of the kinetics and thermodynamics of fibril formation and dis-assembly; such measurements that to date have remained elusive for these peptides. In this work we report for the first time a through thermodynamic and kinetic study of fibril formation and fibril dissociation using quartz crystal microbalance with dissipation (QCM-D) and bulk experiments for Oxm and Aib2-Oxm. We investigated the speed of peptide attachment and detachment as well as related thermodynamics processes via the Gibbs free energy change for fibril formation as well as fibril dissociation. Our study showed that Oxm and Aib2-Oxm peptides are spontaneously self-assembling into fibrils whilst Oxm fibrils are more stable than Aib2-Oxm fibrils. Therefore, Aib2-Oxm fibrils are more feasible and faster to dissociate *in vivo* relative to Oxm fibrils which indicates higher bioactivity of Aib2-Oxm in serum relative to Oxm. On the other hand, the higher fibrillation speed of Oxm relative to Aib2-Oxm

highlights higher propensity of Oxm for fibril elongation than Aib2-Oxm.

SESSION SB10.11: Biomaterials for Plants, Food and Agriculture
Session Chair: Benedetto Marelli
Thursday Afternoon, December 2, 2021

4:00 PM SB10.11.01
Bioinspired Seed Coatings to Boost Germination and Mitigate Abiotic Stressor Augustine Zvinavashe[1], Manal Mhada[2], Lamfeddal Kouisni[2] and Benedetto Marelli[1]; [1]Massachusetts Institute of Technology, United States; [2]UM6P, Morocco

Changes in climate patterns and soil depletion are major challenges that agriculture needs to address to build a sustainable food infrastructure that can feed the growing human population. In semi-arid regions, water is the determining factor for crop production and water stress during seed germination and early seedling growth is the highest cause of crop loss, with dramatic impact on food security for 1 billion people that are threatened by desertification. In nature, some seeds (e.g. chia, basil) produce a mucilage-based hydrogel that creates a germination-promoting microenvironment by retaining water, regulating nutrients entry, and facilitating interactions with beneficial microorganisms. Inspired by this strategy, a two-layered biopolymer-based seed coating has been developed to increase germination and water stress tolerance in semi-arid, sandy soils. Seeds are coated with a silk/trehalose inner layer containing *rhizobacteria* and with a pectin/Carboxymethylcellulose (CMC) outer layer that upon sowing reswells and acts as a water jacket.
Using *Phaseolus vulgaris* (common bean) cultured under water stress conditions in an experimental farm in Ben Guerir, Morocco, it is demonstrated that the proposed seed coating effectively delivers *rhizobacteria* to form roots nodules, results in plants with better health, and mitigates water stress in drought-prone marginal lands.

4:15 PM SB10.11.02
An Edible Electronic Pill for Tunable and Monitored Drug Release Leonardo Lamanna[1], Pietro Cataldi[1], Marco Friuli[2], Christian Demitri[2], Alessandro Luzio[1] and Mario Caironi[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Università del Salento, Italy

The use of wearable and implantable devices allows continuous monitoring of physiological metrics, personalized drug treatment and rapid sharing of data between patients and caregivers, offering unprecedented diagnosis and treatment opportunities. In this contest, ingestible electronics devices represent a key tool supporting medicine since the ‘60s [1]. To date, these devices are used mainly in diagnostic and administrated in controlled hospital conditions because of costs, need of recollection, and risk of retention.
Nowadays, the research has a chance to move from ingestible to edible electronics to develop safe and self-administrable edible devices[2]. This transformation requires the introduction of new materials coming from food derivatives or approved by FDA/EFSA. In this context, new communication strategies to deliver diagnostic and treatment progress information are required. The most promising communication strategy is the Intra Body Communication (IBC) [3]. IBC is a wireless bioinspired communication platform that exploits body's ionic conductivity to propagate a signal (*e.g.* nervous system), generating a body area network (BAN). Such technology has the advantage of low power consumption (<10pJ/bit) and the possibility to employ high impedance conductors[4], compatibles with present edible batteries and conductors[2].
To date, IBC has been mainly exploited for wearable applications. The only example of IBC for an ingestible device was proposed by Proteus Digital Health *Inc*. to monitor the pharmacological adherence[5]. These models of IBC show static systems where the signal is not modulated in time by physiological processes. In this work, we introduce IBC through a fully edible pill employed for tunable and monitored drug release.
In particular a fully organic edible pill is proposed, composed by:
1. A green and large scale processable edible conductor (0.01 S/cm) exploited for the IBC signal transmission;
2. An insulating edible composite, including a transient bioinert matrix and the drug (Metformin and Amoxicillin), enabling erosion triggered drug release mechanism along different parts of gastrointestinal (GI) tract.
Upon ingestion, the IBC signal is triggered by the pill contacts with GI solution. Then, the signal is modulated along the GI tract by the insulating edible composite dissolution and consequent system impedance variation occurring during the drug release. The signal is switched-off by the complete pill dissolution. In combination with a wearable patch the system will provide information on pharmacological adherence and real-time drug release monitoring.
The drug release mechanism has been characterized *in vitro* employing simulated gastric and intestinal fluids. Multiple and controlled drug release along the GI tract has been obtained tuning the dissolution properties of the insulating edible matrix through its composition, resulting in release time tunable between 20 minutes to 3 hours. Meanwhile, the insulating material dissolution leads to an impedance reduction of 3 order of magnitude, which modulate the IBC signal and describe the drug release profile.
This technology could pave the way to higher personalized medicine being tailored by patients needs, response, and risk.

Molecularly Targeted Polymerized Shell Microbubbles to Treat Abdominal Surgical Adhesions Joyce Y. Wong; Boston Univ, United States

We have developed microbubble ultrasound imaging contrast agents with specific molecularly targeting ligands with the goal of detecting and treating abdominal surgical adhesions. Abdominal surgical adhesions are a major burden to the US healthcare system with estimated annual costs of over $5 billion. During abdominal surgery, the inflammatory response combined with surgically induced ischemia leads to the formation of a fibrin-rich exudate into the peritoneal cavity which can crosslink apposing tissues. Example complications are small bowel obstruction and female infertility. Current FDA-approved strategies to prevent abdominal surgical adhesions are limited because they are site-specific and require the surgeon to predict a priori where the adhesion will form. Moreover, surgical adhesion removal often involves a second surgery, which ironically can lead to additional adhesions. A desired feature of the ultrasound contrast agent is particle and size stability in physiologically relevant fluids. Specifically, an optimal balance must be struck between microbubble stability (maintaining imaging contrast for diagnosis) and reasonable inertial cavitation thresholds (allowing for fibrin breakup). Moreover, care must be taken to ensure no unwanted damage is done to the underlying mesothelium throughout the process. By tuning the crosslink density of the microbubble shell, we show particle and size stability can be controlled. This finding is important for eventual clinical translation because current microbubble in vivo lifetimes are much too short for targeted imaging applications. We will describe our combined in vitro and in vivo approach toward developing a theranostic agent for detecting and treating nascent abdominal surgical adhesions.

11:00 AM SB10.12.02
Orally Fast-Disintegrating Delivery System of Ferulic Acid/Cyclodextrin Inclusion Complex Nanofibers Asli Celebioglu and Tamer Uyar; Cornell University, United States

The fast-disintegrating oral delivery systems are gaining more interest in the pharmaceutical and food industry [1]. Recently, electrospinning of nanofibrous webs incorporating active agents was shown to be a very favorable approach for the development of fast-disintegrating delivery systems. The very large surface area and highly porous structure along with the amorphous state of the active ingredients make these nanofibrous webs suitable for fast-disintegrating oral delivery systems since they can readily dissolve or disintegrate upon contact with liquid medium [2-4]. Cyclodextrins (CyDs) are classified as cyclic oligosaccharides and they are even being used in drug formulations since hydrophobic drugs become water-soluble by inclusion complexation with the doughnut-shaped cavity of CyD molecules. Moreover, such inclusion complex systems can enhance the bioavailability and stability of drugs [5]. The electrospinning of polymer-free inclusion complex formulations can be yielded into nanofibrous webs with fast-disintegrating character and such electrospun nanofibrous webs would be quite proper for designing fast-disintegrating oral delivery systems for pharmaceutical products and/or dietary supplements [3-4]. Additionally, the electrospinning of nanofibers from aqueous solutions of CyD inclusion complexes has the advantage where it is possible to use only water for the electrospinning without the need of polymeric carrier and without the need of using organic solvents. Moreover, CyDs are highly water-soluble compared to polymeric matrices, hence, CyDs being as a fiber matrix and inclusion complex host, nanofibers solely electrospun from inclusion complexes would dissolve instantly in the oral cavity without the need for water and provide enhanced solubility to active compounds by inclusion complexation. Also, by polymer-free electrospinning of these systems, much higher active compound loadings are possible if needed for the finished dosage forms. In our studies, we have chosen ferulic acid as a model bioactive compound for the electrospinning of polymer-free nanofibrous webs of inclusion complex for the development of orally fast-disintegrating delivery systems [6]. Recent studies have shown that ferulic acid displays a wide range of physiological properties such as antioxidant, anticarcinogen, anti-inflammatory, antimicrobial and neuroprotective. However, the low water solubility and stability of ferulic acid result in a lack of bioavailability and activity which limits further applications. On the other hand, its water solubility and bioavailability can be enhanced by inclusion complexation with CyD. Here, the free-standing inclusion complex nanofibrous webs of ferulic acid were produced using electrospinning technique from two different modified cyclodextrin derivatives of hydroxypropyl-beta-cyclodextrin (HP-β-CyD) and hydroxypropyl-gamma-cyclodextrin (HP-γ-CyD). It has been detected from the *in vitro* release and disintegration tests that, the amorphous state of ferulic acid based on inclusion complex formation, and the highly porous feature and high surface area of nanofibrous mats have ensured the fast dissolution/release of ferulic acid and disintegration of nanofibrous mats into the liquid medium and artificial saliva. The results elucidated that electrospun nanofibrous webs of ferulic acid/CyD could be promising material as a fast disintegrating oral delivery system.

Cyclodextrin/Prednisolone Inclusion Complex Nanofibers for Fast-Dissolving Drug Delivery Nancy Wang, Asli Celebioglu and Tamer Uyar; Cornell University, United States

Fast-dissolving drug delivery systems are receiving increasing attention lately due to their enhanced bioavailability and physiochemical properties. One technique of such studies is to create an electrospun nanofiber web of an inclusion complex with the drug of study. The porous nature of these electrospun nanofiber webs renders this system readily soluble in liquids, thereby improving the bioavailability of the drug of study. A fast-dissolving system is developed for prednisolone, a drug that is often used to treat allergic reactions [1]. The system aims to create an inclusion complex with hydroxypropyl-beta-cyclodextrin (HPβCD) and generate electrospun nanofibrous webs from this system. Cyclodextrin is a starch derivative often known for its presence in enhancing solubility, shelf life, stability of such products as drugs, essential oils, dietary supplements, flavor/fragrance, etc. [2]. There are mainly three native types of cyclodextrin molecules (α-, β-, and γ-CD) in addition to some engineered varieties, which includes HPβCD [2, 3]. Because HPβCD is a ring-shaped molecule with a cavity in the center [2], it can envelope individual drug molecules, commonly at a CD-to-drug ratio of 1/1 or 2/1 [4]. The usage of HPβCD is known for increasing the physical and chemical properties of various substances [4]. Here, HPβCD is used to improve the aqueous solubility of prednisolone, a drug that is barely soluble in water on its own. The HPβCD/prednisolone inclusion complex allows the drug to dissolve quickly in the presence of saliva so that the consumer does not need to struggle with swallowing a large pill. The inclusion complex with the drug molecules is initially in the form of a spinning dope, which will yield a sheet of flexible, free-standing nanofibers after going through the electrospinning process. By connecting the spinning dope to one end of the circuit and a metal collector on the other end, an application of voltage will create the electromagnetic field that enables the collection of nanofibers [5]. The simple sheet of nanofibers produced here, composed of the inclusion complex, is to be placed on the tongue. The sheet will instantly dissolve when in contact with saliva, thereby eliminating the difficulty of swallowing. On the other hand, pullulan is a common polymer for creating electrospun nanofibers and pullulan/prednisolone nanofibers were produced as a control sample. The use of HPβCD thereby eliminates the need for polymer dopes to provide structural integrity in producing free-standing nanofibers. This fast-dissolving drug delivery system with a freestanding nanofiber web appears favorable and offers new potential for the pharmaceutical industry.

Development of Vitamin C Loaded Plant-Based Microfibers for Wound Healing Applications Fabrizio Fiorentini[1,2], Giulia Suarato[1,1], Maria Summa[1], Rosalia Bertorelli[1] and Athanassia Athanassiou[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Università degli Studi di Genova, Italy

The wound healing process is a dynamic and highly regulated series of events, comprising four main steps: hemostasis, inflammation, proliferation and remodeling. Fibroblasts and keratinocytes represent the main cell types involved in the process, as they synthetize cytokines and collagen to regulate the inflammation process and to build the extracellular matrix, respectively. For this reason, tissue repair mechanisms can be improved by stimulating cell proliferation through the employment of microfibrous scaffolds, that can effectively mimic the 3D conformation of the extracellular matrix, and, when loaded with bioactive molecules, to boost the cellular restoration at the wound area. Nowadays, materials derived from natural resources are becoming an optimal choice to create alternative wound dressing.
In this work we fabricate natural 3D microfiber scaffolds loaded with vitamin C for the treatment of skin lesions, by combining four plant-based molecules: zein, an alcohol-soluble protein derived from corn; low-methoxy pectin, the most abundant hydrophilic polysaccharide in the plant cell wall; soy lecithin, used as emulsifier agent; and vitamin C, able to exert antioxidant activity and stimulate collagen synthesis. The polymeric microfibers were produced via vertical electrospinning of emulsions. Five samples (labeled ZPC0, ZPC1, ZPC2, ZPC3, ZPC4) containing different concentrations of vitamin C (0 – 10 mg/mL) were fabricated and their cross-linking via $CaCl_2$ was optimized, in order to enhance their water resistance. SEM imaging was conducted to analyze the morphology of the samples and FTIR analysis was carried out for the chemical characterization. An *in vitro* drug release assay was set up by incubating the samples in PBS (pH 7.4) at 37°C for up to 24 hours, while a DPPH assay was performed to test the radical scavenging activity of the VitC released in the PBS from the microfibers. The antioxidant activity was evaluated *in vitro* on Cultured Human Keratinocyte (HaCaT) cells, testing their response toward H_2O_2 by DCFH-DA assay. Swelling and degradation rate were monitored by immersing at 37°C for a week the fibrous matrices in PBS alone or with a protease. The biocompatibility was evaluated on Human Dermal Fibroblast adult (HDFa) cells and HaCaT cells by MTS assay.
SEM micrographs showed bead-less and ribbon-like microfibers. The increase of vitamin C content in the samples resulted in an expansion in the fiber average diameter, from 0.84 to 1.19 μm and the $CaCl_2$ cross-linking strategy helped maintaining the microfibers structure. *In vitro* drug release indicated a burst release of the vitamin C from the microfibers within 3 hours of immersion. The cross-linking treatment was successful in slowing down the release of the bioactive molecule in the first hour of immersion in PBS. The DPPH assay results indicated that the radical scavenging activity was present both in non-cross-linked and cross-linked microfibers, even if this propriety was higher for the non-cross-linked ones. The DCFH-DA *in vitro* assay on HaCaT cells showed a response to the H_2O_2 proportional to the amount of VitC loaded inside the samples. Degradation assay showed a higher weight loss of the samples when immersed in PBS with protease, compared to the immersion in PBS alone. *In vitro* MTS assay on HDFa and Keratinocyte cells resulted in good biocompatibility for each sample under study. Taken together, these results confirmed that our designed plant-based electrospun microfibrous patches represent a suitable, naturally-derived biocomposite for wound healing applications.

11:45 AM SB10.12.05

Griseofulvin/Cyclodextrin Inclusion Complex Nanofibers for Fast-Dissolving Oral Drug Delivery Systems Emmy Hsiung, Asli Celebioglu and Tamer Uyar; Cornell University, United States

Fast-dissolving oral drug delivery systems are gaining more interest in the pharmaceutical industry as a means of administering active pharmaceutical ingredients through tablets, films, and, recently, electrospun nanofibrous webs [1,2]. The large surface area and highly porous structure of nanofibrous webs make nanofibers a promising means of drug delivery, as they readily dissolve in the oral cavity [3-5]. Cyclodextrins (CDs) are classified as cyclic oligosaccharides and are used in drug formulations to increase the water-solubility of hydrophobic drug molecules via inclusion complexation with the doughnut-shaped cavity of CD molecules [2,6]. In this study, an orally fast-dissolving drug delivery system was developed by incorporating inclusion complexes of Griseofulvin/Cyclodextrin with pullulan—a non-toxic, water-soluble biopolymer—to form nanofibrous webs via electrospinning. Griseofulvin is used widely as an antifungal, but it is poorly water-soluble and suffers from low bioavailability. In this study, hydroxypropyl beta cyclodextrins (HPβCD), which have been already used in the pharmaceutical industry due to its high-water solubility, were used to form inclusion complexes [6]. Through inclusion complexation with HPβCD, the water solubility and thus bioavailability of the drug were enhanced. The electrospinning of Pullulan-Griseofulvin/HPβCD solutions yielded defect-free nanofibers collected in the form of self-standing and flexible nanofibrous webs. The formation of inclusion complexes between cyclodextrin and the drug was confirmed using FTIR and XRD analysis, the thermal analysis of the fibers were examined using DSC and TGA, and increased solubility of the drug after complexation was confirmed with UV-Vis spectroscopy. The generated electrospun nanofibrous webs readily disintegrated when wetted with artificial saliva indicating that electrospun Pullulan-Griseofulvin/HPβCD web could be a promising material as a fast-dissolving oral drug delivery system.

Hierarchical Assembly of Podocyte Structures on Fractal Substrates for Kidney-on-a-Chip Engineering Milica Radisic[1,2] and Anastasia Korolj[1]; [1]University of Toronto, Canada; [2]University Health Network, Canada

Podocytes are highly branched and specialized epithelial cells in the kidney that wrap around glomerular capillaries to form a filtration barrier for the purification and regulation of blood. Many kidney diseases are related to podocyte dysfunction, and limited treatment options make kidneys the most waitlisted transplant organ around the world. Physiologically relevant tissue-engineered models of podocyte function are thus needed to improve our understanding of kidney disease and discover new treatments.

However, in vitro, podocytes have severely limited maturation, reach a plateau of gene expression and morphological development that remains far from native levels, and thus lacks relevance to modeling of the native condition, which is a major bottleneck in research progress. Not only are the cells unable to develop multi-level branching morphology, but there is a lack of reliable read-outs that can assess this complex interdigitating morphology in vitro in a way

that cross-references with in vivo practices.

We have taken an interest in the role of fractal structures and how they contribute to the development of cells and tissues in which these patterns are so ubiquitous.

Fractals are structures with features that repeat at multiple scales, like the leaves of a fern or a cascading Russian doll. The fractal self-similarity adds complexity to these structures, in the way that makes a mountain different from a simple cone. Our hypothesis was that fractal complexity in shape cues, akin to those of looping glomerular capillaries on which podocytes grow, will trigger fractal complexity in podocyte maturation, leading to more fractal branching, by patterning relevant machinery on multiple scales.

First, biomimetic fractal substrates were designed by tracing native histology cross-sections
of glomerular capillaries, patterning the designs onto positive photoresist using direct laser writing lithography, and then reflowing to generate curvature. These patterns were then inverse-molded with PDMS to generate 2.5-D scaffolds which were inserted into well plates to use in standard cell culture techniques. Cells cultivated on fractal scaffolds developed higher expression and localization of integrin, cytoskeletal, glycocalyx, and slit diaphragm proteins compared to flat and non-fractal topographical scaffolds, and revealed greater maturation extent by RNA sequencing results. Cells also grew preferentially on topographic features when present.

Remarkably, we observed that the 2.5-D fractal substrates exhibited curvature-dependent patterning of collagen I molecules overtop of the scaffold topography, in perfect correlation with kelvin probe force microscopy measurements of increased charge density and zeta potential on curved versus flat regions of the material surface.

Thus, we present the notion that fractality induces clustering of proteins by concentrating charge in the material interface, which facilitates hierarchical assembly of cell structures resulting in overall advancement of whole cell branching morphology. We observed that 2.5-D fractal shape patterning was dose-dependent, that cells were more sensitive to stimuli when grown on fractal scaffolds, and the morphology could be directly compared with in vivo experiments, thus supporting physiological relevance and reliability. To document platform utility, we demonstrate that this new kidney-on-a-chip model can be used for screening of nephrotoxic drugs, for studies of the effects of coronaviruses on the kidney and screening of factors that lead of kidney rejection in patient serum.

SESSION SB10.13: Biomaterials for Drug Delivery, Regenerative Medicine and Tissue Models II

1:00 PM SB10.13.02
Static and Dynamic Analysis of Naturally-Derived Coatings for Drug-Eluting Stents Martina Lenzuni[1], Giulia Suarato[1], Luigino Criante[1], Silvio Bonfadini[1], Dalila Miele[2], Marco Ruggeri[2], Giuseppina Sandri[2] and Athanassia Athanassiou[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Università degli Studi di Pavia, Italy

Over the past few years, naturally-derived polymers are being increasingly considered as promising coating materials to obtain novel drug-eluting devices, such as drug-eluting stents (DES). Natural biodegradable polymers include proteins (e.g. zein), and polysaccharides (e.g. alginate), which are not only biocompatible but also release non-toxic degradation products, easily cleared from the body [1]. Moreover, coatings fabricated with naturally-derived polymers may limit adverse effects such as exaggerated inflammatory response and delayed re-endothelialization, which often occur when residual synthetic polymers remain in place [2].
In our study, we developed novel biodegradable zein-based bilayer coatings on stainless steel with improved biocompatibility with respect to synthetic coatings and bare metal cardiovascular devices. Rutin, a plant-based flavonoid, with several biological properties, including anti-inflammatory and antioxidant potential, was loaded into a zein polymer layer. Experiments were carried out to assess the release profile of rutin from single and bilayer coated substrates (up to 21 days) and the resulting antioxidant activities. The fabricated coated surfaces were subjected to extensive physico-chemical characterizations and *in vitro* biocompatibility testing using human umbilical vein endothelial cells and primary human fibroblasts.
To better mimic the physiological conditions and recreate the dynamic release mechanisms that exist *in vivo* in a coronary artery, we studied the behavior of our zein-based coating in contact with a flowing liquid. In particular, for these dynamic analyses, we designed and developed a versatile microfluidic platform, which is modeled to mimic the microenvironment of a coronary DES. Experiments were performed to monitor the degradation behavior and drug release from the coated microfluidic channels in contact with several blood-simulated fluids (differing in terms of viscosity and chemical composition), flowing at various flow rates.
Our findings confirm that the proposed plant-based coatings fulfill the key requirements for successful drug-eluting cardiovascular devices. The exclusive use of green solvents and natural polymers can indeed ensure biocompatibility, promotion of cell proliferation, and sustained release. Moreover, our on-chip platform allowed recapitulating the physiological bloodstream microenvironment. Therefore, we consider this study as an important contribution towards a better understanding of polymer degradation and drug release under static and dynamic conditions, which are critical for developing more efficient and optimized local drug delivery systems featuring naturally-derived polymers.

Fluorescent Polymeric Nanoparticles with Unfunctionalized, Inert Surfaces for Nano-Bio Interaction Studies Leisha M. Martin, Jian Sheng and Wei Xu; Texas A&M University, United States

Nanoparticles that can be optically tracked are of interest for cell and organismal biodistribution studies. NPs with surface functionalizations linking or adsorbing dyes or fluorophores may detach or leach, resulting in artifacts. Materials with encapsulated fluorescent molecules or quantum dots (QDs) are of interest for bio tracking while avoiding artifacts due to leaching. NP surfaces altered to carry dyes or fluorophores are also anticipated to affect toxicity profiles, protein interactions, and cell-uptake. We have prepared two types of polymeric nanoparticles with encapsulated quantum dots or fluorescent dyes

in order to characterize cell interactions, uptake, and toxicity of polymeric NPs with inert surfaces. These materials have applications in nanoplastics toxicity as well as other applications in which pristine surfaces are necessary. Transparent polymer encapsulated fluorescent molecules or QDs can also be surface functionalized for cell targeting, drug or protein conjugation, while avoiding steric hindrance, electrostatic compatibility issues, and enhanced hydrodynamic sizes imparted by surface bound fluorescent molecules or QDs.

Towards a Sustainable Skin Wound Management—Biomaterials from Biomasses for Novel Nature-Inspired Tissue Regeneration Platforms Giulia Suarato[1,1], Marco Contardi[1], Giovanni Perotto[1], Marco Ruggeri[2], Giuseppina Sandri[2], Rosalia Bertorelli[1] and Athanassia Athanassiou[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]University of Pavia, Italy

The skin wound healing process comprises multiple mechanisms, as a result of intricated biochemical events and external factors. Any impairment within the correct interplay of these events could lead to the onset of chronic lesions, with potential effects on the patience quality of life. To correctly support the tissue regeneration, the appropriate design of a wound dressing relies on the fine tuning of its mechanical properties and its degradation process, which need to follow the dynamics of the lesion repair, preserve the physiological healing evolution, act as a shield against infections, and release bioactive principles. By providing structural framework and biochemical cues, the extracellular matrix (ECM) is fundamental for cellular organization and tissue formation.
Nature itself can constitute the source of inspiration for the development of fully biodegradable materials, with enhanced bioactive potentialities. In today's World, the use of natural polymers and materials of biomass origin, either of protein derivation or polysaccharide-based, is becoming a pressing need, to meet the demand of environmentally sustainable technologies to support our future challenges. including applications in the fields of healthcare and wound management. Within this frame, keratin from wool (textile waste, animal biomass) and mycelial materials constitute a valuable source of renewable raw materials.
Keratins are characterized by a high content of cysteine residues, which promotes disulfide inter- and intra-molecular bonding and confers chemical stability and mechanical resistance. Moreover, keratin and its derivatives have gained consideration within the biomedical field, thanks to their good cyto-compatibility and cell adhesion properties. In our recent studies, keratin has been extracted from wool and characterized analytically. From the extracted protein, keratin-based fibrous biocomposites have been obtained using all water-based approaches, suitable for cell culture applications. Thermal crosslinking greatly affected the electrospun matrices biodegradability and water stability, without altering the 3D fibrous network, crucial for primary human fibroblasts attachment. Moreover, encapsulation of active principles within the keratin fibrous structure enhanced the mechanical compliance of the dressing and conferred bioactive properties to the resulting patch.
Another very promising biomaterial alternative is constituted by mycelia, self-growing materials, composed of elongated cells (hyphae), that penetrate a substrate uptaking nutrients and developing a fibrous, 3D interwoven structure. Their chemical constituents can be finely tuned by changing either strains and growth conditions or the feeding substrates. The distinctive porous architecture and the chemical biofunctional groups elect mycelia as potential candidates for the design of novel bio-scaffolds. We therefore conducted an explorative study on the direct use of two edible fungal mycelia, *Ganoderma lucidum* and *Pleurotus ostreatus*, as sustainable alternative for the controlled fabrication of an all-natural and low-cost biomedical scaffolds. Several physicochemical properties of the inactivated systems were thoroughly investigated, and biocompatibility *in vitro*was tested with primary human dermal fibroblasts, revealing how cells successfully adhered to the 3D matrix. Moreover, in a preliminary *in vivo*study of a chronic wound model, rats treated with mycelial scaffolds showed well-formed granulation tissue, collagen deposition and completely regenerated epithelium
The above-mentioned biocomposites can be processed using water-based strategies or by simply tuning their self-growth, in a quest of a more environmentally "green" approach in the biomaterial design.More importantly, their physico-chemical properties and morphologies can be customized to design a new generation of scaffolds for skin wound healing.

1:45 PM SB10.13.05
Flexible Multifunctional Titania Nanotube Arrays Platform for Biological Interfacing Thomas J. Stegall[1,2], Yi Yang[1], Deepti Naruka[1], Jeffrey Capadona[1,2], Allison Hess-Dunning[2] and Hoda Amani Hamedani[1,2]; [1]Case Western Reserve University, United States; [2]Louis Stokes Cleveland VA Medical Center, United States

Multifunctional nanostructured inorganic materials provide unique advantages in interfaces for applications in medicine and biology. When coupled with organic soft polymer substrates that more closely match the mechanical properties of biological tissues, stable devices can be created for monitoring and maintaining health. This work reports on the growth and integration of self-organized nanotube arrays on biocompatible and bioinspired polymer substrates as a novel drug-eluting platform for controlled drug release from flexible devices. To this end, we developed techniques for the growth as well as the integration of titania nanotube arrays (TNAs) on two types of polymer substrates. Successful growth of TNAs is shown via optimization of electrochemical anodization parameters in anodic oxidation of sputtered coated titanium films to facilitate formation of nanotube arrays on the insulating polyimide substrate. In addition, the microfabrication process for the selective (site-specific) growth of TNAs on the polyimide substrate is discussed. Finally, integration process of TNA membranes with a bioinspired mechanically-compliant polymer nanocomposites (composed of poly vinyl acetate reinforced with cellulose nanocrystals) is demonstrated.
The morphology of the nanotube arrays was investigated using scanning electron microscopy (SEM). By varying the anodization conditions (e.g., applied electrochemical potential and time), we obtained highly-ordered vertically-oriented nanotube arrays with an average pore diameter ranging from ~30 – 100 nm and a length of ~0.5 – 20 μm. The nanotube array geometries were defined using either laser micromachining or by selective anodization. Laser-micromachining employed a picosecond laser operated at low power (<2 mW) as a subtractive fabrication method. Alternatively, we optimized a selective-anodization process in which titanium was anodized through a AZ nLOF 2070 negative-tone photoresist mask. By hard baking the photoresist, we were able to maintain a high degree of selectivity even during anodization times exceeding 5 hours. The photoresist was then removed by oxygen plasma exposure, leaving behind defined regions with titania nanotube arrays surrounded by non-anodized titanium.
To demonstrate use in drug-delivery applications, preliminary release tests for the fabricated devices were performed by filling the nanotubes with the food-coloring dye (for the initial tests) and the anti-oxidant resveratrol. Drug release from the resveratrol/dye-loaded TNAs was measured using UV-VIS spectroscopy at various timepoints. After an initial burst phase, the release of both types of molecules follows a highly controlled linear profile (with 47 ng/day as the release rate of resveratrol from 1 mm^2 sample area) that extends beyond one month. In conclusion, we have demonstrated a facile approach to achieve nanotubes/non-conducting polymer flexible devices with precisely controlled drug release properties. The nano/microfabrication methods developed in this work will enable the development of novel flexible devices with controlled drug delivery systems for use in precision medicine and biological interfacing applications.

2:00 PM *SB10.13.06
Rapidly Mineralizing Dense Collagen Gels Functionalized with Bioactive Sol-Gel Borate-Glass Ehsan Rezabeigi, William C. Lepry, Hyeree Park, Qiman Gao, Megan Cooke, Alaa Mansour, Derek H. Rosenzweig, Faleh Tamimi and Showan N. Nazhat; McGill University, Canada

There is a significant need to develop novel scaffolding materials for the repair and regeneration of bone. Ideally, these scaffolds should mimic the mineralized extracellular matrix of bone, which is an organic-inorganic nanocomposite consisting primarily of carbonated hydroxyapatite (CHA) and

fibrous type I collagen. However, reconstituted collagen gel scaffolds lack structure and mechanical integrity. More importantly, they mineralize poorly *in vitro* or *in vivo.*

Our research has shown that bioactive sol-gel derived borate glasses (SGBGs) rapidly convert to CHA, *in vitro,* which can be attributed to their high reactivity and enhanced textural properties. In particular, a boron substituted Bioglass 45S5 formulation; [(46.1)B_2O_3-(26.9)CaO -(24.4)Na_2O-(2.6)P_2O_5; in mol %] with at least two-orders of magnitude greater specific surface area and pore volume values compared to melt-derived equivalents, has demonstrated rapid ion release rates and conversion to CHA. This CHA formation is also associated with an increase in pH upon SGBG dissolution, a feature that can be used to simultaneously fibrilize and functionalize injectable and 3D-printable dense collagen hydrogels.

In this study, we demonstrate a one-step process wherein acid-solubilized collagen molecules self-assemble in the presence of dissolving SGBGs without the use of NaOH, thereby generating highly hydrated collagen gels. These gels were then subjected to the gel aspiration-ejection technique, which imparts both fibrillar compaction and meso-scale anisotropy, thus forming a SGBG-functionalized dense collagen gel. The resulting bone extracellular matrix-mimicking scaffolds exhibited rapid mineralization along the collagen fibrils within 2 hours of immersion in simulated body fluid, and by day 7, CHA formation in dense collagen gels reached native bone levels, *in vitro*.

In order to investigate the potential *in vivo* bone regenerative capability of these rapidly mineralizing scaffolds, they were injected into a critical size defect using a rat tibia model. The short-term mineralization capacity of acellular SGBG-functionalized dense collagen gels was compared to dense collagen gels alone. Micro-CT analysis showed that the bone volume fraction significantly increased in both scaffold implants from weeks 1 to 2. While there was no significant difference between the two scaffolds at week 1, SGBG-functionalized dense collagen gels showed significantly higher bone volume fraction at week 2. In terms of bone microarchitecture, at week 2 of implantation, the SGBG-functionalized dense collagen gels showed less trabecular separation than dense collagen gels alone. These analyses were complemented by histological staining of implants, where Von Kossa, Toluidine blue, alkaline phosphatase, tartrate resistant acid phosphatase, were performed on recovered tissue sectioned samples at weeks 1 and 2 to investigate potential new bone formation in implanted scaffolds. Compared to dense collagen gels alone, the histology of SGBG-functionalized dense collagen gels revealed high levels of positive phosphate staining, suggesting mineralization, and high cellular infiltration with indications of osteoblast and osteoclast activity.

Therefore, the ability to simultaneously fibrilize and functionalize collagen gels via the incorporation of SGBG particles enables the production of injectable scaffolds with promise in bone repair. Moreover, this latest breakthrough allows for the development of bespoke gel bioink formulations, which can be used with a novel biofabrication/3D printing technology based on automated-gel aspiration-ejection. This can facilitate the building of rapidly mineralizable tissue-mimicking structures with varying micro-architectures to mimic native protein fibril density and alignment, as well as cell loading and density according to the intended use.

SESSION SB10.14: Micro and Nanofabrication of Biomaterials

Biomimetic Silk Biomaterials in Cardiovascular Device Development and Tissue Vascularisation Jelena Rnjak-Kovacina; University of New South Wales, Australia

Biomaterials play a central role in modern regenerative medicine and tissue engineering strategies, where they serve as tunable biophysical and biochemical environments that direct cellular behavior and function. However, one of the biggest obstacles in translating the advances in biomaterials/tissue engineering research to clinical applications has been the lack of sufficient vascular tissue regeneration in current synthetic and natural biomaterials. We develop silk fibroin-based biomaterials for cardiovascular applications, including vascular grafts and cardiac patches, with a particular emphasis on enhancing vascular ingrowth and integration of these devices with the host tissue.

Silk fibroin biomaterials serve as a highly versatile biomaterial platform that allows us to study how biomaterial properties drive biological processes and apply these design criteria to cardiovascular device optimization. In this talk I will discuss our work toward (1) development of 3D silk biomaterials with tunable pore morphology/architecture, (2) effect of silk biomaterial architecture and pore morphology on immune responses, tissue integration, and vascularization of implants, including vascular grafts (3) biofunctionalization of silk biomaterials with basement membrane proteoglycan perlecan to create vascular niche-like environments that support growth factor signaling and angiogenesis.

7:00 PM SB10.14.02
Tailor-Made RNA Microneedle System for Subcutaneous Drug Delivery Dajeong Kim[1], Hyejin Kim[2] and Jong Bum Lee[1]; [1]University of Seoul, Korea (the Republic of); [2]Harvard Medical School, United States

Microneedles (MNs) are prominent tools for efficient subcutaneous drug delivery in a non-invasive manner. In particular, dissolving MNs have been widely exploited for the rapid transfer of the massive amounts of biomacromolecules from MN to the skin followed by the sustainable release of drugs. However, scaffold materials for dissolving tip should be carefully chosen due to biocompatibility and safety issues. The microfabrication process often needs complicated procedures regardless of the formulation of MNs, limiting the general usage of MNs. Moreover, degradation-susceptible biomolecules such as nucleic acid require careful address and design for intact delivery. Thus, developing a straightforward and universal approach to fabricate MNs to ensure stability of drugs, particularly nucleic acids, with high loading efficiency is inevitable.

To address the concerns, we establish a novel and simple method to fabricate custom-made RNA MNs (RMNs) based on RNA membrane for a universally applicable drug delivery system. The free-standing RNA membrane was fabricated from rolling circle transcription with two complementary circular DNAs, followed by evaporation-induced self-assembly. By coating scaffold MNs with RNA membrane bearing high stability and RNA packing density, RMNs with a large amount of RNA were successfully achieved. RMNs can be customized by controlling material features of the RNA membrane and 3D printer-based fabrication of scaffold MN in a purpose-oriented way. Remarkably, RNA membrane-based fancy coating method enables a full coverage of the scaffold MN regardless of the shape and material. In addition, RMNs facilitate a massive delivery of RNA along with various types of other drugs, demonstrating the universal applicability of RMN-based drug delivery system. Altogether, this novel strategy presents a general platform to fabricate tailor-made MNs for an efficient and universal drug delivery system.

Novel Exosome-Liposome Hybrid Nanoparticles for Central Nervous System (CNS) Drug Delivery Wisawat Keaswejjareansuk, Katawut Namdee and Mattaka Khongkow; National Nanotechnology Center, National Science and Technology Development Agency, Thailand

The blood-brain barrier (BBB) is a barrier preventing the influx of compounds to diffuse from the blood to the brain. It prevents macromolecules penetrate the central nervous system (CNS). Hence, the BBB is a major challenge for drug delivery and a factor to limits the development of new pharmaceuticals for CNS. Rabies virus glycoprotein (RVG) is known for the rabies virus infection that targeting the extracellular surface of neuron and microvascular endothelial cells due to the binding with nicotinic acetylcholine receptor (nAchR). Many CNS therapeutic drugs were designed with the conjugation of RVG to transport the CNS drugs across the BBB, non-invasively. Exosomes are the vesicles comprise of lipid bilayers membrane. The exosomes function as nanocarriers that can be easily loaded with different types of biomolecules. However, the loading of the therapeutic agents to the exosomes poses difficulty. Liposomes are spherical artificial vesicles formed by non-toxic phospholipids and cholesterol. Besides different properties that are greatly affected by the size, surface charge, and sources of a phospholipid, the liposomes are showing biocompatible by nature and promising vesicles for drug delivery. In this study, RVG decorated exosomes were mechanically fused with the drug-loaded liposomes to formed exosome-liposome hybrid nanoparticles. The hybrid nanoparticles were designed to cross the BBB due to the RGV decoration and deliver the CNS therapeutic agents that encapsulated in the liposomes. The fusing of exosome and liposome was confirmed by Förster resonance energy transfer (FRET). FRET is a photophysical phenomenon that energy transfers from a donor fluorophore to an acceptor molecule at a distance in a range of 1-10 nm. FRET intensity, transmission electron microscopy (TEM), dynamic light scattering (DLS), and fluorescence microscopy were used for the characterization of the hybrid nanoparticles.

In this presentation, physical and optical characteristics of the exosome-liposome hybrid nanoparticles will be discussed. Biological characterizations and the preliminary results of the delivery of therapeutic agents across the blood-brain barrier in mice will be presented.

7:30 PM SB10.14.04
Enzymatically Generated Elongated siRNA Nano Complex for Cancer Therapy Hyangsu Nam and Jong Bum Lee; University of Seoul, Korea (the Republic of)

Introduction: siRNA has been received great attention as emerging gene therapeutics due to its superior capacity of specific gene silencing on the post-transcription level. However, the clinical application of siRNA is still hampered due to its inherent properties and delivery problems. Herein, we proposed a novel systemic siRNA delivery system. We synthesized elongated siRNA via rolling circle transcription and developed nano complexes with a glycol chitosan derivative to systemically deliver the elongated siRNAs to cancer tissues. These elongated siRNA nano complexes (ENCs) showed the highly enhanced in vivo stability and less cytotoxicity, compared to conventional polyelectrolyte complexes. Because ENCs were designed to release active siRNA in the cytoplasmic region, they showed high gene silencing efficacy with efficient tumor target ability. Overall, the proposed RCT-based elongated siRNA nano complexes can provide a new platform technology for efficient cancer therapy.
Method: 5'-phosphorylated linear single-stranded DNA oligonucleotides were circulated by hybridizing with the T7 promoter sequence. To synthesize 0.5uM of circular DNA, ligated the nick in the circularized DNA with T4 ligase. Then, closed circular DNA templated was incubated with T7 polymerase at 37 C 5h with rNTPs. Elongated siRNA was complexed with thiol glycol chitosan (tGC). GC was modified by sulfhydryl groups. We analyzed the stability of ENCs by heparin competition assay, cellular uptake and intracellular distribution on human prostate cancer cells (PC3). In vivo biodistribution of ENCs was investigated through PC3 cells were subcutaneously inoculated to the left flank of male.
Results: We developed the periodically repeated siRNA through the RCT process band its delivery system using glycol chitosan derivatives. The synthesized ENCs have stable formation and protect the siRNA therapeutics against polyanion and nucleases attack formation in blood circulation.
Conclusion: In this study, we developed elongated nano complexes, which were synthesized by a uniquely designed RCT method, as an RNAi therapeutics platform technology for cancer therapy. The ENCs formulation can be considered as a potential candidate for tumor-targeted siRNA delivery system.

7:45 PM SB10.14.05
Late News: Multi-Walled Carbon Nanotube/Cellulose Composite for Phthalate Detection in Solutions Thusitha N. Etampawala[1,2], Hansini Abeysinghe[1], Susira Perera[3] and Gimhani C. Wickramasinghe[3]; [1]Faculty of Applied Sciences, University of Sri Jayewardenepura, Sri Lanka; [2]Center for Advanced Material Research, Faculty of Applied Sciences, University of Sri Jayewardenepura, Sri Lanka; [3]Faculty of Natural Sciences, The Open University of Sri Lanka, Sri Lanka

Phthalates or Phthalic acid esters (PAEs) are one of the most widely used plasticizers in the flexible plastic product manufacturing processes. These chemicals leach, migrate, or evaporate into the surrounding with time, as they do not form chemical interactions with the polymer matrix. As a result, PAEs have become a ubiquitous environmental pollutant that humans and animals could get exposed to and cause health complications even endocrine disruptions. Therefore, qualitative and quantitative detection of PAEs in different environments becomes crucial, especially in water, food, and beverages. Even though there are various PAE detection techniques, the use of complex, time-consuming laboratory processes of advanced technology has emphasized the need for easy, in-situ, and real-time detection technologies. In this study, a Multi-Walled Carbon Nanotube (MWCNT)/Cellulose composite paper was developed as an electrochemical PAE sensing material, where its electric conductivity change after PAE absorption was used as an indicator in qualitatively detecting PAEs in solutions. This technique was developed based on the hypothesis that the absorbed dielectric PAEs would interfere with the electron transfer across the MWCNT network by distancing the MWCNTs due to the presence of their bulky hydrocarbon side chains. The developed sensing material is an electric conductive, flexible, biocompatible, and biodegradable composite paper with potential for recycling and reusing. It was determined that the percolation threshold of MWCNTs in the cellulose composite had to be 250 ppm to form electric conductive papers. These papers were prepared by vacuum filtering an ultrasonicated solution containing MWCNT dispersion in cellulose pulp. The effect of these absorbed PAEs on the electric conductivity of the composite paper was observed using the three-electrode Electrochemical Impedance Spectroscopy (EIS) technique, where the composite paper was used as the working electrode. The electric conductivity of the PAE-absorbed composite paper was analyzed with respect to the pristine composite paper. The reduction in the electric conductivity of the composite paper after PAE absorption was clearly observed through the Nyquist plot, which indicated an increase in the charge transfer resistance between the electrolyte and the electrode, and the Bode magnitude plot, which indicated an increase in the impedance of the composite paper. This novel technique was specifically tested for di(2-propylheptyl) phthalate (DPHP) in methanol solution using a PAE sensing composite paper of 0.001:1 MWCNT:Cellulose composition. The conductivity change of the paper was

tested using EIS over a 0.1 Hz – 1 MHz frequency range. The charge transfer resistance of the pristine composite paper was 6130 Ω. It was increased by 1.15 fold for the PAE-absorbed composite paper, when the DPHP methanolic solution concentration was 1000 ppm, whereas an increase of 1.38 fold was observed when the solution concentration was increased by one order of magnitude. However, the charge transfer resistance of the paper was slightly increased (1.46 fold increase with respect to the pristine paper) when the concentration of DPHP methanolic solution was continued to increase by another order of magnitude. Furthermore, it was discovered that the PAE sensitivity of the composite paper varied with its MWCNT composition, showing potential at developing PAE sensing materials with different sensitivity ranges. More studies are conducting to identify the different PAE detecting ranges for different MWCNT compositions. Based on the experimental results, this qualitative technique shows potential to be developed as a quantitative PAE detection technique. Being able to detect the presence of PAE through the conductivity change of the MWCNT/Cellulose composite paper using EIS shows that this PAE sensing material could be used to develop comparably easy, quick, real-time, and in-situ phthalate detecting sensor.

8:00 PM SB10.09.03
***In Situ* Assembled Microgel Scaffolds—An Emerging Generation of Injectable Microporous Hydrogels for Accelerated Tissue Regeneration** Amir Sheikhi; The Pennsylvania State University, United States

Bulk hydrogels with nanoporous structures have widely been used in tissue engineering and regenerative medicine. These gels are typically made up of randomly crosslinked hydrophilic polymer networks, which have coupled stiffness and porosity. In a simplified model, the stiffer the gel the smaller the pores. Such characteristic limits the applications of bulk hydrogels in 3D cellular engineering wherein stiff scaffolds with large pores are required. In this presentation, we will discuss some of our recent advances in microengineering chemically modified protein microgels based on their orthogonal thermo-chemical response to fabricate biomimetic microporous hydrogels with decoupled stiffness and porosity. We show how these hydrogels support 3D cell viability and proliferation while their bulk counterparts result in cell death. We further demonstrate how the properties of individual microgels regulate the behavior of self-assembled, macro-scale hydrogel constructs. This technology may be generalized for other polymers, opening a new horizon for converting bulk hydrogels to beaded hydrogels with decoupled porosity and stiffness for a broad range of applications in healthcare.

8:15 PM SB10.02.02
Hairy Cellulose Nanocrystals—An Emerging Class of Nanocelluloses for Advanced Applications Amir Sheikhi; The Pennsylvania State University, United States

For decades, cellulose nanocrystals (CNCs) have been produced by hydrolyzing the amorphous regions of hierarchical cellulose fiber structures. These colloidal particles are made up of highly ordered arrays of cellulose chains, impeding the physicochemical modifications of inner crystalline layers, which in turn result in limited/compromised dispersion stability, functionalizability and charge, response to external fields, and transport. Nanoengineering cellulose fibrils via controlled oxidation partially disintegrates the amorphous cellulose chains attached to the crystalline body, which yields Janus-like nanoparticles with a needle-shaped crystalline body (similar to CNCs) sandwiched between two highly functionalized disordered cellulose regions (hairs). This newly emerged class of nanocelluloses are called hairy cellulose nanocrystals (HCNC). The protruding soft brushes from HCNC poles impart significant modifications to the colloidal properties of HCNCs, enhancing their functionality, charge density, stability, and self-assembly. In this presentation, we will review our recent progress in engineering HCNCs for advanced applications, such as water treatment, scale inhibition, biomimetic mineralization, rheology modification, nanocomposites, hydrogels, and so forth. We will show how HCNCs enable several technologies that would otherwise be impossible to develop using conventional CNCs. The outcome of our research may leverage universal biomass-based sustainable, green solutions for long-lasting industrial challenges in water, healthcare, food, and energy sectors.

Disease Control with Microencapsulated Synbiotics in Shrimp Aquaculture M. B. Chan-Park and Guangmin Wei; Nanyang Technological Univ, Singapore

Bacterial diseases in shrimp aquaculture are the major concern to the industry and are typically controlled by eradication of the pathogen. Treatment with antibiotics is a traditional way but it was banned recently because of the concern of antibiotic resistance. To seek an alternative way to control bacteria diseases in shrimp aquaculture, we developed synbiotic (probiotic and prebiotic) microencapsulated beads. We encapsulated probiotic cells in beads (~ 100 mm) prepared through co-gelation of matrix and prebiotic. Compared with physical mixture of synbiotic, microencapsulated synbiotic beads can greatly decrease pathogen viability. *In vitro* coculture method indicated that both probiotics and pathogen can use prebiotic as their food source. While synbiotic encapsulation could trap probiotic and prebiotic inside of beads, thus blocking the access *of* pathogens to prebiotic, leaving pathogen to starve while flourishing encapsulated probiotic only. In addition, co-encapsulation of probiotic and prebiotic would promise more success in terms of viability and stability of probiotic when used in shrimp aquaculture.

8:30 AM SB10.15.02
Electrochemical, Enzymatic, Flexible Sensor for Fatty Acids Detection Jacopo Giaretta, Haowei Duan, Farshad Oveissi, Syamak Farajikhah, Fariba Dehghani and Sina Naficy; The University of Sydney, Australia

Non-esterified fatty acids (NEFA) are carboxylic molecule which is worth detecting in both food and health applications. In food, NEFAs are related to the handling, storing, and cooking condition, making them excellent quality indicators. In health, the NEFA concentration in blood plasma can be related to some metabolic disorders, cardiovascular diseases, cancer mortality, and even sudden death. Hence, detection of NEFA is of the utmost importance in both fields. However, fatty acids are difficult to decompose, which hinders the development of portable sensors.
This research aims to develop an electrochemical, enzymatic, flexible biosensor for fatty acids detection. Filter paper and hydrogels are porous, flexible, and cost-effective substrates which can absorb a conductive ink and can also accommodate enzymes. Poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) conductive polymer is used due to its biocompatibility and safety for use in health and food application. Regarding the enzyme needed, a multi-enzyme system needs to be designed to detect NEFAs. As mentioned, fatty acids are stable, and their metabolic decomposition is complex. Hence, more than one enzyme is required, obtaining a cascade reaction.
Since many oxidase enzymes produce hydrogen peroxide (H_2O_2) as a by-product, the first step was to be able to detect H_2O_2. Therefore, the first enzyme

used is horseradish peroxidase (HRP). As part of the peroxidase family, HRP reacts with hydrogen peroxide while oxidizing a substrate. In this case, HRP uses H_2O_2 – possibly the one produced by other enzymes - to react with PEDOT:PSS. Consequently, a hydrogen peroxide chemiresistive sensor based on an HRP-PEDOT:PSS ink was produced. This sensor is simply produced by 3D printing the sensitive ink on a filter paper, making the manufacturing simple and keeping the cost low. The sensor's limit of detection for H_2O_2 in liquid is 61.3 nM, and it shows a linear range from 61.3 nM to 61.3 µM. The sensor is also sensitive to hydrogen peroxide vapors. Despite the limitations, such as sensitivity to humidity and a relatively long response time (≈ 1 hour), this sensor could be used in controlled environment applications – e.g. food packaging and face masks.
To improve the drawbacks observed in the paper-based sensor, paper was replaced with a hydrophilic polyurethane hydrogel (HPU). Given their crosslinked structures, hydrogels are characterized by porous structures which allow them to swell when absorbing water. At the same time, the pores can be filled with other compatible materials. By combining HPU with the optimized HRP-PEDOT:PSS ink, it was possible to trap both the conductive polymer and the enzyme in a biocompatible, elastic hydrogel scaffold. Contrarily to what was achieved with the paper-based sensor, the use of HPU enables continuous monitoring of H_2O_2 in liquid. The sensor shows a limit of detection of 613 nM and a linear range between 613 nM and 6.13 mM. Once developed a suitable mechanism for H_2O_2 detection in two different substrates, lipoxygenase (LOX) was added to the ink. LOX is an enzyme that takes part in the digestion mechanism of polyunsaturated fatty acids (PUFAs). LOX works in the first stage of this process by adding a peroxide group in a specific position of the fatty acid chain. This site is meant to be the position where the carbon backbone is split. However, in the absence of the following enzyme in the sequence, the peroxide group is not consumed and instead is freed as hydrogen peroxide. This hydrogen peroxide is in turn used by HRP as the reagent to interact with PEDOT:PSS, consequently allowing PUFAs detection. This bi-enzymatic system allows the detection of PUFAs in a relatively simple, speedy, and cost-effective way compared to the traditional method of fatty acids detection.

8:45 AM SB10.15.03
Simultaneous Cross-Linking and Cross-Polymerization of Enzyme Responsive Polyethylene Glycol Nanogels in Confined Aqueous Droplets for Reduction of Low-Density Lipoprotein Oxidation Nazila Kamaly; Imperial College London, United Kingdom

A key initiating step in atherosclerosis is the accumulation and retention of apolipoprotein B complexing lipoproteins within artery walls. In this work, we address this exact initiating mechanism of atherosclerosis, which results from the oxidation of low-density lipoproteins (oxLDL) using therapeutic nanogels. We present the development of biocompatible polyethylene glycol (PEG) crosslinked nanogels formed from a single simultaneous cross-linking and co-polymerization step in water without the requirement for organic solvent, high temperature or shear stress. The nanogel synthesis also incorporates *in situ* non-covalent electrostatically driven template polymerization around an innate anti-inflammatory and anti-oxidizing paraoxonase-1 (PON-1) enzyme payload - the release of which is triggered due to matrix metalloproteinase (MMP) responsive elements instilled in the PEG crosslinker monomer. Results obtained demonstrate the potential of triggered release of PON-1 enzyme and its efficacy against the production of ox-LDL and therefore a reduction in macrophage foam cell and reactive oxygen species formation.

9:00 AM SB10.15.04
Hierarchical Nanocomposites for Biocatalysis Julie Goddard; Cornell University, United States

Enzymes enable high specificity in applications such as production of value-added agricultural products, environmental remediation, and diagnostics, but are often limited by challenges in stability and recovery in these complex biological systems. Hierarchical structures, incorporating both macrostructures and nanostructures, can harness the benefits of each size regime for the stabilization of enzymes. Here we describe two case studies. In one, lipase B from *Candida antarctica* was interfacially assembled with iron oxide nanoparticles into hierarchically ordered structures consisting of a cross-linked core of poly(dicyclopentadiene). Microparticles were characterized for performance in extreme environments (low/high pH, high temperature, solvents) which are denaturing for native lipase. Kinetic analysis revealed a significant increase in the turnover rate following immobilization. After two hours exposure to 50% acetonitrile, there was no measurable leaching of enzyme from the microparticles, while Novozym 435 lost 99.8% protein under the same conditions, suggesting robust design for use in solvent applications. Per unit protein, microparticles outperformed Novozym 435 in direct esterification and transesterification. In another study, we demonstrate the synthesis of copper microflowers in which the enzyme b-galactosidase is incorporated with retained activity. We explore the nuance of considering both biological and non-biological system performance in the pragmatic assembly of these hierarchical biocatalytic nanocomposites. Such understanding of hierarchical biocatalytic systems can permit their application in complex biological systems to improve the safety and sustainability of food, bioprocessing, and diagnostic applications.

9:15 AM *SB10.15.05
"Designer" Oral Delivery Systems for Agri-Food to Pharmaceutical Applications Joachim Loo and Kaarunya Sampathkumar; Nanyang Technological Univ, Singapore

Delivery or encapsulation systems can be developed to achieve controlled-, sustained-release and targeted delivery for a myriad of applications, ranging from agri-food, biomedical, nutraceutical to pharmaceuticals applications. In addition, delivery systems simultaneously function as a protective carrier for labile compounds that may otherwise degrade under harsh environments; for instance, when exposed to gastro-intestinal fluids. By incorporating specific design parameters to each functional system, it is hypothesized that bioavailability of drugs or nutrients can be enhanced. In this presentation, we shall fist discuss how oral delivery systems can be designed to improve patient compliance in the delivery of pharmaceutics, using Parkinson's disease as a model. With the current shift in paradigm in disease prevention through better nutrition, there has been immense interest in augmenting health with nutraceuticals. On this note, we will also report the design of food-based, enteric-coated carriers that can target nutraceutical release along specific parts of the gastro-intestinal tract. Using animal models, we will discuss how this targeted delivery system can improve shelf-life, increase bioavailability and enhance efficacy of nutrients and other nature-derived compounds. In addition, we will also explore alternative oral encapsulation technologies for the development of functional foods, e.g. synbiotics, for agri-food applications.

9:45 AM SB10.15.06
Cost-Effective Cultured Meat Developed on Cell Sheets Containing Tunable Microstructured Gelatin Powders Sohyeon Park and Jinkee Hong; Yonsei University, Korea (the Republic of)

Cultured meat is artificial meat produced by culturing cells extracted from living animals based on cell engineering technology which allows a continuous supply of meat without unnecessary slaughter. Recently, this slaughter-free meat is coming into the limelight due to its advantages of lowering environmental pollution, protecting animal ethics, and enhancing the safety of meat. In addition, the hunger for a sustainable form of meat has grown even more as the meat industry has been hit by the import and export suspensions caused by the COVID-19 pandemic. However, the fatal limitations of cultured meat production such as using excessive animal-derived materials and high production costs put the brakes on the popularization of cultured meat. To overcome this limitation, we propose the introduction of well-organized biomaterial science into the cultured meat process.
In this research, we first report on a strategy to develop scaffold-free advanced cultured meat using fish gelatin microsphere (GMS) and myoblast sheet. The GMSs are edible and exhibit various morphologies and binding activities based on the degree of crosslinking. We also select insulin-like growth factor 1 (IGF-1) and C-phycocyanin (C-PC), blue algae extract, as reasonable and eco-friendly nutrients to improve the proliferative activity of myoblasts in fetal

bovine serum (FBS)-reduced growth medium. Each of these nutrients was incorporated into GMSs with different surface properties. The loading and release behaviors of nutrients for each GMS are analyzed, and subsequently the most effective GMSs to improve the proliferation of myoblasts under an FBS-reduced medium are selected.
GMSs applied to cell sheet culture produce more cost- and time-effective meat-like cell sheets than conventional methods by exerting four important functions. Finally, we prepare two types of cost-effective cultured meat with GMS-based cell sheets. We evaluate the quality of the cultured meat by comparing the tissue properties with soy meat and chicken breast. GMS is a versatile functional material that can be applied to both batch and continuous processes as well as cell sheets. This technology can economically produce cultured meat with high cell content by overcoming the low cell content and high production cost of conventional cultured meat. We believe that this material engineering technology will provide a significant contribution to the commercialization of cultured meat.

Surfactant-Like Cellulose Nanocrystals to Stabilize Pickering Emulsions for Use in Agricultural Applications Gurshagan Kandhola, Joseph Batta-Mpouma and Jin-Woo Kim; University of Arkansas, United States

Surfactants are materials with hydrophobic and hydrophilic sites that adsorb at the interface between an oil and aqueous phase, allowing immiscible liquids to mix easily and produce stable emulsions. These surface-active materials are of immense significance in the agrochemical industry for the development of adjuvant formulations for pesticides and fertilizers. Surfactants are one of the most commonly used adjuvants that increase the efficacy of crop protection products by enhancing their spreading, sticking and wetting properties. However, most commercially available surfactants in agriculture are derived from petroleum sources, and environmental concerns over toxicity and low degradability are key drivers for the growing market demand of renewable, non-toxic, biodegradable surfactants. Thereby, developing efficient and ecofriendly surfactants is of great interest, particularly in the agricultural sector. Biologically extracted materials, such as cellulose nanocrystals (CNCs), are good candidates to fulfill that need. The surface of CNCs is rich with accessible and hidden hydroxyl groups, lending these renewable, non-toxic and biocompatible nanoparticles, an amphiphilic nature and surfactant-like characteristics. While emulsions stabilized by conventional surfactants have been the norm in most industries for many decades, Pickering emulsions stabilized by solid particles; for example, inorganic particles, such as colloidal silica and graphene oxide, and organic particles, such as nanocellulose, are increasingly becoming favorable choices due to their excellent long-term stability.

In this work, cellulosic Pickering emulsions (CPEs) were developed by blending negatively charged CNCs and cellulosic polymers. The tuning of surfactant-like behavior of CNCs was achieved by salts of magnesium nitrate ($Mg(NO_3)_2$) and zinc nitrate ($Zn(NO_3)_2$), respectively. The emulsions were prepared at varied CNC and salt concentrations, without the use of any petroleum-derived surfactants or prior functionalization of the original CNCs with any hydrophobic molecules. The preparation of CPEs was achieved by mixing colloidal CNCs in aqueous phase with oleic acid in oil phase using high-energy ultrasonication. Various interface parameters were investigated, such as surface tension and surface charge as well as shear viscosity, to understand the effect of CNC and salt concentration on the physicochemical characteristics of the CPEs. In addition, the emulsions were also analyzed under an optical microscope to study droplet coalescence and emulsion stability. Results showed that CNCs in the presence of salts influenced the formation and stabilization of the CPEs and were more effective in emulsifying oleic acid compared to when CNCs were used alone. This study not only showed that CPEs can be stabilized by CNCs in the presence of divalent cations, but also established a platform to produce CNC-based PEs with customizable properties and functionalities with new insights into their application as eco-friendly surfactants in agriculture. Such a strategy will be useful to develop advanced products in liquid and solid forms as emulsions and beads not only in agriculture but also in several applications ranging from food and pharmaceutical to paint and coating industries.

This project is supported by the Center for Advanced Surface Engineering (CASE), under the National Science Foundation (NSF) Grant No. IIA-1457888 and the Arkansas EPSCoR Program, ASSET III.

10:45 AM *SB10.16.03
Silk Fibroin as an Edible Food Coating Adam Behrens; Mori, United States

Food waste has far-reaching socioeconomic and environmental impact. Nutrient-rich fresh foods are particularly susceptible to waste resulting from cold chain breaks. Further, the decomposition of wasted food and the subsequent energy and water inputs required for redundant production, processing, and distribution are severely detrimental to the environment. Recent developments have demonstrated the ability of silk fibroin to extend the shelf-life of various classes of foods by minimizing oxidation and dehydration. This work will highlight the physical and chemical features of silk fibroin that allow it to accel as a barrier coating as well as discuss the safety and integration requirements for successful scale up and commercialization within the food industry.

11:15 AM *SB10.16.04
Synthetic and Natural Occurring Polymers—Their Blends and Composites with 1D/2D Nanomaterials for Agriculture Applications Tony McNally, Chaoying Wan and Fengwei D. Xie; University of Warwick, United Kingdom

Biodegradable polymers, those synthesized from monomers derived from either the biomass or fossil fuels, or those naturally occurring continue to attract intense research interest given the increased global impetus to address the carbon footprint of plastics and issues around climate change and pollution. The largest single use of plastics is in all forms of packaging, including food packaging and *de facto* aligned with agriculture, although there are numerous other uses of mostly fossil-fuel derived plastics in agriculture, from pipes to mulch film. Here, we describe two approaches to the development of biodegradable polymer blends and composites that critically can be prepared using sustainable, environmentally friendly processes and at scale in high volumes.
Firstly, focusing on poly(glycolic acid) or PGA, a polymer with a similar structure to poly(lactic acid)(PLA) minus a methyl side group, with the resulting polymer having crystalline content as high as ~55%, high thermal stability (up to 230°C), excellent gas barrier properties as well as high strength (115 MPa) and stiffness (~7 GPa)[1]. However, PGA is 100% compostable and biodegrades rapidly with a profile similar to cellulose. Despite these useful properties, PGA has a number of intrinsic properties, most notably brittleness which have hindered its application. Classically, this has in part been overcome by co-polymerising glycolic acid with lactic acid (PLGA) or to a lesser extent physically blending PGA with other polymers, with the latter

strategy being more commercially viable. Here, PGA was melt blended with poly(butylene adipate-co-terephthalate)(PBAT) using a terpolymer of ethylene, acrylic ester and glycidyl methacrylate (EMA-GMA) to promote interfacial interactions between the blend components. The resultant blends had improved ductility (strain at break increased from 10.7% to 145%), reduced oxygen permeability, enhanced water vapour barrier performance (improved by 47%) and thermal stability up to 300°C, properties required for hot food packaging. Further improvements in barrier properties were achieved by treating the surface of blown films of these blends with electron beam treatment with, further manipulation possible for controlled agrochemical release. A second approach focused on the blends and composites of natural occurring polymers based on chitosan, carboxymethyl cellulose (CMC) and alginate and, 1D/2D materials, both organic and inorganic, including montmorillonite (MMT) and sepolite (SPT). Thermo-mechanical kneading is used to prepare blends and composites of chitosan, a cationic polysaccharide, with negatively charged biopolymers such as CMC, allowing for the preparation of films with excellent dimensional stability and structural integrity [2]. This advance in hydrolytic stability is derived from physical crosslinks due to polyelectrolyte complexation between chitosan and CMC. Furthermore, it is possible to manipulate the properties of these films by the addition of naturally occurring negatively charged MMT or SPT for application in food packaging [3]. The properties of these films were further modified by selective plasticisation using natural molecules and ionic liquids and other 2D materials such as graphene oxide [4].

Polyethylenimine Based Nanoparticles for Enhancing Photosynthesis in Plants Cyril Routier[1], Lorenzo Vallan[2], Eric Cloutet[2] and Eleni Stavrinidou[1]; [1]Laboratory of Organic Electronics, Department of Science and Technology, Linköping University, Sweden; [2]Laboratoire de Chimie des Polymères Organiques (LCPO−UMR 5629), Université de Bordeaux, Bordeaux INP, CNRS, France

During photosynthesis, plants use light energy to transform carbon dioxide and water into carbohydrates. The photosynthetic process comprises many steps that can in principle be optimized to have higher efficiency. Rubisco (Ribulose 1,5-bisphosphate carboxylase/oxygenase) catalyzes the carboxylation reaction that is the initial reaction for carbon fixation and conversion of CO2 to sugars. The reaction occurs in organelles called chloroplasts present in leaf cells. However, Rubisco has naturally a poor affinity for CO2 and the transfer of the atmospheric CO2 to the Rubisco enzyme is highly limited by the diffusion of CO2 through the stomata and the intercellular space which ultimately considerably reduces the photosynthesis rate. Polyamines have been shown in-vitro to be able to transfer carbon dioxide to Rubisco for the carboxylation reaction. In this work, we present biocompatible fluorescent polyethylenimine nanoparticles for enhancing the CO2 transfer to the Rubisco enzyme. With in-vitro studies we evaluated the nanoparticles uptake of atmospheric CO2 and transfer kinetics to Rubisco for the carboxylation reaction. Then we introduce the nanoparticles in-vivo into the plant apoplast via agroinfiltration. First, we studied the toxicity of the nanoparticles and results showed no evidence of a direct harmful impact. We then investigated their localization within the plant leaf with fluorescent microscopy and preliminary observations indicate that the nanoparticles are present in the intercellular space but also in the direct centers of photosynthetic activity: the chloroplasts. Finally, we investigated the impact of the nanoparticles on the plant photosynthesis.

Role of the Assembly Conditions and Macromolecular Structure on Drug Delivery Properties of Multilayer Thin Films Rogerio A. Bataglioli, João Batista M. Rocha Neto, Mariana C. Costa, Patricia F. Martinez and Marisa M. Beppu; University of Campinas, Brazil

The layer-by-layer technique for film deposition presents several advantages for preparing materials for drug delivery, including the mild chemical conditions for handling therapeutics, simple and scalable processing. However, this technique lacks information describing the role of the deposition parameters and film moieties on the drug release process. This study investigated the influence of the assembly parameters (pH, ionic strength, capping layers, and the loading method) on the drug delivery properties in multilayer films. Hyaluronan/chitosan (HA/CHI) films were assembled at different pH (4.5 and 7.2) chitosans with different degrees of deacetylation (40%, 65%, and 85%) to test their role in the loading and release of ionic Rose Bengal dye in the multilayer films. Films assembled at pH 7.2 were rougher and thicker than those deposited at more acidic conditions, presenting superior drug loading capacity and a more sustained release profile. This result was attributed to the more coiled conformation of chitosan during film deposition, which led to a higher number of free amino groups interacting with rose Bengal during drug loading. Drug release data were fitted to the Higuchi model, indicating an increase in the diffusional coefficient with chitosan deacetylation degree. Ritger and Peppas model demonstrated an anomalous drug release mechanism and the
more sustained release profile for films assembled at pH 7.2. This study also investigated the drug delivery properties of the traditional poly (acrylic acid)/poly (allylamine hydrochloride) (PAA/PAH) multilayers, which presented the superior calcein (model drug) loading capacity for films prepared at basic pH (> 8.5) with MgCl 2 or NaCl in the polyelectrolyte solutions. This result was attributed to the higher number of free, no complexed amino groups of the PAH chains in the multilayers, available for interacting with carboxylate groups of calcein molecules
via salt bridges. The drug loading method (post- or during-film deposition) also affected the film loading capacity and release mechanism in the PAA/PAH films, leading to the highest drug loading signal in films prepared using the postassembly method. The limited amount of drug in PAA/PAH films using the during-assembly method may be attributed to the washing out of calcein molecules during film deposition, possibly leading to a matrix with tightly bound drug molecules for this condition. Data fitting to Higuchi and Ritger-Peppas models demonstrated an
increase in the drug release constant with the number of bilayers deposited for films prepared using the postassembly method, whereas the opposite trend was observed for the during- assembly drug loading method. The Berens-Hopfenberg model enabled the decoupling of the individual contribution of different drug release mechanisms (diffusion and polymer chain relaxation), demonstrating an increase of the chain relaxation contribution with the number of bilayers. The stronger interaction between the polymer and the calcein molecules for samples
prepared using the during-assembly method may have hindered the fast, drug diffusion process, enhancing the effect of the matrix swelling in the drug release process and leading to a more sustained drug release profile. PAA/PAH films loaded with calcein were also spin-coated with different capping films (fatty acids and phospholipid monolayers, and ALG/CHI multilayers) to reduce the initial burst release effect. The densely packed phospholipid

monolayers led to the most substantial decrease in the release rate with minimal reduction in the drug cargo during the capping layer deposition, highlighting the importance of single-step methods to avoid the drug leaking. These findings illustrate alternatives to modify the drug release profile of small molecules in nanostructure thin films based on the building blocks, film assembly, and drug loading methods, aiming to design drug delivery devices with precise architecture and performance.

1:30 PM SB10.17.02
Tuning Proton Transport in *m*-Polyaniline Through Chemical Functionalization Gloria Bazargan and Daniel Gunlycke; U.S. Naval Research Laboratory, United States

Proton transport is essential to many physiological processes. For this reason, devices that deliver a controlled flow of protons to living organisms show promise for advancing medicinal/therapeutic treatments. These bioprotonic devices depend on conductive, biocompatible polymer membranes to facilitate protonic movement. Herein, we present *ab initio* molecular dynamics (AIMD) simulations to quantify proton transport in a candidate polymer for bioprotonic membranes, *m*-polyaniline, and its chemically functionalized derivatives. By demonstrating how polar, acidic, and aromatic chemical groups influence protonic movement, our results show that chemical functionalization can be used as a tool for tuning the transport properties of *m*-polyaniline.

1:45 PM SB10.17.03
Late News: Application of Tn5 Transposases to Surface-Immobilized DNA Adsorbed on Grating Surfaces Jonathan Sokolov[1], Anthony Del Valle[1], Hannah S. Saks[2], Junzhi Xie[3], Robin Xiong[4] and Leon L. Zhou[5]; [1]Stony Brook University, The State University of New York, United States; [2]Walt Whitman High School, United States; [3]Richard Montgomery High School, United States; [4]Ward Melville High School, United States; [5]Shenzhen Middle School, China

Recently, modified transposases have been used to both fragment and attach end-groups to DNA molecules in solution and on beads. This process, termed 'tagmentation,' has been commercialized and used to improve library preparation for DNA sequencing. We report the application of transposase tagmentation to DNA linearly stretched and immobilized onto grating surfaces with micron-sized periodicities. The use of gratings is done to prevent the steric hindrance inherent to DNA strongly adsorbed to flat surfaces. The places where the DNA bridges across the grating provide open regions where tagmentation can occur. Gratings were produced using standard integrated circuit lithography techniques on silicon substrates. The gratings were either coated with polymethylmethacrylate (PMMA) thin films or used to produce polydimethylsiloxane (PDMS) replicas. DNA was adsorbed and stretched over the gratings by withdrawing a substrate from DNA-containing solutions, a method called molecular combing. Loaded Tn5 transposase (Diagenode) solutions in tagmentation buffer were applied to the surface-adsorbed DNA via microliter droplets and reacted at 40°C for 10 minutes, followed by soaking in sodium dodecyl sulfate (SDS) for 5 minutes. Fragmentation of the DNA (stained with SyBr Gold dye) was confirmed by fluorescence microscopy. Surface tagmentation has the potential to maintain long-range order of the fragments for sequencing applications.

2:00 PM *SB10.17.04
DNA Nanotechnology—A Promising Tool to Target Cancer Efrosini Kokkoli; Johns Hopkins University, United States

DNA is a popular material for constructing complex, multidimensional nanostructures due to its ability to organize in a precise and predictable manner. Popular approaches to create nanostructures from DNA include DNA origami, DNA tile and DNA brick assembly. An alternate approach to direct the assembly of single-stranded DNA (ssDNA) is to conjugate a hydrophobic moiety (i.e., polymer or lipid-like tail) to the ssDNA to form an amphiphilic molecule that spontaneously self-assembles when added to aqueous solutions. However, the majority of structures created by the assembly of ssDNA-amphiphiles have been spherical and cylindrical micelles. In this presentation I will discuss how we design ssDNA-amphiphiles that self-assemble into supramolecular nanostructures such as nanotubes, and how we use them to target glioblastoma (GBM) in an orthotopic mouse model of GBM.

2:30 PM *SB10.17.05
Nanofibers as Functional Surfaces for Concentration and Capture of Biomolecules in Microfluidic Devices Margaret Frey; Cornell University, United States

Nanofiber membranes can be prepared rapidly and inexpensively using the electrospinning process. These fibers have very high surface to volume ratio and a wide range of surface functionalities have been developed for purifying, capturing and mixing fluids within a microfluidic channel. Specific examples of nanofibers with persistent and switchable positive or negative surface charge and biotinylated surfaces for biotin-streptavidin sandwich style assays and their use in microfluidic devices will be presented. Additionally,two strategies for functionalizing electrospun nanofibers for specific capture of biological molecules will be discussed. First, silver-doped carbon nanofibers (SDCNF) are used as the base material for the selective capture of Escherichia coli in microfluidic systems. Polyacrylonytrile nanofibers containing silver nitrate were electrospun and carbonized to form carbon fibers with silver particles at the surface. Antibodies are immobilized on the surface via a three-step process. The negatively charged silver particles present on the surface of the nanofibers provide suitable sites for positively charged biotinylated poly-(L)-lysine-graft-poly-ethylene-glycol (PLL-g-PEG biotin) conjugate attachment. Streptavidin and a biotinylated anti-E. coli antibody were then added to create anti-E. coli surface functionalized (AESF) nanofibers. Functionalized fibers were able to immobilize up to 130 times the amount of E. coli on the fiber surface compared to neat silver doped fibers. To demonstrate selectivity and functionalization with both gram negative and gram-positive antibodies, anti-Staphylococcus aureus surface functionalized (ASSF) nanofibers were also prepared. Experiments with AESF performed with Staphylococcus aureus (S. aureus) and ASSF with E. coli show negligible binding to the fiber surface showing the selectivity of the functionalized membranes. Second, biotin-cellulose nanofiber membranes are successfully fabricated via "click" chemistry. Cellulose acetate (CA) is electrospun, deacetylated and substituted with an alkyne group in either a one or two step process. Azide-biotin conjugate is then "clicked" onto the alkyne-cellulosesurface via Copper-catalyzed Alkyne-Azide Cycloaddition (CuAAC). FTIR,Scanning ElectronMicroscopy (SEM), Energy Dispersive X-ray spectroscopy (EDX), and X-ray Photoelectron Spectroscopy (XPS) are used to confirm addition of biotin without damage to the fiber structure. The biotin-cellulose nanofiber membranes are used in example assays (HABA colorimetric assay and fluorescently taggedstreptavidin assay) where streptavidin specifically binds to the pendant biotin without requiring blocking agent. Both methods yield durable attachment of the specific capture functionality at the fiber surface.

8:00 AM SB10.18.01
Nanomechanical Analysis of Coronavirus Spike Proteins and Correlation with Infectivity and Lethality Yiwen Hu and Markus J. Buehler; Massachusetts Institute of Technology, United States

The novel coronavirus disease, COVID-19, has spread rapidly around the world. Its causative virus, SARS-CoV-2, enters human cells through the physical interaction between the receptor-binding domain (RBD) of its spike protein and the human cell receptor ACE2. As an increasing number of variants of SARS-CoV-2 circulates globally, estimates of infectiousness and lethality of newly emerging strains are important. Here, we provide a novel way to develop a deeper understanding of coronavirus spike proteins, connecting their nanomechanical features – specifically the vibrational spectrum and quantitative measures of mobility – with virus lethality and infection rate. The key result of our work is that both, the overall flexibility of upward RBD and the mobility ratio of RBDs in different conformations, represent two significant factors that show a positive scaling with virus lethality and an inverse correlation with the infection rate. A quantitative model is presented to make predictions on the infectivity and lethality of SARS-CoV-2 variants based on molecular motions and vibrational patterns of the virus spike protein. Our analysis shows that epidemiological virus properties can be linked directly to pure nanomechanical, vibrational aspects, offering an alternative way of screening new viruses and mutations against high threat levels, and potentially exploring novel ways to prevent infections from occurring by interfering with the nanoscale motions.

8:05 AM SB10.18.02
Potassium Incorporated Titanium Dioxide Nanoparticles Modulate the Production of Immune Mediators Associated with Lepromatous Leprosy by Human Dendritic Cells Upon Infection with *Mycobacterium leprae* So Yoon Lee[1], Sam Warren[2], Jose Barragan[2], Ai Serizawa[1] and Jorge Cervantes[2]; [1]Shibaura Institute of Technology, Japan; [2]Texas Tech University Health Sciences Center, United States

Introduction: Leprosy is a chronic infectious disease caused by *Mycobacterium leprae*, which is still endemic in many parts of the world including Southern Texas. The two polar clinical forms of leprosy, termed tuberculoid and lepromatous, have polarized cellular immune responses, with complex immunological distinctions.
Dendritic cells (DCs) are the primary antigen presenting cells in the immune system. TiO2 nanoparticles have shown to induce maturation of these cells leading to an inflammatory response.
Objective: We aimed to evaluate the effect of potassium incorporated TiO2 nanostructures, namely KTiOx, in the response of human monocyte-derived-DCs to *M. leprae*.
Methodology: THP-1 human monocytes were differentiated and maturated into DCs using commercially available media, and then treated with KTiOx for 24 hours. Following, cells were infected with *M.leprae* at an MOI of 10:1 for 24 hours. Secreted human cytokines were measured in the culture supernatants by a multiplex ELISA system.
Results: We observed an increase in the levels of secreted IFN-a and TNF-b upon *M. leprae* infection in cells treated with KTiOx. IFN-β and its downstream gene IL-10 are preferentially expressed in disseminated and progressive lepromatous lesions, while TNF-β gene is identified as a major risk factor for early-onset leprosy. Interestingly, the levels of cytokine secretion differ comparing 1 M KOH treated Ti and 10 M KOH treated Ti. This can be explained by a wider surface area of the 10M preparation compared to 1 M KOH treated Ti. It is possible that this wider KTiOx area can activate more DCs due to an increase in the contact area.
Conclusion: This study demonstrates the effect of nanostructures of KTiOx and the usefulness of nanoparticle technology in the *in vitro* activation of human DCs against an infectious disease with a puzzling immune spectrum. Our findings may prompt future therapeutic strategies such as DC immunotherapy for disseminated and progressive lepromatous lesions.

8:10 AM SB10.18.03
Enhancing Antibacterial Property of Aluminum Foil by Nanostructuring its Surface through a Simple Hot Water Treatment Quinshell Smith, Kenneth Burnnett, Nawab Ali, John Bush and Tansel Karabacak; University of Arkansas at Little Rock, United States

Foodborne pathogens have led to many hospitalizations and deaths. They have been responsible for several outbreaks in recent years. Bacteria are able to survive on a range of surfaces and environments. The risk of bacterial infection from a contaminated surface has increased exponentially due to the formation of biofilm. Bacteria have been able to form a resistance to the modes of action of current antibacterials. This study utilized a hot water treatment (HWT) method for introducing antibacterial property to aluminum surfaces relevant to food processing and packaging applications. The HWT process produces a nanostructured oxide layer on a wide range of metallic materials by simply immersing the metal in water at relatively low temperatures, which can enhance the antibacterial properties. In this work, aluminum foil was hot water treated at 75°C for 30 minutes. Concentrations of *E.coli* (192 cells) and of *S.epidermidis* (185 cells) were placed on aluminum foil for different times, ranging from 1 minute to 60 minutes. The survival time was measured and the results indicate, the longer the bacteria was on the HWT aluminum foil surface, the more bacteria was killed. As the temperature of the HWT increased to 85°C and 95°C we observed a decrease in bacterial growth, which is consistent with the more pronounced nanostructures at higher HWT temperatures. Overall, the HWT aluminum foils were 95-100% more effective in killing the bacteria within 1-60 minutes than the untreated foil. HWT aluminum oxide nanostructures are believed to utilize multiple mechanisms to deactivate bacteria, ranging from contact killing to the production of reactive oxygen species (ROS), which requires the bacteria to form multiple defenses in order to maintain vitality.

8:15 AM SB10.18.04
Precise Control of RNA Microstructure Fabrication by Viscosity Regulation Moon S. Hyun, Hyejin Kim and Jong Bum Lee; University of Seoul, Korea (the Republic of)

RNA nanotechnology has advanced extensively for its potential biomedical applications by leveraging a wide range of biological functions of RNA. Especially, RNA microstructures fabricated by rolling circle transcription (RCT)-based enzymatic RNA self-assembly has gained much attention as one of the promising approaches to enhancing the loading capacity and delivery of therapeutic RNA. In this respect, we controlled the enzymatic RNA polymerization by regulating viscosity and studied how viscosity affects the RNA microstructures fabrication by altering the enzyme activities and molecular interactions between reaction components. The solution viscosity was manipulated by increasing a glycerol contents. The increment of viscosity in reaction conditions resulted in reduced RNA polymerization rate, which means that the polymerase activity is regulated by viscosity. Furthermore, the inorganic crystallization of magnesium pyrophosphate, which has an important role as a structural basis of RNA microstructures, decreased as the solution viscosity increases. As a results, the size of the RNA microstructure was decreased as the solution viscosity was increased. Also, the flower-like structure was disappeared in highly viscous conditions. Finally, the size of the RNA microstructure was fine-tuned by regulating viscosity with other previously reported size reduction method that modulates template DNA to monomer rNTP ratio. The required size of the RNA microstructures would be different depending on the biomedical application. Therefore, we suggested new approaches to manipulate the size of RNA microstructures to satisfy diverse biomedical demands precisely.

Late News: (Garcia High School Student) Designing Chitosan-Cellulose Composites for Heavy Metal Absorption Using Deweaved Cotton

Cloth Ivan J. Yuan[1], Elizabeth Zhang[2], Jacob T. Zerykier[3], Guanchen Zhu[4], Ayush Agrawal[5], Tianyu Dong[6], Haojun Xu[7], Michael Cuiffo[8] and Miriam Rafailovich[8]; [1]Shanghai High School International Division, China; [2]Phillips Academy, United States; [3]Rambam Mesivta-Maimonides High School, United States; [4]Experimental High School Attached to Beijing Normal University, China; [5]Canyon Crest Academy, United States; [6]Northview High School, United States; [7]The Madeira School, United States; [8]Stony Brook University, The State University of New York, United States

Chitosan is known to have a high capacity for metal absorption, though it exhibits low mechanical strength. Cellulose, on the other hand, has high mechanical strength but low metal absorption capacity. We propose combining the two materials to form a composite that has both metal-absorbing abilities and high mechanical strength. An abundant source of cellulose is in waste cotton fabric, due to the 10 million tons of fabric the textile industry disposes of each year.[1] Citric acid was used to deweave cotton fabric into fibers and also to cross-link chitosan and cellulose through esterification, which produces a stronger and more chemically active cotton-chitosan composite while retaining its biodegradability.[2] One application of cellulose-chitosan composites is the absorption of heavy metals, such as chromium. Chromium pollution is largely caused by industries in energy, mining and metal works, fertilizer, paints, and more. Chromium pollutants, especially chromate, dichromate, and chromium trioxide, have toxic effects on plants, animals, and microorganisms and pose risks to human health ranging from skin irritation to DNA damage and cancer development. Existing methods for removal include chemical reduction, adsorption on porous surfaces with ion exchange, and electrocoagulation, but such methods often produce sludge, require large amounts of chemicals, and pose a risk of secondary pollution.[3] Cellulose-chitosan composites, being fully biodegradable, provide a greener method for heavy metal cleanup.

A 12.5 g/L solution of chitosan was prepared at a pH of 5 (adjusted by HCl). Pieces of fabric, cut across the weave in a diagonal to maximize the number of fibers exposed, were placed in 40 mL of 0.5 M citric acid and stirred at 800 rpm and 60 °C for 15 minutes. The fibers were then placed in a beaker, mixed with approximately 20 mL of chitosan solution, and cured with two different methods: ultraviolet irradiation for 10 minutes and heat lamp for one hour. The UV-cured composite exhibited gel-like properties, suggesting how it can be used as a hydrogel. The heat lamp-cured composite was a stiff material and far more rigid than both the UV-cured composite and the cotton raw material. Scanning electron microscopy (SEM) of the heat lamp-cured composite showed the cotton fibers supporting the chitosan matrix, suggesting that cross-linking was successful and able to provide mechanical reinforcement.

To test the chitosan composite's ability to absorb heavy metals, the heat lamp-cured composites and a control of untreated fabric were immersed in 15 mL of 0.01 M potassium dichromate solution for one hour. The samples were then retrieved from the solutions and dried overnight. The chromium content of the two samples, before and after absorption, was analyzed with X-ray fluorescence (XRF). XRF showed that the chitosan composite contained 149 900 ppm of chromium, which was significantly higher than the 38 000 ppm in untreated fabric and 50 300 ppm in deweaved fibers. To use the composite as an in-line water filtration system, we demonstrated that it was also possible to grind the material into a fine powder after cooling with liquid nitrogen, which can then be contained in a packed-powder filter or incorporated into a porous nanocomposite membrane.

Late News: Mesoporous Pd@Au Film Integrated with Blood Plasma Separation Membrane for Surface-Enhanced Raman Scattering (SERS) Biosensor Hyun-Jong Kim and Hana Lim; Korea Institute of Industrial Technology (KITECH), Korea (the Republic of)

Surface-enhanced Raman scattering (SERS) sensor has been recognized as one of the most versatile tools for ultrasensitive detection of trace chemical and biological analytes. It is now well understood that the plasmonic coupling effect at the nanometer-sized gap junction between particles, that is so called 'nanogap' or 'hot spot' induces enormous electromagnetic enhancement that allows SERS signal to be detected with single-molecule sensitivity. However, inhomogeneous distributions of the location and intensity of the nanogaps lead to varying and non-uniform Raman intensities over substrate, and consequently provides irreproducible measurements. It seems to be practically impossible to obtain both of high sensitivity and good signal reproducibility in a large area.
Currently, SERS sensor is actively employed for the detection of diagnostic biomarkers which provides information about disease from biological fluids. Blood is the most important biological fluid which stands as the medium for transporting nutrients, oxygen and immune cells throughout the body and also maintains body temperature and pH. Therefore, it is an active indicator of various pathological disorders. For the analysis of blood, however, the separation of blood plasma has to first be accomplished to remove red blood cells. The conventional process of blood plasma separation is performed in macroscale centrifugation which requires several milliliters of blood and bulky and expensive apparatus. For patients, it is quite inconvenient due to the high volume of sample blood and transportation time.
To address this problem, we propose a novel strategy for simultaneous separation and SERS sensing of whole blood without additional blood plasma separation. The SERS-active porous metal film is integrated onto the blood plasma membrane. Then, blood plasma is separated from whole blood through the membrane and reached at the surface of SERS-active porous metal film through its pores. For the SERS-active porous metal film, a commercially available pluronic P123 block copolymer was used as a pore former, and physicochemical properties such as porosity and pore size of the metal thin film were controlled by electrodeposition process. As a result, mesoporous palladium thin film with homogeneously perpendicular 6-nm-sized channels was formed onto the blood Pd separation membrane. The homogeneous and perpendicular nanopores was very advantageous for the reproducibility of SERS signals and the facile diffusion of blood plasma. Also, Au layers with the thickness of 1 nm were carefully deposited on the mesoporous Pd thin film by electroless plating process. The obtained mesoporous Pd@Au film integrated with blood plasma separation membrane successfully detected various chemicals and biomarkers from whole blood without interfering with red blood cells.

8:30 AM SB10.18.08
Modification of Bacteriophage Capsid to Improve Bacteria Separation and Detection in Complex Food and Water Samples Kathryn Hufziger, Emma Farquharson, Sam Nugen and Julie Goddard; Cornell University, United States

The ability to detect bacteria in complex matrices with a rapid, low-cost, and simple method is paramount to improving food and water safety worldwide. Bacteriophages (phages), which are natural predators of bacteria and have been used to detect and treat bacterial infections, are a potential solution for bacteria separation and detection. Phages immobilized on magnetic nanoparticles can separate bacteria from their surroundings and then concentrate and detect low concentrations of bacteria in a short time. Our bacteria separation and detection system consists of T7 phages with modified capsid proteins that give a specific and directional binding to silica-coated magnetic nanoparticles. No modification of the phage genome is required; instead, phage capsid modification was accomplished by modifying the bacterial host, which was confirmed with sequencing. Expression of the modified phage capsid protein and assembly on the phage capsid was confirmed by western blotting. The immobilization of modified phages on the silica-coated magnetic nanoparticles was confirmed by infectivity studies, where the infectivity of the modified T7 was higher than wild-type T7. The phage-nanoparticle construct could then separate and detect bacteria in relevant water conditions. Expanding the range of complex conditions in which phage-based detection platforms can perform is an essential step towards improving food and water safety and, in turn, global public health.

Scalable Production of Crosslinked Alginate Microparticles Using Spray Drying for Bioactives Encapsulation in Aquaculture Manish Mahotra, Li Ling Tan, Sharad Kharel, Yu Lin Lim and Joachim Loo; Nanyang Technological University, Singapore

Encapsulation of bioactives like nutrients, probiotics, and drugs is of great interest in the aquaculture industry recently. For oral delivery systems, scalable microencapsulation techniques using food-grade materials, protection of the nutrients against harsh environments, and targeted delivery in a certain portion of the Gastro-Intestinal (GI) tract are considered important. In an aquaculture setting, the nutrient delivery system must be able to prevent the leaching of the nutrient in the water environment and ensure release at the specific site of the fish's GI tract, usually the intestine. Alginate-based microparticles are one of the most studied microencapsulation systems for oral delivery applications. Traditionally, crosslinked alginate microparticles are fabricated using a multi-step technique that involves wet extrusion-gelation using calcium salt solution, followed by additional drying steps. The multistep fabrication makes the process less feasible for large-scale production and application in the food and agriculture industry. In this study, a one-step, and scalable fabrication process was designed using spray drying to fabricate crosslinked alginate microparticles. The presence of the crosslinking between the calcium ion and the alginate polysaccharide network was studied using different material characterization techniques. Additionally, the microparticles were studied for encapsulation of a carotenoid, β-carotene— a vitamin A precursor and an antioxidant. The process enabled a high yield production (~60.0%) of the crosslinked microparticles with high encapsulation efficiency (~50.72%) of β-carotene. The microparticles were found to be stable against disintegration in the aqueous environment due to the crosslinking effect. Additionally, the release studies in the simulated gastric and intestinal fluids showed that the crosslinked microparticles had a minimal release in the gastric fluid (3.42% in 2 hours), while a faster and complete release of the β-carotene in the next 4 hours of dissolution in the simulated intestinal fluid. While typical release behavior comparable to crosslinked alginate microparticles prepared using the traditional extrusion-gelation technique was observed, the optimized process is superior in terms of ease of fabrication, scalability, and cost-effectiveness for the use in bioactives encapsulation in the aquaculture industry.

8:40 AM SB10.18.11
Wireless Monitoring of Polymer Degradation for Noninvasive Assessment of Microbial Metabolic Activity in Food Safety Applications Jose F. Waimin, Sarath Gopalakrishnan and Rahim Rahimi; Purdue University, United States

Bioprocessable and biodegradable polymers can be used as functional material for assessing the metabolic activity of microbes within their environment. Current methods for detecting, assessing, and quantifying microbial activity in soil are limited to time consuming and expensive procedures requiring skilled labor, and can rarely be done directly on site. Simultaneously, as the world faces a growing population, the demand for IoT technology that allows for real-time sensing is crucial in precision agriculture to achieve maximum yields. Previous work has shown the feasibility of using an impedimetric method of detection to monitor the degradation of a cellulose acetate film, cast on interdigitated electrodes (IDEs), to assess the cellulolytic activity of microbes directly in soil. Cellulose degradation, which is a plant product specifically degraded by microbes and fungi in soil, can be directly linked to the metabolic activity of microbes, which has been previously used as a marker for soil health and could provide insight into crop yields and soil performance. Other biopolymers found in soil, such as lignin and chitin, can be used as representative to characterize the diverse metabolic activities of microbes. Similarly, monitoring the degradation of similarly relevant parameters is possible. Materials with pH-dependent solubility, such as cellulose acetate phthalate (CAP) and several methacrylates, can be used to detect sudden changes in pH in several environments.
In this new concept, we have developed a wireless method for assessing microbial activity based on the same system of material degradation. Wireless sensing tags based on RF backscattering (0.5 – 1.5 GHz) have been designed using simulations done on CST microwave studio to achieve miniaturized sensing systems that can be buried and monitored directly in soil. In this method, the wireless reader transmits an interrogation signal to the sensor tag buried in the soil and collects the backscattered signal from it. The sensor tag embeds its resonance as an electromagnetic signature on the frequency spectrum of the reflected signal. Since the resonant frequency of the sensor tag is a function of the dielectric constant of the surrounding media, variations in the thickness and dielectric properties of the soil as well as the coatings on the sensor tag influence the resonant frequency. The sensor tag consists of a sensing unit and reference unit of size 2 cm x 2 cm each. By passivating the sensing unit with the biodegradable material, shifts in the resonance frequency as the material is decomposed can be measured and correlated to the microbial metabolic activity within the environment. The reference unit is coated with an anti-microbial film which makes it insensitive to microbial activity but sensitive to all the other environmental stimuli the sensing unit is exposed to. This differential pair configuration helps in extracting microbial activity by eliminating the effects of other soil parameters, such as volumetric water content (VWC) and temperature. These small, low-cost, battery-less sensing tags have been manufactured using scalable processes like 3D printing and laser cutting. By making sensing tags from extruded polylactic acid (PLA) filament, the meander-structured antennas using Zinc tape, and using a biodegradable polymer as functional material, we've achieved a fully biodegradable environmentally-friendly sensing system that can be buried in the soil and left for natural resorption without any concerns. These tags have been successfully used to monitor VWC (5% - 30%) in soil and the decomposition of materials with pH-dependent solubility with applications in food packaging and storage.

Late News: Thermodynamics of DNA Looping for Origami Folding Jacob M. Majikes, Paul N. Patrone, Michael Zwolak, Anthony Kearsley and Alexander J. Liddle; National Institute of Standards and Technology, United States

DNA-based self-assembly provides an exciting materials platform with which to build composite nanostructures impossible to fabricate with top-down techniques. While biological DNA is well characterized, much work must be done to develop a mature understanding of DNA as a nanoscale construction material.
In metals defects contribute only a small fraction of the system free energy, but control material microstructure and properties. In DNA origami, where the scaffold molecule is forcibly routed into a predetermined shape, conformational energy contributions are small compared to those of base pairing and base stacking but control assembly properties.
By leveraging the high throughput of qPCR equipment, we examine the thermodynamics of single folds *via* van't Hoff analysis of melt curves.
We then examine the effect of staple excess revealing unintuitive results in both cases. In contrast to whole origami, increasing staple excess for a single fold significantly reduces yield. We present these results and show how they can inform an understanding of whole-origami systems.

SYMPOSIUM SB11

Photo/Electrical Phenomena at the Interface with Living Cells and Bacteria
November 30 - December 8, 2021

Symposium Organizers

Rational Design of Phenazine Mediator Promoted Extracellular Electron Transfer in *Escherichia coli* Shelley Minteer; University of Utah, United States

The ability to establish successful and efficient extracellular electron transfer (EET) between bacteria and electrode surfaces is critical for the development of mediated microbial electrochemical technologies. Here, we describe a phenazine-based mediator system to facilitate electron transfer from the model bacterium *Escherichia coli* during glucose metabolism. Phenazine redox mediators were experimentally evaluated, demonstrating distinct mediated currents, dependent on mediator structure. Our results show that the choice of a mediator with the appropriate redox potential is not the single aspect to consider when rationally designing future mediator-based EET systems. We will discuss the use of density functional theory and multivariate linear regression for understanding the structural properties that control phenazine mediated EET.

11:00 AM SB11.01.03
Nanomaterial–Bacteria Ensembles for CO_2 and N_2 Conversion to Tunable Value-Added Products Stefano Cestellos-Blanco and Peidong Yang; University of California, Berkeley, United States

In order to limit and revert the effects of climate change we must find a strategy to convert nearly inert CO_2 to value-added chemicals to close the carbon loop. CO_2 utilization has been industriously studied resulting in a variety of catalysts aiding to reduce CO_2. One auspicious approach integrating both solar energy generation and CO_2 reduction consists of pairing autotrophic whole-cell bacteria with semiconductor nanomaterials. Nanomaterials at length scales similar to those of bacteria absorb light and provide the microorganisms with the requisite energy to undertake CO_2 reduction. The microorganisms convert CO_2, N_2 and H_2O with unparalleled selectivity and low-substrate activation all while self-repairing and reproducing. We present on the evolution of photosynthetic semiconductor biohybrids and how we have built on the earliest demonstrations of the concept. Our enhanced ability to control the microenvironment in a silicon nanowire array, led to an increase in loading of acetogenic bacteria *S. ovata* which in turn improved CO_2 to acetate conversion. We were able to drive this reaction with solar power resulting in a 3.7% solar-to-chemical conversion. We have also undertaken a process to quicken the autotrophic metabolism of *S. ovata* via methanol adaptation yielding a 50% increase in CO_2 turnover rate. Furthermore, acetate can be upgraded by a secondary biocatalyst. Therefore, we have designed co-cultures to upgrade the acetate to value-added products. We demonstrate a co-culture between acetogenic *Sporomusa ovata* and diazotrophic *Rhodopseudomonas palustris* for tandem CO_2 and N_2 fixation to tunable value-added products including acetate, NH_3, nitrogenous biomass, and biopolyester. The dynamics between these two organisms and the products of the co-culture can be directed by electrochemical inputs. Lastly, we present on a strategy to generate sugars through abiotic CO_2 electrosynthesis. Copper nanoparticles and boron doped diamond electrochemically reduce CO_2 to glycolaldehyde and formaldehyde respectively which together form sugars including glucose. These sugars are used to culture *Escherichia coli* which can be engineered to produce chemicals and materials.

11:15 AM SB11.01.04
Tunable Electrochemical Activity and Conduction in Light-Patterned *Shewanella* Biofilms Marko Chavez, Fengjie Zhao, Christina M. Cole, Kyle Naughton, James Boedicker and Moh El-Naggar; University of Southern California, United States

Electroactive bacteria, such as the model organism *Shewanella oneidensis* MR-1, can couple the oxidation of organic electron donors to the reduction of external solid surfaces, including minerals and electrodes, utilizing outer membrane multiheme cytochromes that carry charge from within the cell to external surfaces. In addition to transporting electrons across the cell envelope, the multiheme cytochromes can also facilitate long-distance (micrometer-

scale) redox conduction along the outer membrane and across multiple cells bridging electrodes. While electroactive bacteria are commonly used in the construction of bioelectrochemical energy technologies, the development of more advanced living electronics has been challenged by the inability to control the size and shape of the conductive biofilms in relation to solid-state components. To overcome this challenge, we developed an optogenetic deposition strategy in which projected blue light patterns control the expression of a cell-surface adhesion protein in *S. oneidensis* and direct cell attachment to the illuminated areas of transparent conductive surfaces. Using this technique, we showed that the electrochemical activity of the engineered light-patterned biofilms remained comparable to that of the wild-type and scaled with controlled biofilm size. Furthermore, by depositing biofilms onto transparent interdigitated electrode arrays and performing electrochemical gating measurements, we confirmed that biofilm conduction current can also be tuned as a function of patterned biofilm size. Precise control of biofilm geometry allowed us to determine the intrinsic conductivity of living *Shewanella* biofilms for the first time. Thus, we have developed a facile technique to direct the deposition of living conductive biofilms; we anticipate that this approach will enable further innovations for both studying and harnessing bioelectronics, akin to the role that traditional photolithography played in the development of solid-state electronics.

SESSION SB11.02: Systems Design
Session Chair: Giuseppe Paternò
Tuesday Afternoon, November 30, 2021
Sheraton, 2nd Floor, Back Bay A

1:30 PM *SB11.02.02
Polydopamine—A Bioinspired Polymer to Interface Photosynthetic Bacteria with Electrodes Gianluca M. Farinola[1], Danilo Vona[1], Rossella Labarile[1], Gabriella Buscemi[1,2], Roberta Ragni[1], Maria Varsalona[1,2], Francesco Milano[3], Matteo Grattieri[1,2] and Massimo Trotta[2]; [1]University degli Studi-Bari Aldo Moro, Italy; [2]CNR-IPCF Institute for Physical-Chemical Processes (IPCF), CNR, Italy; [3]CNR-ISPA, Institute of Sciences of Food Production, Italy

Photosynthetic microorganisms are capable of interacting with light by specific proteins, called Reaction Centers (RCs), which are located into cell membranes and convert photons into charge separated states, in a process with efficiency close to 100%. Our work has demonstrated that the light harvesting capability of the RC extracted from *Rhodobacter sphaeroides* R26 bacterium can be ameliorated by covalently binding tailored molecular organic antennas [1-3]. RCs have been directly exploited in electronic and electrochemical devices [4], acting as photoactive systems in photoelectrochemical cells [5], photosensors [6] and photoactive transistors [7]. Interestingly, intact living photosynthetic bacteria cells can be also integrated in devices for bioelectronic applications [8]. However, the use of conductive artificial materials, like polymers or inorganic electrode surfaces, could lead to detrimental effects for the bacterial viability. Conversely, adhesive biomimetic polymers such as polydopamine (PDA) are promising biocompatible coating materials for application of *Rhodobacter sphaeroides* R26 bacterial cells in bioelectronics. Here, the approach is based on *in situ* polymerization of dopamine monomer in cell medium, with the PDA polymer self-assembling around cells, allowing them to thrive by light absorption and ensuring their interaction with conductive electrode surfaces. Polydopamine has been already successfully exploited to stabilize the interface between *Rhodobacter sphaeroides* RCs with electrodes, avoiding protein denaturation and facilitating the integration in electronic systems [9-10]. Preliminary electrochemical characterization also unveils that PDA layer around living bacterial cells adhered onto electrodes does not alter their viability and it does not hinder the diffusion of mediators and their capability to react at the electrodes.

2:00 PM SB11.02.03
P3HT Nanoparticles with Core-Shell Architecture—Tuning the Photophysical Properties Jonathan Barsotti[1], Sara Perotto[1,2], Andrea Candini[3,4], Elisabetta Colombo[1,5], Franco V. A. Camargo[3], Stefano Di Marco[1,5], Mattia Zangoli[3,4], Samim Sardar[1], Alex Baker[1], Cosimo D'Andrea[2], Giulio Cerullo[2], Shlomo Rozen[6], Fabio Benfenati[1,5], Francesca Di Maria[3,4] and Guglielmo Lanzani[1,2]; [1]Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Milano, Italy; [3]Consiglio Nazionale delle Ricerche, Italy; [4]Università di Bologna, Italy; [5]IRCCS Ospedale Policlinico San Martino, Italy; [6]Tel Aviv University, Israel

Organic nanoparticles (NPs) are promising functional materials for the development of advanced photonic and biophotonic systems. We already demonstrated that blind laboratory rats treated with P3HT nanoparticles were able to recover vision highlighting the potential biomedical applications in the context of neuronal stimulation and neuroprostheses [1]. Here, we investigated thiophene-based core@shell NPs, made of poly(3-hexylthiophene) (P3HT) in the core and oxygenated P3HT (PTDO) in the shell [2], proving their role as highly effective photon nanotransducers. This structure supports long-lived charge separation, originating from the type II alignment at the core/shell interface. Here we provide a general photophysical picture in accordance with the morphology and the oxidation degree of the nanoparticles. Atomic force microscopy and Kelvin probe force microscopy allowed to characterize the nano-organization within the NPs core@shell configuration and their surface photovoltage characteristics. Steady-state and time-resolved spectroscopic measurements suggest that energy transfer is taking place form the core to the shell, followed by charge separation at the surface. Living cells photostimulation can be achieved exploiting different physical mechanisms such as chemical reaction, current injection, capacitive coupling and thermal effect. Each mechanism can be ascribed to a specific material or a particular geometry [1]. The application of these core@shell systems may

advance our understanding of the coupling mechanism at the biotic/abiotic interface.

Shedding Light on Thermal Induced Optocapacitance at the Organic Bio-Interface Gaia Bondelli[1,2], Samim Sardar[1], Greta Chiaravalli[1,2], Vito Vurro[1], Giuseppe M. Paternò[1], Guglielmo Lanzani[1,2] and Cosimo D'Andrea[2,1]; [1]CNST@PoliMI, Italy; [2]Politecnico di Milano, Italy

The possibility to control selectively the electrical activity of living cells with low invasiveness has opened up new therapeutic paths in neurodegenerative medicine. Optical technologies are particularly suited for this purpose, as light enables precise and localised perturbation of cell activity in a remote and spatiotemporal precise manner. In particular, cell membrane potential modulation occurs via the photoinduced modification of the membrane electrical properties, either through direct photostimulation or by using selected transducers that are able to convert light into an electrical, mechanical, chemical, or thermal stimulus. In these regards, organic semiconductors have emerged as powerful photoactuators for the development of functional interfaces with living cells and organisms, thanks to their relatively high absorption coefficient and to their bio-mimetic nature. Although many efforts have been dedicated to investigate the biophysics underpinning photostimulation with organic semiconductors, the exact stimulation mechanism is still matter of debate.
To shed light into these aspects, we employed an all-optical spectroscopic approach, based on the use of well-established fluorescence probes, to monitor the membrane polarity, viscosity and order directly in living cells under thermal excitation transduced by a photoexcited polymer film. Briefly, our findings demonstrate that the opto-capacitive process induced by temperature is not simply due to a geometrical effect, as it is commonly believed. Indeed, our results suggest that a thermal induced phase transition promotes water penetration into the disordered phase of the plasma membrane. Thus, we speculate that the resulting change in dielectric response of the plasma membrane is the ruling phenomenon explaining the temperature induced enhancement in capacitance. Furthermore, we find experimental evidence that optostimulation mediated by a photovoltaic organic film brings about an additional phenomenon reinforcing the perturbation effect. We tentatively assigned this to the surface charging at the bio interface, suggesting that optostimulation mediated by organic semiconductors is not simply due to thermal effects, but it is also related to the capability of the photogenerated charges to polarize the plasma membrane.

2:30 PM SB11.02.05
Hierarchical Mathematical Models of Polythiophene Devices to Understand the Interaction Occurring at Abiotic/Biotic Interface Greta Chiaravalli[1,2], Giovanni Manfredi[2], Riccardo Sacco[1] and Guglielmo Lanzani[2,1]; [1]Politecnico di Milano, Italy; [2]Istituto Italiano di Tecnologia, Italy

The development of a fully organic photovoltaic prosthesis of poly(3-hexyltiophene) (P3HT) for subretinal implants was proposed to treat degenerative blindness (Maya-Vetencourt et al.,2017 and 2020). Although the efficiency of organic polymer-based retinal devices in vivo has been proven, the interpretation of the working mechanisms that grant photostimulation at the polymer/neuron interface is still a matter of debate. In order to contribute solving this issue, we have first focused on the characterization of the interface between P3HT films and watery-electrolytes by the combined use of electrochemistry and mathematical modeling.
In particular, the electric behavior of P3HT is modeled through a system of time dependent Drift-Diffusion non linear partial differential equations. The model takes into account the working principles of the organic semiconductor in contact with the electrolyte solution, with a detailed description of its interaction with the dissolved oxygen. This effect experimentally proved to be crucial in the photoelectrical switch of P3HT.
In order to compare and validate the results of our mathematical model, we have performed several electrochemical measurements of photovoltage on P3HT film deposited onto an ITO substrate samples, in different oxygenating conditions and with active layers of various thicknesses. Mathematical simulations well reproduce the experimental results upon illumination of the device in the various conditions.
Besides validation, the good agreement between measurements and simulations can be used to highlight the main effects, secondary to the illumination of the P3HT device, necessary to reproduce the experimental behaviour. Upon illumination, the essential unipolar transport in the photoexcited film leads in few μs to a drift-diffusion equilibrium associated to a space charge separation, responsible for the initial negative photovoltage. Electron transfer reactions towards oxygen at the polymer/electrolyte interface extract negative charge from the polymer and are responsible for the positive signal that we observe after several *ms*. The quantitative description of the phenomena also permits the estimation of the charge accumulated at the interface, possibly responsible for an electrostatic interaction with a biological system.
In spite of the simple model studied, all these considerations shed light on the possible coupling mechanisms between the polymeric device and the living cell, supporting the hypothesis of pseudo-capacitive coupling arising from an electrostatic interaction between the polymeric film and the watery environment. In addition to this, once the fundamental mechanisms of P3HT have been quantitatively reproduced and formalized, it is possible to start developing models to reproduce the effects of P3HT nanoparticles in a watery-electrolyte, a system whose electric properties are hard to characterize experimentally but which appears to be the new frontier of retinal devices.

Optoelectronic Studies of Hydrothermally Grown Microcrystalline ZnO Employed in Antibacterial Assays with Staphylococcus Aureus Dustin Johnson, John Reeks, Iman Ali, Shauna McGillivray, Yuri M. Strzhemechny and Jacob Tzoka; Texas Christian University, United States

Nanoscale and microscale ZnO particles are utilized in a wide variety of applications due to their optoelectronic properties and high biocompatibility. One application is the use of ZnO as an antibacterial agent. Antibacterial action of ZnO is well documented, exhibiting growth inhibition for gram-positive and gram-negative bacteria as well as antibiotic resistant bacterial strains. In spite of considerable amount of research in this field , there is no clear consensus on the fundamental mechanisms behind this phenomenon. Suggested mechanisms include: cell internalization of the ZnO particles, release of Zn ions, generation of different reactive oxygen species, surface-surface interactions, etc. In our work, we address, in conjunction with the antibacterial assays, surface and near-surface optoelectronic properties of ZnO microcrystals participating in those assays. In particular, we look at the influence of crystalline morphology and crystallographic polarity on the interaction between bacterial cells and ZnO surfaces. To produce our antibacterial specimens we utilized a bottom-up hydrothermal growth method to synthesize ZnO microcrystals of tunable morphology and relative abundance of polar and non-polar surfaces. Scanning electron microscopy, energy-dispersive X-ray spectroscopy and surface photovoltage experiments were used to characterize the quality and morphology of the ZnO microcrystals. To establish the antibacterial activity of our particles, we ran minimum inhibitory concentration assays of staphylococcus aureus. By utilizing ZnO crystals larger in size than the s. aureus bacteria cells, we confirmed that internalization of the ZnO particles is not necessary to inhibit the growth of the bacteria. The larger microcrystals exhibited inhibition of bacterial growth comparable to that of nanoscale ZnO particles. To determine the influence of structural and surface properties of ZnO on the assay outcomes, we performed a series of optoelectronic experiments using photoluminescence spectroscopy as well as spectroscopic and transient surface photovoltage. These investigations were performed on ZnO crystals prior to and following exposure to s. aureus. Our results revealed significant spectral changes due to interactions with bacteria and growth

media. We demonstrated that growth media have a significant impact onto the nature and efficacy of antibacterial activity of ZnO.

3:00 PM SB11.02.07
Photophysical Characterization of Previously Unidentified Intrinsic Charge Transfer States in Proteins Leah Spangler, Michael Hecht and Gregory Scholes; Princeton University, United States

The intrinsic optical properties of proteins (*i.e.*, absorbance at 280 nm and fluorescence around 340 nm) are known to originate from the electronic transitions of aromatic amino acids, such as tryptophan. As aromatic amino acids are present in nearly all proteins, intrinsic absorbance and fluorescence have limited use in protein characterization. Recently however, a new weak intrinsic absorbance signal has been uncovered in the visible region, even in proteins which lack aromatic amino acids. This previously overlooked visible absorbance signal has been theorized to arise from charge transfer states which form between charged amino acids within the protein. The unique interactions between charged amino acids likely affect this new intrinsic absorbance signal, and could be used to identify specific protein structures or sequences. Despite experimental observation of this new optical state, the exact photophysical mechanism has not yet been elucidated spectroscopically. Here, we characterize this newly uncovered optical state using advanced spectroscopy techniques in three highly charged proteins. The absorbance spectra of each protein was carefully measured using an integrating sphere to minimize contributions from scattering. We then used transient absorption spectroscopy to fully characterize the energy transfer within each protein, uncovering states with charge transfer character, consistent with theoretical simulations. By fully understanding this intriguing new charge transfer state, protein absorbance could eventually find use as an intrinsic probe for in vivo optical microscopy, or as a new method for the identification of specific protein conformations.

3:15 PM SB11.02.08
Nanosensor Chemical Cytometry to Support Cellular Therapeutics Sooyeon Cho, Xun Gong and Michael Strano; Massachusetts Institute of Technology, United States

Cell therapeutics is a rapidly growing medicinal innovation being applied to cancer immunotherapy and degenerative diseases among others. Conventional pharmaceutical standards dictate a regulatory need to understand each and every cell placed within a patient. Thus, cellular therapeutic elements need to be monitored and assessed through various cell production process step to keep consistent and safe clinical outcome. However, this necessarily requires a new generation of non-destructive and label-free techniques that can characterize a single cell and their product at high-throughput, but otherwise leave it unadulterated before administration to the patient. Such a tool would bring unprecedented spatiotemporal resolution to intracellular and pericellular biochemical interactions at the scale of the fundamental building block of life with significant high-throughput. The scientific challenges include the need to measure at a rate and magnitude commensurate with the size of cell population and this goal has remain elusive over the past decades.
In this research, we utilize a power of nanosensor array and develop a new class of cell population monitoring platform that addresses those limitations. An array of near infrared (nIR) fluorescent single walled carbon nanotube (SWNT) nanosensors are integrated along a microfluidic channel through which a population of flowing cells will be guided, using specific integration technique of particulate form of fluorescent nanosensors. We show that one can utilize the flowing cell itself as highly informative Gaussian lenses projecting nIR emission profiles and extract rich information on a per cell basis in real-time and a non-destructive manner. This unique biophotonic waveguide allows users to quantify the cross-correlation of the biomolecular information with physical properties such as cell size, eccentricity and refractive index (RI). We show that it operates as a label-free chemical cytometer for the measurement of cellular heterogeneity with unprecedented precision for various type of cells and their target analytes. Our platform can be exploited to new class of chemical cytometry tools for cell-based therapeutic applications, where there are urgent needs for high-throughput characterization of biochemical properties cellular targets with therapeutic potential for new treatments.

SESSION SB11.04: Biostimulation
Session Chair: Herdeline Ardoña

Organic Actuators for Cell Photo Stimulation Guglielmo Lanzani[1,2]; [1]Italian Inst of Technology, Italy; [2]Politecnico di Milano, Italy

The overarching goal of our research is to manipulate the light-bio-matter interaction to obtain control over the functioning of living systems. Light can control cell activity, with high space and time resolution and a virtually infinite number of configurations, free from wiring constrains. We develop and study non-genetic cell opto-stimulation techniques based on artificial light actuators that establish functional abiotic-biotic interfaces able to transduce a light signal into a biological stimulus. This talk reports on the state of our research regarding organic bio interfaces for inducing light sensitivity in cells, both in vitro and in vivo. Light actuators comes in different shapes: planar patches, nanoparticle, intra-membrane probes. Their coupling mechanism is still far from being understood and attempts to shed light will be introduced. The research aims at a new technological platform for application in life enhancing technologies or new cyborg technologies. One of the most appealing application of this emerging technology is rescue vision in blind people.

11:00 AM SB11.04.02
Cyborg Brain Organoids Paul Le Floch[1], Qiang Li[1], Ren Liu[1], Kazi Tasnim[1], Siyuan Zhao[1], Zuwan Lin[1,2], Han Jiang[1] and Jia Liu[1]; [1]Harvard University, United States; [2]Broad Institute of MIT and Harvard, United States

Human induced pluripotent stem cell-derived brain organoids have shown great potential for studies of human brain development and neurological disorders. However, quantifying the evolution and development of electrical functions in brain organoids is currently limited by measurement techniques that cannot provide long-term stable three-dimensional (3D) bioelectrical interfaces with brain organoids during development. In this lecture, I will present the cyborg brain organoid platform, in which 2D progenitor or stem cell sheets can fold “tissue-like” stretchable mesh nanoelectronics through organogenesis, distributing stretchable electrode arrays across 3D organoids. We previously demonstrated this technique in cardiac organoids, and I now expand it to two types of brain organoids, early-stage brain organoids, where the mesh nanoelectronics is integrated to the tissue culture before differentiation and organogenesis, and more mature brain organoids, where the mesh nanoelectronics is integrated after four months of differentiation. I will demonstrate that the tissue-wide integrated stretchable electrode arrays do not interrupt neuronal differentiation, adapt to the volume and morphological changes during organogenesis, and provide long-term stable electrical contacts with neurons within brain organoids during development. Then, I will show that the seamless and non-invasive coupling of electrodes to neurons enables a 6-month continuous recording of the same brain organoids and captures the emergence of single-cell action potentials from early-stage brain organoid development. The increase of action potential

amplitude, synchrony, and firing rate as well as narrowing of action potential duration suggest changes in neural network connectivity and cellular ion channel expression level. Finally, I will discuss the integration of cyborg brain organoid platform with organoid-wide connectomics and spatial transcriptomics mapping to further test this hypothesis. Furthermore, cyborg brain organoid technology can potentially become a useful tool for quantifying the functional development of brain organoids and standardizing the culture conditions across different types of protocols by tracing organoid-wide tissue and single-cell electrical activity during the entire organoid development. It will also be useful for studies of developmental neuroscience and drug screening.

11:15 AM SB11.04.03
Cardiac Cell Non-Genetic Photostimulation Vito Vurro[1], Francesco Lodola[2], Carlotta Ronchi[1], Valentina Sesti[3,1], Maria Rosa Antognazza[1], Chiara Bertarelli[3,1] and Guglielmo Lanzani[1,3]; [1]Istituto Italiano di Tecnologia, Italy; [2]Università degli Studi di Milano-Bicocca, Italy; [3]Politecnico di Milano, Italy

Nowadays stimulation and control over cellular activity and physiology is an emerging and hot topic. In particular, contactless and wireless methods are extremely appealing due to their ability to leave unaltered the cell and tissue condition. Following this idea, light represents a clean and spatiotemporal precise tool to achieve effective bio-stimulation. Light-transducers, such as conjugated molecules and macromolecules, have proven their efficacy at the interface with living cells and tissue. This interaction is possible thanks to their high optical absorption/emission, biocompatibility and versatility in chemical synthesis.
In this work, we employ a lipid membrane-targeted photochromic molecule to photomodulate signalling in cardiac cells. We characterized the single cell-molecule interaction, to evaluate its ability to photocontrol electrophysiological and functional behaviours. The ultimate goal of this project is the realization of a bio-hybrid photoresponsive smart tissue for future applications in robotics and pharmacology, as well as for tissue regeneration.

SESSION SB11.05: Imaging and Sensing
Session Chair: Giuseppe Paternò

1:30 PM *SB11.05.01
Imaging the Resting Membrane Potential and Elongation of Individual Bacteria Cells Christine Payne; Duke University, United States

All cells, including bacteria, maintain an ion gradient across their membrane. This ion gradient results in a resting membrane potential that is essential to cell health. The use of light or electricity to control the resting membrane potential, compared to solution-based reagents, is unique in providing spatial control. We have designed a fluorescence microscopy-based platform to monitor and control membrane potential, while also imaging cell elongation and division. Our recent work has focused on the relationship between resting membrane potential and cellular elongation. Resting membrane potential is controlled by exposing *B. subtilis* cells to blue light, thereby limiting the effect to a subset of cells. Neighboring cells, not exposed to blue light, are used as a control. The elongation rate is measured for each cell, thereby incorporating the heterogeneity of cellular populations into each measurement. Our experiments distinguish two populations of cells with correlated membrane potential and elongation rates. The ability to modulate the resting membrane potential with light, and thereby control the growth of a subset of bacteria within a larger population, provides a method to better understand the fundamentals of bioelectricity and ultimately modulate cellular growth in a spatially-controlled manner.

2:00 PM *SB11.05.02
Conducting Polymer Devices Integrated with Cell Membranes for Diagnostics and Drug Discovery Roisin Owens; University of Cambridge, United Kingdom

In vitro models of biological systems are essential for our understanding of biological systems. Many difficulties exist in interfacing complex, biologically relevant models with technology adapted for monitoring function. Polymeric electroactive materials and devices can bridge the gap between hard inflexible materials used for physical transducers and soft, compliant biological components. In this presentation, I will discuss our recent progress in adapting conducting polymer devices, both OECTs (organic electrochemical transistors) and electrodes, to integrate with both mammalian and bacterial cell membranes supported lipid bilayers, preserving native membrane function. The conducting polymer devices preserve native membrane function, including transmembrane protein function, but also provide a means to readout changes to membrane properties such as permeability or binding or fusion with the membrane. Since the cell membrane is the gateway to the cell, this platform allows monitoring of pathogens such as viruses that may enter the cell, or drugs or toxins that may interact with the membrane compromising normal function (e.g. toxins binding to ion channels in the membrane or antibiotics that disrupt bacterial membranes). In this presentation I will describe the development of this platform and showcase how it may be used as a rapid and highly quantitative method for monitoring events occurring at the membrane in a robust and scalable manner without recourse to live cells.

2:30 PM BREAK

3:30 PM *SB11.05.04
Multimodal Nanoelectronics for Charting Cell Electrophysiological and Molecular Phenotypes in Three-Dimensional Tissues Across Time and Space Jia Liu; Harvard University, United States

Charting single-cell gene expression and electrophysiology in intact three-dimensional (3D) tissues across time and space is crucial to fields ranging from developmental biology to cardiology and neuroscience. Such multimodal methods require stable and continuous recording of individual cell electrical activity with high spatiotemporal resolution across 3D tissue, multiplexed profiling of a large number of genes in electrically recorded cells, and cross-modal computational data integration and analysis. In this talk, I will discuss 1) “tissue-like” electronics that possess tissue-like properties for long-term stable single-cell electrophysiology in tissues, organs, and behaving animals; 2) “cyborg organoids”, where stretchable sensor arrays are embedded in 2D sheets of stem/progenitor cells and reconfigured through 2D-to-3D organogenesis, enabling 3D electrophysiology over the time course of organoid development; and 3) “*in situ* electro-sequencing” that integrates “tissue-like” electronics, *in situ* sequencing, and machine learning to chart cell electrophysiology and gene expression at single-cell resolution across time and space.

4:00 PM SB11.05.05
Direct Measurements of Long Distance Electron Transport in Freshwater Cable Bacteria Tingting Yang, Marko Chavez, Christina M. Cole, Shuai Xu and Moh El-Naggar; University of Southern California, United States

Filamentous multicellular cable bacteria facilitate long distance electron transport (LDET), up to centimeter scales, in vast marine and freshwater sediments, indicating that LDET is an essential process in global geochemical cycling.
Through this process, cable bacteria couple sulfide oxidation by cells that dwell in the deeper sulfidic zone to oxygen reduction by cells near the surface sediment. Recent electronic measurements of cable bacteria enriched from marine sediments demonstrated that the electron transport pathway consists of a network of periplasmic fibers that run along the unique cell envelope of entire cables. Here we focus on demonstrating and understanding the electron transport characteristics through cable bacteria from freshwater sediments.
Long cable bacteria filaments were recovered from incubations of freshwater lake sediments (Ballona pond and Mungi Lake) in Southern California. The Southern California Freshwater cable bacteria share >97% sequence similarity to the 16S rRNA gene sequences from the freshwater cable bacterial genus *Candidatus* Electronema within the Desulfobulbaceae family. Current-voltage measurements of cable bacteria bridging 3-mm gaps between interdigitated electrodes reveal nano- to microampere currents through intact single filaments. A combination of atomic and electrostatic force microscopy measurements revealed the characteristics of the underlying periplasmic fiber network, as previously described in marine cable bacteria. In addition, conductive atomic Force microscopy was used to directly assess the conductivity of locations on individual cells. Using four-probe electronic measurements, the conductivity of single fiber in freshwater cable bacteria filaments is found to be ca. 0.1 S/cm. Our study expands the knowledgebase of centimeter scale LDET in cable bacteria to the freshwater niche and shed light on the mechanisms underlying their remarkable conductivity.

4:15 PM SB11.05.06
Electrical Monitoring of Cell Epithelial-to-Mesenchymal Transition Induced by Tumor-Derived Exosomes Using Bioelectronic Technologies Walther Traberg-Christensen[1], Johana Uribe[2], Adel Hama[3], Miriam Huerta[2], Victor Druet[3], Anna-Maria Pappa[1], Susan Daniel[2], Sahika Inal[3] and Roisin Owens[1]; [1]University of Cambridge, United Kingdom; [2]Cornell University, United States; [3]King Abdullah University of Science and Technology, Saudi Arabia

Exosomes are nanosized, lipid bilayer-delimited particles that act as mediators in cell-cell communication and have the ability to transfer RNAs and proteins between donor and recipient cells to elicit a variety of cellular responses. Tumor cell-derived exosomes (TDEs) have recently been reported to play an active role in tumorigenesis and metastasis owing to their ability to transmit oncogenes. One hypothesis is that TDEs contribute to metastasis by inducing the epithelial-to-mesenchymal transition (EMT), characterized by the loss of barrier function in barrier tissue-forming cells.

This study aims to elucidate the role and mechanisms of TDE uptake by investigating the process by which TDEs “infect” normal cells inducing EMT prior to metastasis. Current strategies for investigating the spatial and temporal aspects of exosome uptake, often optical, lack the ability to obtain quantitative data in real time. We have shown that organic electronic devices based on the conducting polymer poly(3,4-ethylenedioxythiophene): poly(styrenesulfonate) (PEDOT:PSS) can be interfaced with biological systems of varying complexity allowing for quantitative real-time monitoring of biological interactions. The optical transparency of our PEDOT:PSS-based devices provides the unique advantage of dual transduction increasing the credibility of our platform and enriching the biological information obtained. Moreover, their compatibility with microfabrication methods allows for high throughput studies.

We have shown that TDEs derived from the triple-negative breast cancer cell line MDA-MB-231 can induce an EMT-like process in MCF-10A non-tumorogenic breast epithelial cells as demonstrated by changes to cell morphology, loss of apico-basal polarity, reorganization of filamentus actin, and gain of mesenchymal proteins, such as vimentin and N-cadherin. An integral feature of EMT is the dissolution of tight junctions and the consequential loss of lateral cell-cell adhesion leading to a phenotype with increased motility and invasiveness. In ongoing studies, this decrease in barrier integrity of the cell monolayer is monitored electrically using organic electrochemical transistors, gaining of truly quantitative insight into TDE-induced EMT with higher temporal resolution than conventional, orthogonal methods. This data will be further substantiated by monitoring the expression of immunofluorescently labelled barrier-forming tight junction proteins. These combinatorial optical and electrical measurements of TDE interactions with cell monolayers provide invaluable information for developing strategies that may inhibit TDE interactions by e.g. blocking specific surface markers, thereby preventing TDE-induced EMT with implications for preventing cancer metastasis.

4:30 PM SB11.05.07
Azobenzene Photoisomerization Probes Cell Membrane Nanoviscosity Arianna Magni[1,2], Gaia Bondelli[2,1], Giuseppe M. Paternò[1], Samim Sardar[1], Valentina Sesti[2,1], Cosimo D'Andrea[2,1], Chiara Bertarelli[2,1] and Guglielmo Lanzani[1,2]; [1]Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Milano, Italy

The viscosity of cell membranes is a crucial parameter that affects the diffusion of small molecules both across and within the lipidic membrane and that is related to several diseases, such as atherosclerosis, Alzheimer's, diabetes, and cell malignancy. In general, the precise determination of viscosity at the molecular scale represents itself an important issue in cellular biophysics. Despite the great interest of viscosity measurements on the nanoscale, it is still challenging to retrieve reliable values, as the traditional mechanical methods used for probing viscosity are not suitable for living cells.
We investigated the photophysics of a recently synthesized amphiphilic membrane-targeted azobenzene (ZIAPIN2) and we validate its use as viscosity probe for cell membranes. Indeed, we proved that the possibility of ZIAPIN2 of undergoing *trans-cis* photoisomerization depends on the viscosity of the environment. This led to the development of a molecular viscometer based on time-resolved fluorescence spectroscopy, that we used to assess the viscosity of *Escherichia coli* bacteria membranes. Lifetime measurements of ZIAPIN2 in *E. coli* bacteria suspensions correctly indicate that membrane viscosity decreases as the samples were heated up. Our results estimate a membrane viscosity value in living *E. coli* cells going from 10 to 5 cP, increasing the temperature from 22 °C up to 40 °C.

SESSION SB11.06: Poster Session: Photo/Electrical Phenomena at the Interface with Living Cells and Bacteria

Monitoring and Modulating Bacterial Electrophysiology at the Single Cell Level: Photolithography for High Throughput Devices Xu Han and Christine Payne; Duke University, United States

The resting membrane potential regulates bacterial division, elongation, and electrical signaling. Use of an external electric field is an effective method to

regulate these properties with the advantage of providing spatial control, altering only a subset of cells. The challenge is to develop devices for precise control of the applied electric field with simultaneous monitoring of membrane potential and bacterial growth. Our initial research developed a device using two gold wires as electrodes to apply an electric field while imaging, with either brightfield or fluorescence microscopy, bacteria, including a control population in the absence of an electric field. Although useful for initial studies of membrane potential-regulated bacterial elongation and division, this device was low throughput. A second-generation device has been designed and fabricated by photolithography. The gap distance between the two electrodes, which determines the electric field, can be controlled from 10 μm to 1 mm, largely expanding the range of electric fields that can be achieved. Three pairs of electrodes with different gap distances can be integrated into the same device, increasing experimental throughput. Multiple electrode materials, including gold and platinum, can be used for these devices. In addition, the shape of the electrodes can be customized to achieve the desired electric field distribution. With this device, we can control the frequencies, amplitudes, and waveforms of applied electric fields while simultaneously imaging bacterial growth and membrane potential. We use this single cell-level imaging to understand and control heterogeneity of bacterial cells. Within any population of cells, individual cells will have different membrane potentials, which change in time, even in the absence of an applied electric field. This device allows us to track the membrane potential of individual cells over hours to address fundamental questions of bacterial electrophysiology.

SB11.06.03
Monitoring the Nanoscale Heat Penetration Profile in Laser-Induced Thermal Therapies with Ultrafast Vibrational Spectroscopy Sara Makarem, John A. Tomko, Kimberly Kelly and Patrick E. Hopkins; University of Virginia, United States

The growing interest in the development of minimally-invasive therapeutic strategies has opened the doors to the introduction of one (or several) therapeutic needle(s) inside the tumor target that aim at inducing a controlled change of tissue conditions and environment to achieve tumor necrosis and apoptosis. Amongst all the treatment methods, ablative photothermal therapies are emerging as potential alternatives for the management and treatment of the tumor of which the laser-induced heated region are enabling the use of even finer 'needles,' where the spatial resolution can exceed the diffraction limit. Thus, studying the nanoscale heat transfer mechanisms within the target tissues and across their respective interfaces to gain a fundamental understanding of the dominant mechanisms within this class of therapies are critical for developing the next-generation of thermal ablation treatments.

In this study, we experimentally investigate these fundamental heat transfer mechanisms that dictate photothermal therapy efficiencies in nanoparticle-mediated systems. In particular, we employ ultrafast time-domain thermo-transmission (TDTT)[1] measurements to monitor the heat flux from heated nanoparticles directly into surrounding biological cells. Further, by implementing a tunable-wavelength mid-infrared probe to these measurements, these measurements can directly resonate with different vibrational modes of interest, thus providing insight to which modes dictate the interfacial heat transfer from nanoparticles into surrounding biological tissues. In this study the biological parameters on the temperature distribution, the heat penetration depth, and degree of irreversible damage as a result of the heat source parameters are investigated. These experimental measurements provide direct insight into the vibrational modes that dictate interfacial heat transfer during photothermal therapies and the means of which material parameters can be tuned to enhance these heat transfer pathways.

SB11.06.04
Spin Filtering in Bacterial Periplasmic Electron Carriers Christina M. Cole[1], Debkumar Bhowmick[2], Ron Naaman[2], Justus Nwachukwu[3], Miyuki Thirumurthy[3], Anne Jones[3] and Moh El-Naggar[1]; [1]University of Southern California, United States; [2]Weizmann Institute of Science, Israel; [3]Arizona State University, United States

A multitude of microbes have adapted to gain energy by transferring electrons to external abiotic surfaces ranging from minerals to solid-state electrodes. In the model metal-reducing bacterium *Shewanella oneidensis* MR-1, this extracellular electron transfer (EET) is achieved through a network of multiheme cytochromes that span the cell envelope and incorporate along microbial nanowires. Recent studies of biomolecules, including cell surface electron conduits, have shown that electron transport in these proteins is spin selective through the chirality induced spin selectivity (CISS) effect. However, the physiological impact of CISS on electron transfer by living cells remains unclear. To further investigate CISS, we perform Hall effect measurements to screen for spin filtering in the *S. oneidensis* periplasmic Small Tetraheme Cytochrome (STC), which bridges the periplasmic gap between inner-membrane components and the cell surface electron conduits. STC has one of the highest heme-to-volume ratios of any known proteins, resulting in closely packed hemes and fast electron transport rates. By performing spin polarization measurements of an STC variant engineered to better interact with electrodes we show that, similar to previous reports of the cell surface cytochromes MtrF and OmcA, electron transport through STC is also spin selective. Our study provides an improved understanding of the electron transport physics in biomolecules and sheds light on an intriguing phenomenon whereby biology may exploit both electron spin and charge for interacting with abiotic surfaces.

SB11.06.05
Enhanced Cascade Biocatalysis by Enzymes Bound to Multi-Walled Carbon Nanotubes Made from Scalable, One-Step Exfoliation by Simple Stirring on the Benchtop Ankarao Kalluri[1], Mansi Malhotra[1], Prabir Patra[2,2] and Challa V. Kumar[1,1]; [1]University of Connecticut, United States; [2]University of Bridgeport, United States

Efficient, multi-enzyme cascade biocatalysis is currently an unmet challenge, with a high potential in industrial biofuel cell applications. To address this issue, we developed a single-step exfoliation combined with enzyme binding by simply stirring the enzymes and commercially available, inexpensive, multi-walled carbon nanotubes (CNTs). This resulted in highly active biocatalysts that showed very high activities, greater than those of the free enzymes, under otherwise identical conditions of pH, temperature, and ionic strength. This major breakthrough is reported here, where bovine serum albumin (BSA) is used as a co-exfoliant to assist in the formation of the biocatalytic dispersions of CNT/BSA/glucose oxidase (GoX)/horseradish peroxidase (HRP) complexes. The BSA not only promotes exfoliation of CNTs but also passivates the high energy sites on the CNTs and protects the delicate enzymes from denaturation on the hydrophobic surface. The CNT/BSA/HRP complex showed ~2 times higher activity than that of the free HRP, and the CNT/BSA/GOx/HRP showed 6-times greater activity than that of the corresponding mixture of the free enzymes, under otherwise identical conditions. We hypothesize that the CNT surface couples the active sites of these two redox enzymes, promoting the overall activity of the enzyme cascade events. Hence, the biological CNT enzyme complex forms a complex interface, achieving efficient and robust binding while preserving the biological activities of these delicate enzymes. Further, the cascade enzymes are being developed for the construction of industrial-scale biofuel cells. Thus, an improved, simple method is developed to produce highly active cathodes that can be readily adapted even under resource-limited conditions.

SESSION SB11.07: Device Integration
Session Chair: Herdeline Ardoña
Thursday Morning, December 2, 2021
Sheraton, 2nd Floor, Back Bay A

10:30 AM SB11.07.01
Shaping the Electrical Phenomena at the Interfaces of a Photo-Capacitive Electrode Vedran Derek[1], Aleksandar Opančar[1], Marta Nikić[1], Anja Miokovic[1], Nikola Habek[2], Malin Silvera Ejneby[3] and Eric Glowacki[4,3]; [1]University of Zagreb, Faculty of Science, Croatia; [2]University of Zagreb, Croatia; [3]Linköping University, Sweden; [4]Brno University of Technology, Czechia

A highly localized and effective, minimally invasive, physiologically stable and wireless electro-stimulation capability would present an important instrument in the toolbox of bioelectronic and electrophysiological methods. It is a milestone in the development of bioelectronic therapies, neural prostheses such as artificial retinas, artificial limbs and auditory prostheses, and brain-machine interfaces. Photo-capacitive organic electronics-based bioelectronic devices – organic electrolytic photocapacitors (OEPC), have demonstrated effective, chronic and localized in-vivo wireless peripheral nerve electric stimulation[1], as well as in-vitro wireless single cell[2] and retina electrostimulation[3]. Planar OEPCs fabricated on micrometer-thin flexible substrates have enabled conformal adhesion of the devices to the target tissue. Furthermore, a choice of organic pigment-based semiconductor PN bilayer has enabled effective and stable long-term operation of the devices in-vivo. The bioelectronic interface of an OEPC consisting of a circular-shaped PN bilayer as the active electrode deposited on top of an extensive, transparent conductor comprising the back electrode has been shown to stimulate peripheral nerves effectively. However, the simple circular shape of the top electrode in conjunction with the planar back electrode disperses the stimulating electric currents radially, which may not present the optimal use of the photogenerated charge in applications where high charge density and spatial localization are essential. Similar reasoning can be applied to various trivial electrode shapes, which are often used elsewhere.
We will show how spatial planar and 3D structuring of the OEPC's PN and back electrode layers affects their optoelectronic, bioelectronic and mechanical properties, simultaneously shaping their functionality. We will demonstrate how a complete 3D numerical model comprising the excitable tissue in contact with the photo-capacitive device can be used to tailor the effects of an optically driven device at the interface with living cells. We have manufactured 3D and planar OEPC devices with spatially optimized interfaces, which showed multifold improvements in performance compared to the trivial geometries previously used.

Plasma membranes represent a biophysical barrier separating the cytoplasm from the extra cellular matrix across living organisms. Their heterogeneous structure consists of a lipid bilayer embedded with proteins and other vital components, which largely determine the interaction of cells with their environment. Recently our group, in collaboration with the Daniel and the Salleo groups, have demonstrated that authentic plasma membranes in the form of supported lipid bilayers (SLBs) can be formed on top of poly(3,4-ethylenedioxythiophene) polystyrenesulfonate (PEDOT:PSS) based transducers. The bilayers were produced by a vesicle fusion process of native extra-cellular components (blebs) combined with synthetic liposomes and polymeric healing agents. Due to the transparent nature of PEDOT:PSS, the occurring biological phenomena were transduced in electronic output in real time, while the results were verified by state-of-the-art optical techniques.
Here, we demonstrate a general surface functionalization approach as a tool to introduce a variety of chemical groups on top of the PEDOT:PSS based electronic transducers. In the context of membrane-on-a-chip devices, our approach was used to tune the electrostatic interaction between the lipid bilayers and their electroactive supports. As a result of the increased affinity, membrane-on-a-chip devices with minimized and even eliminated synthetic component were made possible. Those devices were then used to provide mechanistic insight on biological events such as the binding and fusion of viruses. To demonstrate the capabilities of our platform, we monitored the interaction of a SARS-CoV-2 surrogate virus with a mouse-derived bilayer. When this coronavirus strain gets incubated and the virus fuses with the bilayer, a significant increase in impedance is observed, indicating that real-time electronic monitoring on such interactions is possible using our cell-free approach.
This simple platform has potential in assisting and re-directing drug discovery by providing real-time feedback early in the process, helping to reduce the high attrition rates during later stages when the costs are considerably higher.

SESSION SB11.08: Photo/Electrical Phenomena at the Interface with Living Cells and Bacteria I
Session Chair: Daniela Comelli
Tuesday Morning, December 7, 2021
SB11-Virtual

8:00 AM *SB11.08.01
The Proton Motive Force Determines Escherichia coli's Robustness to Extracellular pH Guillaume Terradot[1], Amritha Janardanan[1], Soner Sonmezoglu[2], Stefano Soneda[3], Michel Maharbiz[2], Peter Swain[1] and Teuta Pilizota[1]; [1]University of Edinburgh, United Kingdom; [2]University of California, Berkeley, United States; [3]Università degli Studi di Cagliari, Italy

Living cells can maintain their internal properties within a certain range, so-called homeostasis, e.g. intracellular pH. However, pH homeostasis has thus far not been looked at in the context of all the cellular physiological variables that are influenced by it, and the intertwined nature of these variables suggests that we need to so, to understand the homeostasis of even just one of them.

Here we build a simplified mathematical model of cellular electrophysiology. We show that bacteria use proton-ion antiporters to generate an out-of-equilibrium cytoplasmic membrane potential and so maintain the proton motive force (PMF) at the constant levels observed empirically. As a consequence, the strength of the PMF determines the range of extracellular pH over which the cell preserves a near-neutral cytoplasmic pH. We employ assays for time-course, single-cell, concurrent measurements of the PMF and pH and find agreement with our model prediction. We also demonstrate our efforts to measure the PMF in individual cells, but on thousands of them at the same time.
Our results suggest a new perspective on bacterial electrophysiology with cells maintaining their PMF and cytoplasmic pH by actively regulating the plasma membrane potential through changing activities of antiporters.

8:30 AM SB11.08.02
Late News: Understanding Photocapacitive and Photofaradaic Processes at the Organic Semiconductor/Water Interface for Biophotomodulation Luca Bondi, Beatrice Fraboni and Tobias Cramer; University of Bologna, Italy

Photoactive organic semiconductors are envisioned as a novel class of materials able to transduce light into stimulating signals inside biological cells or tissue [1]. The direct interface between the semiconductor and the electrolyte gives rise to different, competing electrochemical phenomena such as the photofaradaic or the photocapacitive processes, depending whether the photogenerated charges get involved in redox processes or accumulate at an interface. A detailed understanding of such chemical and photo-induced interactions is necessary to develop and optimize future devices.
We addressed the problem in organic photoelectrodes considering both polymeric single-layer and organic molecular p/n junction thin-films [2]. Both are material systems that have been recently demonstrated to achieve the photomodulation of cardiac regeneration processes [3] or retinal neurons response [4]. By spectroscopic photovoltage and photocurrent measurements we gain insight into the energetics of the involved processes, while performing transient measurement we are able to identify the kinetics of light stimulated charge transfer processes. By combining these techniques with impedance spectroscopy, electric modelling and kinetic modelling, we identify the role of interfacial energy levels in the photoactivated processes and distinguish photocapacitive and photofaradaic contributions. The findings are further combined with nanoscale morphological investigations and Kelvin-Probe Force Microscopy leading to a quantitative interfacial energy diagram. We highlight how the energy diagram enables a comprehensive understanding of the photoelectrochemical reaction pathways and how the findings can be translated to predict the response of novel materials and devices, such as transducers based on floating semiconducting nanoparticles.

8:45 AM SB11.08.03
Late News: (Garcia High School Student) The Influence of TiO2 and ZnO Nanoparticles on Bacterial Infection of HeLa Cells Joanna Li[1], William Strutton[2], Emily Zhou[3], Fan Yang[4] and Miriam Rafailovich[4]; [1]Townsend Harris High School, United States; [2]Hastings High School, United States; [3]The Harker School, United States; [4]Stony Brook University, The State University of New York, United States

Due to the widespread use of Titanium dioxide (TiO2) and Zinc oxide (ZnO) nanoparticles (NPs) in products such as sunscreen, cosmetics, and food additives, an improved understanding of their possible negative effects on cells may help to better ensure consumer safety and public health [1, 2]. Previous research showed that TiO2 NPs in the rutile and anatase forms may impair cell function and defense against bacterial infection in HeLa cells and human dermal fibroblasts [3]. ZnO NPs have also been shown to exhibit cytotoxicity to cancer cells; a recent study found that, when compared to controls, HeLa cells with added ZnOs had significantly lowered cell viability [4].
This study aimed to measure the doubling time of HeLa cells exposed to TiO2 NPs, ZnO NPs, and lecithin-coated TiO2 (L-TiO2) NPs to further the understanding of the effects of different NPs on HeLa cell proliferation. HeLa cells were infected with Staphylococcus aureus bacteria at a multiplicity of infection (MOI) of 1000. The cells in each well were counted at both 24 hours and 96 hours after their initial exposure to the NPs to calculate the average doubling time for each condition.
To this end, 6-well plates were used to culture 3-well groups of HeLa cells to which 3 types of NPs were added: TiO2, lecithin-coated TiO2 (L-TiO2), and ZnO NPs. Each type of NP was added at a concentration of 0.1 mg/L, which was determined in an earlier study to be the concentration at which TiO2 NPs negatively affected cells without killing them [5]. One group serving as the control received no NPs. The cells were plated after reaching 80% confluency, and TiO2 and L-TiO2 NPs mixed in cell culture media were added to the wells. Cells were plated and cultured with ZnO later in the study, as there was an initial lack of access to ZnO NPs. The cultured cells were counted at 24 hours and 96 hours after exposure to NPs using a hemocytometer, and the average doubling time of HeLa cells growing under each condition was calculated. There was no significant difference between the average doubling time of the control group and those of the TiO2 group or L-TiO2 groups.
The cells were stained with Alexa Fluor 488 Phalloidin and the S. aureus bacteria were stained with a live dead stain to count the total number of cells and infected cells and the number of live and dead bacteria, respectively. An EVOS cell imaging system (fluorescence microscopy) was used to produce images for cell and bacteria counting.
For the ZnO sample, bacteria cell counts and doubling time have been obtained, and preliminary data suggests that the bacteria per infected cells count on average for ZnO samples is higher than for the TiO2 samples. This suggests ZnO NPs may be more nanotoxic than ZnO NPs. Future studies may include other NPs, or additional experiments on the nanotoxicity of ZnO if it is found to significantly more affect the proliferation of HeLa cells or their resistance to S. aureus infection.

9:00 AM SB11.08.04
High Resolution Correlative Microscopy for the Characterisation of Gram-Negative Outer Membrane Supported Lipid Bilayers Karan Bali[1], Zeinab Mohamed[2], Clemens Kaminski[1], Susan Daniel[2], Roisin Owens[1] and Ioanna Mela[1]; [1]University of Cambridge, United Kingdom; [2]Cornell University, United States

Supported lipid bilayers (SLBs) are a useful tool in the investigation of membrane proteins and their interactions at the single molecule level. Outer membrane vesicles (OMVs) can be combined with synthetic liposomes to form complete SLBs that contain the natural components of the bacterial outer membranes (Hsia *et al.*, 2016). These systems show potential as novel antimicrobial screening platforms especially when integrated with bioelectronic devices. However, to date these hybrid SLBs have not been characterised at the molecular level. We employ correlative atomic force (AFM) with structured illumination microscopy (SIM) to gain detailed structural and functional information on those model systems (Ben-Sasson *et al.*, 2021). SLBs containing OMVs derived from *E. coli BL21(DE3)* are studied to fully characterise the membrane protein, bacterial lipopolysaccharide and synthetic lipid

components of the bilayers. We then increase the complexity of the system by engineering OMVs to contain proteins of interest, in this case a GFP binding nanobody-LppOmpA hybrid protein, and show that lipid patches that contain the overexpressed protein can be specifically identified and characterised. The relevance of these hybrid SLBs to antimicrobial screening applications is then demonstrated by SIM-AFM visualisation of known bacteria-targeting DNA nanostructures (Mela *et al.*, 2020) binding selectively to bacterial components of the bilayers. Our study introduces correlative AFM-SIM as a powerful microscopy technique for the characterisation of lipid bilayers with multiple components and demonstrates the need for reproducible, programmable model systems for antimicrobial screening.

9:15 AM *SB11.08.05
Microscopes on a Chip for Automated 3D Imaging Petra Paiè[1], Federico Sala[2,1], Roberto Memeo[2], Matteo Calvarese[1], Andrea Comi[2], Gianmaria Calisesi[2], Alessia Candeo[2], Roberto Osellame[1,2], Andrea Bassi[2,1] and Francesca Bragheri[1]; [1]IFN-CNR, Italy; [2]Politecnico di Milano, Italy

Heterogeneity is an omnipresent feature of biological populations, and the possibility to investigate it allows revealing important information that might be hidden otherwise. In this regard, it is fundamental to develop tools and techniques capable to investigate the specimens automatically and at high throughput, without affecting the quality of the analysis.
Among different 3D microscopy techniques, significant advantages in sample investigation are offered by light sheet fluorescence microscopy (LSFM). This method is based on a non-invasive optical sectioning approach that permits to obtain 3D information, by illuminating the sample plane by plane with a sheet of light. Standard implementations foresee the use of a cylindrical lens to focus the light in one direction only, while the excited the fluorescence is orthogonally collected by a microscope objective. The specimens are manually positioned in a sample chamber, aligned by the user in the optical system and automatically translated or rotated to allow multiple planes acquisition. This method permits fast image acquisition, low photobleaching and high signal to noise ratio. Nevertheless, the manual sample alignment requires up to several minutes, limiting the throughput of this technique.
The use of microfluidics to perform automatic sample delivery and translation could allow high throughput image acquisition of specimens diluted in a liquid suspension. Nevertheless, the integration of microfluidic channels in LSFM setups is not straightforward. This could introduce aberrations both to the excitation and collection path and it demands a very precise a stable alignment between the optical and fluidic system. Considering these constraints, we propose microfluidic based microscopes on a chip, integrating in a single substrate the optical elements necessary to create the light sheet such as optical waveguides and integrated cylindrical lenses as well as the microfluidic channel for automatic sample delivery. The integration of different components in a single platform guarantees the necessary alignment stability.
These microscopes on a chip have been fabricated in glass substrates by femtosecond laser micromachining (FLM) followed by chemical etching. Indeed, by focusing a pulsed laser beam into a transparent substrate, non-linear absorption processes occur and induce a permanent modification of the focal volume. This can lead to an increased etching selectivity or to a local increase of refractive index with respect to the pristine material, depending on the laser parameters. During sample irradiation, a 3D substrate translation permits to define the custom layout of the different components. Therefore, both microfluidic channels, integrated lenses as well as optical waveguides can be fabricated in the same substrate and within the same irradiation step by FLM. Taking advantage of the versatility and capabilities of this technique, we propose different devices that have been adapted to the specificity of the specimens under investigation, such as cellular spheroids, *Drosophila* embryos and even single cells. Indeed, the sample channel size as well as the optical properties of the light sheets must be tailored considering the different size and shape of these samples in order to guarantee a good optical sectioning and a uniform illumination over the entire sample. Zemax simulations have been used to optimize the lens profile and to reduce both spherical and chromatic aberrations. Dual color and dual side illuminations have been demonstrated, with an image quality comparable of the one of standard LSFM, highlighting the capabilities of these microscopes on chip. In addition, the setup automation and the throughput of these devices have been optimized, proving an image acquisition rate of about 1 cell/second. Recently, by modifying the illumination path we have been able to further improve the image quality, proving a subcellular resolution.

SESSION SB11.09: Photo/Electrical Phenomena at the Interface with Living Cells and Bacteria II

A Universal Microfluidic Approach for Quantitative Study of Bacterial Biofilms Jintao Liu; Tsinghua University, China

Bacteria usually live in densely packed communities called biofilms, where the interactions between the bacteria give rise to complex properties. Quantitative analysis is very useful in understanding these properties. However, current biofilm culturing approaches impose various limitations. We developed a microfluidic approach for quantitative study of biofilms, which is universal and can be used to study biofilms of various bacterial species. To demonstrate the utility of this approach, we will present two examples, both of which revealed new biological insights. In the first example, we will explore the response of *Escherichia coli* biofilms to exogenous hydrogen peroxide. We found biofilms gained tolerance to H_2O_2, but their growth was slowed down due to the metabolic cost of maintaining the tolerance; However, under certain conditions, H_2O_2 can anti-intuitively boost growth. In the second example, we will show that in *Pseudomonas aeruginosa* biofilms, the extracellular matrix acts as a diffusion barrier for iron chelator, minimizing its loss into the environment and therefore potentially promoting the sharing of the chelator within the biofilm as a public good.

8:30 AM SB11.09.02
Label-Free Rapid Detection of Biomolecule Using Surface-Enhanced Raman Spectroscopy (SERS) for Point-of-Care Testing Wisawat Keaswejjareansuk, Katawut Namdee and Mattaka Khongkow; National Nanotechnology Center, National Science and Technology Development Agency, Thailand

Exosomes are extracellular vesicles with phospholipid bilayer membrane that carry the encapsulated lipids, proteins, genetic materials and transmit *in vivo*. The exosomes those were secreted by specific cells and tissues show unique biological component and characteristics. Raman spectroscopy is a non-destructive and non-invasive technique that measuring the inelastic scattering of photons. It enables the analysis of the vibration mode of different biomolecules caused by monochromatic laser radiation. Distinguish and analysis of the Raman signal are difficult due to the low signal intensity. To overcome this problem, the surface-enhanced Raman spectroscopy (SERS) technique has been utilized. Gold and silver nanoparticles are typical used to amplify the signals in many systems include biosensing. A variety of SERS chips have been widely developed to obtain the signature spectra of the biomolecules. By using the SERS chip, liquid biological samples are dropped and dried before proceeding with the SERS technique. In this study, the SERS technique was employed in the colloid of the exosome-liquid mixture. Colloidal SERS offers the Raman spectra without the cell disruption and suitable for cells and tissues analysis. The exosomes purified from human embryonic kidney 293 (HEK 293) and rabies virus glycoprotein (RVG) were

used. An only a small volume of exosomes (in a range of microliter) was decorated with silver NPs and diluted with 1 mL of phosphate-buffered saline (PBS). PBS is a water-based salt solution that has a pH similar to that of the human body. It is typically used to prevents the cells rupture and shrivels up. Interestingly, the SERS spectra were obtained with only 15 µL drop of the exosome-PBS mixture. The goal of this study is to develop a reliable and less complex point-of-care testing for practical usages with a handheld Raman spectrometer.

In this presentation, the colloidal SERS technique for detecting tissue-specific and nonspecific exosomes includes the concentration of the exosome-PBS mixture, the optimal volume of NPs, and the materials characterizations such as transmission electron microscopy (TEM), dynamic light scattering (DLS), and SERS spectra will be discussed.

8:45 AM *SB11.09.03
Electronic Communication Between Catalytic Enzymes and Electron-Transporting Conjugated Polymers Sahika Inal; King Abdullah University of Science and Technology, Saudi Arabia

Establishing close interactions between biological systems and synthetic materials is the key to form biohybrid assemblies that find use in sensors, actuators, and robotics. In this work, I will present an electronic platform based on an n-type conjugated polymer that is tailored to form favorable interactions with catalytic enzymes.[1,2] When this biohybrid is applied in an enhancement mode organic electrochemical transistor (OECT), the device detects glucose and lactate in blood serum or saliva with excellent sensitivity, and selectivity over six orders of magnitude wide detection range. The same biohybrid serves as the anode of a glucose fuel cell, extracting enough power from bodily fluids to drive the microscale OECT sensors. While showing the unique characteristics of these devices, I will discuss the possible pathways through which the polymer film generates charges as the enzyme reacts with its metabolites.

Electrically Induced Membrane Potential Dynamics in Yeast Tailise Souza G. Rodrigues, Orkun S. Soyer and Munehiro Asally; University of Warwick, United Kingdom

Membrane potential is known to be important for cross-membrane trafficking of ions and nutrients in all forms of life, but they are not limited to that. New discoveries show that electrophysiology plays a role in broader cellular and organism functions, ranging from antibiotic persistence to wound healing. Electrically induced membrane potential dynamics was recently shown to enable rapid detection of live bacteria with single-cell sensitivity, bridging an electro-bio hybrid system to diagnostics. It is still unclear, however, whether electrical stimulation can be used for the detection of live eukaryotic microbes. Here we show that proliferative and growth-inhibited budding yeast, *Saccharomyces cerevisiae*, exhibit distinct electrically induced membrane potential dynamics, enabling detection of proliferative eukaryotic cells from non-growing ones. When proliferative cells were stimulated by an electrical field, it induced hyperpolarization in plasma membrane. The same electrical stimulus, however, caused depolarisation when the cells were inhibited. The ability to detect not only prokaryotic, but also eukaryotic vital cells at single-cell level shows how promising electro-bio hybrid systems are as a tool for diagnostics. And the possibility to modulate membrane potential by applying an exogenous electrical stimulus sheds light on the potential use of electro-bio hybrid systems to regulate electrophysiology-dependent cellular functions, paving the path for future engineering of environment responding living-materials.

9:30 AM SB11.09.06
Late News: Probing the Electrophysiology of Germinating and Outgrowing Spores of Bacillus subtilis Jonatan Benarroch and Munehiro Asally; University of Warwick, United Kingdom

Bacterial spores are highly resistant to many conventional microbial elimination techniques. Their resistances to radiation, extreme temperatures, and bactericidal chemicals are in part due to the spores' unique electrochemical properties: namely, decreased hydration, high cationic concentration, a very negatively charged coat, and low permeability across their membranes. Hence electrochemical perturbation can provide novel approaches to overcoming the extreme resistances of spores.
This has led us to probe deeper into the electrophysiology of spores during germination, when they exit dormancy and lose their resistive properties. However, germination timing and speed is heterogeneous as is time taken to return to a vegetative state. Thus, control of these timings is essential for maximising elimination. We study the model organism Bacillus subtilis using time-lapse microscopy with electrochemically sensitive dyes to investigate how spore electrophysiology can change on a cellular level. We have discovered that membrane potential dynamics reveal two phenotypic populations. Their significance is still yet to be determined, however it is controlled by varying media salinity and buffering capacity. Finally, we discovered that outgrowth into vegetative cells could be delayed by use of cationic agents providing an opportunity to kill a large population of spores. This fits in with the exciting and emerging field of bacterial electrophysiology, which has seen recent growth due to research demonstrating how microbes use ion flux and membrane potential for dynamic signalling and environmental sensing.

SESSION SB11.10: Photo/Electrical Phenomena at the Interface with Living Cells and Bacteria III

1:00 PM *SB11.10.01
From Single Molecules to Living Electronics—Biophysical Studies of Bacterial Extracellular Electron Transport Moh El-Naggar; University of Southern California, United States

Electronic components that bridge the biotic-abiotic interface will have vast implications for both studying and harnessing the activity of living cells. While much ongoing research focuses on applying traditional rigid electronics to biology, an alternative is to discover bioelectronic solutions that life itself evolved to interact with the abiotic world. Towards realizing this vision, recent studies at the interface of microbiology, electrochemistry, and physics have uncovered metalloprotein electron conduits and nanowires that electronically link bacteria to extracellular surfaces ranging from environmental minerals to

solid-state electrodes. Since this extracellular electron transport naturally evolved to interact with external surfaces, a fundamental understanding has special implications for new bioelectrochemical technologies and living electronics that harness the advantages of microbes in detecting external signals or hosting synthetic genetic circuits.

This talk will describe our group's recent progress in understanding extracellular electron transport at multiple length scales, from the biophysics of individual multiheme cytochromes to the electrophysiology of whole bacteria and multicellular communities ranging from biofilms to cable bacteria. Using single molecule tracking and stochastic simulations of cell surface multiheme cytochromes in the metal-reducing bacterium *Shewanella oneidensis* MR-1, we describe how the interplay of cytochrome dynamics and electron hopping can give rise to long-distance electron conduction along bacterial membrane surfaces. In addition, we describe strategies to characterize and harness the electrochemical activity, spin filtering, and conduction properties of bacterial electron conduits in both synthetic structures and living biofilm materials.

1:30 PM *SB11.10.02
Electrical Control of Nerve Growth on Insulating and Conductive Substrates Ann M. Rajnicek; University of Aberdeen, United Kingdom

Electrical stimulation therapies are increasingly useful for nervous system disorders but even state of the art (metal) electrode materials have limitations, such as unwanted production of heat, free radical species, pH changes and associated tissue necrosis. Implanted electrodes also may need to be hard wired to a power source, though indirect electrostimulation is possible by creating an electrical gradient wirelessly through generation of dipoles at the borders of implanted materials by bipolar electrochemistry. Improved understanding of how neurons and materials interact to influence nerve growth would be valuable for future restorative electro-therapies.
By delivering a voltage gradient through the culture medium in vitro we have explored neuron growth on insulating materials, such as glass or tissue culture plastic, and compared it to conducting materials, such as gold or platinum and also to conducting intercalation materials. Materials were prepared as thin coatings to permit optical transparency and to allow observation of growth dynamics. Neurons from the developing amphibian spinal cord were used, mainly because, unlike mammalian neurons, they do not require any adhesion factors between the cell and the underlying substrate.
Neurons grew faster and more directly toward the external driving cathode when plated onto tissue culture plastic (insulating material) and, when the stimulation was within a safe window, they turned to grow toward the cathode on gold. Differences were apparent between conducting and mixed conducting intercalation materials, with neurons grown on IrOx favouring speed of growth (but no directional growth) and those on PEDOT-SS based materials favoring turning towards the external driving cathode (but not faster growth).
The data suggest that indirect electrical stimulation of neurons can be tuned to achieve specific growth responses by designing implant materials with specific bipolar electrochemical traits, even in challenging situations where transparency is required. This has clear potential to for designing neural prostheses or neural repair strategies but the concepts could also be applied to other wound healing and regeneration situations.

2:00 PM *SB11.10.03
Electrogenetics for Dynamic Bidirectional Communications Between Engineered Cells and Electronics Tanya Tschirhart; U.S. Naval Research Laboratory, United States

One of the ultimate goals of bioelectronics is an ability to electronically access all that biology has to offer - to control and record the myriad of native and engineered biological processes inside of cells and organisms. This could be enabled by seamless and dynamic bidirectional communication between electronic and biological components. As a step towards realizing these capabilities, electrogenetics offers tools to use electrical stimuli to modulate engineered gene expression. Electronic control of the oxidation state of redox molecules modulates redox-sensing proteins and gene expression from the promoters they activate. We have co-opted the SoxR and OxyR redox-sensing proteins from *Escherichia coli* in two distinct electrogenetic systems. These allow us to electronically control the expression of a number of engineered genes and behaviors in various environments and configurations. We developed a multi-functional microbial community, the BioLAN, which reliably facilitates on-demand bioelectronics communication and electrogenetic control of a programmed biological task. The BioLAN also provides electronically-recordable cell-based reporting to allow for feedback control. The electrogenetic systems presented here can be incorporated into genetic circuits and logic gates alongside chemical and light-driven components. They present a melding of synthetic biology and bioelectronics towards building seamlessly-integrated bio-hybrid devices.

2:30 PM *SB11.10.04
Encoding Spatio-Temporal Memory in Bacterial Biofilm Communities Gurol Suel; University of California, San Diego, United States

I will present our recent efforts to understand and manipulate the membrane potential of bacteria that make up biofilm communities. In particular, I will talk about our efforts to encode memory in space and time within biofilms using the membrane potential of bacteria. This work can set the stage to utilize biofilms for performing computations. I will end by showing some new results regarding our ability to control biofilms.

Bone Regenerative Engineering—The First 30 Years of Materials Science Cato T. Laurencin; University of Connecticut Health Ctr, United States

The treatment of bone injuries that necessitate bone regeneration continues to be a major challenge for the orthopaedic surgeon. This burden is compounded by supply constraints and associated morbidity with autograft tissues, the gold standard of repair. The use of allografts, xenografts, or metal and ceramic implants overcomes many of these limitations, but fail to provide a viable solution. Over the past 30 years, we have worked to engineer bone with a focus on biomaterial selection, material matrix development, cell/material interaction studies, and the development of inducible materials.

We have developed poly(ester), poly(anhydride), and poly(phosphazene) biomaterials for bone engineering applications through biocompatibility, degradation, and mechanical analyses. We developed a novel three-dimensional sintered microsphere matrix possessing a pore structure and mechanical strength within the range of human cancellous bone, a version of which is now clinically available. We also reported on attachment, growth, proliferation, and differentiation of osteoblasts, mesenchymal-, and marrow-derived stem cells on several of the material matrices we have developed. We have demonstrated regenerative bone formation *in vivo* using these biomaterial technologies. This entire body of work over more than thirty years has largely been responsible for the awarding of the highest honor for technological achievement in the United States, The National Medal of Technology and Innovation, and the American Association for the Advancement of Science's highest award, the Philip Hauge Abelson Prize for 'signal contributions to the advancement of science in the United States'.

11:00 AM SB12.01.02
Late News: Helically Aligned Biohybrid Models of the Left Ventricle John Zimmerman[1], Huibin Chang[1], Qihan Liu[2], Keel Y. Lee[1], Michael M. Peters[1], Michael Rosnach[1], Suji Choi[1], Sean L. Kim[1], Herdeline Ardoña[3], Luke MacQueen[1] and Kevin Kit Parker[1]; [1]Harvard University, United States; [2]University of Pittsburgh, United States; [3]University of California, Irvine, United States

Human ventricles are made up of helically arranged myofibers, that transition across the ventricle wall from a left- to right-handed helix. For more than fifty years, it has been argued that this helical structure is critical for achieving the large ejection fractions (60-80%) observed during healthy cardiac contraction while maintaining minimal ventricular strain. However, testing this fundamental structure-function relationship has been challenging, as *in vivo* studies are often characterized by concomitant changes in protein expression and metabolism, while *in vitro* studies have difficulty in reproducing the complex three-dimensional (3D) structures of the heart. Addressing this challenge, here we show how additive textile manufacturing approaches, such as Focused Rotary Jet Spinning (FRJS), can be used for the rapid manufacture of micro/nanofibers scaffolds with controlled alignments and helical architectures. As aligned micron-scale fibers can be used to direct tissue orientation and subsequent morphogenesis, we reasoned this approach would allow for the biofabrication *in vitro* models that are reminiscent of early simulations of cardiac contraction. Producing both helically and circumferentially aligned 3D biohybrid models of the left ventricle, we show that helically aligned ventricles displayed increased strain uniformity, axial shortening, cardiac output, and ejection fractions as compared to circumferential models. Additionally, we demonstrate how helically aligned scaffolds preserve some features of ventricle twist, a phenomenon observed in clinical readouts, but not previously reported in engineered biohybrid systems. Overall, this work shows that myofibril alignment plays a critical role in regulating cardiac performance, with important implications towards cardiac disease. Additionally, this approach suggests that additive textile manufacturing may serve as a valuable approach for future biofabrication, which can be used in conjunction with, or as a potential alternative to, more traditional methods such as 3D bioprinting.

11:15 AM *SB12.01.03
Moving Forward on the Engineering of Biomaterials and Optimizing their Interactions with Cells for Specific Regenerative Medicine Application Rui Reis[1,2]; [1]University of Minho, Portugal; [2]ICVS/3B's-PT Government Associate Laboratory, Portugal

The selection of a proper material to be used as a scaffold, as a proper matrix, or as a bioink in 3D bioprinting approaches to support or encapsulate cells is both a critical and a difficult choice that will determine the success of failure of any tissue engineering and regenerative medicine (TERM) strategy.

In our research group we have been mainly using natural origin polymers, including a wide range of marine origin materials, for many different approaches that allow for the regeneration of different tissues. Several innovative bioinks with quite specific properties were developed and proposed for several specific uses. We have also been optimizing the respective formulations for using these novel materials in distinct biomanufacturing strategies. This will be presented and discussed during the present keynote talk.

Furthermore, an adequate cell source should be selected. In many cases efficient cell isolation, expansion and differentiation methodologies should be developed and optimized. We have been using different human cell sources namely: mesenchymal stem cells from bone marrow, mesenchymal stem cells from human adipose tissue, human cells from amniotic fluids and membranes and cells obtained from human umbilical cords.

The potential of each materials/cells combination, as related to different manufacturing technologies, with details when appropriated focusing on bioprinting, to be used to develop novel useful regeneration therapies will be discussed. Several examples of TERM strategies to regenerate different types of tissues will be presented. The use of different cells and new ways to assess their interactions with different natural origin degradable scaffolds and bioinks will be described. A unique high-throughput platform to better understand material/cells interactions and optimise their performance and biological performance will be discussed. This rather innovative platform is based on the use of unique microfluidics-based approaches.

SESSION SB12.02: Polymeric Biomaterials for Regenerative Engineering II

Engineered Extracellular Matrices that Emulate Periosteal-Mediated Bone Healing Yiming Li, Michael Hoffman and Danielle Benoit; University of Rochester, United States

INTRODUCTION: Despite serving as the clinical "gold standard" treatment for critical size bone defects, decellularized allografts suffer from long-term failure rates of ~60% due to the absence of the periosteum. To promote allograft healing, our lab has pioneered the tissue engineered periosteum (TEP) based on poly(ethylene glycol) (PEG) hydrogels. The hydrogels entrap mouse mesenchymal stem cells (mMSCs) and mMSC derived osteoprogenitors (mMSC-OPs) and surround allografts to emulate native periosteum cell populations and subsequent paracrine factor production to coordinate periosteum-mediated healing. Despite robust angiogenic factor production, the TEP showed only modest increases in vascular volume versus unmodified allograft controls. Additionally, even though the maximum torque of TEP modified allografts was 2-fold higher versus unmodified allografts after 9 weeks, it was only ~40% of autografts, indicating delayed healing. These results are attributed to limited vascular recruitment within the hydrolytically degradable TEP (hydro-TEP), as its mesh size (~15 nm) is smaller than that of leading filipodia of migrating cells (0.2-0.4 μm). Therefore, to investigate the hypothesis that the degradation mechanism of the TEP is critical for coordinating host tissue infiltration necessary for successful bone, this study compared healing of Hydro-TEP, which bulk degrades, with that of the matrix metalloproteinase (MMP) degradable TEP (MMP-TEP), which enables host cell-dictated degradation.

MMP-degradable hydrogels supported endothelial cell migration *in vitro* whereas no migration was observed in hydrolytically degradable hydrogels. At week 3 post-implantation, ~2.5 and 1.8-fold, and ~3.5 and 2.6-fold greater vessel and nerve densities with high levels of vessel/nerve co-localization was observed using MMP-TEP-modified allografts versus unmodified and Hydro-TEP-modified allografts, respectively. At 3, 6, and 9 weeks post-implantation, the graft-localized vascular volumes of MMP-TEP-modified allografts (0.22 ± 0.8, 0.20 ± 0.8, and 0.17 ± 0.07 mm^3) were significantly greater than those of unmodified allografts (0.002 ± 0.0004, 0.05 ± 0.04, and 0.12 ± 0.03 mm^3) and Hydro-TEP-modified allografts (0.06 ± 0.004, 0.02 ± 0.001, and 0.05 ± 0.02 mm^3). Furthermore, MMP-TEP-modified allografts showed 4.5, 4.6, and 2.8-fold increase in bone volume versus unmodified allografts after 3, 6, and 9 weeks respectively, and enhanced mineralization density of bone callus after 9 weeks versus unmodified and Hydro-TEP-modified allografts. MMP-TEP-modified allografts exhibited approximately 8 and 2-fold enhancements in maximum torque strength versus Hydro-TEP-modified allografts after 6 and 9 weeks respectively, reaching a comparable maximum torque to that of autografts at 9-week post-surgery.

Bone regeneration is synergistically mediated by angiogenesis and innervation. Consistent with this synergy, endothelial sprouting within MMP-degradable hydrogels *in vitro* paralleled significantly increased and co-localized vessel and nerve densities observed *in vivo*, and longitudinal graft-localized vascularization. Furthermore, the robust early stage neurovascularization of MMP-modified allografts significantly increase bridging endochondral callus formation with greater mineralization versus unmodified and Hydro-TEP modified allografts, leading to enhanced maximum torque, which was comparable to that of autografts at 9 weeks post-surgery. In summary, these data indicate that the MMP-TEP effectively coordinates allograft healing via early stage recruitment and support of host neurovasculature. The MMP-TEP improved allograft healing, while overall outcomes still lagged behind those of autografts. In future studies, additional matrix cues, such as alternative extracellular matrix-derived peptides and MMP-degradable crosslinkers can be explored to further orchestrate improved healing.

2:00 PM SB12.02.02
Tissue Engineered Bone Mimetic Scaffolds as Testbeds for Bone Metastasis of Breast Cancer and Prostate Cancer Kalpana Katti[1], Haneesh Jasuja[1], Sibanwita Mohanty[1], Anu Gaba[2], Jiha Kim[1], Farid M. Solaymani[1] and Dinesh R. Katti[1]; [1]North Dakota State University, United States; [2]Sanford Health, United States

According to the World Health organization, there were 2.26 million women diagnosed with breast cancer and 1.41 million men with prostate cancer in 2020. Further, over a million deaths were reported due to breast cancer and prostate cancer globally in 2020. Both breast cancer and prostate cancer have the propensity to metastasize to bone, leading to a terminal prognosis for the patient. As of 2020, breast or prostate cancer that has metastasized to the bone is essentially incurable, and only palliative treatments exist. In the event of bone metastasis, skeletal failures are often the cause of death in patients. The inefficacy of anticancer drugs and failure of animal models necessitates the need for in vitro models. We have developed a novel bone mimetic scaffold that uses tissue engineering approaches to generate bone mimetic scaffolds for generation of bone that is in a remodelling stage; a preferred niche to which breast and prostate cancer migrate towards. Thus besides providing valuable opportunities for bone regenerative treatment the tissue engineered bone has additional uses as a testbed to evaluate bone metastasis of cancer. The bone mimetic scaffold utilizes unnatural amino acid modified nanoclays to mineralize hydroxyapatite mimicking the process of biomineralization. We report the generation of bone metastasized tumors at the stage of mesenchymal to epithelial transition on seeding the bone scaffold with commercial cell lines of breast cancer and also prostate cancer. We have developed cell lines from patient derived tissues that are also seeded onto the bone mimetic scaffolds to develop patient derived in vitro tumors of breast cancer bone metastasis. Further, we evaluate the mechanisms of influence of cancer cells on osteogenesis pathways (the Wnt bcatenin pathway) and demonstrate the specific role of cancer cell factors DKK and ET-1 on osteogenesis at the bone site. We have also developed unique mechanics-based biomarkers that use direct nanoindentation to evaluate the change in elastic and viscoelastic properties of cancer cells as a measure of progression of bone metastasis with the use of the testbeds. We also report the use of the testbed to screen new drugs for treatment of bone metastasis as well as report their influence on bone. Overall, the use of tissue engineered constructs present a useful testbed for evaluation of cancer.

2:15 PM SB12.02.03
Late News: Unconventional Biomaterials for Regenerative Engineering Gulden Camci-Unal; University of Massachusetts Lowell, United States

Introduction: Across various areas of regenerative engineering, there have been limitations with controlling cell adhesion, stem cell differentiation, viability, growth, and blood-material compatibility. Conversion of simple and abundant items to advanced cell culture substrates addresses some of the current challenges in regenerative engineering. The departure from complex fabrication processes to the applications of unusual and ubiquitous materials provides another dimension to the engineering of viable multiscale tissue constructs and regenerative technologies.[1-4] In addition, the use of sustainable constructs and novel fabrication strategies has the potential to increase access to regenerative engineering technologies on a global scale. In this work, we used unconventional biomaterials such as eggshells and paper for tissue repair.

Materials and Methods: We fabricated eggshell micro/nanoparticle (ESP) reinforced gelatin-based hydrogels to obtain mechanically stable and biologically active three-dimensional (3D) constructs that can differentiate stem cells into osteoblasts. The ESP-reinforced gels were then subcutaneously implanted in a rat model to determine their biocompatibility and degradation behaviors. In addition, these composite scaffolds were used to regenerate critical sized cranial defects in a rat model. We also used mineralized paper scaffolds through an origami-inspired approach to test their osteoinductivity and potential for tissue repair in *in vitro* and *in vivo* studies.
Results and Discussion: The ESP-reinforced scaffolds enabled the differentiation of stem cells without the use of specialized osteogenic growth medium. The ESP-reinforced gels exhibited significant enhancement in mineralization by the cells. Our findings indicated that the ESP composites exhibited superior mechanical properties and showed a favorable *in vivo* response by subcutaneous implantation in a rat model. These scaffolds were highly responsive to cells, and did not elicit inflammatory responses *in vivo*. The implants were easily accepted by the host, allowed for cellular infiltration in 3D, and highly vascularized. Implantation of ESP-reinforced scaffolds into critical sized calvarial defects in a rat model resulted in significant bone regeneration in 12 weeks. The resulting bone volume and bone density were as high as the native bone using these composite scaffolds as determined by micro-computed tomography analyses.
We also fabricated origami-inspired paper-based scaffolds for biomineralization. Material properties of the paper-based mineralized scaffolds were determined to be highly tunable. The tensile modulus of the scaffolds increased significantly after the mineralization process. Gene expression results for the osteogenic differentiation markers revealed the osteoinductivity of the mineralized paper scaffolds. Subcutaneous implantation of the samples in rats demonstrated biocompatibility, vascularization, and integration *in vivo*.
Conclusions: Unconventional scaffolds that are readily available and adapted from nature exhibited biomimetic characteristics including porosity, structure, and bioactivity resulting in physiologically relevant constructs. The use of existing naturally derived materials for regenerative engineering provides an inexpensive and sustainable approach that benefits the economy and environment while providing unique solutions to unmet clinical needs. Many of the unconventional biomaterials are overlooked and under-studied for biomedical applications, partially for their simplicity as mundane items.

Combination of Ultrasound Stimulation and 3D Printed Piezoelectric Hydrogel for Skeletal Muscle Tissue Engineering Federica Iberite, Claudia Paci, Lorenzo Vannozzi, Lorenzo Arrico and Leonardo Ricotti; Scuola Superiore Sant'Anna, Italy

Introduction 3D bioprinting has the potential for becoming a breakthrough method in the implementation of skeletal muscle (SM) tissue engineering. Bioink chemical cues and mechanical properties have been widely investigated in the last decade[1]. Less explored is the incorporation of exogenous stimulations (e.g. electrical, magnetic, mechanical) to boost cell differentiation. Piezoelectric nanoparticles (NPs) have been used as nanoscale transducers able to convert mechanically-induced deformation into an electrical cue when invested by an ultrasound wave (acting as a wireless source of mechanical energy). This paradigm has shown beneficial effects on different cell types, accelerating the differentiation of neural and muscle precursors[2,3]. No research groups have yet explored the inclusion of piezoelectric NPs in a bioink for SM cells 3D bioprinting. This work shows preliminary results on the properties of a piezoelectric bioink based on Pluronic/alginate doped with barium titanate NPs (BTNPs) and the biological response of C2C12 cells encapsulated in it.
Methods BTNPs (diameter=~60 nm) were added to propylene glycol alginate (PGA, ratio 1:1). A hydrogel of 20% w/w Pluronic F127 and 2% w/w alginate was prepared as described in[4]. Four bioinks (one bare bioink and three ones with BNTPs at 100, 250, 500 μg/mL respectively) were loaded with $2x10^6$ C2C12 cells/mL, printed with a 3D Bioplotter (Envisiontec GmbH) in one layer of parallel fibers (7x7 mm^2, nozzle diameter=250 μm, 37°C, pressure=0.4 bar, speed=10 mm/s), and then crosslinked (25 mM $CaCl_2$, 10 min). Hydrogels were characterized through SEM, EDX and rheometry. Viability tests at 72 h were carried out using LIVE/DEAD and PrestoBlue assays. For differentiation experiments, two constructs (non-doped and doped with 250 μg/mL BNTPs) were cultured in growth medium (5 days) and for 4 days in differentiation medium (DM=DMEM, 1% ITS, 1% FBS, 1% P/S). Half of the constructs were treated with low-intensity pulsed ultrasound (LIPUS; frequency=1 MHz; spatial average pulse average intensity=250 mW/cm^2; pulse repetition frequency=1 kHz; duty cycle=20%; exposure time=5 min) in DM, through a dedicated setup allowing precise control of the LIPUS dose at the cells[5], while the other half was not stimulated. After 4 days, the expression levels of *MYOG, CSRP3, MYH2 and GAPDH* (reference gene) were assessed through real-time qRT-PCR. Cells stained with TRITC-phalloidin and DAPI were imaged using a confocal microscope. All experiments were performed in triplicate for each condition.
Results and Discussion SEM images and EDX results showed that BNTPs were uniformly dispersed in the printed hydrogels, even at high concentrations of BTNPS. Rheometric results highlighted no significant differences between the different bioinks in terms of storage, loss moduli and viscosity. Viscosity decreased under shear strain, showing a shear-thinning behavior. High cell viability was observed up to a BNTP concentration of 250 μg/mL. Constructs with 500 μg/mL BNTPs showed lower cell viability, therefore were excluded for further studies. Differentiation tests showed that the LIPUS-treated doped bioink (250 μg/mL) promoted a significantly higher expression of *MYOG*, *CSRP3* and *MYH2* (key genes in early myogenesis), with respect to the control (bare bioink).
Conclusion The preliminary results here reported, demonstrate the potential of piezoelectric bioinks for the development of 3D printed SM constructs and the myogenic effect of the interaction between LIPUS stimulation and piezoelectric nanomaterials, in this context.
Acknowledgments This work received financial and technical support by INAIL, in the framework of the project MIO-PRO.

Effect of the Synthesis Route on the Antimicrobial Response of Calcium Phosphates Doped with Magnesium in 3D Printing—Potential Application in Regeneration of Dental Tissue Carlos Paucar[1], Natalia Jaramillo[2], Ana Moreno[1], Ricardo Sanchez[2], Alejandro Pelaez[3] and Claudia Garcia[1]; [1]Universidad Nacional de Colombia, Colombia; [2]Fundación Maria Cano, Colombia; [3]Universidad Cooperativa, Colombia

Dental demineralization, tooth resorption and endodontic treatments have a high impact on dentistry. Bioglass and calcium phosphate 3D printed scaffolds with suitable degradability and compatibility characteristics are a suitable choice for your solution. However, due to oral lesions, it is necessary to consider the behavior of these materials against pathogens in the dental area. These effects can be reduced by doping with elements associated with the biological processes of bone repair and / or regeneration such as boron (B) and magnesium (Mg), which also affects the reabsorption process of the material due to the release of ions that they generate. an antimicrobial effect. The objective of this work is to compare the antimicrobial activity of calcium phosphate powders obtained by sol-gel and self-combustion routes and scaffolds formed with these powders by 3D printing against C. albicans. and S. mutans. Calcium phosphates in sol-gel processes present a mixture of various types of crystalline phases, whereas self-combustion leads to a single β-TCP phase. The in vitro antimicrobial activity study showed that calcium phosphate obtained via self-combustion and magnesium doped (β-TCP / Mg) had a better effect than calcium phosphate obtained via sol-gel (CP-S) with and without doping against C. albicans. For S. mutans no inhibitory effect was found. In addition to the

co-cultivation of these two species, it showed an inhibitory effect on the evaluated materials. These results made it possible to formulate a ceramic paste based on the β-TCP / Mg / bioglass system by Design of Experiment (DOE) to obtain 3D printing scaffolds. These ceramic materials show promise as devices in the regeneration of dental tissues.

Primers for the Adhesion of Gellan Gum-Based Hydrogels to Cartilage Laura Riacci[1,2], Diego Trucco[1,2,3], Lorenzo Vannozzi[1,2], Leonardo Ricotti[1,2] and Gina Lisignoli[3]; [1]Scuola Superiore Sant'Anna, Italy; [2]Scuola Superiore Sant'Anna, Italy; [3]IRCSS Istituto Ortopedico Rizzoli, Italy

INTRODUCTION A stable adhesion to the cartilage tissue is a crucial requisite for hydrogels used in the fields of cartilage substitution and regeneration. Indeed, the presence of a weak interface between the cartilage and the implanted material may lead to an early detachment, thus causing the failure of the cartilage repair or regeneration process [1]. Using an adhesive primer, namely a coating applied to the cartilage surface to promote the adhesion of materials, may overcome such an issue. Different primers (fibrin glue (FG) [2], cellulose nanofibers (CNF) [3] and catecholamines (CAT) [4]) have been proposed in the state-of-the-art. However, no studies have systematically compared their performance. This study aims at evaluating the adhesion strength between the cartilage tissue and gellan gum (GG)-based hydrogels, crosslinked using ions or, after methacrylation, through a light source.
METHODS GG was dissolved in d-H_2O at 2 % w/v by stirring for 1 h at 37°C, while gellan gum methacrylate (GGMA) was dissolved in PBS at 2 % w/v for 1 h at 37 °C. Then, ruthenium (Ru) and sodium persulfate (SPS) were added to GGMA at a concentration of 0.2 and 2 mM, respectively.
FG was deposited evaluating different waiting times before hydrogel deposition, namely 30 s, 5 min, 15 min and, 30 min. CNFs, dispersed in d-H_2O, were added to GG and GGMA at two concentrations (0.1 and 0.5% w/v) to form a CNF-based primer to be added before GG and GGMA. CAT-modified gelatin was dissolved in a Tris-buffered saline buffer at two concentrations (100 and 125 mg/mL). Then, the solutions were mixed with 1 mM Ru and 20 mM SPS and then crosslinked through a white LED for 30 s.
Before performing adhesion tests, GG or GGMA were cast on each primer and crosslinked for 10 min with $MgCl_2$ (1 % w/v in d-H_2O) (GG) or with the LED light (GGMA).
To evaluate the adhesion strength, two cartilage-hosting parts were used to block bovine cartilage samples and a top hydrogel-hosting part allowed pouring the primer and the hydrogel solution onto the cartilage. A traction test was performed through an Instron machine.
RESULTS Results showed that the photo-crosslinked GGMA showed higher adhesion strength than GG in absence of primers. However, the adhesion strength of both GG and GGMA improved in the presence of FG with respect to the control. In particular, the waiting times of 5 min for GGMA (9.80 ± 3.03 kPa for GGMA) and 15 min for both the hydrogels (12.64 ± 0.87 kPa for GG and 10.99 ± 3.14 kPa for GGMA) guaranteed to match the clinical goal (10 kPa) [5]. The adhesion strength using CNFs and GG hydrogels reached a value of 12.13 ± 4.69 kPa (clinically acceptable) in the case of 0.1 % w/v CNFs, while the strength was smaller for the higher concentration of CNFs.
The adhesion strengths obtained with the CAT-based gelatin for GG increased from 6.16 ± 1.87 kPa (100 mg/mL) to 8.85 ± 2.40 kPa (125 mg/mL) and for GGMA from 2.93 ± 1.52 kPa (100 mg/mL) to 8.06 ± 1.38 kPa (125 mg/mL), without reaching the clinically accettable value.
CONCLUSIONS We found that the use of primers can guarantee an increased adhesion of GG-based hydrogels onto the cartilage. In the case of FG primer the best condition was represented by a waiting time of 15 min between primer pouring and subsequent hydrogel deposition on the cartilage, in all cases. In the case of embedded CNFs, the fiber concentration of 0.1 % w/v considerably increased the adhesion strength of GG and GGMA hydrogels. The CAT-modified gelatin layer was less effective in promoting the adhesion between the hydrogels and the cartilage.

Gradual and Distributed Exchange of Cryoprotective Agents with Hydrogel Beads Protects Cells from Osmotic Damage Derin Sevenler[1,2], Hailey Bean[1], Mehmet Toner[1,2] and Rebecca D. Sandlin[1,2]; [1]Massachusetts General Hospital, United States; [2]Harvard University, United States

Cryopreservation of patient immune cells is an essential step in the scaled-up production of cell therapies such as stem cell and T cell therapies. Despite the rapidly expanding importance of cryopreservation for cell therapy, clinical best practices remain inadequate, unreliable, and harmful to patients. Cell recovery remains a critical problem: insufficient T cell yield results in manufacturing failure rates of chimeric antigen receptor T cell therapy (for 13%-20% of patients in recent trials). Also, the co-injection of approx. 10 mL of dimethyl sulfoxide (Me2SO) along with thawed cell therapy product is widely acknowledged to be responsible for the nausea and vomiting experienced by up to 60% of patients and is implicated in sometimes life-threatening neurological complications. Regrettably, this exposure is medically unnecessary and only permitted due to the unacceptably low and unreliable recovery rate of exchanging the cryo media with centrifugal cell washing at the point of care (for hematopoietic stem cells, 60% on average). A central challenge is that cryoprotective agents must be diluted gradually (i.e. over the course of several minutes) to prevent hypotonic shock and cell lysis.

We have recently developed a technology to gradually exchange cryoprotective agents (CPAs) from cell suspensions in a distributed manner based on hydrogel beads. We show that these beads exchange common cell-penetrating cryoprotective agents (CPAs)—glycerol and dimethyl sulfoxide (DMSO)—with the surrounding solution at a rate prescribed by the agent's coefficient of diffusion within the gel and bead size.

Calcium alginate hydrogel beads of uniform controlled size (CV 2%) were synthesized by dripping alginic acid into a calcium alginate bath with an adjustable sheath flow of compressed air. Rates of CPA release with the solution were measured by pre-loading the beads with CPA, then gently mixing them with an agent-free solution and measuring the osmolarity of the solution over time. Rates of CPA uptake from solution were measured similarly. Hydrogel beads with volume 25 μL had an equilibration rate constant of about 1 minute for both uptake and release of glycerol, and about 45 seconds for

DMSO. The rates of CPA exchange were well described by numerical models of diffusion.

We used these uncoated hydrogel beads to mediate glycerol unloading from Jurkat cells (a CD4 T cell line), in a model system of cryoprotective agent-induced hypo-osmotic damage. In this model system, Jurkat cells were loaded with cryo-media containing 15% glycerol, and then unloaded by either immediate dilution in hypotonic phosphate buffer, or by mixing with hypotonic (i.e., glycerol-free) hydrogel beads. The beads gradually diluted the CPA, preventing hypotonic shock and cell lysis. Altogether cell recovery and viability after 4 hours was increased from about 55% (single-step dilution) to about 90% (hydrogel bead mediated dilution).

We further explored the use of polyelectrolyte multilayer films on the beads to allow controllable permeability independent of bead size. Alternating layers of poly(allylamine) and dextran sulfate were adsorbed onto the negatively charged alginate beads, resulting in films which were less permeable to glycerol and DMSO than to water. These semipermeable membranes resulted in the beads acquiring a characteristic shrink-swell behavior when immersed in hypertonic cryoprotective agent solutions, allowing indirect measurement of membrane permeability to both water and the cryoprotective agent by measurement of the bead size over time and fitting with a two-compartment Kedem-Katchalsky formula.

Altogether, the simplicity and control afforded by this system may provide an attractive alternative to centrifugal cell washing for controlled-rate addition and removal of CPAs for large volumes of fragile and precious cell samples.

3D Confinement Regulates Cell Life and Death Oksana Dudaryeva and Mark W. Tibbitt; ETH Zurich, Switzerland

Cell function is influenced by the biochemical and biophysical cues provided by the extracellular matrix (ECM) and neighboring cells. [1,2] To study the role of geometric and mechanical signals from the ECM on cell fate, we developed a single cell culture platform that offers robust control over properties of the individual cell environments. [3] This microwell platform allowed for a decoupled investigation of geometric and mechanical cues. We used our microwell platform to investigate how niche volume and stiffness affect human mesenchymal stem cell (hMSC) function, with an emphasis on the role of 3D confinement. We found that viability and proliferation of hMSCs were affected by confinement of 3D niches compared with unconfined 2D culture. Observed differences in hMSC fate correlated to YAP localization. These results demonstrate that 3D geometric confinement is an important regulator of cell fate.
Single cell niches with controlled geometry and stiffness were patterned on PEG hydrogels through soft lithography. The patterned hydrogels were formed via thiol–ene photopolymerization between norbornene-functionalized star PEG and thiolated linear monomers. The network was functionalized with the RGD adhesion motifs to enable cell attachment. hMSCs were seeded and cultured in the niches, and their fate was assessed using cell viability and proliferation assays. Mechanical activation in hMSCs was assessed using the primary antibody against YAP.
We investigated cell function in three niche volumes: small, intermediate and large (35, 60, and 125 x 10^3 μm^3); and three stiffnesses: low, medium and high (5, 16, and 30 kPa, respectively). The cells were cultured in the niches for 24 and 72 h and the viability and proliferation rates were quantified. The cells in small niches expressed high death rates that increased with decreasing elastic modulus of the hydrogel; cells expressed maximum viability at high stiffness. The proliferation rate was markedly low in 3D confinement than for 2D controls. Observed differences in hMSC viability and proliferation correlated to YAP localization. hMSCs displayed primarily cytoplasmic YAP localization [Nuclear/Cytoplasmic ratio (N/C) < 1.7], indicating reduced mechanical activation upon confinement.
3D confinement regulated cell function and the effect was influenced by other biophysical parameters of the niche, such as stiffness. We anticipate that our platform, with defined 3D single cell niche arrays, will provide new insights on the role of microenvironmental control of cell fate.

3D Biofabrication of Human Stem Cell Derived Spinal Cord Motor Circuits Sudeep Joshi, Cathleen Hagemann, Kelly O'Toole, Pacharaporn Suklai and Andrea Serio; The Francis Crick Institute and Kings College, United Kingdom

A bioengineered 3D neural tissue construct mimicking the structural and functional characteristics of native neural tissue offers the possibility of recapitulating biological events in-vitro, and acts as a potential tool to understand basic biology and human disease. A major bottleneck in modelling 3D neural tissues in-vitro is to control the interaction between neuronal cells and ECM within these complex 3D arrangements, both across space and time. As a result, several 3D platforms focus on modelling short range circuitry, which makes them less suited to modelling; for example, spinal cord circuitry, where motor axons span vast lengths and interacts with different environments. Recent advancements in 3D bioprinting offer precise control over direct positioning and timing of the cell-ECM interaction, allowing to create better models of these long-range connections.

In the present work, we introduce a biofabrication technique that combines 3D bioprinting, microfabrication, and human induced pluripotent stem cell (hiPSC) populations. This allows us to engineer a functional in-vitro spinal cord like construct capable of modelling physiological motor axons guidance and development. These spinal cord constructs were fabricated via extrusion-based multi-material 3D bioprinting, wherein aggregates of hiPSC-derived motor neuron progenitors (MNPs) were precisely positioned within 3D printed hydrogels. The location for placing these MNPs within a bio-compatible hydrogel construct is controlled using a dot-dispensing printing method, both across space (positional arrangement) and time (different timepoints) within one experiment. Mechanical stability of 3D printed neural construct is ensured by printing MNP-laden hydrogels comprising of biodegradable polymers. Moreover, the biofabricated neural tissue construct facilitated diffusion of essential nutrients and oxygen required for cell survival and differentiation. The optimized 3D printable bio-inks facilitated successful neuronal differentiation and axonal elongation throughout hydrogel-based spinal cord construct, and the activity of these 3D neuronal networks is confirmed by physiological spontaneous calcium flux studies.

Future development of these 3D spinal cord constructs is directed towards modelling complex PNS tissue architectures to address clinically relevant approaches for addressing motor neuron diseases and spinal cord defects. Techniques developed in this research work can also be extended for bioprinting other neuronal and glial cells from CNS and PNS with smart hydrogel materials to determine mutualistic interaction between cells in co-culture and ECM matrix. Taken together, our experimental efforts lead towards better control over complex cell/tissue culture environment for understanding the possibility of recapitulating biological events to answer fundamental questions in neural circuit engineering.

4:45 PM SB12.03.04
Fabrication of Tissue-Engineered Oral Mucosa with Micropatterned Fish Scale-Collagen Scaffold Using 3D Printing Technology and Soft Lithography Kazuma Kishimoto[1], Orakarn Suebsamarn[2], Yoshihiro Kodama[3], Takafumi Komatsu[4], Ayako Suzuki[5], Shuichi Shoji[1], Kenji Izumi[2] and Jun

Mizuno[1,6]; [1]Waseda University, Japan; [2]Niigata University, Japan; [3]Taki Chemical Co., Ltd., Japan; [4]Komatsuseiki Kosakusho Co., Ltd., Japan; [5]Niigata University Medical and Dental Hospital, Japan; [6]Suwa University of Science, Japan

In this study, we developed a novel scaffold for oral mucosa tissue regeneration, which is safer and more biomimetic. Fish scale collagen was used as a scaffold to avoid the risk of transmissible infectious diseases for human clinical use. In order to mimic the unique and complex structure that biomedical tissue possesses, a high-precision 3D printing technology was employed to deliver maximized design flexibility. The results showed that 3D printer was capable of manufacturing micro-sized structure with the error rate less than 10% from the original design. The structure from 3D printed mold was transferred to PDMS with soft lithography, and collagen scaffold was fabricated by molding fish scale collagen solution onto PDMS mold. The histological evaluation of the tissue-engineered oral mucosa confirmed the successful formation of the epithelial layer mimicking oral mucosa *in vivo*. This study not only established a method for fabricating a new type of safe scaffold material, but also showed high potential of 3D printing technology as a tool in tissue engineering. By adjusting the structure's geometry with 3D printer, we believe our scaffold derived from tilapia can be applicable in the area of extraoral grafting such as skin as well.

Collagen derived from human or animal tissues have proved to be a success in healing damaged oral mucosa. However, the use of animal-derived collagen is restricted in many countries due to ethical reasons and the risk of transmitting infectious diseases cannot be ignored. Instead, considerable attention has been drawn to fish-derived collagen as a potential material for biomedical applications because the risk of transmitting zoonotic is considerably low compared with animal-derived collagen. The interface area between epithelial layer and connective tissue has a unique three-dimensional undulated structure, also known as the dermal-epidermal interface (DEJ). A lot of studies have shown that mimicking DEJ is crucial in tissue engineering. In our previous study, micro electro mechanical systems technology was used to mimic this structure. However, the result showed a lack of mechanical stability between epithelial layer and connective tissue due to rectangular configuration. We established a technique for fabricating micropatterned fish scale collagen scaffold using 3D printing technology for achieving safety concerns and structural optimization.

The undulated micro-sized structures were manufactured using 3D printing technology. The 3D printed mold was then exposed to UV-ozone irradiation to improve wettability, and mold release agent was coated on its surface. After applying release agent, liquid polydimethylsiloxane (PDMS) was poured directly onto the mold for soft lithography replication. PDMS was specifically chosen for this process because of its biocompatible and gas permeable properties. Soft lithography was again used to fabricate the structures by molding fish scale collagen solution on the PDMS mold. Finally, to create tissue engineered oral mucosa, human oral keratinocytes were seeded on the micropatterned fish scale collagen and cultured for 11 days.

Scanning electron microscopy (SEM) was used to observe 3D printed molds, PDMS molds, and fish scale collagen scaffolds, and optical coordinate measuring machine (μCMM, Bruker Alicona) was used to determine geometrical measurements of 3D printed molds and PDMS molds. The measurement of the molds' geometries demonstrated high accuracy with the error rate less than 10% from the original design. In addition, SEM images of PDMS molds and fish scale collagen scaffolds showed the structures of the 3D printed molds were successfully replicated. The histological images of the tissue engineered oral mucosa revealed the successful formation of epithelial cell layer along the undulated structures.

SESSION SB12.04: Poster Session I: Biomaterials for Regenerative Engineering
Session Chairs: Gulden Camci-Unal and Natesh Parashurama
Tuesday Afternoon, November 30, 2021
8:00 PM - 10:00 PM
Hynes, Level 1, Hall B

SB12.04.01
Late News: Self-Assembly of Pro-Angiogenic Anti-miRs on Wound Dressings to Promote Diabetic Wound Regeneration Adam G. Berger[1], Michael G. McCoy[2], Mark W. Feinberg[2] and Paula Hammond[1]; [1]Massachusetts Institute of Technology, United States; [2]Brigham and Women's Hospital, United States

Impaired regeneration of damaged skin tissue is a common complication of diabetes, resulting in decreased quality of life and increased mortality. Despite decades of research, few advances have been made in treating these burdensome wounds. Most current treatments do not address the underlying molecular pathophysiological processes, such as impaired angiogenesis. Adequate vascularization is necessary to bring oxygen and nutrients to the healing wound. Non-coding microRNAs (miRNAs or miRs) play a role in regulating the angiogenic state through post-transcriptional modulation of gene expression, and 4 miRNAs - miRNA-26a, -92a, -135a-3p, and -615-5p - have all been implicated in the anti-angiogenic state. One promising approach to promote the regeneration of non-healing wounds is through delivery of miRNA inhibitors (anti-miRs), which block the effects of these anti-angiogenic miRNAs; however, current application of anti-miRs in pre-clinical studies requires numerous intradermal injections of excessive amounts of anti-miR. A packaging and controlled release strategy could enhance the translational potential of this approach. Specifically, we have investigated the coating of wound dressings with electrostatically assembled thin films containing anti-miRs and cationic transfection polymer to enable anti-miR transfection of endothelial cells (ECs). We have demonstrated the emergence of pro-angiogenic phenotypes in a 3D EC spheroid sprouting assay and an EC scratch assay after treatment with each of the 4 anti-miRs delivered using our cationic transfection polymer. Additionally, we have shown the ability to coat woven Tegaderm wound dressings with anti-miRs and to retain the bioactivity of these anti-miRs coated onto wound dressings. Finally, we have begun to explore potential synergies between these pro-angiogenic anti-miRs when dosed in combinations, which could further enhance wound regeneration. Ultimately, this work will enable translational pro-angiogenic anti-miR delivery to promote the regeneration of non-healing diabetic wounds.

SB12.04.02
Late News: The Characterization of SynOss Putty and Its Impact on Dental Pulp Stem Cells Shi Fu[1], Daniel Xie[2], Mira Rosovsky[3], Sabreen Alam[4], Prabuddha G. Dastidar[5], Elizabeth Wang[6], Marcia Simon[1] and Miriam Rafailovich[1]; [1]Stony Brook Unversity, United States; [2]Panther Creek High School, United States; [3]SAR High School, United States; [4]Portola High School, United States; [5]North Carolina School of Science and Mathematics, United States; [6]BASIS Chandler, United States

SynOss Putty is a biocompatible synthetic calcium phosphate mineral matrix with type I collagen derived from bovine Achilles tendon. SynOss has been associated with the clinic use of regeneration of cell tissue in teeth and bones in periodontal, oral and maxillofacial surgery. Previous studies have determined that a more predictable tissue regeneration was found in the majority of samples using SynOss and blood as a scaffold. However, the mechanism of its properties in reconstruction of teeth and bones remains unknown. Analyzing the impact of SynOss on the proliferation of dental pulp stem cells helps to bring insight into the clinical applications of SynOss such as the recovery of dental pulp after dental surgery. The proliferation assay

shows that the dental pulp stem cells treated with SynOss reduce the cell number initially but have a higher growth rate compare to the control group. This leads to the belief that the SynOss material promotes the proliferation of the cells.
SynOss was then measured using the XRF to decide the elemental content. The spectra from the XRF shows that there is a large quantity of calcium and phosphate which provides a ratio of 2.5 +/- 0.011, higher to that of bones which has a ratio of 2.2. This would help with the mineralization since it has a similar ratio and therefore would provide similar properties to bones. And traces of cadmium and tungsten were also found in the material which may help to explain why the cells with SynOss treatment have lower cell counts than the control group in the day 0 of proliferation. Cadmium and tungsten have properties that are carcinogenic which proves to be detrimental to the survival of the cells. To analyze genetic expression of the dental pulp stem cells with SynOss Putty, a 28-day reverse transcription polymerase chain reaction (RT-PCR) test was performed for the 3 groups: control, SynOss treated and SynOss with fibrin. The cells were lysed and RNA were collected on day-0, day-14, day-21 and day-28.
An acellular test is undergoing with different conditions are made to check the mineralization of SynOss. The conditions are: deionized(DI) water, phosphate buffered saline(PBS), PBS with fibrinogen, osteogenic differentiation medium, osteogenic differentiation medium with fibrinogen, osteogenic differentiation medium with fibrinogen and thrombin to simulate the environment of blood.
Future works will include the Raman spectroscopy test to analyze the chemical structure and morphology of SynOss Putty and the impact of SynOss with different amount on metabolic status of dental pulp stem cells .

SB12.04.03
Late News: The Impact of TiO2 on the Network Mechanics of HUVECs Shi Fu[1], Elizabeth Wang[2], Sabreen Alam[3], Prabuddha G. Dastidar[4], Daniel Xie[5], Mira Rosovsky[6], Marcia Simon[1] and Miriam Rafailovich[1]; [1]Stony Brook Unversity, United States; [2]BASIS Chandler, United States; [3]Portola High School, United States; [4]North Carolina School of Science and Mathematics, United States; [5]Panther Creek High School, United States; [6]SAR High School, United States

Titanium dioxide(TiO_2) is commonly used in consumer applications such as cosmetics, electronics, and sunscreen. Previous studies have determined that in combination with UV light, titanium dioxide has the capability of killing bacteria and microorganisms Given that endothelial cells aid in angiogenesis which provides nutrients and oxygen to newly formed tissue, evaluating the effect of titanium dioxide on endothelial cells could help to realize the impact on the healing factor in humans. In this study, we aim to investigate the effect of TiO_2 nanoparticles on network formation of endothelial cells. Two types of TiO_2 were used to test the effect of TiO_2 on cellular network formation and cell migration of endothelial cells: regular rutile TiO_2 and lecithin coated rutile TiO_2 to reduce the toxicity. Human Umbilical Vein Endothelial Cells (HUVECs) were treated with rutile TiO_2 and lecithin-coated rutile respectively in a concentration of 0.1mg/mL for 24 hours. The angiogenesis tube formation assay on Matrigel was performed for 16 hours. Timelapses spanning the whole process with time interval of 10 minutes were taken for the both treatment group, along with the control group. Cell migration speed and network quantification by total length of branches and number of nodes were analyzed.
Our assumption was that, TiO_2 nanoparticles may cause tangling of actin fibers, making it difficult for cells to stretch out, make connections and create tubes. However, the results from the network quantification indicate that rutile had significantly more network formation than the lecithin-coated rutile and control at all hours. Next was the lecithin-coated rutile with control having the least amount of networks. This data suggests that TiO_2 might be a pro-angiogenic factor as treating the cells with rutile and lecithin-coated rutile, both containing TiO_2 nanoparticles, resulted in more network formation than the control group. It is very likely that TiO_2 increase the cholesterol level of HUVECs, will in turn soften HUVECs and make the cells easier to migrate and reach out. Future tests will re-run the experiment to make sure that TiO_2 is a pro-angiogenic factor, and have cholesterol test and further investigation of HUVECs' metabolic status under the impact of TiO_2.

SB12.04.04
Late News: Analyzing the Toxicity of Titanium Dioxide and Zinc Oxide on HUVECs and Evaluating the Antibacterial Properties of Titanium Dioxide Shi Fu[1], Daniel Xie[2], Prabuddha G. Dastidar[3], Elizabeth Wang[4], Sabreen Alam[5], Mira Rosovsky[6], Marcia Simon[1] and Miriam Rafailovich[1]; [1]Stony Brook Unversity, United States; [2]Panther Creek High School, United States; [3]North Carolina School of Science and Mathematics, United States; [4]BASIS Chandler, United States; [5]Portola High School, United States; [6]SAR High School, United States

In this study, we aimed to investigate the effect of varying concentrations of titanium dioxide(TiO_2) on the viability of Human Umbilical Vein Endothelial Cells (HUVECs). HUVECs were plated in a 24-well plate. Triplicates were made respectively with Rutile TiO_2 treatment, Lecithin-coated Rutile TiO_2 treatment, and a control group with no treatment was used for comparison. The cells were treated with 4 different concentrations: 0.05 mg/ml, 0.1 mg/ml, 0.2 mg/ml, and 0.4 mg/ml. Afterwards, the cells were left in the incubator at a temperature of 37 ºC with 5% CO_2 and 80% humidity for 24 hours. From the test results, 0.05mg/mL has no impact compare to the control group since the concentration is too small. For the other concentrations, the impact of TiO_2 start to become effective at 0.1mg/mL, a decrease in the cell count can be seen as the concentration increases for both treatments. This demonstrates that titanium dioxide nanoparticles inhibit the growth and proliferation of the HUVEC cells to a certain extend.
To test TiO_2's antibacterial properties, after 24 hours treatment of 0.1 mg/mL rutile TiO_2 and 0.1 mg/mL lecithin-coated rutile TiO_2, along with control group, HUVECs were then infected with Staphylococcus aureus bacteria for another 24 hours in order to determine TiO_2's effect on the infection. The alive and dead cells and bacteria for the bacteria infection test were analyzed, the results shows that live bacteria per cell for the control is greater than that of the rutile TiO_2 test which shows that TiO_2 may have antibacterial properties.
Future tests will look at the impact of TiO_2 nanoparticles on the doubling time of HUVEC cells, as well as study the cell modulus by atomic force microscope(AFM) to gain further insight on the impact that TiO_2 has on cell survival and proliferation.

SB12.04.05
Late News: Localized Delivery of siRNA from Biodegradable Wound Dressings via Layer-by-Layer Assembly Mariss Haddad, Adam G. Berger and Paula Hammond; Massachusetts Institute of Technology, United States

The delivery of therapeutic short interfering RNA (siRNA) directly into a localized area holds significant potential for the treatment of non-healing, cancerous, and other difficult-to-treat lesions. siRNA has the ability to downregulate genes that may be overexpressed in these disease states; however, its delivery is challenged by the need to enter the cell for bioactivity and its degradation by nucleases. Previously, we have shown that siRNA can be coated onto a non-degradable wound dressing using Layer-by-Layer (LbL) assembly, which creates a thin polyelectrolyte film that directly incorporates siRNA and cationic polymer to aid transfection into cells. We have noted that removal of these dressings upon termination of lesion treatment can lead to destruction of the underlying tissue. Biodegradable scaffolds circumvent the need to remove the dressing and thus the associated local tissue damage. Films containing poly(β-aminoester) (Poly2), siRNA, and other polymer excipients were assembled on Endoform™, a biodegradable dressing comprised of reconstituted ECM and collagen. We show that biodegradable scaffolds can be coated with a thin polyelectrolyte film using LbL technology at an average loading 3.7 times greater than the loading on non-biodegradable scaffolds per layer, depending on assembly and substrate conditions. We have also characterized the coating of Endoform™ with siRNA using surface measurement techniques. Finally, we have demonstrated that fluorescently labeled siRNA released from coated Endoform™ dressings can be taken up by mammalian cells and have begun investigating the bioactivity of delivered siRNA from Endoform™ films. Ultimately, this work will enhance the localized delivery of therapeutic siRNAs to localized lesions while preventing damage to the surrounding tissue caused by dressing removal.

SB12.04.07
Polyvinyl Alcohol/ Graphene Oxide/ Polypyrrole Nanocomposites for Applications in Wound Healing Shamrock Barrera, Ky Duyen Le, Chizimuzo Chibuko and Isaac Macwan; Fairfield University, United States

Graphene oxide (GO), an oxidized form of graphene, a carbon allotrope, is a very attractive nanomaterial with potential biomedical applications in tissue engineering owing to its electrochemical activity. However, it lacks the ability to form freestanding films that can actively function as an electrochemical substrate. To work around its inability to do so, different methods have been reported such as annealing, ultrafiltration, electrophoresis, and mid-infrared polarizers. Two of the popular techniques to synthesize free standing films are electrospinning and electropolymerization through cyclic voltammetry (CV). In recent years nanofibrous substrates have found unique applications in the field of biomedical engineering, especially in wound healing. Nanofibrous films are ideal for preventing bacterial contamination in open wounds and in conjunction with viable materials can serve as biocompatible skins for wound dressings. These films can also be coated or mixed with different antibacterial topical medications that can aid in further protection from infections. Similarly, CV is a popular electrochemical technique that is utilized to investigate the reduction and oxidation processes of a species and to synthesize novel substrates for biomedical applications. This work deals with utilizing these two techniques of electrospinning and CV to synthesize nanocomposite GO films with polyvinyl alcohol (PVA) and polypyrrole (Ppy) polymers acting as scaffolds. PVA, which is a biocompatible, water-soluble, synthetic polymer, is simultaneously electrospun with GO to create a scaffold capable of supporting the GO film. Polypyrrole, which is both chemically and thermally stable and has good biocompatibility both in-vivo and in-vitro, can significantly impact cell adhesion, proliferation and differentiation, as well as tissue regeneration and repair. It is theoretically and experimentally supported that Ppy functionalized GO greatly improves the biocompatibility of GO. First, PVA/GO nanocomposite is electrospun using a 5 wt. % solution of PVA and 0.5mg/ml concentration of GO at 25kV and 0.5 ml/hr flow rate. The obtained GO/PVA nanofibrous film is then used as a substrate for the electropolymerization of pyrrole monomers, thereby forming a PVA/GO/Ppy nanocomposite film. After electropolymerization of pyrrole, the thin films are peeled off to test for impedance using electrochemical impedance spectroscopy (EIS). SEM analysis, together with EIS and CV data agrees well with the molecular understanding of the interactions at the interface of PVA, GO and Ppy from the simulated trajectories. The developed composite improves the mechanical properties of tissue engineering scaffolds and is anticipated to be utilized as a wound dressing material.

SB12.04.08
Micro Patterned Polymer Interfaces for Muscular Cells Alignment and Stimulation Vito Vurro[1], Alberto Scaccabarozzi[1], Francesco Lodola[2], Filippo Storti[3,1], Fabio Marangi[1,3], Aaron M. Ross[3], Giuseppe M. Paternò[1], Francesco Scotognella[3,1], Luigino Criante[1], Mario Caironi[1] and Guglielmo Lanzani[1,3]; [1]Istituto Italiano di Tecnologia, Italy; [2]Università degli Studi di Milano-Bicocca, Italy; [3]Politecnico di Milano, Italy

By and large the research on human machine interface is constantly attracted by the idea to act in a contactless and wireless way. In particular biological and medical areas can benefit from optical method for introducing innovative ways to probe and stimulate the biological matter. Conjugated molecules and polymers offers a promising platform to interface with cells and living organisms thanks to their high optical absorption/emission cross section, chemical synthesis' easiness and relatively low toxicity.
In this work, we developed a simple and fast method to fabricate and a micro-machining technique to pattern an interface with a double functionality made possible by the blend of photoactive poly(3-hexylthiophene) and polyethylene. The pattern on the surface of the film is designed to mimic the physiological condition and to help living cells to organize in a tissue. At the same time, the active component is able to transduce light into a stimulus for excitable cells. The mechanical properties and easiness of process are due to the presence of polyethylene while the optoelectronic properties are given by the poly(3-hexylthiophene).
We demonstrate that the obtained scaffold combines he capability to align with that to photostimulate living cells. The ultimate goal of this project is to produce an artificial tissue for future applications in the robotic, pharmacological and regenerative medicine fields.

SB12.04.09
Mechanical Properties, Translucency and Low-Temperature Degradation (LTD) of Yttria (3–6 mol%) Stabilized Zirconia Sharon Uwanyuze[1], Sulekha Ramesh[2], Mark King[3], Nathaniel Lawson[3] and Manoj Mahapatra[3]; [1]University of Connecticut, United States; [2]Bob Jones School, United States; [3]The University of Alabama at Birmingham, United States

The market share of zirconia as metal-free dental restoratives continues to grow globally, especially 3 mol% Y_2O_3 stabilized tetragonal zirconia (3YZ). However, premature failure of zirconia femoral heads and subsequent recall of hip implants by the manufacturers in 2001, triggered concern on whether zirconia dental prosthesis could incur similar failure. Here, we investigate the mechanical properties (hardness and biaxial flexural strength), optical properties (translucency and gloss), and low-temperature degradation (LTD) of 3–6 mol% yttria-stabilized zirconia. The specimens were prepared by conventional solid-state sintering at 1400 °C. The mechanical and optical properties were evaluated for sintered and polished specimens. X-ray diffractometer (XRD) and scanning electron microscope (SEM) were used, respectively, for structural and microstructural investigation. LTD was determined by XRD analysis of the samples aged in a hydrothermal autoclave at 134 °C for 5–108 h. We found the mechanical and optical properties are found to be microstructure sensitive, and the LTD due to tetragonal to monoclinic phase transformation decreased with increasing Y_2O_3 content. The mechanical strength, translucency, and LTD were lowest for 6 mol% Y_2O_3 stabilized zirconia.

SB12.04.10
3D Printing of Silk-Bioceramic Nanocomposites for the Regeneration of Innervated and Vascularized Bone Tissue Vincent Fitzpatrick, Zaira Martin Moldes, Anna Deck, Ruben Torres-Sanchez, Chunmei Li and David L. Kaplan; Tufts University, United States

Bone is a dynamic, innervated and vascularized tissue with the inherent ability to regenerate after injury. Nevertheless, non-union fractures remain a major issue in orthopedic surgery. Autografts and allografts are the gold standard for repair but can be associated to donor site morbidity, donor material availability, and increased operative times. Alternative biomaterial-based solutions are promising, including synthetic bone fillers. However, these fillers do not allow refined control of graft geometry, and seldom offer adequate porosity for rapid cell colonization, efficient nutrient exchange, or implant degradation. Further, these approaches usually do not actively promote bone growth, nor account for the complexity of bone, and in particular the neurovascular network.

We developed a silk-ceramic bioink to 3D print porous constructs for bone regeneration. The resulting material was mechanically close to bone, promoting osseointegration. These structures were biocompatible, their shape well-controlled even for complex geometries, and their porosity could be precisely tuned for efficient osteogenesis.

Our constructs supported osteoblastic differentiation in vitro, and a rapid cell response and efficient neoosteogenesis when combined with osteoinductive factors (BMP-2). We further loaded this bioink with angiogenic and neurotrophic morphogens (VEGF and NGF), and precisely patterned these biomolecules, promoting the migration, organization and differentiation of human umbilical vein endothelial cells and human induced neural stem cells,

respectively. Coculture conditions showed that the multiple morphogens and cell types promoted the osteogenic differentiation of human mesenchymal stem cells.

Finally, our bioink could be loaded with antibiotics, providing an encouraging solution for the prophylactic treatment of osteomyelitis in non-union fractures.

SB12.04.11
Porous Collagen-Based Matrices for Embedded Bioprinting Daniel Reynolds, Irene de Lazaro, David Mooney and Jennifer Lewis; Harvard University, United States

Embedded bioprinting can recreate the complexity of the *in vivo* microenvironment by spatially patterning multiple cell types and perfusable vasculature within biological matrices. However, most biological inks and matrices that permit cell growth, spreading, and migration exhibit a narrow “printing window”. Here, we report a new class of porous, printable biological matrices for creating 3D vascularized human tissues and tumor models. These matrices contain sacrificial microparticles that both broaden the printing window and generate microporosity upon their removal after printing. We have demonstrated that this porous collagen-based matrix enables the embedded printing of a murine melanoma cell ink in the form of a 3D tumor model. Confocal microscopy reveals that the resulting collagen network is fibrillar, an important *in vivo* feature of collagen type I. Importantly, we find that melanoma cells readily spread and proliferate, and that effector T cells migrate within this collagen-based matrix. Our biofabrication platform enables the formation of a 3D microenvironment that is conducive to cell growth, spreading, and migration – key cellular processes involved in anti-tumor immunity.

SB12.04.12
Actin Cytoskeletal Structure and the Statistical Variations of the Mechanical Properties of Non-Tumorigenic Breast and Triple-Negative Breast Cancer Cells Killian C. Onwudiwe[1,2], Jingjie Hu[2], Vanessa Uzonwanne[2], Toyin Aina[1], Josephine C. Oparah[1] and John Obayemi[2]; [1]African University of Science and Technology, Nigeria; [2]Princeton University, United States

This paper explores the actin cytoskeletal structures and the statistical variations in the actin fluorescence intensities and viscoelastic properties of non-tumorigenic breast cells and triple-negative breast cancer cells at different stages of metastases. The actin contents of the cell cytoskeletal structures are shown to decrease significantly with cell progression from non-tumorigenic to more metastatic states. The corresponding viscoelastic properties of the nuclei and the cytoplasm (Young’s moduli, viscosities, and relaxation times) of the cells are also measured using Digital Image Correlation (DIC) and shear assay techniques. These are shown to exhibit statistical variations that are well characterized by normal distributions. The changes in the mean properties of individual cancer cells are tested using Fisher pairwise comparisons and the analysis of variance (ANOVA). The probabilistic implications of the results are then discussed for the development of shear assay techniques and mechanical biomarkers for the detection of triple-negative breast cancer at different stages of progression.

SB12.04.13
Green-Mediated Approaches in the Design of Prostate Cancer Targeted Drug Delivery System—Investigation of Underexplored Prostrate Tumor-Specific Biomarkers Using Immunohistochemical Approach Josephine C. Oparah[1,2,3], Toyin Aina[1,3], Killian C. Onwudiwe[1,3], Chukwudi Ezeala[1,3], Theresa Ezenwafor[1,2], John Obayemi[3] and Winston W. Soboyejo[1,3,3]; [1]African University of Science and Technology, Nigeria; [2]National Biosafety Management Agency, Nigeria; [3]Worcester Polytechnic Institute, United States

This paper presents results using immunohistochemical techniques for prostate cancer tumor characterization in males of African ancestry using Nigeria as a case study.100 paraffin-embedded prostate tissues blocks were collected from the tissue repository of National Hospital Abuja, following ethical approval from the Institutional Review Board. Hematoxylin and Eosin staining were carried out to determine tissues with suitable characteristics for inclusion in the study. Benign prostate Hyperplasia tissues were used as control while prostatic adenocarcinomas were studied to identify underexplored biomarkers of interest as drug targets. The tissues were stained with tissue-specific proteins to determine over-expression of selected biomarkers; an investigation as to its use as targeted drug therapy. Comparative analysis of tumour biomarkers were carried out using statistical tools to determine the optimal choice of tissue specific proteins. The results reveal significant differences in the individual intensities that predispose different proteins as tumor specific biomarkers for targeted drug delivery.

SB12.04.14
Synthesis of Nano-Biomaterial and the Study of the Kinetics of Localized Cancer Drug Release from Silica Based Nanoparticles Toyin Aina[1,2], Josephine C. Oparah[1,2], Killian C. Onwudiwe[1,2], Chukwudi Ezeala[1,2], John Obayemi[1], Ali Salifu[1] and Winston W. Soboyejo[1]; [1]Worcester Polytechnic Institute, United States; [2]African University of Science and Technology, Nigeria

This paper presents the synthesis of inorganic mesoporous silica nanobiomaterial functionalized with a boronic group and capped with a polymer. The functionalized duo were then characterized and thereafter loaded with cancer drug (doxorubicin). The kinetics study was carried out using the Zero, First, second order, Higuchi and Korsmeyer and Peppas model in different buffers of pH ranging from 5.00 to 7.40. The drug release profile reveals anomalous transport from nanoparticle and supper case II transport from the polymer capped nanoparticle. The release exponent, n, of the silica nanoparticles were found and the diffusion coefficients were also obtained. The suitable phases along the drug release profile was explored in administering the drug loaded silica nanoparticles to act as a drug delivery cargo. Computational models using Comsol multiphysics was carried out to reveal the flux of the doxorubicin from the mesoporous silica nanoparticles. The nanoparticle was characterised using SEM, FTIR, TGA and TEM analysis and the diffusion coefficient. Further test would be carried out to reveal the effect of the nanobiomaterial to inhibit the growth of a prostate cancer cell.

SB12.04.15
High-Plex Profiling Reveals Implants to Drive Spatiotemporal Protein Production and Innate Immune Activation for Tissue Repair Prajan Divakar[1,2], Jason Reeves[2], Jingjing Gong[2], Fred W. Kolling IV[1], P. Jack Hoopes[1,1] and Ulrike G. Wegst[1,3]; [1]Dartmouth College, United States; [2]NanoString Technologies, Inc., United States; [3]Northeastern University, United States

While reducing foreign body capsule formation and increasing regenerative infiltration are central goals in the development of implants, there is surprisingly little clarity as to the effects of biomaterial properties on spatially localized protein expression, which drives implant success. Desired is that wound healing and tissue regeneration are optimally supported by the implant, adsorbed proteins, innate and adaptive immune cells, and fibroblasts. Cells play a central role in repair and functional recovery through the production and regulation of proteins. It is not fully understood, however, how an implant differentially drives the spatial quantity of individual proteins both in the interior of the implant and in the exterior tissue surrounding it. Here we apply GeoMx® digital spatial profiling to site-specifically investigate protein production in porous implants. Data is collected on the location and quantity of 40+ proteins from formalin-fixed, paraffin-embedded tissue slides of anisotropic tissue scaffolds (n=18) with differing pore sizes (35 µm, 53 µm) and implantation durations (2, 14, 28 days). In parallel, matched bulk high-plex gene expression data (700+ genes) was collected for the identical implant

samples. Notably, we discover fundamental spatial relationships in protein localization in the interior and exterior of implants that are uniquely independent or dependent of implant microstructure. In particular, dendritic cell marker CD11c and fibronectin significantly dominate the scaffold interior of the scaffolds, while cell-to-cell adhesion marker CD34 and anti-inflammatory M2 polarization marker CD163 localize in the scaffold exterior. Lastly, collating spatial and bulk information, we report unique spatiotemporal expression patterns for markers such as fibronectin that were otherwise hidden in differential bulk expression analyses and only uncoverable through spatial profiling. Together, these discoveries motivate the critical importance of quantifying and discovering spatial expression patterns for implants, facilitating a paradigm shift in the iterative design, mechanistic understanding, and rapid assessment of biomaterials.

SB12.04.16
Ultra-High Throughput On-Chip Synthesis of Microgels with Tunable Mechanical Properties Jingyu Wu, Sagar Yadavali, David Issadore and Daeyeon Lee; University of Pennsylvania, United States

Hydrogel particles (microgels) generated using microfluidic methods have superb properties such as high size uniformity and precise control over degradation and release profiles, making them useful for applications in wound healing and injectable drug delivery. However, the throughput of microfluidics is constrained by the physics governing the flow of immiscible fluids confined within microchannels. This throughput tends to be several orders of magnitude lower than what would be necessary for commercial and clinical applications. Here, we demonstrate the scaling up of on-chip synthesis of microgels by parallelizing the microfluidic channels. Taking advantage of the established fabrication technologies developed by the semiconductor industry and a high flow control system, a 4-inch silicon microfluidic chip integrating more than 4,000 microfluidic devices is developed. By incorporating a high energy flood UV source, this chip allows the synthesis of poly (ethylene glycol) diacrylate microgel particles with diameter down to 30 µm at a throughput above 1kg/hr. By using photomasks that enable milli-second scale control of the UV exposure, the stiffness of microgels can be varied between 10^3 to 10^4 Pa. Large-scale production of microgels will enable construction of large-scale tissue scaffold with well-defined physiochemical properties, and will provide scalability for translation to clinical settings.

SB12.04.17
Effect of Surface Modification on Cell Adhesion and Tissue Growth Przemyslaw Kurtyka[1,2,3], Roman Major[1], Roman Kustosz[2], Justyna Wiecek[1], Amanda Bartkowiak[1], Karolina Janiczak[2], Aniela Grajoszek[4] and Kamil Joszko[3]; [1]Polish Academy of Sciences, Poland; [2]Foundation of Cardiac Surgery Development, Poland; [3]Silesian University of Technology, Poland; [4]Medical University of Silesia, Poland

Introduction Recently, the number of patients with heart failure has been increasing. When pharmacological treatment does not bring the expected effects, there may be a need for mechanical circulatory support (MCS). One possible solution is to use blood pumps such as Ventricular Assist Devices (VAD). This devices are nowadays widely used as an effective treatment for patients with advanced heart failure and are the only alternative to heart transplantation. Over the years many new devices were introduced to the clinic. However, based on clinical experience, despite undeniable evidences of VAD effectiveness, many components could still be improved. The ongoing optimization performed by many producers does not concern only improvements in terms of their function, but also in terms of patient comfort and reduced mortality. According to the information provided by INTERMACS, patient survival drops to 50% after four years of support. However, the VADs, are designed to be wear-resistant and in some cases are used as a destination therapy. It is therefore important to further improve the devices biocompatibility in order to reduce the occurrence of complications. One of possible complications may be the pump thrombosis and inflow obstruction, caused by the ingrowth of tissue into the lumen of inflow cannula. According to reports from clinics and literature it seems that the solution to this problem may be the use of surface modification. Appropriate topography allows for controlled scar tissue formation, which results in reduction of inflammatory processes and appearance of thromboembolic events.
Materials and Methods The paper presents surface modification performed using vacuum sintering intended for use in an VAD inflow cannula. The study presents an analysis of the relationship between surface parameters on the susceptibility of cells to proliferate and the strength of their adhesion to the implant. Samples were prepared from titanium alloy Ti6Al7Nb in form of cylinders Ø14mm x H 3mm. During the initial research the base material was verified for compliance with the standard including the microstructure study, the chemical composition analysis and the study of mechanical properties. Then samples were subjected to tumbling before performing modification. Roughness was measured with the use of contact profilometry and was characterised by Ra=1,5µm and Rz=12,5µm. The sintering process included modifications with the use of Comercially Pure Titanium (Cp-Ti) powder with two different grain morphologies - spherical and irregular. The grain size was changed in rage of 50 to 250 µm. The obtained surfaces were then analysed by scanning electron microscope [SEM]. Additionally the porosity of obtained surfaces was determined. All samples revealed high roughness with the potential for cell anchoring and scar tissue formation. Fibroblasts were then applied to the samples for three periods of time. The number of cells was assessed on the basis of the stained cell nuclei and the presence of adhesive molecules. In addition, in vivo studies were performed in which samples were implanted into the dorsal muscle of New Zealand rabbits. After 4 and 8 weeks, the specimens were deplanted and the force of detachment of formed tissue from the implant surface was tested.
Results and Discussion The results have shown that surface after powder sintering is characterized by high porosity and complex 3D morphology. The obtained roughness was in rage Ra=21-36 µm. The porosity was in rage 27-49% depending on the size and shape of the powder grains. The detachment force differed by 0.5N depending on the shape of used powder grains.
Conclusions The presented modification has the potential to anchor cells and form controlled scar tissue on the surface of the implant, both in the context of cardiac and other medical implants.

E-Sutures—Electrical and Ionic Conducting Sutures for Medicine and Bioelectronics Onni Rauhala and Dion Khodagholy; Columbia University, United States

Although advances in wireless signal acquisition systems have reduced the invasiveness of many implantable medical and research devices, wire-based systems continue to be necessary for applications directed at treating or analyzing certain areas of the body that are incompatible with wireless device use or conventional surgical approaches. Traditional metal wires provide the high conductivity that is needed for *in vivo* electrophysiological signal transmission. However, due to their rigidity, metal based wires are susceptible to mechanical damage and discomfort to the subject. The ideal bioelectronic wire is thus both highly conducting as well as mechanically and chemically similar to live tissue. In this work, we transform surgical sutures into conducting and biocompatible wires (e-sutures) that can be concomitantly used for wound suturing, electrophysiological signal acquisition, transmission, and power delivery. We use a solution of the conducting polymer PEDOT:PSS together with solvents and a cross-linking agent to coat surgical sutures and make them electrically conductive. Our coating method increases the e-suture conductivity such that we can record ECG and EMG data from rodents, as well as stimulate muscles and evoke movements. We evaluate additional methods to further increase the conductivity of the e-suture such as acid treatment and nanolayer metal deposition. We develop an insulating layer (wire jacket) for the e-suture using a combination of parylene-C, polyurethane and silicone elastomer and characterize its electrical properties over time in an *in vivo* environment using electrochemical impedance spectroscopy. The resulting e-

suture is highly conductive, electrochemically stable and biocompatible. The high yield and ease of creating e-sutures combined with the widespread use of sutures in medicine suggests high translational potential to a broad range of medical procedures that require surgical intervention and monitoring or electrical modulation of tissue.

SESSION SB12.05: Scaffolds for Regenerative Engineering I
Session Chair: Gulden Camci-Unal

Development of Tissue Engineered Bioelectronic Implants for Integrating with the Brain Alexander J. Boys, Alejandro Carnicer Lombarte, Damiano G. Barone, Christopher M. Proctor, George G. Malliaras and Roisin Owens; University of Cambridge, United Kingdom

Stable, long-term interfaces between implanted devices and the brain remain a challenge. Properly interfaced neural implants provide the potential for recording brain activity, enabling the generation of neurally-driven prosthetics, treatment of neuroses, and a deeper understanding of brain function, among other applications. One of the major issues inhibiting long-term recordings of the brain is the lack of integration between an implant and surrounding tissue. This lack of integration often results in an inflammatory and subsequent scarring response driven by mechanical mismatches between the probe and adjacent tissue. Tissue engineered implants provide a solution to this problem through their superior integrative capacity *in vivo* but traditionally lack any interactive components. To generate a tissue engineered neural probe, we have combined the recording capabilities of bioelectronic devices with the regenerative capacity of tissue engineered implants to create a new type of device designed for long-term implantation. Here, we discuss the design, development, and testing of a tissue engineered implant with an integrated microscale conducting polymer-based recording system for monitoring in the brain.

We aimed to build a device that contains a series of discrete recording sites within a tissue engineered gel. The active portion of the probe was fabricated to consist of individually articulated electrodes on the scale of single neurons. Implants were microfabricated using photolithographic procedures to produce a flexible bioelectronic recording device. The device consists of gold tracks, insulated with parylene-C, which terminate in exposed pads with poly(ethylene dioxythiophene):poly(styrene sulfonate) (PEDOT:PSS)-based coatings to enhance recording efficacy. To embed these devices in gels, a mold was produced to encompass the entirety of the active portion of the device. Collagen was then injection molded around the device, resulting in a three-dimensional spread of the recording sites within the gel. To test the integrative capacity of these implants, we chose a subcutaneous intramuscular model to examine the ability of tissue to grow between the individual leads. Initially, implants without gels were positioned within the musculature of rats. Rats were sacrificed at days 3, 7, and 14 post-implantation to examine the healing response around the implant. By day 14, tissue was observed growing between the individual leads, and tissue around the probes appeared indistinguishable from tissue elsewhere at the insertion site. This result indicates excellent potential for widespread recording at the implantation site and for integration of these implants into the body.

In this study, we have developed a tissue engineered neural implant to promote integration with surrounding tissue. Our next step will be the implantation of gel-based probes to examine the ability of the tissue engineered probe body to promote tissue ingrowth. Ultimately, we will incorporate cells into these devices and move towards intracortical implantations in the brain. Overall, we have generated a new type of neural implant, utilizing tissue engineering and bioelectronic principles, to enhance regeneration at the implantation site and enable long-term recordings of the nervous system.

10:45 AM SB12.05.02
Antioxidant Microreactors as Supports for HepG2 Cells in 3D Cell Aggregates Stefan Pendlmayr, Xiaomin Qian, Noga Gal and Brigitte Städler; Aarhus University, Denmark

In the field of cell mimicry, bottom-up approaches are explored to resemble cells, organelles and enzymes using both natural and synthetic materials. Micro/Nanoreactors that can perform encapsulated catalysis are popular examples for the former cases. However, the first examples of their integration with mammalian cells only start to emerge. For instance, we recently demonstrated that microreactors loaded with catalase could support HepG2 cells in 3D cell aggregates when stressed with hydrogen peroxide. The artificial moieties did only their task for only up to 24 h because the encapsulated enzyme lost its activity.

Here, we use the superoxide dismutase/catalase mimetic Eukarion (EUK) as the active unit in alginate-based microreactors to alleviate the oxidative pressure in 3D cell aggregates. To this end, we first synthesized an EUK derivative that was water-soluble and could be conjugated to alginate resulting in EUK-Alg. Droplet microfluidics was used to fabricate microreactors with incorporated EUK-Alg. Then, the long-term activity of molecular EUK, EUK-Alg and the microreactors was assessed considering both, the catalase- and superoxide dismutase activity. The microreactors were coated with e.g., poly(L-lysine) or cell membrane vesicles, to facilitate integration in 3D cell aggregates with HepG2 cells. The viability of these bionic tissues was followed over time and the integration of the natural and synthetic units was visualized. Finally, bionic tissues could tolerate higher levels of hydrogen peroxide over longer times compared to pristine HepG2 cell spheroids.

Taken together, we advanced the concept of bionic tissue by illustrating the benefits the integration of the biological and synthetic world could have.

11:00 AM SB12.05.03
Material Defects in the Fetal Membrane's Role in Immunomodulation of pre-Term Premature Rupture of the Membrane (pPROM) Joshua M. Grolman; Technion-Israel Institute of Technology, Israel

Preterm labour, representing nearly 20% of births in the United States, is one of the leading and rising causes of infant mortality and nearly 40% of these cases are linked with preterm premature rupture of membrane (pPROM). Despite this, there are no treatments currently available aside from antibiotics, which do not address the cause of pPROM. This is a life-threatening condition that can sometimes be reversed by spontaneous sealing of the membrane, suggested recently to be mediated by fetal macrophage recruitment and polarization. However, the role in the recruitment and polarization of macrophages of amnion-derived mesenchymal stem cells (MSCs), a major constituent of the most loadbearing part of the fetal membrane, is not well understood. We demonstrate that understanding the mechanics of fetal membranes with regard to rupture and repair can drive secretion of proteins from MSCs. This in turn affects recruitment and programming of macrophages, and as a result, pPROM healing. Collecting patient samples from both full-term and pre-term birth patients, we demonstrate we can make large-scale physical property maps of the amnion such as dynamic rheological maps of Storage and Loss Modulus,

as well as millimeter-scale topographical maps to characterize defects in the fetal membrane. We characterized of both sides of the fetal membrane (chorion and amnion), as the intrinsic mechanical cues and resident mechanosensitive resident cells differed. We found that there were substantial topological differences in the amnion due to embrittlement of the fetal membrane, and the viscoelastic properties varied depending on the delivery mechanism. These viscoelastic properties had significant immunomodulatory effects on resident macrophages, responsible for inflammation and overall remodeling in the fetal membrane during birth.

11:15 AM SB12.05.04

Correlating Rheology and Printability of Silk-Hydroxyapatite-Based Inks for Micro-Prosthetic Applications Mario Milazzo[1,2], Vincent Fitzpatrick[2], Crystal Owens[1], Igor Carraretto[1], Gareth H. McKinley[1], David L. Kaplan[2] and Markus J. Buehler[1]; [1]Massachusetts Institute of Technology, United States; [2]Tufts University, United States

Devices for micro-prosthetic applications must maintain a reduced footprint in small implant sites while still repairing or restoring a specific function lost following trauma or pathology. We focus on the prosthetic for the middle ear, for which piston-like struts replace the complex arrangement of bones and soft tissues to recover hearing. The selection of a suitable material for such applications is critical in order to generate devices that meet stringent mechanical and biological requirements. Silk-Hydroxyapatite (S-HA) composites have been extensively used in the biomedical field as materials to replace bone-like structures, due to their mechanical properties, biocompatibility, and fabrication versatility via additive manufacturing. Most current medical applications have employed compositions with high percentages of HA over S, leading to stable constructs that, however, have limited toughness. Our study aimed at unveiling correlations between S-HA compositions, rheology, and printability to improve the final part properties with this composite system, in view of micro-prosthetic applications for which geometrical precision and accuracy play a key role in the final device functions.
Two batches of composite materials with different compositions were prepared and studied. The first consisted of HA microspheres (diameter less than 1 µm) with different contents of water, between 1:1 and 1:2 (w/v). The second was composed of S-HA, using silk extracted for 60 min and concentrated to 15% (w/v). In this case, the ratio of solid/liquid was held constant and values of S and W varied from 1:0.8:0.4 up to a ratio of 1:1:1 (w/v/v). Rheology was performed with a parallel plate geometry to mimic forces exerted during printing. In particular, we evaluated the elastic (G') and viscous (G") moduli across strain to find the main mechanical parameters (yield stress and strain) of the inks. We further monitored the evolution of moduli in a recovery step after the strain was removed. The same inks were printed with a displacement-driven 3D extrusion printer and printed parts were imaged and analyzed to quantify feature fidelity.
The results showed a reduction of elastic properties of the inks with increased water content. The HA showed values of G' above those having S in the composition, up to three orders of magnitude. Yield stresses were also higher, with associated strains two orders of magnitude lower than those of the S-HA composites. This difference highlights the higher toughness for the HA-S composite inks, an important factor for customizations of the constructs. All inks showed a recovery over time for the main viscoelastic parameters (G', G"), resulting in a stable solid-like behavior when the solid/liquid ratio was below 1:2 (w/v).
Linking rheology and printability, we observed a direct relationship between the main rheology outcomes and the geometric quality of the constructs. Specifically, high printability with high yield stress independently of the concentration of S was observed. Moreover, increasing the concentration of S reduced the elastic moduli of the inks, making them more extrudable through fine nozzles at achievable pressures. In addition, while large amounts of S reduced the stability of the final products, compositions with about 0.13 ml/ml (dry silk/total water) show geometric precision comparable to those of HA alone, but with significantly higher toughness. In addition, this analysis allowed us for the first time to assess printability for ceramic-polymeric inks with varied critical yield strains.
These results provide an insightful picture of the relationships between rheology and printability of S-HA composites, drawing clear relationships about the influence of S on the composition of the ink in view of micro-prosthetic applications.
This work has received funding from the European Union's Horizon 2020 research and innovation program under the Marie Sklodowska-Curie grant agreement COLLHEAR No 794614.

11:30 AM SB12.05.05

Biodegradable poly(vinyl alcohol) Hydrogels as a Temporary Retinal Tamponade Mimoza Xheka[1], Veronica Holmes[1], Marsela Deshnica[1], Demetrios Vavvas[2] and Gavin Braithwaite[1]; [1]Cambridge Polymer Group, United States; [2]Massachusetts Eye and Ear, United States

Retinal detachment is a serious condition where the thin retina separates from the back of the eye causing immediate vision problems and permanent issues if left untreated. Treatment is aimed at relieving the retina traction and sealing the causative tears. Often this is achieved surgically by removing the existing vitreous from the eye and reattaching the retina into place by drainage of the subretinal fluid through a fluid air exchange and sealing the tears with laser induced retinopexy. However, the sealing of retinopexy is not instant and the retina needs to be supported during healing by an agent commonly referred to as "tamponade". Tamponades have been used since 1911, and today both gas and liquid materials are used. Gas tamponades reabsorb over time in the eye, replaced with fluid spontaneously. For liquid tamponades, silicone oil is most commonly used but requires surgical removal. Neither material is density matched and patients are therefore often required to maintain a face-down prone position for weeks to maintain contact of the tamponade against the retina tear and prevent fluid migration in the subretinal space.
The fluid that comprises the majority of the volume of the eye is known as the vitreous humor. This material is a colorless, transparent crosslinked viscoelastic hydrogel. It is ~99% water, the rest composed largely of collagen, proteoglycans and proteins. If vitreous is removed in patients, the natural fluid turnover in the eye gradually refills the vitreal cavity. The ideal device for support of the healing retina would be one that mimics the properties of the healthy vitreous, at least over the time required to successfully heal. Although a number of attempts to developed permanent replacement vitreous materials have been tried, few have tried to develop a material that will only be present long enough to aid healing. Here we describe a degradable hydrogel for support of the healing retina during recovery from detachment surgery. The added benefit of a designed temporary residence is that regulatory approval is simpler if the device is not considered permanent.
We present work on the development of a thiolated PVA utilizing a polyethylene glycol diacrylate (PEG-DA) crosslinker. This system (termed a Thiogel) reacts through Michael addition, without heat release and formation of by-products, and does not require use of toxic initiators or a UV source. This system is therefore amenable to a mix-and-gel strategy in the operating room and has very low potential toxicity. We will discuss two Design of Experiments (DoE) structured to first screen for an optimal functionalization level, and then to determine the optimal composition for transparency, refractive index, gelation time and tuned degradation kinetics.
Finally, we will describe a pilot rabbit study (New Zealand White (NZW) Rabbits) to examine safety and degradation kinetics of the material *in vivo*. Animals received a vitrectomy using a conventional three port vitrectomy with either Thiogel or control air in the right eye while the left eye was left as the non-surgical control. Full ophthalmic exams, gross ocular exams, Intraocular pressure (IOP), and fundus images were performed to document the response at timepoints out to 8 weeks. Both test and controls exhibited expected IOP reductions immediately following surgery, with the IOP levels returning close to baseline by 3 weeks and thereafter statistically similar.
To attempt to determine the clearance rate of the gel we developed a liquid chromatography based technique to allow us to track the components over time in the excised tissue. This involves separation of the components from the physiological tissue through a purification step, followed by analysis on a liquid chromatography system. These data demonstrate that the gel is almost completely degraded at 14 days and is almost entirely cleared by 28 days.

SESSION SB12.06: Scaffolds for Regenerative Engineering II
Session Chairs: Gulden Camci-Unal and Natesh Parashurama
Wednesday Afternoon, December 1, 2021
Sheraton, 2nd Floor, Back Bay D

1:30 PM SB12.06.01
Incorporation of Glycyl-L-Histidyl-L-lysine (GHK) with Metalized Halloysites for Tissue Regeneration Chris Miller and David K. Mills; Louisiana Tech University, United States

Human adipose stem cells (hASCs) provide a research tool for regenerative medicine in various capacities. There are major research needs for new therapies for bone-related diseases such as osteoporosis, osteomyelitis, and severe trauma. Human ASCs can self-renew for extended durations outside of the body and provide an ideal platform to study therapeutics for the formation of bone-specific modalities or wound healing applications.
Combining hASCs with nanomaterials is a growing area of research that requires additional studies. Halloysites (HNTs) are hollow aluminosilicate nanotubes with an exterior negative charge and a positively charged lumen. These nanoparticles range between 100-900 nanometers and the lumen spanning roughly 20 nanometers across. HNTs have demonstrated biocompatibility in cell and animal-based studies, with additional capabilities for vacuum loading of drugs and coating metal ions such as silver, zinc, strontium, and copper (mHNTs). Metal ions provide synergistic antimicrobial effects on prokaryotes, allowing healthy cells to form in infection risk areas. These unique properties allow a varying of methods to be developed in cell-based therapeutics at the tissue level.
The primary focus of my research is to investigate the therapeutic potential of metalized HNTs with a linked tripeptide; GHK (glycyl-L-histidyl-L-lysine) is known to be essential in the wound healing process. Ultimately, studying these interactions will lead to better bandages to be hemostatic, alleviate pain and inflammation, and cost-effectively possess antimicrobial features. Enhanced wound healing can have drastic implications on military personnel and people without proper medical access. Bone and wound analysis studies were conducted on hASCs after the incorporation of such nanoparticles. Results introducing GHK with metalized HNTs showed increased proliferation of hASCs, collagen production, and an increase in the genes *ki67* and *runx2*, a proliferation and bone marker, respectively. Strontium-coated HNTs increased osteochondral differentiation after analysis by phase-contrast imaging, gene expression, and unique morphological changes of hASCs exhibiting trabecular-like bone formations in culture.
Copper-coated HNTs coupled with GHK increased wound closure after artificial wound analysis, further validating gene expression and proliferation studies. Human ASCs were additionally encapsulated in alginate hydrogels with GHK and mHNTs that increased cell viability and collagen production, leading to differentiated fibroblast clusters within the hydrogel constructs. Given these results, expanding the use of mHNTs with GHK in animal wound healing studies can profoundly impact wound healing if incorporated into FDA-approved materials.

1:45 PM SB12.06.02
Injectable Cellulase-Encapsulated PLGA Microspheres for Degrading Decellularized Bamboo Scaffolds for Bone Tissue Engineering Ali Salifu[1], John Obayemi[1], Chukwudalu Nwazojie[1,2], Sophia Silkaitis[1], Precious O. Etinosa[1], Joshua Gershlak[1,3], Glenn Gaudette[1,4] and Winston W. Soboyejo[1]; [1]Worcester Polytechnic Institute, United States; [2]African University of Science and Technology, Nigeria; [3]Massachusetts General Hospital, United States; [4]Boston College, United States

Many of the proposed alternative strategies to bone grafts for the repair of non-union bone defects rely on the development of synthetic scaffolds for bone regeneration. However, these scaffolds are limited by their structure and scale-up/cost implications. With its well-organized, hierarchical, and functionally graded structure, mechanical strength, and potential for large-scale cultivation for bone tissue engineering applications, decellularized bamboo offers a cost-effective, scalable alternative for scaffold development. In the first part of this work, we demonstrate that decellularized bamboo scaffolds can support the growth of human fetal osteoblasts and the regeneration of bone tissue in vitro. “Lucky” bamboo stems are decellularized into scaffolds using detergents (sodium dodecyl sulfate and Triton X-100), washed with deionized water and Tris buffer, and functionalized with dopamine-conjugated RGD peptides (RGDOPA). Human fetal osteoblast (hFOB) cells are cultured for 28 days on the scaffolds, and cell proliferation is evaluated through DNA content and alamar blue assays. Alkaline phosphatase (ALP) activity is used as an early marker of osteogenesis, while ECM production is quantified by estimating the *de novo* total protein contents using the BCA protein assay. Mineralization is detected through measurements of *de novo* calcium contents (calcium colorimetric assay) followed by alizarin red S staining. Scanning electron microscopy is used to visualize the morphologies of the cell-scaffold constructs. However, the major drawback of using decellularized bamboo scaffolds for bone tissue engineering is their limited biodegradability when implanted into a patient, since human enzymes outside the digestive system have limited ability to break down the cellulose, hemicellulose, and lignin macromolecules found in bamboo. Hence, in the second part of this work, we present injectable cellulase-encapsulated poly(lactic-co-glycolic acid) (PLGA) microspheres as a strategy to facilitate the degradability of the decellularized bamboo scaffolds. The cellulase-encapsulated PLGA microspheres are synthesized via the single emulsion solvent evaporation technique. These microspheres are then characterized using scanning electron microscopy, dynamic light scattering, Fourier-transform infrared spectroscopy, thermogravimetric analysis, and differential scanning calorimetry. The amounts of cellulase enzyme released from the PLGA microspheres over a period of 50 days are monitored using the BCA protein assay. Degradation of the decellularized bamboo scaffolds in phosphate-buffered saline (pH 7.4, 37°C) containing the cellulase eluting PLGA microspheres is assessed via changes in weight, compressive mechanical properties, and glucose content due to enzymatic breakdown of the cellulosic macromolecules by cellulase. Strain mapping is also used to study the local strain distributions in the scaffolds under compressive deformation. The implications of the results are then discussed for the production of these sophisticated, and yet, readily-available decellularized bamboo scaffolds to circumvent the challenges associated with conventional bone tissue engineering scaffolds in an environmentally and economically sustainable way.

2:00 PM SB12.06.03
Effect of Fluid Derived Shear Stress on Bone Metastasized Prostate Cancer Evaluated Using Perfusion Bioreactor and Nanoclay Based Testbed Haneesh Jasuja, Dinesh R. Katti and Kalpana Katti; North Dakota State University, United States

The International Agency for Research on Cancer (IARC) of the World Health Organization reports 1,276,106 incidences and 358,989 fatalities resulting from prostate cancer worldwide in 2018. Prostate cancer is the second leading cause of cancer death among men in the United States. Prostate cancer has the propensity to migrate to or metastasize to bone. Although curative treatments are available for primary prostate cancer tumors, advanced-stage prostate cancer that has metastasized to bone often results in a poor prognosis. The primary cause of morbidity due to prostate cancer is the metastasis to bone. The effects of various biochemical factors in the bone microenvironment have been demonstrated in the disease progression to metastasis; however, the role of physical factors such as mechanical cues induced by the interstitial fluid flow around the bone is poorly explored. It has been established that interstitial flow has a pro-migratory and biomechanical stimulatory effect on cancer cell invasion. To address this issue, we designed a 3D *in-vitro* model to evaluate

the progression of prostate cancer cells at metastasis condition, colonizing the bone site under dynamic conditions. In this study, we developed a 3D dynamic *in-vitro* model employing nanoclay-polycaprolactone-hydroxyapatite scaffolds and a specially designed perfusion bioreactor. Initially, we differentiated human mesenchymal stem cells (hMSCs) on scaffolds under dynamic culturing conditions to duplicate an accurate bone-like microenvironment. Next, we utilized these bone mimetic scaffolds to grow prostate cancer cells under identical dynamic conditions to recapitulate prostate cancer metastasis to bone. Finally, we performed various cellular assays and immunocytochemistry studies to establish the feasibility of dynamic culture. We observed a significant increase in bone growth under dynamic culture conditions evaluated by bone-related biomarkers (ALP, RUNX2, and OCN) compared to static culture. We also noticed upregulation in E-cadherin and downregulation of vimentin levels under dynamic conditions that confirms the occurrence of mesenchymal to epithelial (MET) transition of prostate cancer cells at the metastatic bone site. We further examined the influence of fluid-induced mechanical cues on cells by monitoring alteration in orientation and morphology of hMSCs and prostate cancer cells. Overall, we observed significant differences in cellular morphology and gene expressions of bone cells and prostate tumors grown under flow conditions. The established perfusion bioreactor based 3D dynamic *in-vitro* model can be further utilized to elucidate the mechanisms of prostate cancer metastasis and screen novel drug therapies geared towards bone metastatic prostate cancer.

2:15 PM SB12.06.04
Silica-based Nanoparticle Infused Polymeric Microfibers Enhance Mineral Deposition Michael Ming Chau Chan and Helen H. Lu; Columbia University, United States

Bioactive glass nanoparticles have been used for a wide range of biomedical applications including bone regeneration due to its high specific surface area and reactivity. Inspired by the composite nature of bone, bioactive glass nanoparticles (nBG) derived from a SiO_2-CaO-P_2O_5 ternary system may be incorporated into polymer blend (PLGA:PCL) fibers, and this study explore nBG synthesis and evaluates the bioactivity and osteogenic potential of this composite fiber platform. The development of a Ca-P phase on the polymer-nBG fibers were monitored longitudinally under physiological conditions using FTIR-ATR, XRD and SEM. It is hypothesized that the nanoparticle infused polymeric fibers will be bioactive, and provide structural template for mineralization in situ. Here, A coprecipitation sol-gel method was used to fabricate the nBG (55%SiO_2-40%CaO-5%P_2O_5, wt%). For the fabrication of polymer-nBG fibers, 5 wt% of nBG were added to a polymeric blend of PLGA:PCL (5:1) and electrospun at 10 kV. To test the bioactivity and mineralization potential of the composite fibers, the samples with corresponding controls were immersed in DMEM (1mg/mL) and collected at Day 0, 1, 3, 7 and 14. One-way ANOVA and Tukey-Kramer HSD post-hoc tests were used to study significant differences ($p<0.05$) of pH levels between different experimental groups.
The nBG appeared globular and are 10 – 20 nm in diameter under SEM. The fibers with or without nBG were 2.21±0.64 μm and 2.24±0.58 μm in diameter, respectively. FTIR analysis reveals a peak at 1100 cm^{-1} representing the Si-O bond of the silica network. After immersion in DMEM for 14 days, pH level remained similar across all experimental groups except for day 14 where particle-free control measured significantly lower pH compared to all other groups, indicative of polymer degradation. Coupling the polymer fiber with nBG served to neutralize the negative impact on pH and allow maintainence of physiological pH. XRD patterns showed crystallization peaks at 31.8^o and 45^o suggesting crystallization of phosphate andthe early formation of carbonated apatite. This was confirmed by FTIR spectra showing growing peaks at 603 and 568 cm^{-1} and 960 cm^{-1} suggesting dissociation of Si-O bonds and mineral crystal formation by day 14. These bulk and surface characterization analysis confirm the bioactivity and mineralized in this novel composite system. Future studies will assess both osteoconductive and osteoinductive potential of these composites for bone regeneration.

2:30 PM SB12.06.05
Late News: (Garcia High School Student) F127-DMA—A Reverse Thermo-Responsive Liquid Embolic Agent as a Promising Treatment for Brain Aneurysms Jessica Guo[1], Maya Vendhan[2], Hannah Tao[3], Ifeoluowatobi Alao[4], Chiara Mosca[5], Robert Wong[6], Megha Gopal[6], Nakisa Dashti[6], Aryan Roy[7], Wenxu Xu[8], Matthew Lim[9], Tyler Shern[10], Varun Nimmagadda[11], Chandramouli Sadasivan[6], Aaron Sloutski[12], Daniel Cohn[12] and Miriam Rafailovich[6]; [1]Ward Melville High School, United States; [2]Colorado Academy, United States; [3]Academy for Information Technology, United States; [4]High Technology High School, United States; [5]East Islip High School, United States; [6]Stony Brook University, The State University of New York, United States; [7]Cherry Creek High School, United States; [8]High School Affiliated to Renmin University of China, China; [9]Plainview-Old Bethpage JFK High School, United States; [10]Columbia University, United States; [11]University of Michigan–Ann Arbor, United States; [12]The Hebrew University of Jerusalem, Israel

Brain aneurysms are weak-walled pathological dilations occurring at cerebral vasculatures. If left untreated, they can easily rupture, resulting in stroke or even death. Current prominent treatment methods involve the permanent implantation of metallic devices, flow diversion, and liquid embolic agents (LEA). However, unfavorable primary outcomes occur in 20% to 30% of the treated cases, and the success rate can even be significantly lower depending on the type and location of the aneurysms. This project aims to improve patient outcomes through the development of a novel LEA that is injectable, visible under angiography, has proper mechanical strength, promotes cell adhesion, and is stable within an aneurysm sac. To achieve these properties, the LEA was comprised of the hydrogel F127-DMA, a reverse thermo-responsive, easily injectable, cross-linkable, and shape-conforming polymer system with proper mechanical strength; the catalyst FeCl2, which gives the polymer long term stability by allowing chemical crosslinking; and the biocompatible contrast agent iohexol.

To determine the mechanical strength of the LEA, rheology tests (single-frequency time sweeps and amplitude sweeps) were performed using a Bohlin Gemini 150 HR Nano rheometer. The tests showed that 29% F127-DMA hydrogel exhibited an elastic modulus of 202.1 kPa after chemical crosslinking, and the average wall shear stress of the carotid artery— 0.85 ± 0.2 Pa —was within the gel's linear viscoelastic region[1]. These results prove that the LEA will be able to withstand pressure from blood flow.

Differential Scanning Calorimetry (DSC) is traditionally used to measure phase transitions, where energy is absorbed or released by a substance. Here, it is shown that DSC can also accurately measure the ordering temperature of the micelles in the gel. This corresponds to the gelation temperature of the F127-DMA polymer, in which the micelles were found to form an FCC lattice. This lattice formation found through DSC corresponds to the drastic rise in modulus found through rheology. In this manner, the LEA composition could be tailored to achieve the desired modulus and viscosity during the injection. Additionally, both DSC and rheology confirmed that the contrast agent iohexol did not interfere with the gel's phase transition ability or lattice formation.

Experiments were also conducted to determine the extent to which cells adhered to the LEA. While F127 alone has been shown by multiple authors not to be cell adhesive, it was found that once cross-linked, the F127-DMA was able to support cell adhesion[2]. This indicates that the LEA can support the migration of endothelial cells, which is required for the healing of aneurysms. Ongoing experiments are being conducted to pinpoint how the hydrogel system acquires its cell adhesive properties once crosslinked. This includes testing samples of F127-DMA with F127, F127-DMA with FeCl2 and F127, F127-DMA alone, F127 alone, and F127-DMA with FeCl2.

The radiopacity of F127-DMA was also tested in animal injection experiments (with IACUC approval). The iohexol contrast agent was visible through angiography, and current testing is focused on determining gel stability in vivo.

In addition to the aforementioned ongoing experiments, future development of the LEA will involve monitoring the long-term performance of the agent within animals, enabling the LEA to promote endothelialization, and implementing biodegradability. The results obtained thus far indicate that Pluronic polymers are successful candidates for designing LEAs by meeting the requirements of injectability, radiopacity, and promotion of neointimal layer regrowth.

Engineering Bioactive Material Platforms for the Cell-Based Treatment of Type 1 Diabetes Cherie Stabler; University of Florida, United States

Clinical islet transplantation, the intrahepatic infusion of allogeneic islets, has the potential to provide physiological blood glucose control for insulin-dependent diabetics. The success of clinical islet transplantation, however, is hindered by the location of the implant site, which is prone to mechanical stresses, inflammatory responses, and exposure to high drug and toxin loads, as well as the strong inflammatory and immunological responses to the transplant in spite of systemic immunosuppression. To address these challenges, our research has focused on three primary strategies: the development of scaffolds to house islets at alternative transplant sites; the fabrication of encapsulation protocols for the immuno-camouflage of the transplant; and the production of bioactive biomaterials for the local delivery of oxygen and immunomodulatory drugs and/or cells. Three-dimensional scaffolds can serve to create a more favorable islet engraftment site, by ensuring optimal distribution of the transplanted cells, creating a desirable niche for the islets, and promoting vascularization. Encapsulation can substantially decrease the need for systemic immunosuppression of the recipient, by preventing host recognition of surface antigens. Finally, localization of supportive agents to the site of the transplant can serve to enhance efficacy, while minimizing the side effects commonly observed with systemic delivery. Success in these strategies should increase the efficacy of islet transplantation for the treatment of Type 1 Diabetes, whereby the long-term survival and engraftment of the transplanted islets are significantly improved.

Modular Hydrogels Reveal Impact of Type I Innate Lymphoid Cells on Intestinal Organoids Geraldine M. Jowett, Michael D. Norman, Joana F. Neves and Eileen Gentleman; King's College London, United Kingdom

Pathological matrix remodelling plays a central role in many human diseases, but is challenging to study as *in vitro* models often cannot replicate the complex 3D cell-matrix interactions that drive pathologies. Here, we describe a 3D model of the human gut that allowed us to uncover an unexpected role for a rare immune cell type called Type-1 innate lymphoid cells (ILC1) in driving gut fibrosis in patients with inflammatory bowel diseases. ILC1 are enriched in patient mucosa with active inflammatory bowel disease (IBD), but the impact of this accumulation remains elusive, and therapeutics against ILC1’s signature cytokine IFNγ lack clinical efficacy.

We used molecular dynamics simulations to design tetra-PEG hydrogels that cross-link quickly, but can still mimic the stiffness of normal intestinal tissue. We then co-cultured encapsulated human intestinal organoids with ILC1, and using a combination of atomic force microscopy force spectroscopy and multiple particle tracking microrheology, found that ILC1 drive intestinal matrix remodelling through a balance of MMP9-mediated matrix degradation and TGFβ1-driven fibronectin deposition. Our findings demonstrate the potential of using hydrogels in disease modelling, and open the possibility of unravelling how pathological matrix remodelling contributes to disease.

Aims and Hypothesis: We hypothesized that ILC1 accumulation in IBD is not simply a driver of inflammation, but rather that ILC1 play a role in driving disease pathology itself. Therefore, the aim of this work was to use reductionist models based on intestinal organoid-ILC1 co-cultures to uncover how ILC1 impact the intestinal epithelium and matrix.

Methods: We established co-cultures of murine small intestinal organoids (SIO) with ILC1, and human induced pluripotent stem cell (iPSC)-derived intestinal organoids (HIO) with patient-derived ILC1. We also developed a functionalized, PEG-based synthetic hydrogel system designed to form efficient networks at low polymer concentrations.

Results: Pico-SMARTSeq2 transcriptomics on SIO co-cultures revealed that IFNγ sensitizes epithelial cells to Fas-mediated apoptosis. However, ILC1 also drive expansion of the epithelial stem cell crypt through p38γ phosphorylation and aberrant Cd44v6 expression, which is unexpectedly regulated by ILC1-derived TGFβ1, not IFNγ. We next established that human ILC1 also secrete TGFβ1, and drive CD44v6 expression in both HIO epithelium and the surrounding mesenchyme, though notably this phenotype is only recapitulated by ILC1 from patient biopsies with active inflammation. As TGFβ1 is a master regulator of fibrosis, the leading indicator for surgery in IBD, we next characterized the ability of ILC1 to regulate matrix remodelling. We created modifiable PEG hydrogels that cross-link quickly but at low stiffnesses and harnessed this platform to perform multiple particle tracking microrheology and atomic force microscopy force spectroscopy on encapsulated HIO. We show that ILC1 drive matrix stiffening and degradation, which we posit occurs through a balance of MMP9 degradation and TGFβ1-induced fibronectin deposition.

Conclusion: Our synthetic organoid co-culture system enabled us to tease apart an important role for intestinal ILC1 in epithelial and matrix remodelling, which may drive either wound healing, tumor formation or fibrotic pathologies in IBD. Moreover, this controlled 3D microenvironment provides a broader platform for dissecting interactions between complex human iPSC-derived tissues and rare cell subtypes in development and disease.

Investigation of Parameters Influencing Molecule Delivery Efficiency of Multifunctional Glycan-Based Materials—An Artificial Neural Network

Model Approach Syeda R. Batool, Ismail C. Karaoglu, Fusun S. Murat, Anwaar Nazeer and Seda Kizilel; Koç University, Turkey

Current clinical translation of molecule delivery strategies requires distinctive design of materials that can offer innovative solutions to address the limitations associated with biomedical problems. Glycan-based hydrogels are of great promise in terms of creating new vehicles with responsive behavior and tunable properties for various clinical applications. For example, we developed anthracene-functionalized alginate to create both chemically and physically crosslinked polymer networks. Due to reversible dimerization of anthracene in response to light with alternate wavelengths, where we were able to tune the mechanical properties of the hydrogels precisely, while controlling the gelation behaviour in a light-responsive manner. The same approach can be applied to chitosan, another promising glycan-based polymer, where chitosan was used for dual-crosslinking with the anthracene and photopolymerization was carried out in the absence of a toxic photoinitiator. The nature of dual-crosslinking was modulated to adjust the visco-elastic modulus of both hydrogels. Furthermore, it was shown that alterations on moduli significantly influenced the morphology of seeded cells in a 3D environment. Finally, chitosan can be crosslinked through ionic gelation with negatively charged DNA to produce nanoparticles with gene delivery potential. In summary, glycan-based materials hold significant potential for tunable, reproducible, and responsive biomaterials, which can then be utilized as robust systems to be used in drug delivery applications.

9:30 AM SB12.07.04
Late News: Evaluation of LTL Nanozeolite as Doxorubicin Carrier Adriana Medina Ramírez[1], Daniela F. Rodriguez-Chavez[2], Georgina Garcia-Ruiz[2] and Jesus I. Minchaca Mojica[1]; [1]Universidad de Guanajuato, Mexico; [2]Universidad de la Ciénega del Estado de Michoacán Ocampo, Mexico

The specific properties of the zeolites such as their nanoporous structure, stability in biological environments, textural properties and high adsorption capacity made them useful as drug carrier. The performance as carrier mainly depends on zeolite framework, affinity zeolite - drug molecule and the pH of the media. For these reasons in the present work it was evaluated the behavior of LTL nanozeolite as doxorubicin carrier. The LTL nanozeolite was synthesized by hydrothermal method. The performance as nanocarrier was evaluated at different concentrations of doxorubicin in order to evaluate the doxorubicin adsorption capacity on the nanozeolite. In a second step, the doxorubicin –loaded nanozeolite was submitted to a releasing process at two different pH conditions. The nanozeolite was characterized by XRD, SEM and FT-IR techniques. The concentration of doxorubicin was monitored by UV-Vis spectroscopy at wavelength of 480 nm. The LTL nanozeolite was obtained as unique crystalline phase and presented a rod-like morphology. By FT-IR was evidence the loading of doxorubicin on the LTL nanozeolite. The LTL nanozeolite exhibited a high doxorrubicin adsorption capacity at all the concentrations evaluated. The doxorubicin releasing rate was influenced by the pH of the media, a faster releasing was observed at pH of 7.4 while a slower and controlled doxorubicin releasing was reached at pH of 5.5. These findings allow to infer that LTL nanozeolite has the potential to be used as doxorubicin nanocarrier.

9:45 AM SB12.07.05
Immobilized Gradients of Biomolecules on Conjugated Polymer Substrates for Nerve Regeneration Omid Dadras-Toussi, Milad Khorrami, Sheereen Majd and Mohammad Reza Abidian; University of Houston, United States

Functional nerve recovery following substantial injury is crucial in the field of neural regeneration. Even though various microfluidics and printing techniques have been established, effective axonal guidance over long distances has still remained challenging. Among numerous biomaterials, conjugated polymers such as poly(3,4-ethylenedioxythiophene) (PEDOT) have demonstrated promising results in engineered scaffolds due to their soft mechanical properties, mixed electronic / ionic conductivity, and excellent chemical stability in physiological environment. Laminin, a substrate-bound protein in the extracellular matrix, is a well-known chemoattractant which fosters neurite outgrowth. In this work, we introduce a novel technique to fabricate various profiles of laminin gradients on thin PEDOT films.

To fabricate the device, first a layer of gold (thickness: 150 nm) was deposited on silicon wafers via electron beam evaporation and laser-cut masks. Using AUTOLAB, a thin layer of PEDOT was then electropolymerized gold-coated silicon substrates at charge deposition density of 0.18 C cm^{-2}. Surface of PEDOT films was treated with Poly (L, Lysine) to improve laminin adhesion. Laminin gradients were first printed on the surface of a 2 wt% agarose hydrogel slab (thickness: 10 mm), using micro-scale motorized X-Y-Z stages and a nano-syringe pump. The droplets of laminin solutions with different laminin concentrations were deposited at injection volume of 17.5 nl next to each other (vertical and horizontal distances were 400 µm and 800 µm, respectively). Finally, the printed laminin pattern was transferred onto the PEDOT film using molecular stamping. Laminin was fluorescently tagged via immunohistochemistry; and fluorescent imaging was utilized to visualize and quantify various laminin gradients.

To showcase the potential of the developed methodology, linear and hill gradients were created and quantified. The linear gradient consisted of 10 lines (8 mm-long) with a solution concentration range of 10-55 µg ml^{-1}. In the hill gradient (7.2 mm-long, 9 deposited lines), initially the solution concentration was 10 µg ml^{-1} which linearly increased until it reached a maximum value of 90 µg ml^{-1}, then symmetrically decreased. Measured fluorescent intensity followed a linear trend (R-square= 0.99) with respect to laminin concentrations in the linear gradient. Similarly, both symmetrical sides of the hill gradient showed a good linear fit (R-sqaure= 0.98 and 0.99, respectively) with almost equal absolute slope values.

We aim to assess the neurite response to various gradients and find the optimum gradient type and concentration range for effective axonal regeneration. The outcome of this study will pave the way towards development of more effective engineered conduits for nerve regeneration and will help us unravel fundamental questions of axonal regeneration in the nervous system.

SESSION SB12.08: Scaffolds for Regenerative Engineering III

Adaptable, Protein-Engineered Hydrogels for Organoid Culture Sarah C. Heilshorn; Stanford University, United States

While organoid culture has the potential to revolutionize our understanding of human biology, current protocols rely on the use of Matrigel, a complex, heterogeneous material with large batch-to-batch variations that hinder reproducibility. In response, several groups have begun designing synthetic hydrogel systems to enable the reproducible culture of organoids. Recently, the matrix stress relaxation rate (i.e. the ability of a hydrogel to remodel its network connectivity in response to an applied stress) has been demonstrated to have profound effects on encapsulated cells. To date, the role of matrix

stress relaxation on organoid cultures has not been explored. Here we present the design of a family of double-network hydrogels that undergo two stages of crosslinking: the first stage uses reversibly dynamic covalent chemistry bonds, while the second stage reinforces the hydrogel through thermal-induced protein-polymer aggregation. This double-network of physical interactions results in a gel with a broad dynamic range of tunable mechanical properties, where the gel stiffness is set by the number of crosslinks and the gel stress relaxation rate is independently set by the kinetics of the crosslink binding and unbinding. These novel, double-network hydrogels have been used to study the role of mechanotransduction in the culture of patient-derived, human intestinal organoids. In this system, we find that the organoid cultures display strong phenotypic responses to matrix stress relaxation, which are dependent on cell-matrix interactions with both CD44 and integrin cell-surface receptors.

11:00 AM *SB12.08.02
Engineering Porous Scaffolds for Regenerative Medicine Vasiliki Kolliopoulos, Marley Dewey, Aleczandria Tiffany and Brendan A. Harley; University of Illinois at Urbana Champaign, United States

Defects in craniofacial bones of the skull occur congenitally, after high-energy impacts, and during the course of treatment for stroke and cancer. They affect a broad segment of the US population, are large and irregularly shaped, and heal poorly. Autologous bone or alloplastic implants are the clinical gold-standards for repair. However, limited quantities and the need for time-intensive intraoperative fitting of autologous bone, the non-regenerative nature of alloplastic implants, and surgical challenges that stem from irregular defect margins and the quality of the surrounding bone all contribute to poor healing and high complication rates. Advances in the fields of tissue engineering and regenerative medicine require biomaterials that instruct, rather than simply permit, a desired cellular response. Contemporary tissue engineering efforts combining exogenous mesenchymal stem cells (MSCs), morphogens, and biomaterials have not attained wide clinical use due to the cost and time for in vitro MSC expansion and MSC-biomaterial culture as well as the need for supraphysiological morphogen doses. A unique opportunity exists to develop degradable biomaterials that actively instruct, rather than passively permit, osteogenic differentiation and subsequent bone regeneration. Our laboratory has developed a class of mineralized collagen scaffold to promote MSC osteogenic differentiation and subsequent CMF bone regeneration in the absence of exogenous growth factor supplements. I will describe recent advances to our collagen scaffold system to address barriers preventing regeneration of craniomaxillofacial bones and orthopedic insertions. Ongoing efforts are developing platform technologies to address challenges such as poor biomaterial-defect contact, inflammatory response and reduced cell bioactivity in large defects, and poor matrix remodeling. We are using selective alteration to scaffold structural alignment and proteoglycan content as well as the incorporation of bioinspired structural motifs to create composite biomaterials able to improve cell bioactivity and mechanical competence in order to address mechanistic and translational challenges.

11:30 AM *SB12.08.03
Engineering Tissue-Informed Cell Culture Platforms for Pulmonary Regenerative Medicine Thomas Caracena[1], Rachel Blomberg[1], Predrag Šerbedzija[1], Donald R. Campbell[1] and Chelsea M. Magin[1,2,2]; [1]University of Colorado Denver, Anschutz, United States; [2]University of Colorado, Anschutz Medical Campus, United States

Chronic respiratory disease is the third leading cause of death worldwide. Prevalence of respiratory conditions is rising and expected to increase further as a direct result of lung damage sustained by COVID-19. Unfortunately, there are currently no effective treatments for the majority of advanced lung diseases. Biomaterials engineered to replicate the intricate geometry and dynamic mechanical properties of the lung could accelerate discovery of new treatments based on pulmonary regenerative medicine.

Toward this goal of engineering tissue-informed models for lung disease and regeneration research we have employed a photopolymerizable poly(ethylene glycol)-norbornene (PEG-NB) hydrogel and new microfabrication techniques to create geometrically accurate 3D lung models that closely mimic the mechanical properties of native lung tissue. Briefly, eight-arm PEG-NB macromers were crosslinked with an MMP3-degradable dithiol crosslinker via emulsion polymerization to create hydrogel microspheres. A design of experiments approach determined the optimal emulsion conditions to achieve a median microsphere diameter (d=180.8 μm) that approximates the size of a human lung alveolus (d~200 μm). Bioactive peptide sequences mimicking fibronectin and laminin were incorporated into the microspheres to promote cell attachment and magnetic nanoparticles were included to enable magnetic aggregation into structures replicating distal lung architecture. The microspheres were seeded with magnetically labeled primary murine primary alveolar epithelial type II (ATII) cells and aggregated with a magnetic levitating drive to resemble an alveolar air sac. These aggregates were coated with primary murine fibroblasts to replicate interactions between epithelial cells and fibroblasts that drive many chronic pulmonary diseases. These acinar structures were next embedded in a PEG-NB hydrogel that mimics the mechanics of healthy or diseased lung parenchyma to create a robust, physiologically relevant acinar model.

We envision that ongoing work to incorporate patient-derived induced-pluripotent stem cells (iPSCs) into tissue-informed lung models could lead to pulmonary regenerative medicine advances that bridge the gap between outputs measured in traditional *in vitro* models and outcomes in human clinical trials.

12:00 PM SB12.08.04
Injectable, Pore-Forming, Perfusable Double-Network Hydrogels Resilient to Extreme Biomechanical Stimulations Guangyu Bao[1,2], Sareh Taheri[1,2], Zixin He[1], Sepideh Mohammadi[1], Hossein Ravanbakhsh[1,2], Jianyu Li[1,1] and Luc Mongeau[1,2]; [1]McGill University, Canada; [2]Centre for Interdisciplinary Research in Music Media and Technology, Canada

Injectable hydrogels can be delivered via needle-syringe injection into the human body with low invasiveness. They have found significant use in many branches of medicine. Despite extensive efforts in the field, there remain long-lasting challenges concerning the mass transport and mechanical properties of injectable hydrogels. First, most existing injectable hydrogels are not perfusable. This issue limits the rapid transport of oxygen and nutrients (diffusion depth ~ 600 μm), as well as the trafficking of native or transplanted cells. Immediate vascularization is therefore imperative but difficult to realize through injection. Second, injectable hydrogels show limited mechanical toughness and robustness. They tend to crack and fail under large or repeated force excitation. An extreme case is the vocal folds, where implants in the vocal fold lamina propria are exposed to up to 50% strains at a fundamental frequency that is on the order of 10^2 Hz. Currently, patients with vocal fold injuries suffer from repeated hydrogel injections, due in part to the fracture-induced short lifetime of the hydrogel implants under the dynamic loadings. By contrast, many biological tissues are perfusable and yet tough to tolerate extreme biomechanical stimulations as part of their normal functions, as exemplified by the vocal fold and heart. To close the gap between injectable hydrogels and biological tissues, strategies to achieve a combination of high permeability and mechanical toughness are highly desired.

Here, we describe a design and methodology to fabricate new injectable hydrogels featuring in-situ pore formation, strengthened mechanical performance, and excellent cytocompatibility. We achieved this by orchestrating stepwise gelation and phase separation processes. The resulting hydrogels contain porous double-networks, thereby termed PDNs, which differ from previously reported injectable hydrogels that consist of either nanoporous or preformed porous networks. PDNs can form interconnected cell-sized pores in-situ upon injection. The highly porous matrices enable rapid media perfusion and support cell spreading and trafficking. The permeability of PDNs was at least 2 to 4 order of magnitudes greater than that of most existing hydrogels and

comparable to many biological tissues. Such perfusable hydrogels were demonstrated to support cell survival in organ-sized scaffolds with a dimension beyond 60 mm. To our knowledge, this is the first material reported to support cell viability in centimeter-scale avascular constructs. Meanwhile, unlike many porous hydrogels that are weakened by their pores, PDNs are tough and resist the propagation of moderately-sized cracks below 500 μm. Their fracture toughness was up to 40-fold greater than those of commonly used nanoporous or porous single-network hydrogels. They can be stretched more than 200% of strain without failure. The stiffness of PDNs is tunable between ~ 3 to 10 kPa, which spans the range of various soft biological tissues such as the vocal folds, lungs, heart, and gastrointestinal tract. They also exhibited a fast stress relaxation response within 10 to 100 seconds similar to organs and extracellular matrix.

Thanks to the facile injectability, PDNs can be easily delivered through fine needles and incorporated into 3D cell culture perfusion systems with complex mechanical loadings, such as microfluidic chips and bioreactors. We demonstrated that PDNs can withstand over 6,000,000 cycles of high-frequency (~ 120 Hz) biomechanical stimulations without rupture. Our method is also generalizable to commonly used material systems, such as chitosan and gelatin. With the unparalleled combination of interconnected pores, toughness, cytocompatibility, and injectability, the described material systems and method may open new opportunities for regenerative medicine and serve as biomimetic in vitro 3D cell culture platforms for a broader range of applications.

12:15 PM SB12.08.05
Late News: A Sprayable and Antimicrobial Dressing for Treatment of Burn Wounds Ilayda Firlar[1,1], Sanika Suvarnapathaki[1,1] and Gulden Camci-Unal[1,2]; [1]University of Massachusetts Lowell, United States; [2]University of Massachusetts Medical School, United States

Introduction: Wound healing is a highly regulated complex biological process that includes homeostasis, inflammation, proliferation, and maturation stages to regenerate damaged tissue. The coverage of the open wound by a dressing is the general treatment to prevent bacterial invasion and possible further injuries. Recent wound dressings have been improved by providing multifunctional features to better control the wound and the healing process. There are various key features of wound dressings such as retention of wound exudate, creation of a moist environment around the wound, and prevention of inflammation by anti-inflammatory components. Hydrogels have been widely used in wound dressings due to their ability to retain high amounts of water. For practical and rapid wound treatments, conventional dressings demonstrate limitations with inadequate amounts of oxygen, poor fitting onto the wound, and additional need for antimicrobial treatment. To address these issues, we have developed a sprayable hydrogel dressing with antimicrobial properties using naturally-derived materials and inexpensive components.

Methods: In this work, sprayable, antimicrobial, and cost-effective hydrogel wound dressings were developed for rapid treatment of burn wounds. These hydrogels are composed of photocurable gelatin, which is hydrolyzed collagen (GelMA) as the bioactive component and solid peroxide microparticles as the oxygen forming antimicrobial component. GelMA was synthesized and composite hydrogels were fabricated using 5-10% (w/v) GelMA and different concentrations of peroxide microparticles (0-15 mg/mL). The physical characteristics of the composite hydrogels were investigated by mechanical testing, swelling, degradation, and porosity analyses. The oxygen formation kinetics were measured using an oxygen sensing probe. The antimicrobial capabilities of composite hydrogels were tested against the growth of *Escherichia coli* bacteria. The cellular responses were evaluated by performing viability, adhesion, proliferation, metabolic activity, and cytotoxicity assays upon culturing human dermal fibroblasts with the composite hydrogels.

Results: We developed practical, sprayable, and antimicrobial composite wound dressings. 10% (w/v) of GelMA concentration was chosen as an optimum concentration. The composite prepolymer solutions with 10% (w/v) GelMA have shown less hydrophilic characteristics compared to the 5% (w/v) concentration when they were sprayed on an *ex vivo* pig skin model. The gelatin and peroxide containing composite hydrogels have shown tunability in physical and biological properties. The composite hydrogels have generated oxygen up to two weeks which was beneficial to the *in vitro* cell culture. The metabolic stress of human dermal fibroblast cells was relieved by the sustained formation of oxygen from the peroxide microparticles. The generation and supply of additional oxygen reduced cell death as well as providing antimicrobial properties in this novel sprayable wound dressing.

Conclusion: The sprayable, antimicrobial, and composite hydrogels that are composed of GelMA and solid peroxide microparticles were successfully fabricated. Their physical, chemical, and biological characteristics including swelling, degradation, porosity, mechanical strength, oxygen formation kinetics, antimicrobial activities against bacteria, and cytocompatibility with human dermal fibroblasts were evaluated. Our sprayable hydrogel wound dressings can be applied on wounds without contact, eliminating the risk of infection via handling, and are easily conformable to the morphology of the wound allowing for generation of personalized dressings. The fabricated composite hydrogel dressing will not require a frequent change due to its stability on the wound. In addition to pre-treatment of burn wounds, the developed sprayable and antimicrobial hydrogel dressing can be useful in plastic surgery and dermatology, applications.

1:00 PM *SB12.09.01
Controlling Vascular Smooth Muscle Cell Phenotype in Pediatric Vascular Tissue Engineering Joyce Y. Wong; Boston Univ, United States

Our long-term goal is to tissue engineer and build pediatric vascular patches that will grow with a child to address unmet needs of surgical solutions for children with congenital heart defects. A major cell type of blood vessels are vascular smooth muscle cells (VSMCs) which largely comprise the medial layer of blood vessels. Vascular smooth muscle cell behavior is modulated by various physicochemical factors and their phenotype changes during normal developmental processes and during pathophysiology. Examples of vascular smooth muscle cell phenotype involve differences in extracellular matrix molecule production, cell migration, cell proliferation, contractility.
Our laboratory has investigated the effects of a variety of physicochemical stimuli on vascular smooth muscle cell behavior with the goal of understanding key relationships between VSMC phenotype and the underlying substrate. Using these model systems, we have elucidated the effects of substrate mechanical, chemical, and topographical properties on VSMC phenotype. Furthermore, to better represent physiological and pathophysiological conditions, we have investigated the interplay of multiple stimuli on VSMC phenotype.
From this information, we have developed several technologies such as micropatterned cell sheet engineering to form stacked VSMC patches and have assessed their mechanical strength. We have validated computational modeling of these stacked cell sheets in which we investigate the role of structural orientation on their mechanical properties. Computational modeling enables us to interrogate a large experimental variable space *in silico*.
Finally, we are developing several strategies for using different stem cell sources from patients with clinical translation in mind.

1:30 PM *SB12.09.02
hPSC Derived Pancreatic Islet Organoids Bioengineered for Regenerative Engineering and Disease Modeling Applications Ipsita Banerjee; University of Pittsburgh, United States

Type 1 diabetes results from the auto-immune destruction of inulin secreting cells of the pancreas – the beta cells within Islets of Langerhans. Exogenous supply of insulin is a commonplace procedure in regulating blood glucose levels in diabetic patients. Alternately, cell replacement therapies such as pancreas and islet transplants offer a more permanent solution to maintain blood glycemic control. However cell therapy is restricted by the availability of donor tissue, which can be overcome by deriving insulin producing cells from a regenerative cell source, like pluripotent stem cells (PSCs). With the current advancement of PSC-derived cell therapy from the laboratory to Phase 1 clinical trials, there is an enhanced emphasis on deriving mature and functional islets from hPSCs in a robust and reproducible manner. In parallel to regenerative therapy, there is also a strong emphasis to reproduce disease phenotypes in vitro, using microphysiology systems (MPS) models in tissue chip platforms. Once developed and validated, these models will be invaluable platforms for interrogating disease mechanisms as well as supplementing drug discovery and drug testing activities. Appropriate functioning of the MPS models, however, will largely rely upon successful derivation of mature and functional cells/ tissues/ organs from hPSCs.

Our research focuses on a range of biomaterial strategies for deriving pancreatic islet like cells from hPSCs. We have developed cell encapsulation strategies for scalable culture of hPSCs and its subsequent differentiation to islet like clusters. We have introduced systems engineering techniques to identify robust biophysical conditions for hPSC propagation. In a collaborative team we have developed biomaterial substrate to synthesize controlled, multicellular organoids from hPSCs resembling pancreatic islets. We are currently developing strategies to induce *in-vitro* microvascular network formation within the stem cell derived islet organoids. This talk will highlight ways in which our laboratory has integrated natural and synthetic materials to engineer the cellular environment to closely mimic the natural islet environment. Our current efforts on integrating islet organoid with microfluidic device towards developing Diabetes MPS models for Diabetes will also be discussed.

2:00 PM *SB12.09.03
Alternative Approaches to Mediate Cell Behaviour Sedat Odabas; Ankara University, Turkey

Cells can sense the physical stimuli that may arise from the composition of the material, from the extracellular matrix (ECM) that they surrounded, or the topography and the stiffness of the surface that they interact with. Cells respond to these stimuli by triggering certain metabolic pathways and altering their metabolic activities, which may lead to a change in gene expression and protein synthesis as well as promoting growth and differentiation.
Generally, the transformation of these physical stimuli into biochemical signals is called “mechanotransduction”. There are several methods and mediators to create physical stimuli and induct cells. Magnetic particles and magnetic scaffolds are one of the most convenient methods to construct a mechano-sensitive system as these scaffolds can respond to external magnetic fields. Our research on magnetic cryogels reveal that these scaffolds can induce bone and cartilage differentiation of mesenchymal stem cells both in low and high magnetic strength.
Conductive scaffolds are one of the other alternatives to use as a mechano-sensitive system. Our research on electrically conductive decellularized muscle/polyaniline/ polycaprolactone blend scaffolds possess favorable properties to serve as a matrix for the regeneration of skeletal muscle tissue.
Surface modification is also a very convenient method to obtain desirable surfaces and topography. Polydimethylsiloxane (PDMS) is a widely used polymer due to its biocompatibility, high oxygen permeability and ease of fabrication. Our research on protein-modified PDMS and bone surface mimicked PDMS shows enhanced bone cell-related metabolism.
Cells are surrounded by their own ECM. Therefore, the composition of this ECM may contain several important cues to regulate or affect cell behavior. Engineered decellularized matrices are one of the latest approaches, as decellularization aims to preserve the structural and functional biomacromolecules of ECM while removing the cellular components. We reported both animal and plant derived modified decellularized matrices can provide a suitable biomechanical microenvironment for better cell attachments and proliferation.
Whether using a mechano-sensitive system, modified bio-mimicked surface, or even a decellularized matrices, cells will sense and alter their metabolism as they always do. It should be also noted that tracking and exploring the mechanistic pathways will help us to better explain these behavioral changes.

2:30 PM SB12.09.04
Plasma Immersion Ion Implantation (PIII) in Porous Mesenchymal Stem Cells Expansion Platforms Anyu Zhang, Kuan U. Wong, Giselle Yeo, Behnam Akhavan and Marcela Bilek; The University of Sydney, Australia

Rapidly developing tissue engineering treatment methods address the need to develop three dimensional (3D) porous scaffolds with biofunctionality to promote tissue ingrowth and regulate cell behaviours. Current biofunctionalization strategies rely on wet chemistry to immobilize biomolecules onto the internal complicated porous networks of the 3D porous scaffolds. However, wet chemistry approaches are limited with complicated and time-consuming process, and toxic residues. This project successfully surface-engineered three-dimensional (3D) porous tissue engineering scaffolds using plasma immersion ion implantation (PIII) technology in a customized plasma reactor. The surface-biofunctionalized scaffolds were validated by mesenchymal stem cell (MSC) expansion. PIII is a surface engineering technology that can embed highly reactive radicals in polymeric substrates surface via energetic ion bombardment. Through these radicals, biomolecules can be covalently bonded to the plasma-treated substrates and provide high level bio-functionality for tissue engineering
scaffolds. The PIII modification is typically low cost, versatile, and environmentally friendly compared to wet-chemistry-based covalent immobilization processes.[1] However, conventional plasma treatment strategies are not suitable for uniform surface treatment of porous scaffolds, because the directional approach of these methods relies on diffusion of reactive species into the pores, which has a limited penetration depth.[2] Therefore, there is a strong demand for a new plasma-based method suitable for homogenous plasma activation of porous 3D scaffolds. Here we report the development of a new approach in which a high voltage electrode surrounds the polymeric scaffolds for their homogenous PIII activation. Voltages in the range of 4- 8 kV and working pressures in the range of 1-3 Torr were tuned to optimize the PIII activation high impact PS scaffolds with pore sizes of 300 μm. Using micro-Fourier-transform infrared spectroscopy (micro-FTIR), the homogeneous surface modification of the PIII-treated scaffolds was confirmed by evaluating the relative concentrations of R-OH groups generated throughout the scaffolds by the interaction between the embedded radicals and oxygen in the atmosphere. FGF2 with an optimized concentration were covalently immobilized to partially cover the surfaces of the scaffolds, promoting both MSC adhesion and MSC proliferation. These results show that porous network of the scaffolds can be PIII-treated with using this new strategy, providing an excellent bio-functional platform for MSC expansion.

Effect of Fullerenol on Physical Properties and Biocompatibility of Calcium Phosphate Cements Ilayda Duru[1], Nisa I. Büyük[2], Gamze Torun Köse[2] and Duygu Ege[1]; [1]Boğaziçi University, Turkey; [2]Yeditepe University, Turkey

In this study, physical properties and biocompatibility of polymer/calcium phosphate cement (CPC) bone substitutes are improved with incorporation of fullerenol (Ful) which is a cutting-edge carbon nanomaterial due to its biocompatibility and specific physical and chemical features. The main characteristic of Ful is that it is a powerful scavenger for radical oxygen species (ROS) and some studies suggest that it enhances osteogenic differentiation via scavenging ROS and upregulating the expression of osteogenic markers. However, the data presenting the effect of Ful on the characteristics of bone substitutes is scarce. CPCs are the most dominantly used clinical bone substitutes since they possess a similar structure to natural bone and can easily be applied due to their moldability. CPCs are commercially available in pure form and in a compound with polymers because their drawbacks including low degradability, macroporosity and wash-out resistance can be addressed via degradable polymers, such as carboxymethyl cellulose (CMC) and gelatin (Gel). Then finally, Ful is incorporated to the bone substitutes.

In this study, tetracalcium phosphate (TTCP)/dicalcium phosphate dihydrate (DCPD) particles were ball-milled to obtain particles with diameters of less than 20 µm. The powder phase of CPC consisted of TTCP and DCPD in equivalent mass was used to produce Ca-deficient hydroxyapatite. The liquid phase of control CPC was 0.4 M Na_2HPO_4 solution with a pH of 7.4. CMC, Gel and Ful were homogenized in Na_2HPO_4 solution to synthesize the liquid phase of other CPC groups. The specimens were named control, CMC1/Gel1.5, Ful0.02, Ful0.04, Ful0.1. Gum-like consistency was obtained by mixing powder and liquid in 55.56/44.44 ratio by weight, respectively. Particles and CPCs were characterized by scanning electron microscopy (SEM) and X-ray diffraction (XRD). Setting time of specimens were measured by Gilmore test. Moreover, compressive strength and modulus were measured after their incubation at 37°C in phosphate buffered saline (PBS) for 24h. pH change was also analyzed after the incubation at 37°C in PBS. Finally, % cell viability was measured via Alamar Blue reduction.

The results so far show the beneficial effect of Ful on setting time and compressive strength of CPCs, and % cell viability on CPCs. According to the results of Gilmore test, 0.1 wt/v% Ful significantly decreased the initial setting time of CMC1/Gel1.5 CPCs from 20.78 minutes to 16.18 minutes ($p<0.05$) and final setting time from 27.94 minutes to 18.19 minutes ($p<0.01$). XRD analysis of CPCs at different time intervals reveals that total reaction of Ful containing CPCs took less than 5 hours since all TTCP and DCPD were consumed, and the only phase was apatite at 5th hour. Compression test shows that 0.1 wt/v% Ful significantly increased the compressive strength of control CPCs to 3.68 MPa from 2.14 MPa ($p<0.05$) and modulus of control CPCs to 213.09 MPa from 152.08 MPa ($p<0.05$). pH measurements show that 6.9 was the lowest pH for the groups at the end of the first week. After the first week, the pH of the CPCs raised and remained constant between 7.0-7.4 for one month. Finally, pre-results of Alamar Blue assay demonstrates that Ful significantly increased the cell adhesion on CPCs. % cell viability on CMC1-Gel1.5 CPCs enhanced with the addition of 0.02 wt/v% Ful ($p<0.05$) and 0.04 wt/v% Ful ($p<0.05$) in 24h. The results of this study are considered to enlighten the studies on CPCs which are the main elements of orthopedic, maxillofacial, and craniofacial applications.

SESSION SB12.10: Material-Based Approaches for Regenerative Engineering

Late News: Mineralized Hydrogels for Regeneration of Critical Size Bone Defects Xinchen Wu and Gulden Camci-Unal; University of Massachusetts--Lowell, United States

Bone regeneration is crucial to repair critical sized bone defects that jeopardize the quality of life. Bone tissue is regenerated by intramembranous and endochondral ossification physiologically, however, a critical sized bone defect without remaining bone pieces or periosteum can be challenging to repair on its own. Allo- and auto-grafts have been developed to enhance bone regeneration. However, the risk of infection, the need of secondary surgery, and high cost limit the use of such grafts. In clinical practice, cranial defects are often caused by surgery to release the intracranial pressure, and the defect is subcutaneously covered by non-degradable implants. Biocompatible and biodegradable biomaterials can repair critical sized bone defects and degrade while the bone tissue is regenerated. Protein-based hydrogel scaffolds are suitable for critical size cranial defects regeneration due to their tunable and pliable physical properties as well as their osteoinductivity. We hypothesized that sequential mineralization process can enhance the mechanical properties of the hydrogel scaffolds while rendering the scaffolds more bioactive, osteoinductive, and osteoconductive.
In this work, we developed sequentially mineralized gelatin-based (GelMA) scaffolds to obtain mechanically stable and biologically active three-dimensional (3D) gels that allow for osteogenesis both *in vitro* and *in vivo*. The GelMA hydrogels were mineralized for 10 cycles in which one cycle is defined as an incubation period in calcium chloride dihydrate that is followed by incubation in sodium phosphate dibasic dihydrate. The mineralized scaffolds were characterized by Dynamic Mechanical Analysis (DMA) and Scanning Electron Microscopy (SEM), Thermogravimetric analysis (TGA), and Fourier Transform Infrared (FTIR). Pre-osteoblast cells were seeded on the scaffolds for 14 days and the expression of osteogenic differentiation maker genes were determined by quantitative reverse transcription polymerase chain reaction (RT-qPCR). The scaffolds were then used to repair critical size cranial defects in a rat model.
The mineralized GelMA hydrogel scaffolds have shown outstanding tunability and pliability in physical and biological properties for bone regeneration. The mechanical properties significantly enhanced for the mineralized hydrogels (125 kPa) compared with the pristine hydrogels (4.25 kPa). The 3D scaffolds induced osteogenic differentiation of pre-osteoblasts without the use of osteogenic growth medium or growth factors. The critical sized cranial defects in a rat model were repaired after 12 weeks by the mineralized scaffolds (55.4 mm^3 regenerated bone volume) while no bone regeneration was observed with the use of pristine hydrogel controls or blank control groups. Overall, the findings suggest that our mineralized hydrogel scaffolds show superior mechanical properties and indicate favorable *in vivo* bone regeneration through regeneration of critical sized cranial defects in a rat model.
In conclusion, sequentially mineralized hydrogels were fabricated and characterized for their chemical, physical, and biological properties. They were also evaluated for their osteoinductivity *in vitro* and osteoconductivity *in vivo*. The *in vivo* experiments showed that the scaffolds could simply be applied on top of the dura without causing an increase in cranial pressure. The implants were easily accepted by the host, highly vascularized, and biodegradable. We anticipate that our mineralized hydrogels will be useful for regeneration of mineralized tissues in new biomedical applications.

Structure-Function Relationships in Biomaterials Surface Science Fabio Variola; University of Ottawa, Canada

In the quest for the next generation of functional biomaterials and new solutions in health-related research, investigators have sought inspiration from

nature by developing better performing bioderived materials (e.g. chitosan, polydopamine) and architectures (e.g. nanoporosity), reproducing naturally occurring micro and nanostructures to control cellular response at the material-host tissue interface. In this context, our team has focused on understanding the effects on cells of poly(dopamine), an adhesive polymer derived from mussels, as a multifunctional layer for direct cueing to osteoblastic and mesenchymal stem cells. In addition, we have employed anodization to create reproducible patterns of nanotubes on titanium surfaces, demonstrating their role in controlling osteoblastic and mesenchymal stem cell activities. In parallel, our work has also contributed to the development of collagen-, agarose- and chitosan-based materials for applications in neuronal tissue engineering and disease modelling. For example, we focused on the creation of micro-engineered chitosan substrates for neuronal guidance and on 3D scaffolds to support neuronal adhesion and network formation.

Cells Encapsulated Degradable Alginate Hydrogel Microfibers Fabricated by Microfluidic Aqueous Two-Phase System (ATPS) Wisawat Keaswejjareansuk, Katawut Namdee and Mattaka Khongkow; National Nanotechnology Center, National Science and Technology Development Agency, Thailand

Cells encapsulated hydrogels are a promising material system that immobilizes and protect the cells in porous matrices. Hydrogel allows nutrient and oxygen exchanges between the cells and the matrices, which suitable for tissue engineering and cell therapy. Alginate is a natural anionic polymer that has been used in biomedical applications due to its excellent *in vivo* compatibility and low toxicity. Alginate hydrogels have been utilized for microfibers and implant scaffolds. However, an important limitation of the alginate hydrogels is the gradual degradation in a physiological environment that greatly affects the cell-cell interaction and tissue formation. In this study, microfluidic aqueous two-phase system (ATPS) was employed to fabricate the cell encapsulated hydrogel microfibers. In comparison with other techniques, the ATPS is a less complex and straightforward method to creates continuous microfibers. The microfibers then formed into a bulk mass and called hydrogel microfibers. In the material development, the concentration of the alginate-Dulbecco's Buffered Saline (DPBS) mixture was varied. The corresponding structure, morphology, swelling behavior, elastic modulus, and degradation of the alginate hydrogel microfibers were characterized to determine the optimal concentration. Fibroblast was selected in the biological study. Alginate lyase-loaded poly(lactide-co-glycolide) PLGA nanoparticles (NPs) were fabricated by a double emulsion/solvent evaporation technique. The NPs were then incorporated into the cell-laden alginate to accelerate the degradation and promote cell proliferation. NPs loaded and pristine hydrogel microfibers were studied for comparison. Cell viability, cell toxicity, and cell proliferation in the hydrogel microfibers were tested and observed at the day 1, 3, 7, and 14. Various characterization methods include SEM, DLS, AFM, degree of swelling, degradation, assays include cell proliferation, MTT, cell viability, and micro BCA were used.

In this talk, controls of the laminar flow ATPS to create continuous microfibers will be presented. The physical behavior, structure, and elastic modulus of the hydrogel microfibers will be discussed. The cell viability, toxicity, and proliferation will be reported.

4:45 PM SB12.10.04
Late News: Materials that Breathe for Tissue Engineering Sanika N. Suvarnapathaki and Gulden Camci-Unal; University of Massachusetts--Lowell, United States

Introduction: Oxygen is critical for ensuring cell survival and proliferation. Inadequate oxygen in the cellular microenvironment can trigger cell damage and hypoxia induced necrosis[1]. Tissue constructs of physiologically relevant scale (in cm sizes) face diffusion limitations and are unable to translate into clinics successfully. Biomaterials that can release oxygen over time, for up to 4-5 weeks, can fulfill this oxygen demand of physiological scale tissue constructs for clinical applications[2]. To yield biomaterials with high oxygen content, solid peroxides can be encapsulated within hydrophobic polymers. This novel approach can produce oxygen generating biomaterials that can release oxygen over a 5-week period in a controlled, sustainable manner, and augment cell viability and function[2].

Materials and Methods: We engineered the oxygen-generating microparticles by encapsulating calcium peroxide (CaO_2) within a hydrophobic biopolymer polycaprolactone (PCL). An emulsification technique was used to prepare composite microparticles with 2-10% (w/v) CaO_2 in PCL. The CaO_2 was added to a PCL solution and the blend of CaO_2 and PCL was micro pipetted dropwise to a Polyvinyl alcohol (PVA) solution under constant magnetic stirring at 720 rpm. This process produced CaO2- PCL composite microparticles which were 100mm in diameter. These microparticles were subsequently encapsulated in gelatin methacrylate (GelMA) hydrogels to engineer the oxygen-generating scaffolds. The oxygen release kinetics of these scaffolds were recorded, and the corresponding cellular viability, metabolic activity, cytotoxicity, and apoptosis of the encapsulated primary cardiac fibroblasts were studied. The cellular studies were performed by microencapsulating primary cardiac fibroblasts within the oxygen- generating hydrogels at a cell density of 5 $x10^6$ cells/mL over a 5-week culture period under induced hypoxia.

Results and Discussion: We developed the oxygen-generating scaffolds and characterized their material properties. This was followed by measuring the oxygen release kinetics, and monitoring the cell behavior (viability, growth, and proliferation) and metabolic function *in vitro*. Our results revealed that the scaffolds sustained release of oxygen for up to 35 days under induced hypoxia with primary cardiac fibroblasts microencapsulated. The cellular metabolic activity over these 35 days reported an increasing trend over 14-days and continued to rise up to day 35 in culture. We achieved a precise control over the oxygen release kinetics by varying the CaO_2 concentration within PCL. The negative controls devoid of the oxygen-generating microparticles, were also tested simultaneously and they resulted in no improvement in cell growth and function.

Conclusions: Primary cardiac fibroblasts are high oxygen consuming cells, and they use oxygen at higher rates under hypoxic environments. Our results validated that the oxygen-generating microparticles enabled the maintenance of high cell viability and metabolic activity under induced hypoxia for up to 5 weeks We demonstrated that tunable oxygen release kinetics can be obtained by altering the CaO_2 concentration, PCL concentration, and the quantity of the CaO_2 -PCL microparticles within the hydrogel matrices. To customize the oxygen-release kinetics for culturing cells from different lineages having varying oxygen demands, these parameters can be easily modified. This approach could be used as a scalable, tunable platform for the development of functional off-the-shelf tissue constructs which could be used to surmount hypoxia-induced necrosis.

Bioactive Tissue Derived Nanocomposite Gel for Permanent Arterial Embolization and Enhanced Vascular Healing Jingjie Hu; North Carolina State University, United States

Transarterial embolization is a minimally invasive procedure to selectively deliver embolic agents using a catheter into arteries to occlude diseased or injured vasculature for therapeutic intent under real-time X-ray guidance. It can be used to treat vascular malformations, aneurysms, and hypervascular

tumors. A variety of embolic agents such as coils, beads, and liquids are currently used in the clinic; though their effectiveness is limited by non target embolization, failure in coagulopathic patients, high cost, and toxicity. In this study, a decellularized cardiac extracellular matrix (ECM) based nanocomposite gel is developed to provide outstanding mechanical stability, catheter injectability, retrievability, antibacterial properties, and biological activity to prevent recanalization. The malleable and shear-thinning nature of the nanocomposites gel allows the formation of an impenetrable solid cast to fill various vessel geometries and sizes, avoiding recurrent bleeding, and provides the versatility that cannot be achieved by clinically used agents. The embolic efficacy of gel is shown in a porcine survival model of embolization in the iliac artery and the renal artery. The ECM based nanocomposite promotes arterial vessel wall remodeling and a fibroinflammatory response while undergoing significant biodegradation such that only 25% of the embolic material remains at 14 days. With its unprecedented proregenerative, antibacterial properties coupled with favorable mechanical properties, and its outstanding performance in anticoagulated blood, the bioactive ECM based nanocomposite gel enables wide tunability providing a platform technology for the next-generation in vivo embolic agents to treat a broad range of vascular diseases.

5:15 PM *SB12.10.07
Polypeptide Biomaterials for Photothermal Tissue Repair and Wound Healing Kaushal Rege; Arizona State University, United States

Repair of wounds and surgical incisions is facilitated by primary intention with devices including sutures and staples. However, lack of immediate tissue approximation, high potential for scarring, including in visible areas of the body, propensity for tissue trauma and infection, and long procedure times necessitate new approaches for tissue repair. Light-activated tissue sealing is an emerging strategy that facilitates rapid fluid-tight approximation of ruptured tissues, but the lack of effective biomaterials compromises efficacy. I will discuss our advances in the generation, characterization and evaluation of laser-activated polypeptide biosealants and nanofibers in which, molecular or nanoparticle chromophores are embedded within natural polypeptide matrices and fibers. Irradiation of these biosealants and nanofibers with near infrared light facilitated a photothermal response, which, in turn, engendered rapid, fluid-tight sealing and accelerated repair of soft tissues both ex vivo and in live animals. I will also discuss a new approach in which biomaterials alone can be used for simultaneous photothermal conversion of non-ionizing light as well as concomitant tissue sealing, thus dispensing the need of nanoparticles or dyes. In addition to acute wounds, slow-healing and chronic wounds, including in diabetic and obese patients, place an enormous burden on the healthcare system. Advanced treatments, including biologicals, have shown promise but have largely not succeeded in intractable pathologies likely because of poorer stabilities. I will describe our new findings on the delivery of immune-modulating bioactives molecules and polypeptide biomaterials (e.g. silk) in combination with growth factor nanoparticles with an eye towards modulating different stages of tissue repair, leading to accelerate healing and repair. We describe evaluation of these new combination treatments, including using temporal delivery strategies in immunocompetent, and obese, diabetic mice. Taken together, our studies demonstrate that polypeptide biomaterials, in concert with delivery of light, show strong translational promise for accelerating wound healing, and efficacious tissue sealing and repair.

SESSION SB12.11: Biomaterials for Regenerative Engineering and Poster Session

Monday Afternoon, December 6, 2021
SB12-Virtual

6:30 PM SB12.11.01
Binary Zinc Alloy-Based Biomaterials for Tissue Regeneration Yingchao Su and Donghui Zhu; Stony Brook University-SUNY, United States

Introduction: Zinc (Zn) has been recently proposed as a novel biodegradable metal thanks to its essential physiological and biological roles and its promising *in vivo* degradation rate [1, 2]. Compared to Mg alloys and Fe alloys, the degradation behavior of Zn alloys is more likely in line with clinical demand. One of the main factors limiting the extensive clinical application of Zn and its alloys is their lower mechanical strength [3]. While it can be improved through alloying with different elements (such as Mg, Ca, Mn, Cu, or Li), and plastic deformation processing techniques [34], low mechanical strength still remains an important challenge, and more effort is required to obtain a series of alloys with reproducible mechanical strength and ductility.
Methods: A series of Zn-0.5X and Zn-3X alloys (X = Cr, Fe, Sr, Zr, V, at.%) were prepared and extruded from Φ28 mm down to Φ10 mm cylinder. Mechanical property was measured at a strain rate of 0.04/min using a universal material test machine (Instron 5969, USA) according to ASTM-E8M-09 and ASTM E9-89a (2000) standards. For the cell viability test, extract media was prepared by incubating samples in the corresponding cell culture media at a ratio of 1.25 mL/cm^2 for 3 days. Afterward, the collected extract solution was diluted with culture media to specific concentrations of 25%. The cell viability of human endothelial cells (EA.hy926, ATCC CRL-2922, US) was measured with the MTT assay. A rabbit abdominal aorta model was used for *in vivo* implantation. Different wire samples with dimensions of Φ0.25 × 20 mm were implanted in the abdominal aorta of each rabbit under angiography.
Results & Discussion: All the alloys showed improved mechanical strengths when compared to pure Zn, especially the Zn-0.5Cr, 0.5Zr, 0.5 and 3V alloys have significantly improved mechanical strengths and elongation. The endothelial cells cultured with Zn-0.5Zr, 0.5Sr, 0.5 and 3 Fe and V alloys showed much better cell viability than pure Zn. The *in vitro* and *in vivo* degradation tests of different materials showed similar corrosion behaviors with pure Zn, which is helpful for their potential clinical applications.
Conclusions: Collectively, these data clearly illustrate the different mechanical properties and cell viability on these Zn based materials, which could potentially provide various choices for the tissue regeneration.

***In Vivo* Studies of Additive Manufactured Bioabsorbable Magnesium Scaffolds in a Rabbit Femur Model** Juncen Zhou and Donghui Zhu; Stony Brook University, United States

Introduction: Additive manufacturing (also called 3D printing) techniques have been utilized and developed in the field of orthopedic implants, and various materials, fabrication methods, geometry design were studied. When an implant aims to regenerate bone, the porous structure will be beneficial for mass transfer and cell migration, leading to enhanced angiogenesis and new bone growth. Even though many bioabsorbable materials, including polymers and ceramics, have been applied in 3D-printing scaffolds, their mechanical strength is still considered insufficient, especially in the case of load-bearing

applications. Bioabsorbable metals, such as magnesium and its alloys, have shown great potential as the next generation of biomaterials, thanks to their decent mechanical properties, biodegradation, and biocompatibility. Here, we use additive manufacturing to fabricate porous magnesium scaffolds, the degradation behavior and biological response of which are studied in vivo with a rabbit femur model.
Methods and Materials: Magnesium scaffolds are composed of WE43 magnesium alloy. Titanium scaffolds made of Titan-Grade 1 are used as a benchmark group. Laser Powder Bed Fusion is facilitated for the manufacturing of different scaffolds. The scaffold is in the shape of a cylinder with both diameter and height of 4 mm. The pore size of all scaffolds is around 500 μm. Before the implantation, the compression test is performed on different scaffolds. The rabbit femur defect model is used in this study. Two circular defects with a diameter of 4mm are created by the drill in the distal femur, and then two scaffolds made of the same material are inserted into these two defects separately. Two collection time points are set to 5 and 25 weeks. The collected femur bones with scaffolds are analyzed with the Micro CT scanning. Meanwhile, the blood and internal organs, including the heart, liver, spleen, kidney, and lung, are collected for biotoxicity analysis.
Results: In terms of the compression strength and modulus, the titanium scaffold exhibit a higher value, while the value of WE43 scaffold is more close to the natural human bones. All scaffolds can properly fit into defects and hold well. No systematic toxicity is found for all scaffolds based on the analysis of blood and internal organs. The degradation rate of WE43 scaffolds is derived from the volume change in the Micro CT. For all scaffolds, the new growth of bone into the pores can be observed. Interestingly, neither the degradation behavior nor the new bone ingrowth is homogeneous for the whole scaffold. Different sections of the scaffold show various degradation tendencies due to the local physiological environment (contacted with cortical bones or the marrow cavity) and mass permeation. Furthermore, degradation behavior causes an influence on the new bone growth. Meanwhile, the geometry of scaffolds also has an impact on the local biological response.
Conclusion: Compared to titanium scaffolds, WE43 scaffolds present acceptable biological response, and their biodegradation feature exhibit great potential for bone regeneration application.

7:00 PM SB12.11.03
Late News: The Anti-Aging Effects of Polydopamine Particles in Human Skin Epithelial Keratinocytes Yan Nie[1,2], Xun Xu[1], Weiwei Wang[1], Barbara Bellomo[1], Nan Ma[1,3] and Andreas Lendlein[1,2,3]; [1]Institute of Active Polymers - Helmholtz-Zentrum Hereon, Germany; [2]Institute of Biochemistry and Biology, University of Potsdam, Germany; [3]Institute of Chemistry and Biochemistry, Free University of Berlin, Germany

Skin aging is a multisystem degenerative process, which is characterized by the accumulation of senescent keratinocytes. The exposure of reactive oxygen species (ROS) is one of the major causes that induce growth arrest and cellular senescence in those cells. The preparation of polydopamine (PDA) intended for biomedical applications typically comprises oxidative self-polymerization of dopamine (DA) in a weak alkaline solution [1, 2]. PDA can be deposited as a biofunctional coating on cell culture substrates acting as a ROS scavenger [3]. However, the role of PDA particles, which are formed during the PDA coating formation, is not yet fully explored. This motivated us to investigate the multiple functions of PDA particles, especially its antioxidant and anti-senescence effect, in cultures of human skin epithelial keratinocytes, HaCaT cells. The PDA particles were synthesized through the self-polymerization of DA in a 50 mM Tris(hydroxymethyl)aminomethane hydrochloride (Tris-HCl) solution at pH 8.8. The PDA particles were filtered through Millipore® Stericup® filter units to control the diameter in the range of 220-450 nm. The uptake of PDA particles by HaCaT cells exhibited a dose-dependent manner in control and PDA groups (0, 10, 20, 30, 40, and 50 μg/ml), while the cell viability was not affected by the PDA uptake as no loss of membrane integrity and inhibition of cell growth were observed. The PDA uptake decreased the oxidative stress provoked by ROS. It also decreased the activity of the senescence-associated β-galactosidase in HaCaT cells by ~10%, where a plateau was reached when the PDA-dosage exceeded 30 μg/ml. Conclusively, these findings demonstrate that PDA particles could effectively decrease the level of cellular senescence, highlighting its potential to be translated into a medicine strategy for preventing skin aging.

7:05 PM SB12.11.04
Late News: (Garcia High School Student) The Effect of Surface Chemistry on Neurogenic Differentiation in Dental Pulp Stem Cells Andrew Yuen[1], Layla Shaffer[2], Leigh Baratta[3], Claire Richter[4], Nikhil Mehta[3], Kathryn Rosshirt[5], Kuan-Che Feng[6], Haijiao Liu[6], Marcia Simon[6] and Miriam Rafailovich[6]; [1]Jericho High School, United States; [2]The Lawrenceville School, United States; [3]Smithtown High School East, United States; [4]South Side High School, United States; [5]University of Notre Dame, United States; [6]Stony Brook University, United States

Neurodegenerative diseases represent a major incapacitating health problem that has been proven to be difficult to treat. If the nervous system is injured, neurons are unable to regenerate efficiently. Importantly, a variety of stem cells have been determined as a possible treatment provided that they can be induced to differentiate along neurogenic lineage. Here we present research on the factors which can determine neurogenic differentiation of Dental Pulp Stem Cells (DPSCs). DPSCs are pluripotent stem cells that have been shown to differentiate in vitro along neurogenic, odontogenic, or adipogenic lineage depending on the media in which they are cultured. We have previously shown that odontogenic differentiation of the DPSC is highly dependent on the properties of the substrate, where both chemistry and mechanics combine to determine the differentiation lineage. Here we present a study aimed at determining the optimal material's scaffold for implementing neurogenic differentiation.
Polymer films were spun cast onto HF etched flat Si wafers from solutions of 3% PVDF with Dimethylformamide (DMF), 20 mg/ml PB with toluene, 7 mg/ml P4VP with DMF, and 30 mg/ml RDP/clay with PLA in Chloroform were spun cast onto cleaved silicon wafers, and annealed at 150C overnight to remove residual solvent and stresses, as well as to sterilize the substrates. The quality of the films, as well as the surface roughness or crystallinity, was assessed using scanning force microscopy in lateral and friction modes. The cells were plated on these substrates, as well as on tissue culture plastic (TCP) in alpha MEM with 10% FBS and 1% pen strep, where they were cultured for three days. Subsequently, this media was replaced with neurobasal media and changed twice a week. The neurobasal A media was composed of 100 μg/mL penicillin, 1X B27 supplement, 100 μg/mL streptomycin, 20 ng/mL epidermal growth factor (EGF), and 40 ng/mL fibroblast growth factor (FGF). We then performed EVOS imaging to acquire cell morphology on day 0, day 7, and day 28. Moreover, the degree of neuronal differentiation was investigated using Real-Time Polymerase Chain Reaction (RT-PCR) on day 0, day 14, day 21, and day 28. The neuro markers are Nestin(early), β-Tubulin-III (intermediate), and NEFM (mature). The AFM film topography images provided a measure of surface roughness and revealed that the surface of P4VP and PB films had a smoother surface while PVDF and RDP/Clay films had rougher surface topographies. The aspect ratio of the cells was quantified on the different substrates at day 28, where it was found that the cells on the RDP clay had the largest value. RT-PCR indicated that the P4VP and RDP/clay with PLA substrate had downregulation of neuro markers Nestin and β-Tubulin-III and upregulation of NEFM which confirmed neurogenic differentiation. Unfortunately, differentiation was poor on the PB and most cells died on the PB+tio2 even though these substrates were shown to be very effective in induction of odontogenic differentiation in osteogenic media. It is interesting to note that the PB substrates had much lower moduli than the PLA/RDP substrate confirming that chemical composition was more important than the mechanical response in neurogenic differentiation. Further work is in progress using electrospun fibers of the same polymer composition to determine the role of substrate morphology.

Digital Light Processing (DLP) Based 3D Printing of Polytetrafluoroethylene (PTFE) Scaffolds for Vascular Applications Hyun Lee and Hyun-do Jung; The Catholic University of Korea, Korea (the Republic of)

As entering ageing society, cardiovascular diseases have become highly increasing treats to human life with their fatality. Several efforts using organism derived grafts (autografts, allografts, and xenografts) have been adopted to replace the malfunctioning vessels. However, the use of abovementioned grafts is challenging due to their limited sources. Thus, numerous researches have been conducted to fabricate artificial vascular grafts with non-cytotoxicity and sufficient mechanical properties to withstand blood pressure. Polymeric matrices consisting of polytetrafluoroethylene (PTFE), polyethylene terephthalate (PET), or polyurethane (PU) have been most widely utilized for vascular grafts because of their biological stability. Especially for PTFE, it has been clinically utilized to substitute vessels or bypass blood flow to healthy tissues. Generally, PTFE vascular grafts have been fabricated in the form of tube and it should be cut to fit into the surgical sites. Therefore, creation of PTFE vascular grafts with patient specific structure has been challenging. As a solution for that, we are aiming to adopt digital light processing (DLP) based 3D printing technique to fabricate artificial PTFE vascular grafts with complicated branched structure. Through incorporating photocrosslinking agents and photoinitiator to sustain structural integrity of PTFE emulsion, channel structures of PTFE were successfully produced. After sequential heat treatment to eliminate supplemented materials and sinter the PTFE particles, PTFE tubes with distinctive mesh structure were obtained. Since the purpose of this research is to apply PTFE tubes to vascular grafts, evaluation of mechanical properties (tensile property, elasticity, and suture retention ability) and biological properties using endothelial cells and fibroblasts was performed.

7:15 PM SB12.11.06
Molecular Origin of the Effect of Mutation on the Structure and Mechanical Properties of Human Epithelial Keratin K5/K14 Chien-Yu Pan and Chia-Ching Chou; National Taiwan University, Taiwan

Epithelial keratin, a type of intermediate filament (IF) protein, is one of the key components in maintaining the stability of the cell nucleus in the epidermis of the skin, the largest organ in the human body. It absorbs water and withstands external pressure, affecting the structural stability and mechanical properties of the skin. Epidermolysis bullosa simplex (EBS) is a rare genetic skin disease related to genetic mutations in epithelial keratin K5/K14. The resulting structural defects can cause keratinocytes in the basal layer to become fragile and rupture when subjected to mechanical stress. Its pathological feature is that the skin and mucous membranes are extremely fragile, and wounds and blisters occur even under slight external force. In this study, we focused on the amino acid sequence of the wild-type human keratin K5/K14 and sequences with point mutations, beginning with a full atomistic model of the K5/K14 heterodimer and proceeding to the higher hierarchical structure of the tetramer model. For the heterodimer, the structures of the wild type and the mutants share a high degree of similarity, and the helical structure is preserved. Then, based on the heterodimer model, we considered the keratin tetramer model with ID-1 contact from previous experimental observations. Our results suggestedthat in the wild-type tetramer, the hydrogen bonds formed in the middle and contact regions provide extra stability to tetramer 2B-2B interactions during IF assembly. The probabilities of hydrogen bond formation are lower in the mutant tetramers than in the wild-type tetramer in the contact region; the point mutations do not necessarily affect the structure for dimer formation, but changes in the interactions of amino acids may affect the higher-order assembly of IFs. We observed that, the structures of the tetramers with point mutations were loosely stacked, and the mechanical properties were weaker than those of the wild-type tetramer. We further compare our results with the latest experimental measurements and discuss the relationship between the genotype of EBS disease and the atomic-level mutated structures. The atomistic model allowed us to study point mutations at the molecular level. The results can be further applied to reveal the effect of point mutations on EBS diseases.

7:20 PM SB12.11.07
Late News: Synthesis and Design of PCL-PLA-HAp and PCL-BG-HAsg 3D-Scaffolds for Bone Tissue Applications Nancy Nelly Zurita Méndez, Georgina Carbajal de la Torre, Marco Antonio Espinosa Medina, María de Lourdes Ballesteros Almanza, Citlali Wendolin Rodríguez Páramo and Javier Ortiz-Ortiz; Universidad Michoacana de San Nicolás de, Mexico

Throughout history, human beings have faced the problems of wear and tear of the tissues that compose them, so the need arises to find an alternative to the regeneration, repair, or replace damaged tissues to continue performing their physiological functions; this has led us to the use of materials to help these procedures through the so-called Tissue Engineering, dedicate to the application of chemical and biological principles in the development of substitutes that restore, maintain or improve the function of living tissues through biomaterials. Currently, the bioglass (BG) and hydroxyapatite (HA) are object of study for their high bioactivity, osteoconductivity, biodegradability and because they possess compositional and structural similarities with bone mineral, nevertheless, these biomaterials are relatively brittle and for diminishing this property, they are embedded into polymers. The use of polylactic acid (PLA) had demonstrated a great potential for load-bearing applications when is used as a polymeric matrix with the HAp particles. On the other hand, polycaprolactone (PCL) has been also extensively applied in regenerative medicine applications, among all desirable properties as biocompatibility and flexibility because of its ester bonds, PCL also had shown that enhance the osteogenic differentiation of mesenchymal stem cells, and the incorporation of HAp particles modify its hydrophobic nature, stimulating the cell interaction. In the present study, the synthesis of BG, PLA, hydroxyapatite by sol-gel method (HAsg), and hydroxyapatite by precipitation method (HAp) were performed. Subsequently, those biomaterials were complemented with polycaprolactone (PCL) to elaborate 3D porous scaffolds by the solvent-casting/salt-leaching technique. The PCL- PLA -HAp and PCL-BG-HAsg scaffolds were designed at two weight proportions each. 1. 40%-10%-50% and 2. 40%-50%-10% respectively. The scaffolds were analyzed by infrared spectroscopy (FTIR), X-ray diffraction (XDR), and scanning electron microscopy (SEM) by observing their composition and morphology, besides, as known; the surface reactions of materials with their biological environment occur a few seconds after they are implanted in the body interacting with proteins present in the physiological environment, in this fact lies the importance of evaluating the in-vitro biological behavior of the biomaterials. Simulated body fluid (SBF) and Hank's saline solution at 37 C are the aqueous media that allow us to get closer to the understanding of the biodegradation and bioactivity mechanism of composite biomaterials since their ionic compositions are very close to those of human plasma.

7:25 PM SB12.11.09
Thermosetting and Mechanical Property of poly(2-methoxyethyl acrylate)-Based Polyurethane Synthesized by RAFT Polymerization and Polyaddition Shunsuke Tazawa[1], Tomoki Maeda[1,2] and Atsushi Hotta[1]; [1]Keio University, Japan; [2]Ibaraki University, Japan

Poly(2-methoxyethyl acrylate) (PMEA) is one of the well-known antithrombogenic materials [1,2]. Because of its low glass transition temperature around -30°C, PMEA is a liquid-like polymer at room temperature and thus its usage is limited to antithrombogenic coating. Therefore, solidifying PMEA is important to enhance its biomedical applications as a bulk material. In this study, thermally stable poly(2-methoxyethyl acrylate)-based polyurethane (thermoset PMEA-based PU), chemically crosslinked by covalent bonds, was synthesized through reversible-addition fragmentation transfer (RAFT) polymerization and polyaddition with diisocyanate.
In detail, to obtain thermoset PMEA-based PU, hydroxyl-terminated PMEA with 4 hydroxyl groups (PMEA-$(OH)_4$) was synthesized by RAFT

polymerization, and PMEA-$(OH)_4$ was then reacted with diisocyanate to form urethane bonding acting as chemical crosslinkings in the material. In fact, PMEA-$(OH)_4$ synthesized by RAFT polymerization was a viscous liquid-like polymer. After the polyaddition using diisocyanate, a solid standing film of thermoset PMEA-based PU was obtained. The existence of urethane bonds was confirmed by FTIR.
Thermal and mechanical properties of thermoset PMEA-based PU were evaluated through dynamic mechanical analysis (DMA) and tensile testing. From the DMA results, it was found that the storage modulus (E') of thermoset PMEA-based PU was higher than the loss modulus (E'') at the temperature range between 25°C and 110°C. According to the results of tensile testing, it was also found that E' was almost constant at ~7.0×10^5 Pa in the same temperature range. The Young's modulus, the fracture strain, and the tensile strength of thermoset PMEA-based PU were calculated as 574±54 kPa, 212±78%, and 581±90 kPa, respectively. It was, therefore, confirmed that the synthesized thermoset PMEA-based PU was a thermally-stable solid material.
Intermediate water is a group of water molecules interacting with PMEA molecules, largely contributing to the high antithrombogenicity of PMEA. Therefore, intermediate water was also analyzed by differential scanning calorimetry (DSC). The DSC curves of the hydrated samples of thermoset PMEA-based PU exhibited cold crystallization around -27°C, deriving from the intermediate water, whereas the DSC curves of dried samples of thermoset PMEA-based PU only showed the glass transition. The ratio of intermediate water to all water in thermoset PMEA-based PU was calculated as 2.1±0.03 wt%, high enough to display antithrombogenicity, considering the ratio of other conventional highly antithrombogenic polymers [3]. It was concluded that the newly synthesized thermoset PMEA-based PU effectively possessed intermediate water for antithrombogenicity.

'Sporulation' Cytoprotective Strategy for Room-Temperature Cell Logistics Lydia Chong[1,2], Derrick Yong[2] and Juha Song[1]; [1]NTU, Singapore; [2]A*STAR, Singapore

Considering the time- and temperature-sensitive nature of cell therapeutic products (CTPs), additional protection is important in cell therapy manufacturing where cells are exposed to harsh environmental stressors (i.e. temperature fluctuation) during logistical activities. As market for these products continue to expand rapidly, it is thus critical to look into improved methods of storing and transporting these products to hospitals while ensuring that their standards (i.e. quality, stability) are strictly met via the use of diagnostic tools. Chemically-induced cell 'sporulation' has been recently demonstrated by our group as a bioinspired cell protection strategy for maintaining cell viability in biofabrication, where cells are exposed to UV irradiation during photocrosslinking process. Tapping on the success of this strategy, we proposed its application as a practical solution for room-temperature shipping and short-term storage of CTPs during cell logistics. Herein, plant seed-inspired 'sporulation' of L929-laden alginate microspheres (AlgMS) were induced through the coating of pyrogallol (PG), a plant-derived polyphenol. Thereafter, both 'sporulated' and non-'sporulated' encapsulated cells were subjected to temperature conditions that the CTPs could potentially be exposed to during 3 days of transportation and/or short-term storage. These conditions include, **(i) ET:** extreme temperature increment as a result of heat accumulation in confined storage spaces (e.g. when transportation vehicles with malfunctioned reefers are parked under the sun for a while) – room temperature throughout with temperature increment from 30 to 50°C over 1h at day 2; **(ii) CT:** cyclic temperature simulation based on real-life temperature profile from cell logistics company when CTPs are transported across countries of different seasons – 30°C (day 1), 17°C (day 2), 27°C (day 3). After which, 'germination'/restoration of cell metabolism was achieved by degrading the microspheres and releasing the cells via mild EDTA treatment. The 'germinated' cells were subsequently re-incubated for 72h before cell viability was assessed with LIVE/DEAD cell assay. Regardless of the temperature conditions, majority of cells released from PG-AlgMS remained viable (> 80%), in contrast with those released from AlgMS (< 30%). This suggested the potential of cell 'sporulation' in enhancing protection of encapsulated cells when temperature fluctuation is involved. As expected, when the two temperature conditions were compared, more cells managed to survive when subjected to CT (~91%) than ET (~80%) condition whereby the cells were exposed to much higher temperatures known to cause irreversible cellular damage. Although the viability of cells released from AlgMS was severely compromised (~10%) for ET, a relatively high cell viability (~72%) is still achievable when exposed to the CT condition. This thus, implied the capability of cell encapsulation alone in providing certain degree of protection that could suffice in less harsh temperature fluctuation conditions. Taking into consideration of unforeseen delays that could happen during cell logistics, longer duration room-temperature cell storage and transportation for up to 10 days was also proven to be possible with this bioinspired cell protection strategy, whereby majority of released cells remained viable (>85%). In conclusion, we have demonstrated the potential of translating 'sporulated' encapsulated cells into a cell storage and handling platform that can maintain the quality of CTPs despite the harsh environment that these temperature-sensitive products could be exposed to during cell logistical activities. We envisage that this cell-encapsulated microsphere platforms have great potential for short-term cell storage, cell-involved biofabrication and cell logistics.

7:35 PM SB12.11.11
Design and Development of Inorganic Nanoparticles for Radioenhancement Therapy Lukas Gerken[1,2], Anna Neuer[1,2], Pascal Gschwend[1], Fabian Starsich[1,2], Alexander Gogos[2], Ludwig Plasswilm[3] and Inge K. Herrmann[1,2]; [1]ETH Zürich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [3]Cantonal Hospital St. Gallen (KSSG), Switzerland

Nanoparticle-based radio-enhancement has the prospect to improve cancer cell eradication by amplifying the damage caused by (X-ray) irradiation through ejection of secondary particles (electrons) leading to further oxidative stress. Gold nanoparticles are a natural choice because of their high atomic number and biological compatibility and are therefore most researched nanoparticles. However, due to the heterogeneous results and the lack in mechanistic understanding, these particle systems have not yet entered clinics. Recently, nanoparticles based on more exotic hafnium dioxide have shown promising results in clinical studies. There is increasing evidence that radio-enhancement efficacy does not solely dependent on high atomic numbers but involves a complex cascade of secondary reactions.
Here, we will present a comprehensive nanoparticle-based radio-enhancement study including a selection of inorganic oxide nanoparticles with comparable morphologies, sizes and surface chemistries. Liquid flame spray pyrolysis as synthesis technique allows effective scale up to meet clinical and industrial demands. We will bridge physical and chemical nanoparticle–radiation interactions with biological radio-enhancement effects in a radio resistant tumor cell line using clinically relevant exposure settings. We also show how the nanoparticles can be tailored to incorporate multimodal imaging possibilities for a theranostic approach. Our comprehensive analysis will pave the way for a more rationalized nanoparticle design and development for nanoparticle-based radio-enhancement studies.

7:40 PM SB12.11.12
Osteogenic Potential of a Hematene Reinforced Monetite Cement for Bone Regeneration Rachel Monk, Daniela Vieira, Geraldine Merle and Edward Harvey; McGill University, Canada

Introduction: Autografts presently remain the gold standard for bone growth and regeneration. Associated complications such as their limited availability, increased surgical time, blood loss, and donor site morbidity has urged the exploration of other alternatives. Particularly, non-resorbable graphene-family

nanomaterials combined with calcium phosphate has generated notable findings. However recently, hematene, a 2D nanomaterial of iron oxide has been discovered with rather extraordinary properties. This novel bioresorbable nanomaterial with its physicochemical, optical, magnetic, electrical, and mechanical properties shows a promising osteogenic potency for bone regeneration. Nevertheless, the bioactive potential of hematene combined with calcium phosphate (ie. monetite) remains to be explored. Here, hematene-monetite nanocomposites were synthesized for the first time and their potentials to stimulate osteogenesis were showcased.

Methods: 2D hematene was synthesized by ultrasonic exfoliation from natural iron hematite (α-Fe_2O_3) and confirmed with bright-field transmission electrical microscope (TEM). Monetite was composed of β-tricalcium phosphate (β-TCP) and monocalcium phosphate monohydrate (MPCM) and subjected to hydrothermal treatment. Monetite implants were decorated with hematene nanocomposites of different concentrations using centrifugal force. The two-dimensional morphology, crystallinity, thermal behaviour, and compressive strength of the scaffolds were confirmed by Scanning electron microscopy (SEM), X-ray diffraction (XRD), Thermogravimetric analysis (TGA), and a high-precision testing system (EZ test), respectively. Cytotoxicity and gene expression profiles of bone specific markers of RUNX2, ALP, BGLAP, and SPARC, were evaluated over 21 days within pre-osteoblastic MC3T3-E1 cells.

Results: TEM imaging confirmed the successful exfoliation of ultrathin mono- and bi-layer hematene sheets with a mean lateral size of 200nm. Nanocomposites at different hematene to monetite ratios were successfully prepared with good thermal stability and decomposition profiles. Physicochemical characterization and SEM imaging confirmed the presence and homogenous distribution of the 2D nanomaterials over the monetite implant without affecting its crystallinity. Furthermore, our findings indicate that the mechanical integrity was significantly enhanced when reinforced with hematene nanocomposites of higher concentrations compared to monetite alone. *In vitro* testing demonstrated that gene expression profiles of alkaline phosphatase (ALP), osteocalcin (BGLAP), osteonectin (SPARC), and RUNX2, were significantly elevated over the 21 days when compared to controls. These findings indicate that osteogenesis of MC3T3-E1 cells was accelerated by the hematene-monetite nanocomposites with and without osteoinductive agents.

Conclusions: For the first time, we showcase the osteogenic potency of hematene-monetite nanocomposites and the abilities to enhance cell proliferation and osteogenic differentiation in pre-osteoblastic MC3T3-E1 cells. We demonstrate the simplicity of obtaining ultrathin 2D hematene sheets through ultrasonic exfoliation to decorate monetite implants without affecting crystallinity or thermal stability within or between treatment conditions. Assuring both properties remain unaffected is of special importance to maintain implant consistency, as variations can vastly contribute to differences in physiochemical properties. Excitingly, these preliminary in vitro results suggest that hematene derivatives could be the next big candidate as a scaffold for bone tissue regeneration. Furthermore, the highly unique thermal behaviour of hematene derivatives prompts its potential to open further avenues for therapeutic agents. Future works include the study of this osteoinductive potential on a stem cell culture model, and potentially corroborate those results by an animal study.

7:45 PM SB12.11.14

Long-Term *In Vitro* Degradation Kinetics of Novel Drug-Loaded poly(ε-caprolactone) Implants for Contraception and HIV Pre-Exposure Prophylaxis Archana Krovi[1], Christine Areson[1], Guadalupe Arce Jimenez[1], Pafio Johnson[1], Chasity Norton[1], Zach Demkovich[1], Ellen Luecke[1], Linying Li[1], Daniela Cruz[1], Ariane van der Straten[2,3] and Leah Johnson[1]; [1]RTI International, United States; [2]Center for AIDS Prevention Studies, United States; [3]ASTRA Consulting, United States

Introduction: Most subdermal implants for long-acting (LA) drug delivery for contraception and HIV pre-exposure prophylaxis (PrEP) comprise non-biodegradable materials. The development of new biodegradable subdermal implants can advantageously eliminate the requirement of a second medical procedure to remove the devices at the end of use when drugs are depleted. One slowly degrading polymer, poly(ε-caprolactone) (PCL), is established as a prominent and suitable material for various biomedical applications. While the general mechanism of PCL degradation is understood and documented, we uniquely explore the biodegradation profiles of PCL in novel LA reservoir-biomedical implants for contraception and HIV PrEP, showing the influence of excipients and drug formulations on polymer degradation kinetics.
Methods: Different molecular weights of medical-grade PCL (PC-12 M_n 35 kDa, PC-17 M_n 55 kDa) were extruded into cylindrical tubes with an outer diameter of 2.5 mm and wall thicknesses of 70, 100 or 200 µm. Implants were prepared by loading excipients (castor oil, sesame oil) or drug-excipient formulations (contraceptive hormones or antiretrovirals) into an extruded tube and then enclosing the tubes via heat sealing. Unsealed empty tubes, excipient- and formulation-filled implants were sterilized via gamma irradiation at 18-24 kGy. Implants were submerged in phosphate buffered saline (PBS, pH 7.4) at 37 °C to mimic physiological conditions. Polymer properties were analyzed each month via gel permeation chromatography (GPC) and differential scanning calorimetry (DSC). In vitro exposure conditions were also varied to accelerate polymer degradation.
Results: Overall, the degradation rates were faster for PCL with a higher starting molecular weight (MW) (5 kDa/month), as compared to PCL of a lower initial MW (1.5 kDa/month). The presence of an excipient affected the rate of degradation; implants containing castor oil degraded slower than implants containing sesame oil. Implants with thinner walls were more susceptible to larger changes in MW when filled with sesame oil. Implants containing drug formulations degraded at similar rates, but underwent faster degradation than implants filled with excipient alone. Additionally, when the drug was formulated with sesame oil as opposed to castor oil, the polymer degradation rate was faster. For the same MW PCL, the degradation rates of empty tubes were independent of the wall thickness. Implants subjected to accelerated conditions yielded faster degradation kinetics. For instance, PCL MW at the 3-month timepoint under accelerated conditions was comparable to the PCL MW achieved at the 1-year timepoint under simulated physiological conditions. The development of this accelerated model can support rapid screening of degradation profiles for the new polymers.
Conclusions/Implications: In this long-term study, we explored novel biodegradable implants designed for contraception and HIV PrEP that comprise extruded tubes of medical grade PCL filled with relevant drugs. We studied the influence of excipients and drug formulations on the polymer degradation rate, in real time and under accelerated conditions. Next steps include evaluating the biodegradation profiles of the implants in preclinical studies and correlating the in vitro-in vivo degradation kinetics. An in-depth understanding of the degradation characteristics of this polymer platform will enable new implant designs for varied medical indications that might require tailored degradation timeframes.

7:48 PM SB12.11.15

Late News: The Effects of Hypochlorous Acid on Dental Pulp Stem Cells Shi Fu[1], Mira Rosovsky[2], Sabreen Alam[3], Elizabeth Wang[4], Daniel Xie[5], Prabuddha G. Dastidar[6], Marcia Simon[1] and Miriam Rafailovich[1]; [1]Stony Brook Unversity, United States; [2]SAR High School, United States; [3]Portola High School, United States; [4]BASIS Chandler, United States; [5]Panther Creek High School, United States; [6]North Carolina School of Science and Mathematics, United States

The objective of this study is to investigate the effect of hypochlorous acid (HOCl) on dental pulp stem cells (DPSCs). Analyzing the cytotoxicity of hypochlorous acid contributes important information on the safety and effectiveness of using this compound in root canal irrigation. In addition, examining

the migration and differentiation of dental pulp stem cells in response to hypochlorous acid can provide insight into whether the solution will stimulate mineralization if leakage occurs on live cells around the root.
HOCl was mixed with carbon dioxide enriched DPSCs growth medium to make the HOCl solution in the certain concentrations. The HOCl solution were then applied to DPSCs in the incubator for 5 minutes. The viability test result shows that DPSCs cannot survive in the HOCl solutions with the concentration greater than 30%. Proliferation assay was made in 3 different concentration sets: 10%, 20% and 30% respectively. The readout indicates that all 3 concentration groups showed no significant difference in proliferation rate compare to the control group. To analyze genetic expression of the cell abnormalities after HOCl treatment, a 28-day reverse transcription polymerase chain reaction (RT-PCR) test was performed for the 3 concentrations groups as well as the control group. The cells were lysed and RNA were taken on day-0, day-14, day-21 and day-28.
Future directions would include additional trials of the different concentrations of HOCl on DPSCs migration, observing the effects of HOCl on scaffolds with DPSCs and relevant growth factors, and analyzing the long-term effects of HOCl compared to alternative root canal irrigation solutions on differentiation and dentine-pulp complex regeneration.

7:51 PM *SB12.11.16
Genes that Escape X-Chromosome Inactivation Modulate Sex Differences in Valve Myofibroblasts Brian Aguado; University of California, San Diego, United States

Introduction: Patients with aortic valve stenosis (AVS) can have fibrosis and/or calcification in valve tissue, which leads to heart failure if left untreated. Emerging clinical evidence suggests aortic valve stenosis (AVS) is a sexually dimorphic disease. Characterization of valve tissue from male and female AVS patients reveals that the aortic valve fibrosis to calcification ratio is significantly higher in women relative to men. Surgical valve replacements remain the gold standard of treatment, yet patients experience various post-surgical complications. Non-surgical approaches would be desirable, but no known biomolecular treatment exists to slow or halt progression of AVS in patients of either sex. Here, we developed an *in vitro* hydrogel culture platform for culture of male and female valvular interstitial cells (VICs) and characterized the sex-specific effects of microenvironmental cues on myofibroblast activation.
Materials and Methods: VICs were isolated from porcine aortic valves and seeded on soft RGD-functionalized PEG hydrogels (elastic modulus, E ~ 6 kPa) known to maintain the quiescent VIC phenotype and stiff hydrogels (E ~ 41 kPa) known to activate VICs to a myofibroblast state. Male and female VICs were cultured separately and seeded on hydrogels for 3 days. VICs were immuno-stained for the myofibroblast marker alpha smooth muscle actin (α-SMA) and imaged to quantify the percentage of cells with a-SMA stress fibers. Myofibroblast transcriptomes were analyzed using the HISAT2-Rsubread-EdgeR differential gene expression pipeline, and pathway enrichment analysis was performed in Ingenuity Pathway Analysis (IPA).
Results and Discussion: Our data suggest male and female VICs exhibit sex-specific myofibroblast responses to hydrogel substrates at day 3 in culture. We consistently observed female VICs to have elevated myofibroblast activation on soft gels that mimics the stiffness of healthy valves (E ~ 6 kPa) and stiff gels that recapitulate fibrotic valve stiffness (E ~ 40 kPa). Our transcriptomic data suggest hundreds of sex-specific gene expression differences between male and female myofibroblasts, and we identified the RhoA/ROCK signaling pathway to have increased activity in female VICs using IPA. Indeed, *in vitro* validations revealed female VICs to be less sensitive to RhoA/ROCK inhibition relative to male VICs on stiff hydrogels. Recognizing that sex-dependent variability in cellular phenotypes is attributed to the 15-25% of genes that escape X-chromosome inactivation (XCI) in women, we also found 28 genes differentially expressed in female myofibroblasts that are also known to escape X-chromosome inactivation. Two of these genes, *BMX* and *STS*, which encode for the BMX non-receptor tyrosine kinase and steroid sulfatase and necessary for cardiac hypertrophy and integrin expression, were validated as key genes that regulate RhoA/ROCK activity in female VICs. Using ibrutinib and irosustat to inhibit *BMX* and *STS*, respectively, we observed increased female VIC deactivation in response to RhoA/ROCK inhibition. Collectively, we suggest genes that escape X-chromosome inactivation uniquely regulate myofibroblast activation processes in female myofibroblasts.
Conclusions: Our data support the importance of (1) sex-separating cells and (2) engineering the appropriate culture microenvironment to understand how male and female cells interpret microenvironmental cues. We suggest female VICs are more susceptible to myofibroblast activation due to increased expression of key XCI genes, which may contribute to increased fibrosis found in valve leaflets from female AVS patients. We envision future *in vitro* disease models to appreciate the potent effects of cell sex, which may impact how diseases are understood and treated as a function of sex.

The Versatility of CVD to Synthesize 1D and 2D Nanostructures—Carbon Nanotubes and Transition Metal Chalcogenides for Electronic and Electrochemical Applications Gilbert D. Nessim; Bar Ilan University, Israel

1D Nanosynthesis
Despite the massive progress achieved in the growth of carbon nanotube (CNT) forests on substrate, apart from lithographic patterning of the catalyst, little has been done to selectively (locally) control CNT height. Varying process parameters, gases, catalysts, or underlayer materials uniformly affects CNT height over the whole substrate surface. We show here how we can locally control CNT height, from no CNTs to up to 4X the nominal CNT height from iron catalyst on alumina underlayer by patterning reservoirs or by using overlayers during annealing or growth.
We show how we can lithographically pattern the reservoir material and obtain four different CNT heights during a unique growth process: no growth (Cu/Ag reservoir), nominal growth (no reservoir), 2X growth (Fe reservoir), and 4X growth (Mo reservoir).
Using a complementary technique, we show how a copper or nickel overlayer (stencil or bridge) placed above the catalyst surface during pre-annealing or during CNT growth deactivates the catalyst. We showed how we could pattern regions with CNTs and without CNTs by simply annealing the sample with a patterned overlayer positioned above its surface. We thus synthesized patterned CNT forests using a simple process, without the need for lithography.
We can combine the overlayer technique with one of the above-mentioned reservoirs (no reservoir, Cu/Ag reservoir, Fe reservoir, or Mo reservoir) to further modulate CNT growth by offsetting some or all of the growth enhancements achieved using the reservoirs. This modulation of the CNT height is a significant improvement compared to the "CNTs (one height) / no CNTs" patterning that has been achieved using lithography of the catalyst, and moves us closer to building 3D architectures of CNTs that could be useful for future electronic devices or sensors.

2D Nanosynthesis
Since the excitement about graphene, a monolayer of graphite, with its 2010 Nobel Prize, there has been extensive research in the synthesis of other non-carbon few/mono-layers exhibiting a variety of bandgaps and semiconducting properties (e.g., n or p type). The main approaches to deposit few/monolayers on a substrate are: (a) bottom-up synthesis from precursors using chemical vapor deposition (CVD) or (b) top-down exfoliation (liquid or mechanical) of bulk layered material. Using a Lego approach of superposing monolayers, we can envisage the fabrication of heterojunctions with original electronic behavior.
Here we show a combined bottom-up and top-down approach where (a) we synthesize in one step high yields of bulk layered materials by annealing a metal in the presence of a gas precursor (sulfur, phosphorous, or selenium) using chemical vapor deposition (CVD) and (b) we exfoliate and deposited few/mono-layers on a substrate from a sonicated mixture of our material in a specific solvent. It is interesting to note that, besides the structure being 2D layered, the properties of the nanomaterials synthesized slightly differ from the materials with the same stoichiometry synthesized using conventional chemical methods (e.g., solvothermal).
In this talk, we will discuss the chemical synthesis, the very extensive characterizations, and the lessons we learned in making multiple metal sulfides (Cu-S, Ag-S, Ni-S), metal phosphides (Ni-P, Cu-P), and metal selenides (Ag-Se, Cu-Se, W-Se, Mo-Se). We will see how we integrated these new materials into electrochemical devices and sensors.

11:00 AM SF01.01.02
Fluid Guided Chemical Vapor Deposition of Large-Scale Monolayer Two-Dimensional Materials Bo Li, Qianhong Wu, Dong Zhou and Ji Lang; Villanova University, United States

Chemical vapor deposition (CVD) has been used extensively for synthesizing two-dimensional (2D) materials. Among various CVD methods, atmosphere pressure CVD is of great interest due to its low cost and promise for high-quality monolayer 2D materials. Despite extensive efforts, the understanding of the reaction mechanism and the key controlling parameters is still in its embryonic stage. Hence, it is extremely challenging to achieve large-scale continuous films. Here, we present a fluid-guided growth strategy and use $MoSe_2$ as a model system for understanding and controlling the growth of 2D materials. We have integrated experiment and computational fluid dynamics (CFD) analysis in the full-reactor scale. We have identified three key parameters in obtaining large-scale continuous film: good precursor mixing, low fluid velocity, and low shear rate near the substrate. Following these principles, we modified the geometry of the growth setup and successfully obtained inch-scale monolayer $MoSe_2$. This unprecedented integration of fluid design and simulation lays the foundation for designing new CVD systems to synthesize 2D materials and other thin-film nanomaterials.

11:15 AM SF01.01.03
Polymer Compatible Low Temperature Plasma-Enhanced Chemical Vapor Deposition of Graphene on Electroplated Cu for Flexible Hybrid Electronics Chen-Hsuan Lu[1], Chyi-Ming Leu[2] and Nai-Chang Yeh[1]; [1]California Institute of Technology, United States; [2]Industrial Technology Research Institute, Taiwan

Flexible Hybrid Electronics (FHE) and the Fan-Out redistribution layer (RDL) rely on electroplated Cu. In this work, we demonstrate direct low-temperature (~ 100 °C) plasma enhanced chemical vapor deposition (PECVD) of graphene on electroplated Cu over polyimide substrate, which passivates and strengthens the electroplated Cu circuit on polyimide. We investigate the effect of the H_2/CH_4 ratio on PECVD graphene growth and find that not only the quality of graphene but also the durability of Cu are affected. Folding for 100,000 cycles with a bending radius of 2.5 mm and the corresponding resistance tests show that the Cu circuit when covered with graphene grown with higher H_2/CH_4 ratios could sustain many more bending cycles. In addition, we find that graphene coverage could suppress the formation of Cu oxide under ambient environment for at least 8 weeks after the PECVD process.

Evolution of the Graphene-Metal Interface During Chemical Vapor Deposition Mitisha Surana[1], Ganesh Ananthakrishnan[1], Matt Poss[1], Jad Yaacoub[1], Tusher Ahmed[1], Nikhil Chandra Admal[1], Pascal Pochet[2], Harley Johnson[1] and Sameh Tawfick[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]Université Grenoble Alpes, France

Chemical vapor deposition (CVD) is the most widely used process to synthesize graphene for device applications. In this process, the interaction between graphene and the metal catalyst plays a critical role in the properties and quality of graphene, producing strains, wrinkles, moiré patterns, and in some cases an electronic bandgap in graphene. A very robust and repeatable phenomenon observed after graphene CVD is the modification of the substrate's surface topography. Orientation-dependent large, faceted morphologies have been observed under graphene on all metal substrates. These facets grow by step-

bunching and have a typical size of 50-100 nm. Previous studies are limited to a qualitative description of step bunching, and model the phenomenon as a bending energy-driven process. In this presentation, we present an approach to quantitatively characterize and analyze the facets' orientation. We use electron backscatter diffraction (EBSD) in conjunction with atomic force microscopy to calculate the crystallographic orientation of facets that have step-like and pyramid-like topologies. We will present new approaches to visualize the crystallographic evolution of these steps using inverse pole figures (IPF). We carry statistical analysis on the observed step sizes and orientations on various catalyst grain orientations. We correlate the geometrical facet characterization method to measurements made by Transmission Electron Microscopy. Our studies reveal that the step-like facets comprise a high-symmetry low-index surface on one side and a vicinal surface on the other side, showing that system energy minimization is not the only driving force of the phenomena. We believe that faceting occurs as a result of a trade-off between the diffusion kinetics and the interfacial energy of the complete system which includes van der Waal's interaction, the thermal strains in addition to the bending energy of graphene. MD simulations also show suppression of the substrate's melting under graphene, which we believe plays a role in the kinetics of the faceting process. Our studies provide insights into metal-graphene interfaces that will enable us to better control graphene during synthesis.

SESSION SF01.02: Modeling and Novel Precursors, Mechanisms

1:30 PM SF01.02.01
Applications of a Combined Approach of Kinetic Monte Carlo Simulations and Machine Learning to Model Atomic Layer Deposition (ALD) of Metal Oxides Emily Justus[1], David Magness[1], Bikash Timalsina[1], Judy Z. Wu[2] and Ridwan Sakidja[1]; [1]Missouri State University, United States; [2]The University of Kansas, United States

Metal-oxides such as ZnO or Al_2O_3 synthesized through Atomic Layer Deposition (ALD) have been of great research interests as the candidate materials for ultra-thin tunnel barrier layers is. In this study, we have applied a 3D on-lattice Kinetic Monte Carlo (kMC) code developed by Timo Weckman's group to simulate the growth mechanisms of the tunnel barrier layer and to evaluate the role of various experimentally relevant factors of the ALD processes. We have systematically studied the effect of a wide range of ALD parameters such as the chamber pressure and temperature, pulse/purge times, as well as the coverage of wetting layers on the substrate. The database generated from the kMC simulations was subsequently used as descriptors in the subsequent analyses via Machine Learning (ML) algorithms to gain more insights into the dynamics of the deposition processes. The results of a combined approach of kMC and ML were then compared to the experimental results. The support from NSF (EPMD Division) Award No. 1809284 is gratefully acknowledged. We also thanks to NERSC for the computational support.

1:45 PM SF01.02.02
Modeling Atomic Layer Deposition of Alumina as an Ultra-Thin Tunnel Barrier Using Reactive Molecular Dynamics Devon T. Romine[1], Yuxuan Lu[1], Judy Z. Wu[2] and Ridwan Sakidja[1]; [1]Missouri State University, United States; [2]University of Kansas, United States

In this study, we have utilized the reactive molecular dynamics (MD) simulations to model the Atomic Layer Deposition (ALD) process that forms an ultra-thin film of a tunnel barrier made of amorphous alumina. We chose the reactive MD approach over the ab-initio molecular dynamics simulation used in previous studies due to its lower computational cost, its ability to model over a relatively longer simulation period and its capability to assess atomistic-based dynamics for a larger substrate. To further refine and parameterize the existing ReaxFF potentials, we used the Density Functional based Tight Binding (DFTB) -based in conjunction with the Python toolkit as implemented in the Amsterdam Modeling Suite (AMS) program package. The additional training sets were made from evaluations of the potential energy surface (PES) scans of various ALD-relevant species including H_2O, OH, and the ALD precursors trimethylaluminum (TMA) and Bis(20ethyl-1,3-cyclopentadien-1-yl) magnesium ($C_{14}H_{18}Mg$), as well as the bond-dissociation energies during the reactions that occur when they interact. We systematically evaluated the role of the various ALD precursors including the TMA and $C_{14}H_{18}Mg$ and the water pulse toward the chemical reactions that take place on the surface during ALD. We additionally evaluated the role of experimentally- observable parameters including the operating temperature and precursor concentrations for the internal structure of the amorphous alumina/magnesium as the final deposition products. Lastly, we assessed the role of wetting layers as the means to improve the quality and performance of the tunnel barrier. The support of NSF (Grant No. 1809284) from the Electronics, Photonics and Magnetic Devices (EPMD) Program is gratefully acknowledged. We also thanks to NERSC for the computational support.

2:00 PM SF01.02.03
Thermal Decomposition of Titanium(IV) Isopropoxide Studied by Reactive Force-Field Molecular Dynamic Simulations Benazir Fazlioglu Yalcin, Dundar E. Yilmaz, Adri van Duin and Roman Engel-Herbert; The Pennsylvania State University, United States

The thermal decomposition process of metalorganic precursors, which are frequently used in various thin film deposition techniques, can have a governing effect on the overall growth and reaction kinetics of the thin film deposition methods employed. Particularly in cases of more complex thin-film synthesis schemes, such as combinatorial approaches employing molecular beam epitaxy and chemical vapor deposition, or for the deposition of films with multi-elemental composition, such as ternary and quaternary complex oxide thin films with perovskite structure, a quantitative understanding of reaction pathways, activation energies, and by-product formation at the atomic scale are becoming key towards an improved understanding of the reaction kinetics, as well as providing insights towards tailoring ligand chemistry of the metalorganic precursor employed.
A recently proposed thin film growth technique, dubbed hybrid molecular beam epitaxy,[1] has shown dramatic improvement in the film quality of complex perovskite oxide films in general and $SrTiO_3$ in particular, attributed to the accessibility of a self-regulated growth mechanism enabled by the volatility and decomposition characteristics of metalorganic precursors involved in the growth. Despite remarkable advancements in material quality, no clear understanding of the underlying atomic-scale growth mechanism has been achieved. For the particular case of $SrTiO_3$, where Sr is supplied by a thermal effusion cell and Ti using the metalorganic precursor titanium tetraisopropoxide ($Ti(OiPr)_4$, TTIP), the relatively complex thermal decomposition process of TTIP has thus far prevented a detailed understanding of the growth kinetics at play.
In this talk, we will discuss the first steps towards resolving the mystery of the hybrid MBE growth process by studying the thermal decomposition of TTIP using reactive force field molecular dynamics (ReaxFF-MD) simulations.[2] We find that the total thermal decomposition takes place via multiple steps and is typically initiated by bond breaking between C-O bonds rather than Ti-O bonds without additional hydrogen abstraction, followed by multiple ligand bond breaking steps, all with hydrogen abstraction. Metadynamics simulations were in excellent agreement with the ReaxFF-MD, revealing that the energy barriers to break Ti-O bonds (237-451 kcal/mol) were 4-5 times higher compared to breaking C-O bonds instead (53-119 kcal/mol). Nevertheless, ligand bond breaking subsequent to the first C-O bond breakage can also involve Ti-O bonds, which is attributed to the over coordination of Ti with oxygen.

Performing the ReaxFF-MD simulation in the presence of TiO_2 and SrO terminated $SrTiO_3$(001) surfaces revealed that the particular surface chemistry of $SrTiO_3$ growth front dramatically affected the initialization of the TTIP decomposition process. While the metalorganic was found to be rather stable with a pronounced tendency to thermally desorb from TiO_2 terminated $SrTiO_3$(001) surfaces, its decomposition on SrO terminated surfaces was much pronounced, providing first insights into the intricacies of the hybrid MBE growth process.

2:15 PM SF01.02.04
Plasma-Enhanced Atomic Layer Deposition of Titanium Nitride—Impact of the N-Reactant on the Growth, Conformality and Quality of the Film Badie Clemence[1], Maissa Barr[2], Julien Bachmann[2,3], Thomas Defforge[4], Gael Gautier[4], Héloise Tissot[1] and Lionel Santinacci[1]; [1]Aix-Marseille Université, France; [2]Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany; [3]Saint-Petersburg State University, Russian Federation; [4]Tours Université, France

Titanium nitride thin films can be fabricated by both thermal and Plasma-Enhanced Atomic Layer Deposition (ALD and PE-ALD, respectively). The prevalent precursor couple is TDMAT as Ti-source and NH_3 as co-reactant. This combination is suitable for both routes. Nevertheless, PE-ALD recipes found in the literature exhibit a slower growth rate compared to thermal ALD (see e.g. Ref [1]). This can be disadvantageous for industrial development. However, in addition to NH_3, PE-ALD offers a larger palette of nitriding agent such as N_2, H_2 and N_2/H_2. This work compares therefore the PE-ALD of TiN using NH_3 and N_2, both combined with Ar, to evidence their influence on the final film properties and to maximize the growth rate. Parameters impacting the growth are monitored by in situ characterizations (ellipsometry, OES) while ex situ techniques (TEM/SEM/AFM, XPS, XRD, 4-probes measurements) are used to assess the morphology, the composition, the crystalline structure and the electric properties of the films. A similar approach is applied to the thermal route taken as reference.
To optimize the initial PE-ALD recipe, a set of parameters are investigated: the pulse and purge durations as well as the dilution of the N-sources within Ar and the plasma power. Those parameters are adapted to limit recombination reactions of the generated reactive species between the remote plasma source and the substrate. A large Ar dilution of both N_2 and NH_3 limits the film growth, while a 1:1 gas ratio for N-source and Ar leads to the optimal values. The pulse duration is set at 2 and 5 s for NH_3- and N_2-based plasmas, respectively. The purge duration is also optimized to shorten the ALD cycle duration. The applied plasma power (from 50 to 300 W) has no significant impact on the growth per cycle (GPC) with NH_3 while, using N_2, the GPC is maximum at the highest power. This is consistent with the expected low reactivity of N_2 (inert without plasma activation) regarding to highly reactive NH_3. These measurements are correlated to the plasma signals observed by OES. This indicates that producing less active species enhances their transport by limiting their recombinations. The films grown from both N-sources have a similar roughness, composition and morphology. However, the conductivity and the GPC are superiors using NH_3-based plasma. In addition, this process exhibits a remarkable conformality on high aspect ratio Si substrate for a PE-ALD route. The N_2 plasma process presents an acceptable film quality, it can be considered as well since it is more affordable, and it uses a non-harmful gas.

Growth of SiO_2 by SMFD-ALD and Its Application in Thin-Film Capacitor Mahesh Nepal, Wendifer R. Ramos and Tara P. Dhakal; Binghamton University, United States

We report uniform film growth of SiO_2 on a large surface area (8-inch wafer) using synchronous modulated flow draw ALD (SMFD-ALD) technique. This technique allows greater precursor utilization and shorter deposition cycles time by modulating a pressure gradient between the reaction space and the pumping system. SiO_2 thin films are grown using BDEAS, ozone, and MMH precursors, wherein MMH acts as a catalyst. The use of catalyst is very important in SiO_2 film growth because without catalyst, surface reactions are generally very slow and occur at exceptionally high temperature. This SiO_2 film will be used as a capping layer in Al_2O_3/TiO_2 based nanolaminate capacitors to reduce the leakage current thereby improving working potential. We have already been able to fabricate capacitors with multi-stacked Al_2O_3/TiO_2 nanolaminate (~150 nm) with 4 nm of Al_2O_3 capping layer deposited by SMFD-ALD technology on both rigid and flexible substrates. The stacking of thin layers of these oxides results in a dielectric constant value that is one or two orders of magnitude higher than the individual oxides used due to a process known as Maxwell Wagner relaxation. On a planar substrate, these capacitors have the specific capacitance of ~1.6 /cm^2 and breakdown voltage of 3 V (~2 x10^5 V/cm) with 10 leakage current. To lower the leakage and increase the breakdown voltage, SiO_2 will be employed as a capping layer and new capacitors will be fabricated on both planar and nano-structured high surface area electrodes, and the results will be presented. Since ALD technique is proved to produce uniform and conformal coating on high aspect ratio structures, it allows us to coat these dielectric nanolaminates in high surface area electrodes to further increase the energy density. As we have a well-established process for ZnO nanorods growth, nanostructured capacitors will be fabricated by coating $Al_2O_3/TiO_2/SiO_2$ nanolaminate on ZnO nanorods.

SF01.03.02
Correlation Between Plasma Etching Behavior of Silicon Carbide and Micropipe Defects Je Hoon Oh, Jongbeom Kim, Je Jun Jeong and Kyu Hwan Oh; Seoul National University, Korea (the Republic of)

Silicon carbide (SiC) is a remarkable semiconductor material for high-temperature and high-voltage applications. It is also used as a material for a focus ring in etching process of silicon wafers, due to its high plasma resistance. SiC is commonly fabricated via chemical vapor deposition (CVD) or physical vapor transport (PVT) methods, and CVD-SiC is widely used as a material for the focus ring to protect the electrostatic chuck and create a uniform plasma condition during the plasma etching process of a silicon wafer. It is well known that a defect typically found in SiC known as a micropipe degrades the material's quality. A micropipe density is an important characteristic in SiC quality through SiC development due to the problem of reduced electron mobility.

Currently, CVD-SiC is widely used because it is favorable for manufacturing SiC with a low micropipe density. However, CVD-SiC has an issue in that the unit cost is high. PVT-SiC, on the other hand, offers the advantage of a cheap production cost despite the difficulty of reducing micropipe density. While it has been reported that micropipes reduce electron mobility in SiC, no specific influence on plasma resistivity has been identified.
In this study, we investigated the etching rate of CVD-SiC with small grain size and PVT-SiC with large grain size when SiC crystals grown by PVT and CVD methods are etched by reactive ion etching (RIE) under severe etching circumstances. In addition, we compared the etching behavior of micropipes and other sections.

As a result, the etching behavior in the micropipe was revealed to differ from that at the grain boundary. CVD-SiC with a small grain size has a problem in that SiC particles are peeled off grain by grain during the etching process, affecting the Si wafer quality. In the case of PVT SiC, however, the etching resistance was found to be higher due to lower grain boundary density. We also observed that, despite its relatively high micropipe density, PVT-SiC could be used as a focus ring material due to its high plasma resistance. The lower unit cost of the SiC focus ring, which is required as a consumable in the semiconductor process, is expected to increase production efficiency.

Topologically Controlled Surfaces via Chemical Vapor Deposition Polymerization Joerg Lahann; University of Michigan, United States

There is a broad and increasing interest in chemically controlled surfaces. Potential applications span from biotechnological and medical to antifouling and adhesive coatings. Chemical vapor deposition (CVD) polymerization of substituted [2.2]paracyclophanes is a versatile method that can result in a wide spectrum of functionalized surface coatings [1-3]. Emerging research involves the design of topologically controlled surfaces using templated CVD polymerization. Controlled deposition into thin liquid crystalline films resulted in supported polymer nanofiber arrays where intrinsic properties of the LC phase dictate the lengths, shapes and diameters of the nanofibers [3]. Building upon these earlier efforts, we explored the LC-templated CVD polymerization of chiral [2.2]paracyclophanes for the synthesis of nanohelices with superhierarchical chirality. Intrinsic properties of the precursors such as the side group chemistry and enantiomeric excess critically influence the properties of the resulting enatiomorphic polymer coatings. A more detailed understanding of the underlying mechanisms contributing to the chirality transfer from molecular to meso- and macroscopic scales is emerging and will inform the controlled synthesis of chiral interfaces for biomedical, optical and electronic properties.

11:00 AM SF01.04.03
***In Situ* Synthesis of Ni_3S_2 Nanowires Filled Carbon Nanotubes and Study of Their Electrical Properties** Yuba R. Poudel and Wenzhi Li; Florida International University, United States

Filled carbon nanotubes (CNTs) possess unique physical properties which arise because of the combined effects of the host CNTs and the guest fillers. Until now, many inorganic and organic materials have been successfully encapsulated inside CNTs, however, there is still a lack of a reliable method to achieve a complete filling of CNT cores with transition metal sulfide nanowires. Unlike the conventional ex-situ filling techniques which primarily lead to a partial filling, an in-situ filling method can be used to achieve a continuous and complete filling of the CNT channels. We have developed for the first time, a simple and reliable in-situ method to synthesize the Ni_3S_2 nanowires filled CNTs (Ni_3S_2@CNTs) directly on different substrates such as silicon, nickel foam, and carbon cloth using nickel salt or nickel nanoparticles as the catalyst precursor in a chemical vapor deposition system. The samples have been characterized using SEM, TEM, EDX, Raman spectroscopy, XRD, UV-Vis, TGA, and FTIR. The electron microscopy results show a linear and a tapering structure of Ni_3S_2@CNT completely filled with a continuous and single-crystalline Ni_3S_2 nanowire up to several micrometers in length whereas the Raman spectroscopy indicates a highly graphitized multi-walled CNT system (I_D/I_G= 0.26). The intrinsic I-V characteristics of individual Ni_3S_2@CNTs were studied using both two probe and four-point probe methods which reveal the metallic properties of Ni_3S_2@CNTs with a mean resistivity of 6.1×10^{-5} Ωm. Also, it was observed that an individual Ni_3S_2@CNT having a small diameter (below 150 nm) can undergo an electrical breakdown at a higher current causing the encapsulated Ni_3S_2 nanowire to extrude out from the breakdown region whereas the Ni_3S_2@CNT with a bigger diameter can be emptied by pushing out the Ni_3S_2 nanowire along the direction of the current. Given the high quality and metallic behavior of Ni_3S_2@CNTs, they can find potential applications in future nanoelectronics devices and systems.
This work is supported by the National Science Foundation under Grant DMR- 1506640.

11:15 AM SF01.04.04
Halogenated Polymer Thin Film with Ultra-High Refractive Index Ni Huo; University of Rochester, United States

High refractive index polymers (HRIP) are an incredibly important class of materials given their potential applications in optoelectronic devices, such as anti-reflective components for displays, encapsulants for light-emitting diodes, and optical sensors. Because typical commodity polymers possess refractive indexes (RI) in the range 1.3 – 1.7, obtaining polymers with RI greater than 1.8 while maintaining high optical transparency is an important challenge. Halogen atoms such as chlorine, bromine, and iodine have high atomic refractivity ranging from 5.97 to 13.90, making them useful components in the development of HRIPs.
In this work, a series of halogenated polymer thin films with high refractive indexes (n =1.7 - 2.0) and outstanding optical transparency in the visible range, were prepared via a unique vapor phase process – initiated chemical vapor deposition (iCVD). iCVD is a versatile technique that has been used to fabricate a wide range of polymer coatings for many applications. In this study, poly(4-vinylpyridine) (P4VP) films with thickness ranging from 100nm to 600nm were prepared using iCVD, then treated by halogen vapor to form halogen-containing polymer thin films with high RI. The charge-transfer complex (CTC)

formed between P4VP and halogen compounds, prepared by a simple vapor phase infiltration of halogen compounds, increases the RI of the P4VP thin film from 1.58 to 2.0 or higher, while maintaining the conformal and smooth nature of as-deposited thin films. Specifically, the P4VP-I_2 complex is demonstrated to have an RI of 2.0 and is transparent above a wavelength of 600nm. In another formulation, P4VP complexed with ICl achieved an RI up to 1.77, while still retaining the outstanding optical transparency throughout visible range. The RI of the halogenated polymer films can be further fine-tuned by controlling the concentration of CTC in the polymer film via copolymerization with other monomers that are inert to halogen compounds. In this work, a series P4VP thin films copolymerized with ethylene glycol dimethacrylate (EGDMA) with RI ranging from 1.50 to 1.98 were prepared.
The formation of charge-transfer complex (CTC) in halogenated polymer thin film was confirmed via both Fourier-transform infrared and UV-Vis spectroscopies. The optical performance of these coatings was characterized by spectroscopic ellipsometer and specular reflectometry. The thermal resistance and environmental stability of these films were also investigated as a function of temperature. The refractive index (RI) of P4VP-I_2 film decreased by 7.9% after 24 hours at 20°C. In comparison, the RI of P4VP-ICl film decreased by 0.41% over 24 hours at 20°C. These halogenated polymer thin films are expected to have wide applications in sensors and optoelectronic devices.

Late News: Area Selective Plasma Enhanced Chemical Vapor Deposition of Silicon using a Fluorinated Precursor Ghewa Akiki; Ecole Polytechnique, France

Area-selective deposition (ASD) is a process that controls where the deposition takes place through the underlying surface rather than through any masking step. This process can be achieved by either Atomic Layer Deposition (ALD) or Chemical Vapor Deposition (CVD) techniques [1]. In previous work, we studied area selective plasma enhanced CVD or PECVD using Ar/SiF4/H2 plasma chemistry [2]. For specific plasma parameters, a microcrystalline silicon film is selectively grown on a SiOxNy area while the AlOx adjacent area remains pristine (see figure 1). This effect was then attributed to the formation of Al-F bonds that blocks the deposition of silicon on top of the AlOx area [3].
However, when the plasma conditions are slightly changed or when those two materials are patterned, the selectivity is lost. Each case will be discussed and presented based on in-situ ellipsometry, atomic force microscopy and x-ray photoelectron spectroscopy analyses.

Using Molecular Layer Deposition to Instil Monovalent Selectivity in Cation Exchange Membranes Without Compromising Resistivity Eran Edri, Oded Nir and Eyal Wormser; Ben-Gurion University of the Negev, Israel

Desalination is becoming a vital part of the solution to water scarcity with a current worldwide desalination capacity of approx. 100 million m^3/day, which is expected to grow by 40% by 2030. In 2019, 29% of the global desalination capacity was of brackish and river water (500-20000 ppm TDS). Most (98%) of the brackish water nowadays is desalinated by reverse osmosis (RO) which completely deprives the permeate of Mg^{2+} and Ca^{2+}. Both are critical nutrients needed to sustain human health and agriculture. Replenishing these divalent ions to the desalinated water increases the cost and complexity of the overall process and decreases its sustainability and economic attractiveness. Electrodialysis is energetically more efficient than RO for desalination of brackish water and using monovalent selective membranes—membranes that enable monovalent ions passage, but retain divalent ions—offer a potential solution to preserve the nutrients in the permeate. However, current methods for instilling ion selectivity use large macromolecular building blocks to form the selective layer, which increases ion transport resistance and hence the energy demand and cost of selective electrodialysis. To disrupt the resistance-selectivity trade-off, a method for uniformly depositing an ultrathin and highly charged selective layer is needed.
While low-temperature atomic layer deposition is a suitable method for depositing ultrathin metal oxides on membranes, the elastic mismatch between metal oxides and polymers hinders the stability of the selective layer. Instead, we used molecular layer deposition of alucones to resolve the elastic mismatch. We show that the electrostatic charge of alucone surface leads to monovalent selectivity values on par with commercial membranes, but with only a marginal increase in resistivity. We further investigate the resistance-selectivity trade-off using electrodialysis simulation and suggest “guidelines” for further improvement of performance.

2:00 PM SF01.05.03
Multiscale Materials Bear Multiscale Challenges—Why Bridging the Length Scales is Important for Developing New, Multifunctional, Bulk Nanocomposites. Alexander Plunkett[1], Berta Domènech[1], Diletta Giuntini[2,1] and Gerold A. Schneider[1]; [1]Hamburg University of Technology, Germany; [2]Eindhoven University of Technology, Netherlands

Nanomaterials, in which nanoparticle size-dependent properties are maintained, but also new collective properties derived from the synergy between their individual building blocks emerge, gained significant interest in recent decades. However, the lack on structural integrity when the dimensions are upscaled still limits them to microscale applications. The lack of control over larger length scales when nanomaterials are processed usually leads to defects which scale with the dimensions of the specimen. A promising strategy to overcome this issue is inspired by nature. Nature in fact evolved hard, strong, and tough materials-like bone, teeth, and nacre- by hierarchically structuring nano building blocks with soft interfaces on different length scales.

The synthetic emulation of these multiscale, hierarchical structures based on hard minerals combined with soft biopolymers with structural features down to the nanoscale bears tough practical challenges on each length scale. These challenges start at the atomic level, and expand up to the final macroscopic material and its application. Therefore the cooperation from different scientific disciplines ranging from chemistry and physics to material science and engineering becomes crucial.
This talk will discuss how these different hurdles can be addressed via a bottom-up approach using organo-functionalized ceramic nanoparticles. It will be shown how the quest begins on the atomistic scale, aiming to boost and control the materials’ strength by a crosslinking reaction of the nano-building blocks as well as their self-assembly at the nanoscale level. At the microscale, it will be shown how emulsion-based approaches allow to control the shape of nano- to micro-architected suprastructures. These ceramic nanocomposite suprastructures can be afterwards functionalized in order to process them on the mesoscale with polymers ultimately leading to robust macroscale materials in which nano- and micro-features are maintained.

2:15 PM SF01.05.04
Compliant and Transparent Polymer Barrier Layer for Flexible Optics Yineng Zhao, Ni Huo and Wyatt E. Tenhaeff; University of Rochester, United States

Flexible optics and optoelectronics are becoming increasingly desirable in many advanced technologies. One example is varifocal liquid lenses mimicking the mechanism of a human eye, where transparent fluid is encapsulated between two flexible membranes. Varifocal liquid lens is particularly useful in volume-limited applications, such as miniature medical devices, smartphone cameras, and wearable augmented reality equipment. The focal length is modulated by mechanically actuating the membrane–similar to the ciliary muscle in the human eye. These optical devices present significant material design challenges; flexible, transparent coatings are required to inhibit the diffusion of high-index fluids (optical oil) into the elastomeric membrane, which would otherwise degrade the optical quality of the lens. Conventional optical coatings based on inorganic compounds, such as silica and alumina, can provide the required barrier performance but their intrinsic brittleness limit compatibility with polymer-based flexible optics/optoelectronics. Herein, a flexible and transparent polymer barrier layer was created by initiated chemical vapor deposition (iCVD) of a highly crosslinked and fluorinated diacrylate–poly(1H,1H,6H,6H-perfluorohexyl diacrylate) (pPFHDA). The deposition was realized by a bubbler-enhanced iCVD which enables vapor delivery of nonvolatile monomers such as PFHDA. During the deposition, the monomer and the substrate were kept at around room temperature, and the deposited coating showed high uniformity and conformality. This was believed to be the first report of vapor deposition of pPFHDA. The pPFHDA coating has no optical absorption from the wavelength of 300 nm to 1690 nm and is thermally stable to 300°C. Coatings with thicknesses in hundreds of nanometers were found to be impermeable to high-index optical fluid for more than two months at 70°C, which is equivalent to a four-year lifetime at room temperature. Such barrier performance was achieved even after the layer was subject to equi-biaxial strain, which demonstrated that the pPFHDA barrier layer was able to accommodate mechanical deformation, making it a compelling solution for flexible optics/optoelectronics.

The Triumphs and Tragedies of Spatial Atomic Layer Deposition David Munoz-Rojas; LMGP Grenoble INP/CNRS, France

Spatial Atomic Layer Deposition (SALD) is a recent variant of ALD that offers fast processing, even at atmospheric pressure, while preserving the unique assets of ALD, namely, precise thickness control down to the nanometer, high-quality films even at low temperatures, and unique conformality. As a result, SALD is ideal for applications requiring high throughput at low cost, such as new generation photovoltaics, LEDs or packaging. In particular, the SALD approach based on close-proximity deposition heads is highly versatile since it can be easily customized by proper design of the deposition heads and because the deposition takes place in the open air without the need of any deposition chamber.

In my talk, I will first present the developments on close proximity SALD we are currently carrying out at LMGP. In particular, I will illustrate how 3D printing can be used to prototype and customize the deposition heads, and how in so doing SALD can indeed be tuned to deposit custom patterns without the need of pre-patterning steps. This approach represents a new versatile way of printing functional materials and devices with spatial and topological control, thus extending the potential of SALD, and of ALD in general.
I will then present recent studies showing the effect of air-processing on the properties of the thin films deposited with our close-proximity system, and how the choice of precursor can have a huge impact on the final properties of the materials deposited.
The potential of SALD will be illustrated through different examples of applications of the thin films developed in our group.

11:00 AM SF01.06.02
Area-Selective Atomic Layer Deposition on Graphene Substrates Gordon L. Koerner[1], Quinton Wyatt[1], Nikhila Paranamana[1], Brady Bateman[2], Matthias Young[1] and Matthew Maschmann[1]; [1]University of Missouri, United States; [2]Berea College, United States

In this work we report a new area-selective atomic layer deposition (AS-ALD) approach enabled by a spatially controlled hydroxylation process. The processing occurs within a low-pressure water vapor ambient established within an environmental scanning electron microscope (ESEM). The ESEM electron beam interacts with the water vapor and generates a local region of reactive species (e.g. hydroxyl radicals) in the neighborhood of the focused electron beam. Here, we functionalize exfoliated graphene substrates with a surface hydroxyl layer by selectively scanning the electron beam within the region to be patterned. The electron-beam generates reactive hydroxyls that then dock on the graphene surface. We emphasize that graphene is natively resistant to surface hydroxylation using conventional exposure to water vapor at elevated temperature. As a result, conventional ALD deposition on graphene is limited to defects and edges where functional groups may take root. Our area-selective hydroxylation technique produces dense and well-patterned hydroxylation on a graphene surface, resulting in high-quality patterned ALD deposition.

In the current study, hydroxyl functionalization and ALD deposition occur within 2 x 2 micron patterned regions on the surface of graphene flakes exfoliated from HOPG. A nominal 10 nm layer of alumina and zinc oxide is then deposited using conventional ALD methods. The hydroxylated regions are sufficiently stable to withstand the ALD deposition temperature of 200 ºC. We show that the hydroxyl functionalization and resulting ALD deposition efficacy is highly dependent on electron beam dwell time, electron beam current, pressure, and electron beam acceleration voltage. These processing factors have previously been shown to direct the radiolysis reaction products formed during electron collisions with water vapor. Importantly, all successful hydroxylation experiments required an electron beam dwell time that far exceeds conventional SEM imaging parameters. The patterned hydroxyl functionalization and resulting ALD coatings are characterized using scanning electron microscopy, energy dispersive spectroscopy (EDS) mapping, atomic layer deposition, and Raman spectroscopy. We foresee that this technique may be used to deposit high-quality oxides to traditionally ALD-resistant materials to form field-effect transistor devices, metamaterials, and other nanoscale or microscale devices.

***In Situ* Atmospheric Pressure Chemical Vapor Deposition of Carbon Nanofibers in the TEM** Andrew C. Meng[1], Peifu Cheng[2], Piran Ravichandran Kidambi[2], Yuyang Song[3], Nikhilendra Singh[3] and Eric A. Stach[1]; [1]University of Pennsylvania, United States; [2]Vanderbilt University, United States; [3]Toyota Research Institute of North America, United States

Although carbon nanotubes have a wide variety of uses in electronics, structural composites, and energy storage, questions remain regarding specific growth mechanisms. The interactions between the carbon precursor, the metal catalyst, and the substrate are complex and involve the evolution of the metal catalyst oxidation state under hydrogen and hydrocarbon reductants. As carbon nanotube growth yield is often less than 10%, understanding the growth mechanism may provide insights for more efficient synthesis. We study chemical vapor deposition of carbon species *in-situ* in the transmission electron microscope (TEM) at atmospheric pressure in order to better understand the parameters that most strongly influence the morphology of carbon grown. Recent studies have shown that Na-based catalysts were observed to exhibit significantly reduced growth temperatures for carbon nanotubes. Here we report the influence of alkali metal salts on Fe and Ni based catalysts for carbon fiber growth. *In-situ* chemical vapor deposition experiments in the TEM with ethylene hydrocarbon precursors showed that Na_2CO_3 led to significantly increased yield in carbon nanofiber growth, which we hypothesize to be related to a desiccating effect. We combine these *in-situ* growth experiments in the TEM with *ex-situ* growth experiments on the influence of Na_2CO_3 additive on *ex-situ* carbon nanofiber growth using various substrates and carbon precursors. *In-situ* chemical vapor deposition in the TEM is promising for insights into the growth mechanism for carbon based materials, which exhibit a wide range of structures.

Late News: Using *In Situ* Quartz Crystal Microbalance Gravimetry to Explore the Temperature Dependent Vapor Phase Infiltration of Trimethylaluminum into Poly(methyl methacrylate) and the Solvent Stability of the Resulting Hybrid Films Emily K. McGuinness and Mark Losego; Georgia Institute of Technology, United States

Vapor phase infiltration (VPI) infuses the bulk of polymers with vapor phase metalorganic precursors which are often co-reacted with an oxidant to form air stable hybrid materials. Due to its vapor phase nature, the VPI process can be utilized as for post-fabrication modification of a wide range of polymeric forms (thin films, fabrics, etc.) without significantly modifying the material's macroscale shape. To date, VPI has shown promise in several industrially relevant areas including: the creation of solvent stable hybrid membranes for chemical separations, the modification and stabilization of mechanical properties for polymer and biomaterial-based fibers, and the creation of nanoscale metal oxide structures from block copolymer templates. The properties of these hybrid materials have shown significant dependence on both their chemical and physical structure. This structure is determined by inherent properties of the polymer and precursor system in addition to the processing parameters employed during VPI. Developing a complete understanding of the process-structure-property relationships for hybrids created via VPI is necessary for specific application design and scale-up. In this talk, we will understand the temperature dependent property of solvent stability by exploring changes in the chemical and physical structure of AlO_x / poly(methyl methacrylate) [PMMA] hybrid materials. *In situ* quartz crystal microbalance gravimetry (QCM) will be leveraged to study the long-term mass change behavior of precursor sorption and desorption. Specifically, this work explores the role of temperature on the total mass sorption of TMA into PMMA with insight into contributions from the free diffusing and chemically interacting species. Consistent with literature reports, we find the total precursor uptake for this VPI system displays a complex dependency on temperature with an increase in quantity from 70 ºC to 90 ºC followed by a continuous decrease with further increasing temperature. Using QCM experimentation, we determine that the initial increase is driven by reaction kinetics where the reacted quantity increases with temperature and then saturates at approximately 110 ºC. However, we find the quantity of free diffusing species decreases continuously with temperature and drives the decrease in uptake at higher temperatures. This information is used to explain quantitatively the temperature dependent property of solvent stability observed in this VPI system as well as provide a framework for studies of this nature. Additionally, we extract kinetic behaviors of this VPI system as a function of infiltration temperature for use in scaling the VPI process to industrial levels.

Inorganic-Organic Materials and Interfaces through ALD/MLD for Emerging Energy Technologies Maarit Karppinen; Aalto University, Finland

The ALD/MLD (atomic/molecular layer deposition) technique allows us to fabricate novel hybrid materials not readily accessible through any other fabrication route. These include exciting in-situ crystalline metal-organic framework (MOF) like materials and inorganic-organic interfaces and superlattice (SL) structures in which ultra-thin organic layers are introduced periodically between nm-scale metal oxide layers to e.g. enhance mechanical flexibility, block phonon conduction, or bring photoactivity.[1,2] In this presentation I will briefly discuss exciting examples of properties/functionalities realized for these materials: (*i*) electroactive lithium-organic thin films for battery components (electrodes, solid electrolytes) and artificial solid electrolyte interphase (SEI) layers;[3,4] (ii) lanthanide-organic upconverting layers for solar cells;[5] (iii) ZnO-based oxide:organic SL films for textile-integrated thermoelectrics;[6] (iv) ε-Fe_2O_3:azobenzene SL films for flexible and photo-responsive room-temperature magnets.[7]

11:00 AM SF01.07.02
On the Synthesis of ALD Complex Oxides for Flexible Magnetic Devices Pengmei Yu[1], Pol Sallés Perramon[1], Sebastian Beer[2], Anjana Devi[2] and Mariona Coll[1]; [1]ICMAB-CSIC, Spain; [2]Ruhr-Universität Bochum, Germany

The growth of complex oxide thin films with atomic precision offers bright prospects to study new physics emerging from the films and at their interfaces. Unfortunately, the ALD synthesis of a ternary oxides is, in most of the cases, not a simple addition of the corresponding binary oxide processes. The compatibility of different chemical precursors confined under similar deposition conditions together with a varying surface species after every precursor dose increase considerably the level of intricacy. As a case example, here we will present the challenging synthesis of $Gd_xFe_yO_z$ phase by combining two homometallic Gd and Fe compounds using an ALD-type approach. We investigate the use of tailor-made metalorganic precursors, designed to provide similar thermal behavior, (bis(*N*-isopropyl ketoiminate) iron(II), [Fe(^{i}pki)$_2$] and tris(*N*,*N*′-diisopropyl-2-dimethylamido-guanidinato)gadolinium(III),

[$Gd(DPDMG)_3$]). The deposited films resulted in cation ratio close to nominal stoichiometry with negligible amount of organic species according to the RBS/NRA analysis. Upon thermal treatment, XRD and SQUID measurements confirmed the formation of the garnet $Gd_3Fe_5O_{12}$ phase coexisting with $GdFeO_3$, Gd_2O_3 and Fe_2O_3. [1]
Additionally, when epitaxial growth is pursued for enhanced physical properties, the growth is further limited to specific fragile and expensive substrates hindering the opportunity to integrate such materials into polymeric and silicon substrates. To broaden the applicability of these materials we went one step further developing an all-chemical deposited route based on the use of a water-soluble sacrificial layer, to manipulate complex crystalline oxides as free-standing membranes and integrate them on polymer substrates such as PDMS and PET. [2] As a case example, we will present the synthesis of ALD-$CoFe_2O_4$ membranes followed by the structural and magnetic characterization by means of STEM and SQUID, respectively.
This is a robust chemical and low-cost methodology that could be adopted to prepare a wide variety of complex oxide films to fabricate artificial heterostructures to go beyond the traditional electronic, spintronic, and energy storage and conversion devices.

11:15 AM SF01.07.04
Plasma-Enhanced Chemical Vapor Deposition of P-Type Cu_2O from Metal Organic Precursors Daisy Gomersall[1,2] and Andrew J. Flewitt[1]; [1]Electrical Engineering, University of Cambridge, United Kingdom; [2]EPSRC CDT in Integrated Photonic and Electronic Systems, United Kingdom

Although n-type amorphous metal oxide semiconductors have received commercial traction, and particularly amorphous indium gallium zinc oxide (a-IGZO), large-area electronics is still largely dominated by silicon-based technologies. The advance and development of both display and solar cell technologies is limited by the relatively poor performance or high temperature processing conditions of amorphous silicon or polycrystalline silicon devices. The commercial success of metal oxide semiconductors would be significantly enhanced if there was a good p-type metal oxide material which could complement a-IGZO in low power circuits based on thin film transistors (TFTs) and p-n junctions as required by the display and solar cell industries respectively.

Cuprous oxide (Cu_2O) is a non-toxic, low cost metal oxide that exists naturally as a p-type semiconductor due to intrinsic copper vacancies [1]. Reported Hall mobilities of ~10^2 $cm^2V^{-1}s^{-1}$ suggest potential as a good thin film electronic material [2], but with sputter-deposited Cu_2O TFT field-effect mobilities of ~10^{-1} $cm^2V^{-1}s^{-1}$ and high off-state currents widely reported [3], further research is required to optimise the deposition and device fabrication.

This work looks at the deposition of Cu_2O films using plasma enhanced chemical vapor deposition (PECVD) with pulsed liquid injection of metal-organic precursors. PECVD is used for large-area amorphous silicon growth and has the advantage over physical vapor deposition techniques, such as sputtering, of allowing chemical control of the deposition process and hence potentially the oxidation state of the copper oxide thin film. The pulsed liquid injection is achieved with a Kemstream Vapbox liquid precursor delivery system and Cupraselect (Cu(hfac)(TMVS)) is used as the copper precursor with oxygen as the oxidising agent.

Existing literature using Cupraselect is primarily focussed on CVD of copper films and the presence of a significant incubation period is widely reported, with film deposition delayed by as much as 50 minutes depending on process conditions [4]. However, using PECVD and pre-treating the substrates with oxygen plasma, this work reports the deposition of 20nm thick Cu_2O films from a single 1 ms injection of precursor. Such film thicknesses would be ideal for deployment in TFT structures.

Theoretical-Computational Study of the Nucleation Process of TiO_2 on Carbon Nanostructures Jonathan E. Rodríguez Hueso, Hugo A. Borbon and Jonathan Guerrero; CNyN-UNAM-CICESE, Mexico

There are many fields within the physical and engineering sciences, where the key to scientific and technological progress is the understanding and control of the properties of matter at the scale of individual atoms and molecules, so conducting a study of the mechanisms that occur within the processes that allow us to manipulate matter on this scale; which has become a fundamental part of scientific development in its different areas. However, to carry out the study of nucleation and growth of matter at the atomic-molecular scale few techniques allow us to carry out the growth of materials with such precise control, and in techniques that are capable of doing it, there is a great ignorance of all the phenomena and interactions that occur in them due to the complexity involved in the study at this scale. ALD is one of the few techniques that provide control of film growth at the molecular atomic scale and a high precision of synthesis of nanocomposites, which makes ALD the ideal method to carry out the study of nucleation and growth of the different nanocomposite. Where one of the approaches of greatest interest within the fielid tess is the area of functional hybrid materials at the nanoscale since it is one of the most promising and emerging research areas in materials chemistry. This is because the limitless possible combinations of the different properties of inorganic, organic, or even bioactive components in a single material, in nanometric dimensions, have attracted considerable attention. This approach provides the opportunity to create a host of novel and advanced materials with well-controlled structures and multiple functions. Where the TiO2 / graphene hybrid stands out, which is a new group of nanomaterials whose use and performance are tested with greater thanks to its improved properties and possible applications, which, compared to pure materials, this composite material exhibits improved activities due to the synergistic effect of the GR and TiO2 components. This material is widely used in the area of thin films, so the ideal technique for its growth is ALD thanks to the properties it has and allows the TiO2 / graphene hybrid to grow in a very controlled and precise way, but most of the information on the growth mechanisms is very little known, and to have a greater efficiency of the technique and the materials, it is very important to know all the factors that involve the growth of the material. However thanks to the self-limiting nature of the chemisorption reactions during the ALD growth of the film. allows us to carry out a theoretical study through calculations using density functional theory (DFT) to develop a model of the chemistry involved in the reactions that occur in the ALD process during the early stages of growth of TiO2 on graphene for each grown film. Theories of the electronic structure of matter have become a very useful and powerful tool for understanding the chemistry involved in the early stages of the ALD process. In this work, we have used DFT calculations to present a complete reaction mechanism between OH-functionalized graphene and the 3 main Ti precursors (TDMAT, TIP, TiCl4) using water as the

oxidizing gas. We have studied the ligand exchange reactions. A theoretical-computational study of the initial stages of ALD growth of the TiO2-GR hybrid was carried out from graphene functionalized with hydroxyl (OH) groups as growth sites for the interaction with the main titanium precursors in ALD. It was demonstrated how the chemical nature of the precursor directly affects the reaction mechanism to be carried out, reflecting on the energy required to invest in the system to overcome the barriers and for the reaction to take place. Additionally, we obtained the secondary products that the system produced when carrying out the growth of the film, with which a reaction mechanism was proposed for each ALD half cycle.

11:45 AM SF01.07.07
Late News: Large Single-Crystal Monolayer MoS2 Growth with Halide Activation and Its Mechanism Cong Su[1,2,3], Qingqing Ji[4,3], Nannan Mao[3], Xuezeng Tian[5], Juan C. Carlos[6], Jianwei (John) Miao[7], William Tisdale[3], Alex Zettl[1,2], Ju Li[3] and Jing Kong[3]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Massachusetts Institute of Technology, United States; [4]ShanghaiTech University, China; [5]Institute of Physics, Chinese Academy of Sciences, China; [6]Oak Ridge National Laboratory, United States; [7]UCLA, United States

Two-dimensional (2D) semiconductors such as monolayer MoS_2 are essential building blocks for next-generation ultrathin flexible and low-power electronics. A recent study using semimetal Bi as the electrical contact to monolayer MoS_2 has improved the on-current and contact resistance of the monolayer transistor to be on par with traditional Si-based transistors. As a premise for large-scale electronics, batch production of the 2D semiconductors requires large domain size, large-area continuity, and thickness uniformity. These are difficult tasks in particular for synthetic MoS_2 and other transition metal dichalcogenides (TMDs), considering the less controllable mass flux from solid metal precursors in chemical vapor deposition (CVD), as compared to the case of graphene growth with gaseous hydrocarbons. One recent advance to mitigate this is the use of alkali metal halide salts [*e.g.*, NaCl, KI, and NaBr], which, in conjunction with transition metal or metal oxide powders, could increase the mass flux of metal precursors and accelerate the 2D growth of TMDs. Various research efforts have been made to explain the mechanism, in terms of these metal halides as a molten salt to facilitate the evaporation of the metal oxide precursor, or as a surfactant to modify the substrate surface and the MoS_2 edge. Both the alkali metal ions and the halogens have been proposed to play an important role in the promoted growth. Continued endeavors are being devoted to bringing further lights in understanding the detailed mechanism.
In this work, we provide unambiguous experimental evidence that halogens are closely related to MoS_2 growth dynamics. To achieve this, post-growth Arrhenius analysis is implemented without any involvement of *in-situ* characterizations. We find that within the same reaction family, the halide-assisted growths conform to Brønsted-Evans-Polanyi (BEP) relation, where their reaction barriers are linearly correlated to the Mo-X (X = I, Br, Cl, F, and O) bond dissociation energies (E_b), suggesting the substitution of Mo-X bonds by the Mo-S bonds to be the rate-limiting step for the CVD growth. Based on this, we propose a theoretical growth model that not only reproduces the BEP relation but also explains the sulfur concentration-dependent growth dynamics observed in our experiments. By harnessing the synergistic effect of the KI promoter and the sulfur supply, we can reproducibly and rapidly synthesize near millimeter-sized 2D MoS_2 crystals dispersed over the entire SiO_2/Si substrates. These results not only shed lights on the detailed mechanism of TMD growth activated by the halide salts, but also guide the designer growth towards larger domain sizes that should enable practical applications.

From Functional Polymers to Functional Devices Based on Nanofilms Anna Maria Coclite; Graz University of Technology, Austria

Functional and responsive surfaces have been successfully deposited by initiated Chemical Vapor Deposition (iCVD) on a variety of substrates. Such method allows the full retention of the functional groups of the monomer structure, including, but not limited to, C-/N- containing ones. The high versatility of iCVD in driving application-specific properties into the material, creating a platform for the implementation of polymeric coatings into device fabrication, will be discussed.

A case study will be presented in the field of stimuli-responsive materials, in particular, hydrogels whose size and shape change when stimulated by light, humidity, temperature and aqueous environments. iCVD allows to obtain stimuli-responsive thin films with high chemical specificity and this is important to obtain a large responsiveness amplitude. In addition, the thin film form allows obtaining fast response.

Fast response and large signal amplitude are fundamental requirements for good sensors. Fast and ultra-fast humidity sensors based on the optical detection of the change in thickness of the iCVD hydrogels will be shown. The implemented sensor prototype delivered reproducible relative humidity values and the achieved response time for an abrupt change of the humidity was about three times faster compared to one of the fastest commercially available sensors on the market.

This presentation will focus on the applications of stimuli-responsive nanofilms for drug delivery devices, sensors and actuators. Their combination with piezoelectric/piezoresistive materials will also be discussed for innovative device geometries.

1:30 PM SF01.08.02
ALD Growth of High-κ Dielectrics on Monolayer MoS_2—The Role of the Substrate Emanuela Schilirò[1], Raffaella Lo Nigro[1], Salvatore Ethan Panasci[2], SimonPietro Agnello[3], Franco Gelardi[3], Fabrizio Roccaforte[1] and Filippo Giannazzo[1]; [1]CNR-IMM of Catania, Italy; [2]University of Catania, Italy; [3]University of Palermo, Italy

Two-dimensional materials (2DM), such as graphene and transition metal dichalcogenides (TMDs), always achieve great interest for future applications in electronics, optoelectronics and sensing. The atomic layer deposition (ALD) of ultra-thin high-κ dielectrics (among which Al_2O_3 and HfO_2) on the 2DM materials is an essential requirement to realize some high performance electronic devices, including lateral field effect transistor (FETs) and/or hot electron transistors (HETs). However, the lack of out-of-plane bonds in the 2DM makes that seeding-layers and/or pre-functionalization treatments are necessary to promote the ALD growth, despite the possible adverse impacts on the carrier mobility and the dielectric quality. In some special cases, the peculiar interaction between 2DM and the underlying substrate proved to be beneficial to achieve a direct ALD growth, such as in the case of monolayer (1L) CVD graphene residing on catalytic-metals (Cu, Ni-Au) [1,2], or 1L epitaxial graphene on 4H-SiC [3,4]. So far, similar substrate effects have not been explored in the ALD deposition of dielectrics on TMDs.
In this work, large area (in the order of cm) and high quality monolayer-MoS_2 were exfoliated from the bulk molybdenite on a gold layer and successively

transferred onto Al_2O_3/Si substrate [5]. Hence, the direct ALD growth of ultra-thin (about 4 nm) Al_2O_3 and HfO_2 films was investigated on MoS_2 residing on these two different substrates. Employing the same deposition conditions, an optimal ALD-coverage has been obtained for monolayer-MoS_2 on gold (see Fig.1(a) for 80 cycles of Al_2O_3 deposition), while a highly inhomogeneous coverage was observed for monolayer-MoS_2 on the Al_2O_3/Si substrate (see Fig.1(b)). The beneficial effect of the gold substrate on the ALD gorwth has been correlated to the strong van-der-Waals interaction between the MoS_2 and Au, resulting in a tensile strain and p-type doping of the MoS_2 membrane, as shown by Raman mapping [5]. Good insulating properties of the compact ~4 nm thick Al_2O_3 membrane on Au-supported monolayer- MoS_2 have been found by conductive atomic force microscopy.
These results can have an important impact in the realization of devices based on large area MoS_2 membranes produced by gold assisted exfoliation.
This work has been supported by the FLAG-ERA JTC2019 project "ETMOS"

1:45 PM *SF01.08.03
Hybrid Chemical Vapor Deposition of Heterogeneous Thin Films Yu Mao; Oklahoma State University, United States

The technique of initiated chemical vapor deposition (iCVD) is gaining increasing interest in the fabrication of various polymer thin films. By implementing the chemistry of radical polymerization under the condition of vapor-based deposition, iCVD provides fine control of coating composition and functionality as well as adaptability and conformality to complex substrates. While the uniformity of polymer thin films is pursued in many fabrications, thin films with heterogeneous composition and morphology can provide high level of versatility, especially when holistic solutions are desired. We report our exploration of heterogeneous film fabrication using hybrid chemical vapor deposition with multiple film growth steps in one deposition. Besides changing process variables (such as vapor pressure and temperature) during iCVD, we introduced other fabrication procedures *in situ* to create polymer films with multi-scale heterogeneousness in vertical and planar dimensions. We will discuss three hybrid deposition process and the composition, structure, interfacial strength, surface property, and biocompatibility of the resultant thin films. The technical challenges encountered in the hybrid deposition process will also be discussed. We will conclude by demonstrating our recent work of implanted drug delivery, smart textiles, and sustainable water solutions enabled by fabricating heterogeneous thin films on three-dimensional substrates.

2:15 PM SF01.08.04
Development of Hybrid Organic-Inorganic Nanocomposites via the Atomic Layer Deposition of Nanoscale Metal Oxides Inside SU-8 Negative Photoresist Zhongyuan Li[1], Nikhil Tiwale[2], Ashwanth Subramanian[2], Ying Li[1], Chang-Yong Nam[2] and Seok-Woo Lee[1]; [1]University of Connecticut, United States; [2]Brookhaven National Laboratory, United States

It has been extremely challenging to achieve the uniform distribution of a large volume fraction (>50%) of nanoscale fillers in a polymer matrix because the nanoscale fillers tend to agglomerate, and this agglomeration almost always degrades the mechanical properties of polymer nanocomposites. In this presentation, we show that it is possible to overcome this issue by using the modified atomic layer deposition that deposits metal oxides inside the polymer matrix instead of depositing them on the polymer surface. We use a SU-8 negative photoresist, which has a large-sized free volume due to its cage-like structure of the repeating molecular unit, so both the precursors (trimethylaluminum and diethylzinc) and water molecules can diffuse into SU-8 matrix during the atomic layer deposition process. Compared to the conventional atomic layer deposition, we intentionally used the longer purging time of precursor and water molecules to allow them to diffuse into SU-8 matrix. By repeating the infiltration process several times, it is also possible to control the volume fraction of nanoscale metal oxides. Transmission electron microscopy revealed that the infiltration depth is dependent on the type of precursor, and we obtained the ~50 nm thick infiltration depth of Al_2O_3 and over 150 nm thick infiltration depth of ZnO under the similar deposition condition. The high-resolution composition mapping showed that Al_2O_3 formed the particulate-like structure, but ZnO seemed to form the unique organic-inorganic interpenetrating network structure. We obtained the volume fraction of oxides by using the quartz crystal microbalance measurement, and both cases showed the uniform distribution of nanoscale oxides with ~44 vol.% of Al_2O_3 and ~24 vol.% of ZnO. Therefore, our synthesis technique enabled us to achieve the ideal microstructure of polymer nanocomposite successfully.
To evaluate the mechanical performance of our SU-8 nanocomposites, we performed in-situ nanomechanical testing on polymer nanocomposite nanopillars, which were fabricated by the e-beam lithography followed by the modified atomic layer deposition. Mechanical data revealed that our polymer nanocomposites exhibit metal-like strength (~400 MPa) but still polymer-like Young's modulus (~8 GPa). This unusual combination of strength and Young's modulus results in the giant modulus of resilience (~24 MJ/m^3), the orders of magnitude higher than the modulus of resilience of most engineering materials. Modulus of resilience, the measure of a material's ability to store and release elastic strain energy, is critical for realizing advanced mechanical actuation technologies in micro-/nano-electro-mechanical systems and in robotics. Our hybrid polymer nanocomposite features lightweight, ultrahigh tunable modulus of resilience, and versatile nanoscale lithographic patternability with potential for application as nanomechanical components, which require ultrahigh mechanical resilience and strength such as flexible display or durable three-dimensional structures in SU-8-based micro-electro-mechanical-systems (MEMS).

2:30 PM SF01.08.05
Progress in Growth of Carbon Nanotubes from Catalyst Particles Incorporating Diffusion Inhibitors Michael J. Bronikowski; University of Tampa, United States

Results will be presented of our most recent studies of growth of Carbon Nanotubes (CNTs) by Chemical Vapor Deposition (CVD) from catalyst metals combined with heavy refractory diffusion inhibitor metals. The carbon source gas used in these studies is ethylene, C_2H_4, and various combinations of catalysts and diffusion inhibitor metals are investigated. The key concept is the inhibition of high-temperature erosion and Ostwald ripening of the catalyst particles by inclusion of the diffusion inhibitors, allowing the catalyst particles to have a longer lifetime and thus grow longer CNTs. We have previously demonstrated this effect using carbon monoxide (CO) as a carbon source gas, and we present here the extension of these studies to CNT growth using C_2H_4 as the source gas. Implications will be discussed for the growth of ultra-long (tens of cm or more) CNTs.

2:45 PM SF01.08.06
Probing the Growth of Inorganic Clusters in Polymer Templates During Sequential Infiltration Synthesis Xiang He, Ruben Waldman, David Mandia, Nari Jeon, Nestor Zaluzec, Olaf Borkiewicz, Uta Ruett, Seth Darling, Alex Martinson and David Tiede; Argonne National Laboratory, United

States

Sequential infiltration synthesis (SIS) is a modified atomic layer deposition process to precisely grow inorganic solids in soft material templates (e.g., polymers). Removal of the template via annealing results in the formation of polycrystalline inorganic thin films that inherit the morphology of the template matrix, offering opportunities to create a variety of nanostructured inorganic solid thin films. The properties of the resultant inorganic thin films rely heavily on the growth of the inorganic clusters in the template matrix. Therefore, to gain full control of the final inorganic thin films, it is of great importance to map out how the inorganic clusters grow inside the polymer templates.

In this work, structures of SIS-derived initial nucleating and final annealed indium-based inorganic materials with a PMMA template were systematically investigated as a function of SIS cycles using multiple tools, such as high-energy X-ray scattering (HEX) with pair distribution function (PDF) analysis, extended X-ray absorption fine structure, and transmission electron microscopy (TEM). The results resolved structures for the initial nucleating InO_xH_y clusters in PMMA as a function of the number of SIS cycles, which were found to exhibit similar local structures of cubic In_2O_3 and $In(OH)_3$ crystals. PDF analysis demonstrated that the SIS-derived InO_xH_y clusters in the first SIS cycle are characterized by a combination of mono-, di-, and tri-nuclear structures which and grow to larger clusters with higher aspect ratios during subsequent SIS cycles. Further extended SIS cycles lead to the increased number density of InO_xH_y clusters, which then condense to form larger and three-dimensional networks in the PMMA matrix. Annealing in air removes the PMMA template and converts the amorphous InO_xH_y clusters into crystalline In_2O_3 particles, which also show SIS-cycle-dependent properties.

Overall, this work contributes to the fundamental understanding of how inorganic clusters grow inside polymer matrices during the early stages of the SIS process.

A Chemical Vapor Desposition of High Refractive Index (n>1.9) Functional Polymer Films with Full Transparency in Whole Visible Region Sung Gap Im; KAIST, Korea (the Republic of)

High refractive index polymers (HRIPs) have recently emerged as an important class of materials for use in a variety of optoelectronic devices including image sensors, lithography, and light-emitting diodes. However, achieving polymers having refractive index exceeding 1.8 while maintaining full transparency in the visible range still remains formidably challenging. Here, we present a unique one-step vapor-phase process, termed sulfur chemical vapor deposition, to generate highly stable, ultrahigh refractive index (n > 1.9) polymers directly from elemental sulfur. The deposition process involved vapor-phase radical polymerization between elemental sulfur and vinyl monomers to provide polymer films with controlled thickness and sulfur content, along with the refractive index higher than 1.95. Notably, the HRIP thin film showed unprecedented optical transparency throughout the visible range, attributed to the absence of long polysulfide segments within the polymer, which will serve as a key component in a wide range of optical devices.

7:00 PM SF01.09.02
Late News: Atomic Layer Deposition of c-Axis-Oriented GeTe/Sb2Te3 Superlattice for Low-Power and Large-Capacity Phase Change Memory Chanyoung Yoo[1], Woohyun Kim[1], Jeong Woo Jeon[1], Wonho Choi[1], Byongwoo Park[1], Gwangsik Jeon[1], Yoon Kyeung Lee[2] and Cheol Seong Hwang[1]; [1]Seoul National University, Korea (the Republic of); [2]Jeonbuk National University, Korea (the Republic of)

Despite the extensive research and available commercial memory products based on the phase-change-material (PCM), the Ge-Sb-Te alloy-based PCM's full functionality for low-power and high-density memory has not been accomplished. This is mainly due to the lack of conformal film growth techniques, such as atomic layer deposition (ALD), of the chalcogenide-based PCM. The current PCM architecture relies on the crossbar arrays (CBA) structure due to its condensed and straightforward architecture. However, the CBA cannot keep up with the ultra-high density demands due to the increased fabrication cost of lithography steps and masks required for each stacking layer. It can be best addressed by the state-of-the-art vertical NAND architecture, proven technology with a stack of more than 150 layers. To fabricate highly integrated vertical-type crossbar array (V-CBA) memory, the Ge-Sb-Te phase change layer should be uniformly deposited in the inner surface of the deep etched holes vertical architectures, which could be accomplished only by ALD. Meanwhile, the high power consumption of the Ge-Sb-Te PCM during the write operation also poses another severe drawback.

This work demonstrates the development of $GeTe/Sb_2Te_3$ superlattice film utilizing ALD to achieve a high-performance V-CBA memory device. The chemical affinity of the ALD precursor to the substrate surface and the two-dimensional nature of the Sb_2Te_3 enabled to achieve the *in-situ* crystallized superlattice film where the out-of-plane directions of the two-component layers precisely matched the *c*-axis, while the in-plane directions were random. Such a *c*-axis-oriented Sb_2Te_3 could serve as the seed for the *in-situ* crystallized 111-direction aligned GeTe layer, which would have been either amorphous or randomly oriented polycrystalline layer if it was directly grown on a SiO_2 or TiN surfaces. The peculiar alignment method can be applied to deposit other van der Waals films such as transition metal chalcogenides and topological insulators with such alignments for future electronic device applications. The well-aligned and crystallized $GeTe/Sb_2Te_3$ superlattice film showed a RESET current of ~1/7 of randomly oriented $Ge_2Sb_2Te_5$ alloy films grown by the identical ALD process. The fluent improvement in the resistance switching performance from this $GeTe/Sb_2Te_3$ superlattice originates from the pressure-induced solid-state amorphization by the well-oriented superlattice films. The reduction of RESET current with the aligned $GeTe/Sb_2Te_3$ superlattice film was also feasible in the vertical structures, showing a step forward improvement for fabricating the futuristic V-CBA memory with low operating power and high density.

7:15 PM SF01.09.04
Synthesis of Magnesium-Doped Hexagonal Boron Nitride Films By Chemical Vapor Deposition Ranjan Singhal, Elena Echeverria, Dave N. McIlroy and Raj N. Singh; Oklahoma State University, United States

Hexagonal boron nitride (h-BN) is of great interest and potential due to its excellent electrical, optical, and mechanical properties and is isostructural to graphene. hBN is also a wide bandgap semiconductor with an optical bandgap of ~ 6 eV. To be used in the semiconductor industry, wide-area processing and engineering the bandgap is of utmost importance. As of now, chemical vapor deposition (CVD) is the most promising method to synthesize h-BN as it

provides great control over the thickness of the deposited films and is the best candidate for the industrial scale-up process. To engineer the bandgap, in-situ doping is the most convenient and the most effective way, as it offers great control over the dopant material in terms of selection, introduction into the chamber, controlling the dopant concentration. Synthesizing hBN with in-situ doping directly on silicon, which is the most commonly used substrate in the semiconductor industry, eliminates the need for a post-synthesis transfer process and the employment of another process for doping. In this presentation, we have shown the direct synthesis of Mg-doped hBN films on silicon by chemical vapor deposition. XPS analysis confirmed the incorporation of Mg in hBN films. UV-vis spectroscopy was utilized to find the bandgap of the doped hBN films. As expected, it was concluded that the bandgap of the Mg-doped hBN films was less than the bandgap of the undoped hBN films.

7:30 PM *SF01.09.05
Rapid and Accurate Prediction of the Volatility of Organometallic Precursor Complexes Simon D. Elliott, Asela Chandrasinghe, Anand Chandrasekaran, Yuling An and Mathew D. Halls; Schrödinger Inc, United States

Despite its importance for many industries, a quantitative model for the volatility of inorganic compounds has remained elusive. Vapor-based deposition technologies, including CVD and ALD, make use of certain metalorganic complexes and related compounds that show appreciable vapor pressure under moderate heating. However the rational discovery of new complexes is hindered by a lack of detailed understanding to link chemical identity with the conditions for evaporation or sublimation. To overcome these issues, we present a model for volatility and discuss its accuracy and scope.

We have assembled experimental pressure-temperature data from the literature for over 1,000 inorganic complexes, featuring 70 metal centers and 400 different ligands. We use machine learning (ML) approaches to train surrogate models for the dependence of evaporation, boiling or sublimation temperature on chemical identity and pressure. A variety of ML algorithms (Random Forest, Neural Networks etc) are studied in conjunction with different chemoinformatic descriptors and fingerprints. When supplied with the chemical identity and topology of a candidate inorganic compound, the trained ML model is capable of predicting the evaporation temperature at a specified pressure with a mean error of 10 degrees C for the most common metals. The speed with which the model is evaluated makes this approach suitable for screening thousands of candidate complexes, as one step within computational and/or experimental discovery of new precursors.

10:30 AM *SF01.10.01
Importance of the Substrate on CVD Polymerization Kenneth K. Lau; Drexel University, United States

Polymer thin films can be formed conformally on a substrate by chemical vapor deposition (CVD). Specifically, initiated and oxidative chemical vapor deposition (iCVD and oCVD) can easily form nanometer-thin polymer films conformally on a wide range of substrate topologies and materials, from planar silicon, glass or metal to microporous membranes, fabric and paper to nanoporous particle networks, tubes and fibers. In fact, one of the major advantages of iCVD and oCVD is that they are able to use mild reaction conditions, including mild substrate temperatures (at or near room temperature) and mild vacuum (using only a roughing pump), to conformally deposit on such a varied range of substrate geometries and materials. As such, the solid substrate itself on which the polymer film is deposited has generally not been considered an important or determinant factor in influencing the quality and characteristics of the deposited film.

Here, in this talk, the role of the substrate in influencing the deposition behavior and characteristics of the polymer films, particularly for depositing nanometer-thin films by iCVD and oCVD, will be scrutinized more carefully. Specifically, we will present evidence that indicate the surface energy of the substrate can have a profound impact on the resulting conformality of the deposited polymer film. In addition, we will present results that further indicate the substrate temperature can yield different rate-limiting regimes that impact polymer growth rates, where previously it has generally been considered that deposition rate is only limited by monomer adsorption or availability of the monomer reactant at the substrate surface. These new insights challenge our current understanding and notion of iCVD and oCVD polymerization, and can offer new avenues and opportunities for iCVD and oCVD processing and their applications.

11:00 AM SF01.10.02
MOCVD Fabrication and Downconversion Luminescence of Eu-Doped BaF_2 Thin Films for Photovoltaic Applications Francesca Lo Presti[1,2], Anna L. Pellegrino[1,2], Adolfo Speghini[3,4] and Graziella Malandrino[1,2]; [1]University of Catania, Italy; [2]INSTM Udr Catania, Italy; [3]Università di Verona, Italy; [4]INSTM Udr Verona, Italy

In recent years, considerable efforts have been done in the development of new functional materials for the fabrication of increasingly sophisticated and advanced photovoltaic devices (PV) that can ensure an efficient exploitation of solar spectrum. An advanced approach used to enhance the efficiency of PV systems, is based on the conversion of photons with energies outside the absorption range of the photoactive material (usually silicon) into a more suitable optical region. In this context, lanthanide (Ln)-doped fluoride materials are considered particularly promising for energy conversion (EC) applications due to their unique luminescent properties under light irradiation. The EC process can be achieved by simply integrating, into the PV layers, a material able to host an active luminescent Ln element. Upconversion (UC) and downconversion (DC) are the main luminescence mechanisms used for EC applications which increase the efficiency of photovoltaic devices. Concerning different Ln elements used for DC processes, europium has attracted great attention from the scientific community, thanks to its high peculiar chemical properties, especially in the oxidation state +3. Up to now, for EC processes it has been demonstrated that fluorides, compared to other inorganic matrices are more efficient inorganic hosts. In particular, BaF_2 is considered a suitable host for the UC and DC luminescence of Ln^{3+} ions because of its low phonon energy (similar or even lower than the extensively used hosts such as $NaYF_4$), high chemical stability, wide transparency (i.e. BaF_2 is transparent from 150 nm to 15 μm) and versatile synthetic strategies. It is important to stress that host materials require lattice matches with Ln^{3+} dopant ions. Trivalent lanthanide ions can be well incorporated into crystal structure of alkaline-earth fluorides due to the similar coordination sphere. However, a charge compensation mechanism is required to balance the additional charge introduced after the replacement of divalent alkaline-earth ions with trivalent Ln dopants.
In the present study, we report the synthesis of Eu^{3+}-doped BaF_2 thin films on silicon and quartz substrates, using metalorganic chemical vapor deposition technique (MOCVD) focusing the attention on the fabrication process and the DC luminescence properties. The advantages of the MOCVD approach includes simplified instrumental apparatus, high deposition rate, high purity and easy industrial scale-up. For the fabrication of BaF_2 thin films doped with

Eu^{3+}, a multicomponent mixture of metalorganic adducts in an appropriate molar ratio is used as a single molten source. It is possible to easily tune the chemical compositions of the films, to tailor the energy transfer processes, by changing the composition of the precursor mixture, that is the Ba:Eu ratio in the multicomponent source. X-ray diffraction analysis (XRD), field-emission scanning electron microscopy (FE-SEM) and energy dispersive X-ray analysis (EDX) allowed a structural, morphological and compositional characterization of the films. Finally, the film functional properties have been assessed through luminescence spectroscopy.

11:15 AM SF01.10.03
Nanoscale Investigation of Al_2O_3 Thin Layers by Thermal- and Plasma-Enhanced Atomic Layer Deposition for Power Devices Raffaella Lo Nigro[1], Emanuela Schilirò[1], Patrick Fiorenza[1], Filippo Giannazzo[1], Guido G. Condorelli[2], Marzia Monforte[2] and Fabrizio Roccaforte[1]; [1]CNR, Italy; [2]Università degli Studi di Catania, Italy

The scientific research activity on AlGaN/GaN-based high-electron-mobility-transistors (HEMTs) is always under continuous and progressive development because of their promising performances for future electronic devices ,[1,2]. However, the conventional HEMTs with Schottky contact between the metal gate and AlGaN exhibits some reliability issues related to leakage current and current collapse phenomena, but also to limited gate voltage swings and possible metal inter-diffusion phenomena during the high temperature device processing. In this context, the realization of Metal-Insulator-Semiconductor (MIS)-HEMTs structure, with high-κ insulator integration between the metal gate and AlGaN, is the most favorable method to solve these issues [3]. Among the different kinds of high-k dielectrics (Al_2O_3, HfO_2, ZrO_2, AlN), the aluminum oxide (Al_2O_3) is the most widely reported for the GaN focused technology. The large Al_2O_3 implementation is closely related to the excellent physical properties as insulator, namely high permittivity ($\kappa \sim 9$), high critical electric field (10 MV/cm), large band gap (~8.9) and advantageous conduction band alignment with AlGaN/GaN structure. The ALD is the growth technique of choice for microelectronics high-k gate insulators, and in particular, in the case of Al_2O_3 thin film growth on AlGaN/GaN heterostructures a debate aspect is related to the ALD growth modes to be implemented [4,5]. In fact, some works reported on quite promising physiscal properties by thermal ALD process, while many others claimed the best choice is the plasma enhanced-ALD approach. In this context, we compared of the ALD growth modes of Al_2O_3 on AlGaN/GaN by both thermal (ALD) and plasma (PE-ALD) approaches. In particular, the deposition very thin Al_2O_3 layers have been investigated since the early growth stages (about ~1 nm thick layers) and upon increasing thickness up to 6 nm. Investigation has been carried out by both X-ray photoelectron spectroscopy (XPS) and Conductive- Atomic Force Microspopy (C-AFM), in order to correlate the physical covering upon film growth to the insulating properties of the growing Al_2O_3 layers. Two different growth mechanisms have been found, i. e. a quite ideal “layer-by-layer” growth in the case of PE-ALD process, while the thermal ALD process is quite consistent with an “island growth modes”. C-AFM can also provided nano-scale electrical information on the intimate electrical properties of the ultra-thin dielectrics and besides the standard imaging, it has been used for statistical study on Al_2O_3 thin films reliability upon stressing applied voltages on nanoscale matrix of punctual I-V measurements. The best performance has been entirely obtained for PE-ALD grown Al_2O_3 films both for the complete covering of the substrate surface and for the total and homogeneous insulating properties.

Comparison of ALD grown AZO and ZnO Thin Film Heater Performances Deniz Tugrul, Doga Doganay, Husnu E. Unalan and Bilge Imer; Middle East Technical University / Metallurgy and Materials Engineering, Turkey

Ideal properties for transparent thin film heaters (TTFHs) can be summarized as low sheet resistance, high transmittance in visible range and high thermal stability. Generally, the material of choice converts the electrical energy into heat by “Joule Heating Mechanism”. Therefore, achieved maximum temperature is related with applied voltage, sheet resistance and heat loss. Also, uniformity of such material is important due to heating consistency and stability of the entire film. Oxide films grown by atomic layer deposition (ALD) has advantages such as high uniformity, thickness control at angstrom level and excellent step coverage due to its self-limiting growth mechanisms[1]. Aluminum doped zinc oxide (AZO) thin films growth by ALD expected to show ideal properties for a TTFH. The studies suggest that the AZO thin films are suitable to be used as heater on different substrates with different production methods, reason being chemical and thermal stability of AZO[2,3].
In this work, Al doped and undoped ZnO thin films grown by ALD were demonstrated as TTFH. The growth of the thin films were done on quartz substrates. Growth temperature for AZO was varied between 175 and 225 °C, Al doping was kept between 2-4 atomic percent, and thickness was kept constant as 100 nm for all samples. The varying temperature and doping levels were utilized to establish relation between doping concentration of aluminum on the performance of the thin films. The variables for ZnO were pulse/purge variations, and growth temperatures. Growth temperature for ZnO was in between 125 and 150 °C, and DI water pulse and Diethylzinc (DEZ- $Zn(C_2H_5)_2$) pulse was selected as 15 ms and purge time was kept at 10s. Different growth temperatures were chosen to vary stoichiometry of ZnO. Different temperatures were utilized to establish relation between ZnO thin films. Also, one of the main purposes was comparing Al dopped and undoped ZnO thin films with similar sheet resistance to display Al effect to TTFH performance such as maximum temperature and overall responsiveness. The lowest resistivity values achieved with AZO sample with 3.5 Al atomic percent as 3.3 10^{-3} Ω.cm while the each produced thin films transparency were over 85% in spectral range. The expected maximum temperature values were over 70°C with applied fairly low voltage (≤10V) with heating rate of 20 °C/s.

11:45 AM SF01.10.05
Chemical Vapor Deposition of Cu_2O Thin Films—Optimization of the Process and Applications as Photodetectors and HTL for Solar Cells Anna L. Pellegrino, Francesca Lo Presti and Graziella Malandrino; Università degli Studi di Catania, Italy

In recent years, copper-oxide compounds represent one of the most studied classes of semiconducting materials due to their main advantages of easily tuning the optical and electronic properties within the semiconducting behavior. For this reason, copper oxide materials play a significant role in many technological applications, ranging from batteries to catalysis, from photodetectors to solar cell devices. In particular, among the three most common and stable copper oxide phases, Cu_2O, Cu_4O_3, and CuO, named cuprite, paramelaconite and tenorite, respectively, the cuprite phase (Cu_2O) has been intensively studied and applied as p-type semiconducting material in many technological fields. In fact, Cu_2O represents an attractive material, due to

copper abundance, nontoxicity, a wide variety of synthetic strategies and low-cost production.
Herein, we report an in-depth study of the metalorganic chemical vapor deposition (MOCVD) process for the fabrication of both cuprite Cu_2O and tenorite CuO copper oxide thin films starting from β-diketonate copper (II) precursor, i.e. $Cu(tmhd)_2$ bis(2,2,6,6-tetramethyl-3,5-heptanedionate). Operative conditions of fabrication strongly affect both composition and morphologies of the copper oxide thin films. Deposition temperature has been accurately monitored in order to stabilize and to produce selectively and reproducibly the two phases of cuprite Cu_2O and/or tenorite CuO. The present approach represents a simple, easily scalable and industrially appealing process for the production of compact and homogeneous copper oxide films at relatively low temperature. X-ray diffraction (XRD), field-emission scanning electron microscopy (FE-SEM) and atomic force microscopy (AFM) analyses allowed an accurate determination of the physico-chemical properties of deposited layers.
Moreover, as preliminary studies, two main applications have been tested: i) the use of Cu_2O thin films as hole transporting layer for the hybrid perovskite (methylammonium lead iodide, MAPI) based solar cell devices; ii) a core-shell system of all-oxide ZnO-Cu_2O n-p junction as fast and stable self-powered photodetectors. Morphology, crystalline and electronic structure of the Cu_2O thin films materials play a crucial role in determining the main functional parameters of both applications.

12:00 PM SF01.10.06
Design of Functional Composite and All-Inorganic Nanostructures via Polymer Infiltration Using ALDTechnique Elena Shevchenko[1,2] and Diana Berman[3]; [1]Argonne National Laboratory, United States; [2]The University of Chicago, United States; [3]University of North Texas, United States

Infiltration of polymer templates with inorganic precursors using ALD technique enables the design of composite and all-inorganic structures for a broad range of applications. We will present the strategies for fabrication of conformal coatings with tunable thicknesses and porosities that reveal promising antireflective properties,[1] thermally stable multifunctional catalysts[2] and highly sensitive sensing layers.[3] We will present a systematic study on the conditioning of the polymer templates for its effective use for targeted applications. We will show that combining the infiltration of the polymer template from solution and from gas phase can significantly expand the compositional diversity of the structures that can be generated via ALD processes. We will discuss the perspectives of using plasma and thermal ALD for polymer infiltration. We will show that the choice for postpreparative polymer removal techniques can affect the dimensions, structure and composition of deposited all-inorganic heterostructures.[4]

12:15 PM SF01.10.07
Multiferroic $BiFeO_3$ Films Grown by MOCVD for Hybrid Energy Harvesters Quentin Micard, Guglielmo G. Condorelli and Graziella Malandrino; Univ di Catania, Italy

Multiferroics are materials in which at least two of the three ferroic orders, ferroelectricity, ferromagnetism or antiferromagnetism and ferroelasticity coexist. Among multiferroics, perovskite bismuth ferrite ($BiFeO_3$) and its derived systems are of special interest for keeping their properties in extreme temperature environments because of their Curie (T_C = 1103 K) and Neel temperatures (T_N=643 K) well above room temperature. A lot of research has been devoted to the optimization of $BiFeO_3$ as ceramics, thin films and nanostructures. The interest in BFO is also boosted by it being a lead-free perovskite since the rising importance of environmental issues and questions of process sustainability have contributed to the prominence of lead-free perovskite systems. Photoelectric, pyroelectric, and piezoelectric properties are the most studied and appealing characteristics, which make $BiFeO_3$ an important material for energy harvesting applications. The possibility of combining the above-mentioned properties in a single device, a hybrid energy harvester, makes $BiFeO_3$ one of the most promising materials for the next generation of lead-free harvesters. The main deposition techniques applied to the production of BFO films are chemical solution deposition (CSD), pulsed laser deposition (PLD), sputtering and sol-gel. So far, compared to other methods, Metal-Organic Chemical Vapor Deposition (MOCVD) has been relatively unexplored and never used to develop $BiFeO_3$ deposition on silicon to fit the standard of the MEMs industry. MOCVD deposition technique offers a large number of advantages compared to other thin-film production methods with a wide choice of industrial precursors, high-quality substrates, and upscale opportunities.
In this presentation, a simple synthetic strategy based on MOCVD for the fabrication of pure and doped $BiFeO_3$ perovskite thin films on Si/IrO_2 and STO:Nb (100) substrates will be presented. The carried work aims to bring a methodology for the synthesis of $BiFeO_3$ systems thin films that are compatible with conventional industrial processes. The MOCVD approach proved a powerful tool for the fabrication of Dy-doped $BiFeO_3$ films. An accurate control of the processing parameters, in particular the multicomponent source mixture ratio, resulted selectively and reproducibly in the formation of $Bi_{1-x}Dy_xFeO_3$ (x = 0, 0.06, 0.08 and 0.11) thin films. Ferroelectric, dielectric and pyroelectric properties of $Bi_{1-x}Dy_xFeO_3$ (x = 0, 0.06, 0.08 and 0.11) thin films have been investigated showing that this films may be integrated as lead-free pyroelectric energy harvesters.
As material chemical composition has a critical influence on its properties, precursor thermal behavior has been checked by thermogravimetric analysis (TGA) for complex doped systems. The understanding of the films chemical compositions and homogeneity has been obtained by energy-dispersive X-ray analyses (EDX) and X-ray photoelectron spectroscopy (XPS). The polycrystalline or epitaxial nature of the films has been controlled by X-ray diffraction (XRD) and transmission electron microscopy (TEM) in the case of intricate nanostructures. Morphological study of the materials has been done by field emission scanning electron microscopy (FE-SEM) and atomic force microscopy (AFM). Coupled to the AFM, piezoresponse force microscopy (PFM) and piezoresponse force spectroscopy (PFS) have permitted the imaging of ferroelectric domains and the confirmation of the films piezoelectric properties.

This work was supported by the European Community under the Horizon 2020 Programme in the form of the MSCA-ITN-2016 ENHANCE project, Grant Agreement N.722496.

Rapid, Low-Temperature Growth of *p*-type Oxides by Atmospheric Pressure Chemical Vapor Deposition for Photovoltaics and Field-Effect Transistors Rob Jagt[1], Tahmida N. Huq[1], Mari Napari[2], Maung Thway[3], Tianyuan Liu[3], David J. Meeth[1], Kham M. Niang[1], Andrew J. Flewitt[1], Fen Lin[3], Judith L. MacManus-Driscoll[1] and Robert Hoye[4]; [1]University of Cambridge, United Kingdom; [2]University of Southampton, United Kingdom; [3]National University of Singapore, Singapore; [4]Imperial College London, United Kingdom

Oxides are widely appealing, owing to their high mobility (compared to organic materials) and robust electronic properties. Whilst less common than their *n*-type counterparts, *p*-type oxides are needed as hole transport layers in photovoltaics, as well as for CMOS. For next-generation applications, it is critical to deposit *p*-type oxides at low temperature in order to be compatible with thermally-sensitive underlayers, such as flexible substrates (*e.g.*, for wearable electronics) and photovoltaic device stacks (*e.g.*, based on lead-halide perovskites).

This talk explores the use of atmospheric pressure chemical vapor deposition (AP-CVD) for the growth of *p*-type cuprous oxide (Cu_2O) at low temperature for photovoltaic and field-effect transistor (FET) applications.

In the first part, the deposition of uniform Cu_2O by AP-CVD at temperatures down to 100 °C is developed. The growth rate is 1.3 nm s^{-1}, which is an order of magnitude larger than conventional atomic layer deposition. This is used to create the *p*-type buffer layers on *n*-*i*-*p* structured perovskite photovoltaics. We show that owing to the high density of the Cu_2O films grown, a 3 nm layer of Cu_2O is sufficient to mechanically protect the perovskite device stack from damage when sputter depositing a transparent indium tin oxide electrode on top. The Cu_2O layer has minimal parasitic optical absorption (with >95% transmittance) and hole mobilities of 4±2 cm^2 V^{-1} s^{-1}, which is orders of magnitude larger than that of the PTAA hole transport layer in the perovskite device stack. This leads to semi-transparent perovskite photovoltaics with state-of-the-art efficiencies of 16.7%. By stacking these semi-transparent devices over silicon bottom cells made with industrially-relevant processes, four-terminal tandems with efficiencies up to 24.4% are achieved.[1]

In the second part of the talk, AP-CVD Cu_2O is developed into FETs. The switching characteristics of the devices are examined and compared against Cu_2O grown by atomic layer deposition under comparable processing conditions.[2] The effect of Al_2O_3 passivation on the performance of the FETs is investigated, coupled with in-depth photoemission spectroscopy and transmission electron microscopy to understand the cause of changes in performance.

ALD-Grown IrO_x-TiO_2 Oxygen Evolution Reaction Electrocatalyst Alloys and Multilayers for Enhanced Stability and Performance Aein Babadi[1], Scott Monaghan[2], Christopher O'Rourke[3], Michael Braun[1], Paul Hurley[2], Andrew Mills[3] and Paul McIntyre[1]; [1]Stanford University, United States; [2]Tyndall National Institute, University College Cork, Ireland; [3]Queens University Belfast, United Kingdom

Low temperature electrolysis of water as a source of protons and electrons for electrochemical synthesis of hydrogen, liquid fuels and chemicals is an essential approach for decarbonization of the global economy. Water electrolysis is heavily reliant on highly active and stable electrocatalysts, and the most challenging step, from the perspective of electrochemical kinetics and catalyst stability is the oxygen evolution reaction (OER). High-rate water oxidation leads to acidic conditions in the electrolyte near the anode surface in electrolyzers. Among the highly active OER catalysts, only iridium oxide is relatively stable at acidic pH. However, the efficient utilization of IrO_x-based catalysts is essential for a cost-effective and scalable implementation of water electrolysis systems. The IrO_x catalyst layers need to be mechanically robust and stable during water oxidation and remaining highly active over long time periods.

Atomic layer deposition (ALD) is well-suited for the deposition of ultra-thin catalysts and support materials, and for catalysts surface functionalization to promote stability and enhance catalytic performance. We have synthesized stable nanoscale metal oxide alloys in the IrO_x-TiO_2 system that catalyze water oxidation while achieving high electronic conductivity. Thin TiO_2-IrO_x alloy films were grown by a super-cycle ALD process consisting of alternative cycles of TiO_2 and IrO_2 ALD processes. ALD TiO_2 films were grown using tetrakis(dimethylamido)titanium (TDMAT) and water vapor. IrO_2 ALD was performed by using ethyl cyclopentadienyl cyclohexadiene iridium (I) ((EtCp)Ir(CHD)) and ozone as the oxidant. The alloy compositions were controlled by varying the ALD cycle ratio. X-ray photoelectron spectroscopy (XPS) determined that the Ir/(Ir+Ti) compositions were reproducible and varied in a range from 0.13 to 0.51. Hall-effect analysis exhibits an overall decrease in the resistivity of the TiO_2-IrO_x alloys with increasing the iridium content, and p-type conduction for ALD-IrO_2 films.

Another approach to stabilize the catalyst layers is the application of overlayer coating for corrosion protection. The coating can be an electrochemically active overlayer or a combination of overlayer and catalyst material, which induces activity for catalyst reactions on the surface. It may also be a nominally inactive material, which allows the correct reaction species to come to the catalyst/electrolyte interface, while preventing other components poisoning the surface of the catalyst. We observed coating of ALD-IrO_x catalyst layers with very thin layers (< 1 nm) of TiO_2 which is normally an inactive material for water oxidation, enhances its activity by reducing the activation overpotential for OER. The current associated with water oxidation (electron transfer in OER) at a given potential was higher when we had a thin TiO_2 coating with a thickness on the order of less than one nanometer. We report on possible chemical modification of the IrO_x surface caused by the TiO_2 coating and how this correlates with the observed overpotential and Tafel behavior for OER.

Late News: Atomic Layer Deposition of Nickel Nanoparticles on Boron Nitride Nanotubes for Plasma-Assisted Catalysis Elham Kamali Heidari, Ania Sergeenko and Ken Bosnick; National Research Council Canada, Canada

Boron nitride nanotubes (BNNTs) are a new type of one-dimensional material that is similar to carbon nanotubes. BNNTs have recently attracted attention due to their desirable physical, thermal, and mechanical properties. Due to the high surface area and stability under harsh conditions, BNNTs can be a suitable substrate supporting catalyst particles, including for use in harsh, plasma-assisted reactors. In this research, Ni nanoparticles are deposited on BNNT papers via plasma enhanced atomic layer deposition (PEALD) using bis ethylcyclopentadienyl nickel ($Ni(EtCp)_2$) as the precursor and N_2/H_2 plasma. Scanning Electron Microscopy (SEM) and Helium Ion Microscopy (HIM) studies show BNNTs to be well covered with Ni particles after 150 cycles of ALD at 350 ºC. Elemental analysis (EDS) proves the existence of Ni on the BNNT papers after the ALD process. According to the Transmission Electron Microscopy (TEM) observations, Ni nanoparticles are uniformly distributed over the BNNTs and have a diameter of about 4 nm. The synergy arising from the catalytic nature of the Ni nanoparticles and the high surface area, porosity, and stability of the BNNT substrates makes this

material system a perfect candidate for catalysis applications such as for the plasma-assisted production of ammonia.

2:00 PM SF01.11.04
Atomic Layer Deposition of the Alkali Polyphosphazene Electrolytes to Enable Solid–State Batteries Alexander C. Kozen, R B. Nuwayahid, Daniela Soltano, Keith Gregorczyk, Sang Bok Lee and Gary Rubloff; University of Maryland, United States

Solid state batteries (SSBs) are considered the most promising next-generation energy storage technology both due to their increased safety over conventional wet Li-ion cells and their ability to fabricate novel architectures with simultaneous high energy and power density. However, the ionic conductivities of many solid electrolyte materials are orders of magnitude lower than liquid carbonate-based electrolytes. In order to offer SSBs with competitive charge/discharge rates, SSB layers need to be thin (for fast ion diffusion) but have a large surface area (to enable large ion flux from anode to cathode). These geometric constraints establish the need for 3D electrode (and solid electrolyte) structures for a high performance battery architecture. Atomic layer deposition (ALD) is ideally suited to fabricate such devices due to its low deposition temperature, highly conformal nature, and Angstrom-scale thickness control, however many challenges remain with materials fabrication and process integration.

We have developed both plasma-enhanced ALD (PEALD) and thermal ALD processes for the Li, Na, and K alkali polyphosphazene (A*PON) electrolytes[1,2,3,4]. The PEALD A*PON processes, by virtue of their 4-precursor synthesis route, allow some degree of chemical composition tuning. The thermal A*PON processes, unlike their PEALD counterparts, have a predetermined P-N ratio fixed by use of the precursors, however there is a tradeoff between the low temperature deposition enabled using plasma-based A*PON processes, and the conformality offered using the thermal A*PON processes. I will discuss and compare the reaction mechanisms and growth behavior among the entire family of A*PON solid electrolyte thin films, as well as discuss the integration challenges on the path to developing all-ALD planar and 3D SSBs.

Ceramic Nanocomposites Through Pressureless Sintering of CVD-Produced Hybrid Ceramic Powders Ken Bosnick, Serguei Koutcheiko, Jennifer Bruce, Ruilin Liang and Syed Bukhari; National Research Council Canada, Canada

Theoretically, the integration of nanomaterials, such as carbon nanotubes (CNT), into a continuous matrix will produce a nanocomposite material with new and exciting properties. However, problems with the dispersion of the nanomaterials in the matrix have greatly hindered the realization of this opportunity. For example, mixing a bulk sample of CNTs with a polymer matrix often requires shear forces high enough to damage the CNTs and the polymer in order to be able to get reasonable dispersion. Mixing a bulk sample of CNTs with a ceramic matrix, in order to make a ceramic nanocomposite, would be even more difficult. Fortunately, unlike polymers, ceramics can easily survive at the temperatures needed for chemical vapour deposition (CVD) of CNTs (and other nanomaterials). In this work, CNTs are deposited onto ceramic (alumina) powder by CVD after staining with catalyst precursor and jet milling. The CNTs are well separated from each other and immobilized on the powder. This hybrid CNT-ceramic powder is mixed with a binding agent, pressed into a green body, and pressurelessly sintered to fabricate the nanocomposite. Physicochemical characterization reveals the CNTs to have survived the sintering process. The nanocomposite is characterized for its mechanical properties and the process optimized. A “floating-catalyst”, plasma CVD reactor is under construction that will produce 1 kg/h of sinterable hybrid ceramic powder from a jet of neat alumina powder and a ferrocene / xylene solution, eliminating the need to deposit catalyst precursor and jet mill the powder.

Tuning Conformality in Templated Initiated Chemical Vapor Deposition for Fabrication of Functional Nanostructures Gozde Ince[1,2]; [1]Sabanci University, Turkey; [2]Sabanci University Nanotechnology Research and Application Center, Turkey

Recent advances in technology accomplished by operating at nanoscale, require surface modification and functionalization for improved performance. However, functionalization of patterned surfaces or surfaces that are not directly exposed, present significant challenges in homogeniety and conformality. Functionalization of surfaces with highly conformal and homogenious coatings can be achieved via vapor deposition methods. Initiated chemical vapor deposition (iCVD) as a polymer thin film deposition technique provides conformal coatings of functional polymers on patterned surfaces.

In this talk, methods to obtain conformal iCVD coatings in confined spaces by optimizing the process parameters will be introduced and studies on one dimensional nanostructures and hybrid membranes prepared by templated iCVD method will be presented. The templated iCVD method involves conformally coating the pore walls of a sacrificial porous template with functional polymers. Stimuli responsive polymer nanotubes as nanocarriers for controlled release and biosensor applications, are successfully fabricated by templated iCVD method.

In the second part of this talk, smart membranes, which have tunable pore sizes that depend on the pH or temperature will be presented. Smart membranes are fabricated using the templated iCVD method and the conformality of the coatings are controlled by tuning the process parameters. The performance of these hybrid membranes are optimized for macromolecular separation and for protein gating applications.

Understanding and Tuning Surface Chemistry to Achieve Area Selective ALD Stacey F. Bent; Stanford University, United States

With the growing interest in nanoscale materials for applications such as electronics, catalysts, and batteries, methods for fabricating materials with precise control are becoming increasingly important. Area selective atomic layer deposition (AS-ALD) is gaining attention as an important process to achieve spatial control of materials deposition down to the nanometer length scale. AS-ALD is a bottom-up patterning process in which material is deposited only where desired. This talk will describe how control over the chemical properties of the substrate surface can be used to achieve AS-ALD. A deep understanding of the gas-surface chemistry behind ALD can be critical toward developing area selective processes. Research into the fundamental chemical mechanisms of ALD will be illustrated, including studies into both ALD precursor design and surface treatments that can enhance or inhibit nucleation. The development of inhibitory or enhancing layers to alter the native surface reactivity will be described. We will show that this process provides good selectivity in the deposition of thin films ranging from inorganic to organic on a variety of substrate materials, including dielectrics and metals.

11:00 AM *SF01.12.02
Atomic Layer Deposition of Cobalt Phosphate as Electrocatalyst for the O_2 Evolution Reaction—Process Characterization and Mechanism of Electrochemical Activation Mariadriana Creatore; Eindhoven University of Technology, Netherlands

Storage of electricity into molecules is the most viable answer to the intermittency of renewable sources. In this respect, H_2O splitting to H_2 and O_2 is key to enable the usage of H_2 as fuel for transport, as well as building block together with CO for the electrosynthesis of hydrocarbons. For the O_2 evolution half reaction (OER), cobalt phosphate-based materials (CoPi) are interesting because they are based on earth-abundant elements and behave as bulk electro-catalysts, with Co^{3+} being the electro-chemically active centers.
Atomic Layer Deposition (ALD) is gaining major attention in the field of (electro-)catalysis because of its merit of control over conformality, uniformity, film growth (from nano-particles to thin films) and stoichiometry. Recently, we have contributed to this exciting field by demonstrating the synthesis of amorphous CoPi films by ALD [1]. CoPi is prepared by combining ALD of CoO_x from cobaltocene ($CoCp_2$) and O_2 plasma, with cycles of $(CH_3O)_3PO$ (TMPO) and O_2 plasma, according to an ABCD recipe scheme [1]. The process shows a GPC of 1.12 ± 0.05 Å at 300°C, linear growth and no nucleation delay. Insights into the surface reactions occurring during the ALD process are inferred by mass spectrometry [1]. The $CoCp_2$ dosing is characterized by the absence of by-products, suggesting that the adsorption of the precursor on the surface is likely to occur without ligand exchange. The subsequent O_2 plasma exposure promotes the combustion of the Cp ligands, as supported by the detection of CO_2^+, CO^+ and H_2O^+ species. The presence of $C_4H_4^+$ and $C_2H_2^+$ species in the initial stages of the plasma step, provides indirect evidence that cyclopentadienone (C_5H_4O) is an intermediate product in the Cp oxidation process. Then, C_5H_4O dissociates, generating C_4H_4, C_2H_2 and CO. The TMP dosing is characterized by chemisorption accompanied by abstraction of one methanol molecule. Finally, the conversion of the remaining ligands occurs through the O_2 plasma exposure.
Next to the above-mentioned CoPi growth studies, we have also shown that tuning the Co-to-P ratio, by combining this recipe with extra cycles of CoO_x, leads to the increase in OER performance [2], beyond that achieved by traditional electro-deposited films.
Moreover, we have investigated the mechanism behind the enhancement of the catalytic activity of ALD CoPi when tuning the Co-to-P ratio. We have found that ALD CoPi thin films progressively undergo activation under alkaline conditions with increasing number of cyclic voltammetry (CV) cycles. During this activation process induced by the infiltration of the electrolyte in the bulk of the film, the current density increases in parallel with the leaching of phosphorus out of the electro-catalyst and the shift of the oxidation state of Co from Co^{2+} to Co^{3+} [3]. CV analysis combined with Rutherford backscattering measurements indicate that after activation, as much as 22% of all Co atoms become accessible to the electrolyte and are activated. The electrochemical surface area (ECSA), i.e. the surface area accessible to promote H_2O splitting, increases up to a factor of 30. The increase in ECSA is strongly dependent on the composition of the pristine CoPi films: while the aforementioned increase holds for CoPi films with a Co-to-P ratio of 1.6, for films with a Co-to-P ratio of 1.9 the ECSA only increases by a factor 3.6. We find that for all investigated Co-to-P ratios, the electrochemical activity scales linearly with ECSA upon activation. Thus, the pristine composition indirectly affects the activity of the electro-catalyst by guiding its restructuring during activation.
It can be concluded that the digital control over the chemical composition of ALD CoPi enables to unravel the mechanism behind its electrochemical activation.

Atomic Layer Deposition of Epitaxial Perovskite Nickelates Tae Joon Park, Zhen Zhang and Shriram Ramanathan; Purdue University, United States

Atomic layer deposition (ALD) of correlated oxides is an emerging field. With limited data available in literature on thermodynamics of precursors to deposit rare-earth metals, significant experimental effort and instrumental optimization is essential for robust formation of crystalline phases of complex oxides such as rare-earth nickel oxides. ALD of such complex semiconductors could make them directly relevant to electronic technologies as well as enabling high quality ultra-thin films necessary for electric field control of various physical properties. In this work, we will discuss ALD processing of epitaxial $NdNiO_3$ thin films. By controlling various deposition parameters including precursor pulsing time, deposition temperature, we have successfully optimized the growth conditions to obtain stoichiometric $NdNiO_3$ thin films grown epitaxially on $LaAlO_3$. We will then discuss their excellent functional properties such as large electrically tunable opacity to realize electrochromic window coatings on glass and highly responsive hydrogen gas sensors for environmental monitoring. Finally, we will critically compare these functional properties to those of similar thickness epitaxial $NdNiO_3$ films grown by RF-sputtering.

11:45 AM SF01.12.05
Tuning the Electrochemical Properties of Multifunctional Catalyst Layers by Plasma-Enhanced Atomic Layer Deposition Matthias Kuhl, Alex Henning, Lukas Haller, Laura I. Wagner, Chang-Ming Jiang, Verena Streibel, Ian Sharp and Johanna Eichhorn; TU Munich, Germany

Photoelectrochemical (PEC) energy conversion is a promising route for synthesis of storable chemical fuels from sunlight, thereby providing a route to overcome the current global reliance on fossil fuels. One of the major challenges in such artificial photosynthetic systems are the poor efficiency and material instability of semiconductor photoelectrodes under harsh PEC operating conditions. One strategy to overcome this limitation is to interface the semiconductor light absorber with conformal and ultra-thin catalytic layers, which promote the desired chemical reaction, while permitting efficient interfacial charge transport, maintaining chemical stability, and minimizing parasitic light absorption. In this regard, plasma-enhanced atomic layer deposition (PE-ALD) is a powerful tool for designing surface layers and interfaces with tailored functionality and precise thickness control.

Recently, it was demonstrated that PE-ALD can be used to fabricate conformal, biphasic $Co_3O_4/Co(OH)_2$ catalyst layers on semiconductor photoelectrodes, which are simultaneously robust and electrochemically active[1]. In this system, the nanocrystalline Co_3O_4 layer forms a durable interface to the substrate and the disordered $Co(OH)_2$ surface layer significantly improves the electrocatalytic oxygen evolution reaction (OER) activity. Here, we leverage the

precise control of PE-ALD to further tailor the thickness ratio of the surface and interface layers of the $Co_3O_4/Co(OH)_2$ bilayer by tuning the plasma pulse time during growth. Short pulses lead to the formation of porous, unstable $Co(OH)_2$ layers, while long pulses reduce the thickness of the surface layer and form stable, inactive Co_3O_4 layers. Furthermore, we show that the underlying mechanism for the formation of the $Co(OH)_2$ surface layer is the incomplete decomposition of the precursor at short pulse durations. This work highlights the use of PE-ALD as a promising approach for engineering catalyst/semiconductor interfaces to create efficient and stable photoelectrodes.

12:00 PM SF01.12.06
Development of Strained-Germanium Based Light-Emitting Microstructures via Liquid Phase Epitaxy Buse Unlu[1], Milad Ghasemi[1], Selcuk Yerci[1,1] and Cicek Boztug[2]; [1]Middle East Technical University, Turkey; [2]TED University, Turkey

Germanium (Ge) is a promising candidate to serve as an infrared light emitter in the fully integrated, miniaturized biosensing systems where electronic and photonic components are realized on the same silicon (Si) chip in a CMOS-compatible fashion. Despite the inherently indirect band structure of Ge, its bandgap can be engineered to convert it into an efficient light emitter with the emission wavelength tuned into the mid-infrared range of the spectrum, which is suitable for biosensing applications. Among various techniques utilized to enhance the light emission efficiency of Ge, such as Sn alloying, n-type doping, and application of tensile strain, the latest one provides an additional advantage by enabling the development of the room-temperature-operated infrared light source with a predefined emission wavelength, where the emission wavelength is simply a function of the strain. In this work, we introduce a CMOS-compatible fabrication technique that allows obtaining single-crystalline tensilely-strained germanium microstructures, where both crystallization and tensile strain induction is achieved through a single annealing process. The fabrication procedure of the structures relies on the deposition of the germanium, silicon nitride, and silicon dioxide films all by using a physical vapor deposition, namely sputtering, technique, which is a room-temperature-operation, environmentally-friendly deposition technique as opposed to the chemical vapor deposition methods. The crystallization of the sputtered amorphous germanium is achieved via liquid phase epitaxy following a single rapid thermal annealing process, during which tensile stress is also introduced into the silicon nitride film capping the germanium. A subsequent photolithography process allows the strain transfer from the tensilely-stressed nitride film to the lithographically defined germanium microstructure. Strain, and therefore the emission wavelength, can simply be adjusted by varying the duration of the final wet etching process. The method is suitable for both the fabrication of uniaxially and biaxially tensile-strained germanium microstructures, where uniaxial and biaxial strain levels of around 3% and 1.5%, respectively, have been demonstrated and verified by Raman spectroscopy and micro-photoluminescence (micro-PL) measurements, as well as the finite element method (FEM) simulations. Overall, our results show that infrared light emitters based on tensilely-strained germanium microstructures suitable for the biochemical sensing applications can be realized on Si chips in a CMOS-compatible fashion utilizing cost-efficient and easy-to-use deposition (sputtering) and crystallization (liquid phase epitaxy) methods.

Controlling Reaction Paths for Growth of Inorganic Nanowires Floating in the Gas Phase Richard S. Schaeufele[1,2], Juan J. Vilatela[1] and Miguel Vazquéz-Pufleau[1]; [1]Imdea Materials Institute, Spain; [2]Universidad Autónoma de Madrid, Spain

Synthesis of inorganic nanowires/nanotubes suspended in the gas through floating catalyst chemical vapour deposition (FCCVD) produces exceptional growth rates of 500 - 1000 micron/second, more than two orders of magnitude faster than conventional substrate processes. It leads to nanowire lengths > 100 microns and thus to the possibility of direct assembly into freestanding macroscopic networks as a continuous process. This work studies the different reaction paths controlling conversion and crystallinity in FCCVD applied to the synthesis of silicon nanowires (SiNW) from silane, grown through an aerosol of gold catalyst nanoparticles. There are two main competing reactions: catalysed growth of SiNW and nucleation of amorphous Si nanoparticles. The two populations can be conveniently distinguished for high-throughput screening by their colour and Raman spectra. Their balance is kinetically controlled by the ratio of precursor/hydrogen carrier gas, through its inhibition of the pyrolisis of silane into silylene. This role of hydrogen is common to other nanomaterials grown by FCCVD, but differs with respect to carbon and boron nitride in having little influence on the nucleation stage of 1D nanomaterial growth. As a consequence, we were able to identify effective process conditions for producing large free-standing and pristine SiNW sheets. These yield highly promising results when exploited as active material in lithium ion battery anodes.

1:15 PM SF01.13.03
Atmospheric-Pressure Spatial Atomic Layer Deposition (AP-SALD) Of Metal Oxides for Gravimetric Gas Sensing Applications Masoud Akbari[1], Viet Huong Nguyen[2], Gaëtan Debontride[3], Martial Defoort[1], Skandar Basrour[1], Kevin Musselman[4] and David Munoz-Rojas[1]; [1]University of Grenoble Alpes, France; [2]Phenikaa University, Viet Nam; [3]CIME Nanotech/Grenoble INP, France; [4]University of Waterloo, Canada

Metal oxides are commonly used as sensing material for gas detection applications. The surface of the metal oxide is covered with oxygen ions (ion adsorbed) in presence of air, and these ions act as electron acceptors [1]. Metal oxides have mostly been used in resistive or conductive gas sensors, where electronic events in the material generate a detection signal. However, they are also promising as sensing layer in gravimetric micro-electromechanical systems (MEMS). MEMS-based gravimetric sensors are ultra-fast and highly sensitive and the sensing mechanism is related to mass change. Upon exposure of the metal oxide-coated sensor to a gas, the surface oxygen ions react with the gas molecules, which results in lowering or increasing the sensor mass [2]. The sensing performance of the sensor is highly dependent on the chemical and structural properties of the sensing layer. Recently, Atmospheric-Pressure Spatial Atomic Layer Deposition (AP-SALD) has proven to be an excellent deposition technique that is capable of producing high quality metal oxide thin films with precision control, while being up to 2 orders of magnitude faster than conventional ALD, and working at atmospheric pressure [3][4]. Recently, we developed ZnO-based transparent conductive films deposited with our home-made AP-SALD for resistive gas sensing [5]. In this research, we employed AP-SALD for deposition of different metal oxides for gravimetric gas sensing. We present a complete study on deposition of tin oxide (SnO_2), as a common sensing material, and structural, optical, chemical and electrical properties of the SnO_x thin films will be shown. Gas sensing properties of SnO_2, ZnO, Al-ZnO, etc. deposited by AP-SALD and effect of annealing and doping on sensing behavior will be investigated and discussed in detail. The gas sensors functionalized by metal oxides showed fast response and high sensitivity toward humidity, ethanol and acetone.

1:30 PM SF01.13.04

P-Type Cu_2O Thin Films Deposited via Atmospheric-Pressure Spatial Atomic Layer Deposition—A Step Towards Low-Cost Photovoltaic Solar Harvesters Abderrahime Sekkat[1,2,3], Viet Huong Nguyen[4], Daniel Bellet[1], Anne Kaminski-Cachopo[2], Guy Chichignoud[3] and David Munoz-Rojas[1]; [1]LMGP, France; [2]IMEP-LaHC, France; [3]SIMaP, France; [4]Faculty of Materials Science and Engineering, Phenikaa University, Viet Nam

Cuprous oxide (Cu_2O) is a non-toxic and abundant p-type semiconductor with a direct band gap around 2.1 eV and a large visible absorption coefficient. It has been studied and developed for several devices such as solar cells, thin film transistors or batteries. In this work, Cu_2O think films with thickness below 100 nm and record motilities up to 92 $cm2V^{-1}s^{-1}$ have been obtained. The films have been deposited via AP-SALD (Atmospheric-Pressure Spatial Atomic Layer Deposition) at low temperatures (up to 260 °C), under atmospheric pressure. AP-SALD is an alternative approach to conventional ALD in which the precursors are separated in space rather than in time, allowing fast deposition rates as compared to conventional ALD (up to nm/s in some cases).
The impact of the deposition parameters on the growth rate and transport properties (mobility and concentration of carriers) has been studied, and different Cu precursors have been evaluated. The high mobility values obtained, which are close to values associated to epitaxial Cu_2O thin films or Cu_2O single crystals, have been rationalized based on Raman data. Optimized Cu_2O thin films, combined with n-type ZnO also deposited by AP-SALD, lead to all-oxide solar harvesters with efficiency values rivaling similar devices made with high temperature and/or vacuum approaches, thus opening the door to efficient semitransparent solar harvesters.

1:45 PM SF01.13.05

Bandgap and Defect States Analysis Using Spectroscopy of Chemical Vapor Deposition (CVD) Grown Cu2O Vivek Singh, Jyoti Sinha and Sushobhan Avasthi; Indian Institute of Science Bangalore, India

Cuprous oxide (Cu2O) is a promising material for emerging electronics. Bandgap and defect states estimation of Cu2O film grown by chemical vapor deposition (CVD) technique on SiO2/Si substrate at 600°C was performed in this work using various spectroscopies. XRD and XPS confirmed the phase purity of deposited film. The optical bandgap of Cu2O was 2.35 eV which was calculated from absorption spectroscopy (UV-Vis). Using ultraviolet photoelectron spectroscopy (UPS) and absorption spectroscopy (UV-Vis), the nature of deposited Cu2O was confirmed as a p-type semiconductor. Using UPS, the energy level of the valence band and Fermi level of the intrinsically p-doped Cu2O film were determined as 6.02 eV and 5.62 eV respectively from the vacuum level. The temperature dependence photoluminescence spectra of these films exhibited emission peaks at ~1.4 eV and ~1.72 eV which corresponds to energy states of copper and oxygen vacancies level in the bandgap. Photoluminescence spectra also show a peak at ~2 eV which is due to the relaxation of free excitons to the valance band.

2:00 PM SF01.13.06

A Synchrotron-Assisted Investigation of the Thermal Decomposition of Zirconium Acetylacetonate—Pathways to the Formation of Metal-Containing Intermediates in the Gas Phase Sebastian Grimm[1], Seung-Jin Baik[1], Patrick Hemberger[2], Andreas Kempf[1,3], Tina Kasper[1,3] and Burak Atakan[1,3]; [1]University of Duisburg-Essen, Germany; [2]Paul Scherrer Institute, Switzerland; [3]Center for Nanointegration Duisburg-Essen (CENIDE), Germany

Solid layers[1,2] of ZrO_2 are often deposited by chemical vapor deposition (CVD), where a metal-containing precursor is evaporated and forms a film in a surface reaction. To design such a process, the gas phase reactions, especially their temperature-dependent kinetics, should be known, which is seldom the case. Intermediates, formed in the gas phase can lead to film formation or to a depletion of the precursor and therefore a reduction in growth rate. The analysis of these early stages of growth requires fast and sensitive analytical techniques with sufficiently low detection limits for elusive gas phase species. Experimental limitations precluded the detection of most of the postulated intermediate species, and reaction mechanisms are predominantly hypothetical so far.[3,4] An experimental approach to enlighten the gas phase chemistry of an often used precursor, zirconium acetylacetonate, is presented here, using a microreactor coupled to a mass spectrometer with mild ionization from a synchrotron source. This was demonstrated previously, to be an effective way to detect and characterize gas phase intermediates with short lifetime.[5,6]
A combined numerical and experimental study of the vacuum pyrolysis of zirconium acetylacetonate, $Zr(C_5H_7O_2)_4$, in a microreactor at short residence times of < 60 μs was carried out. The precursor is sublimed, subsequently transported by argon or helium carrier gas, and expanded through a pinhole into a resistively heated 1 mm inner diameter SiC-microreactor. Products leaving the reactor are expanded and ionized by tuneable vacuum ultraviolet (VUV) synchrotron radiation and characterized by imaging photoelectron photoion coincidence spectroscopy (i^2PEPICO) and mass spectrometry at the Swiss Light Source in Switzerland. From the temperature-dependent photoionization mass spectra between 130 and 650 °C, two initial decomposition steps were identified and temperature regimes for the following pathways of thermal decomposition at higher reactor temperatures were determined. In addition, we recorded photoionization efficiency curves and threshold photoelectron spectra (TPES) at photon energies of 6.5-11.5 eV, which gave us direct evidence about the intermediates and products formed. Six important Zr-intermediates were identified for the first time, as for example $Zr(C_5H_7O_2)_2(C_5H_6O_2)$, and $ZrO(C_5H_7O_2)_2$, together with several organic products, which aided us to describe the predominant thermolysis pathways in the temperature range of 130-650 °C. In conjunction with the simultaneous numerical simulation of the flow field in the microreactor, the application of synchrotron radiation coupled to the i^2PEPICO experimental apparatus is a promising way to enlighten pyrolysis pathways and kinetics of metal-organic precursors.

8:30 AM SF02.01.01
Mechanical Characterization of Elastomeric Lattice Parts Produced by Continuous Liquid Interface Production Roozbeh Neshani[1], Davis J. McGregor[2], Sameh Tawfick[2], William P. King[2] and Sezer Ozerinc[1]; [1]Middle East Technical University, Turkey; [2]University of Illinois at Urbana-Champaign, United States

Additive manufacturing of elastomeric parts has become increasingly important due to unique opportunities in biomedical and vibration isolation applications. Continuous liquid interface production (CLIP) is a recently developed technique that addresses some major limitations in this route by providing fast production of high-resolution features in a repeatable and reliable fashion. In this study, we report on the mechanical properties of CLIP-produced parts made of EPU 41, an elastomeric polyurethane developed specifically for CLIP.

Mechanical characterization studies employed a wide range of techniques, including tensile and compression testing and stress relaxation measurements. Tensile strength of EPU 41 exceeds 10 MPa with an elongation at break reaching 175%. A 2-term Ogden model accurately predicts the tensile response. Compressive stress relaxation measurements provided a compressive set of 13% after a 48-hour constant-strain loading. A three-term Prony series based on the generalized Maxwell model fits the experimental results accurately.

The study also considered the compressive response of a series of lattice parts, including octet, cubic, and BCC-based geometries. The structures fully recover after loading to a strain of 75%. The critical densification strain varies in the range of 0.5 – 0.9, and the corresponding plateau stress exhibits a wide range of values in the range of 0.01 – 0.30 MPa. Tuning of the geometry and the strut thickness enables structures to exhibit a wide range of load absorbing characteristics. The results show the great potential of the CLIP process in manufacturing new generation lattice structures and load-bearing components with optimized compliance and absorbance characteristics.

8:45 AM SF02.01.02
Additive Manufacturing of Colloidal Suspensions—Printing Broadband Omnidirectional Reflectors on Surfaces for High Temperature Applications Benedikt F. Winhard, Gerold A. Schneider and Kaline Furlan; Institute of Advanced Ceramics, Germany

Photonic glasses may yield a new class of thermal barrier coatings, due to their broadband omnidirectional reflection capabilities. To apply such photonic structures, precise deposition even on complex substrate geometries is mandatory. However, conventional techniques, like spin coating, are not capable to form homogenous coatings on curved surfaces. Therefore, we combine an additive manufacturing technique, direct writing, with colloidal self-assembly (AMCA) to deposit polystyrene (PS) colloidal suspensions onto metallic and aluminum oxide surfaces, which subsequently assemble into PS-templates. The inverse opal photonic coatings are then formed via ALD infiltration and subsequent burn-out.
When printing low viscosity suspensions by direct writing, the contact line must remain pinned during solvent evaporation to prevent split up of the filament. However, such pinning also enhances capillary flow, usually leading to a coffee ring effect (CRE). In this work, we performed a parameter study varying both writing velocity v_w and dispense velocity $v_{d,}$ as well as particle loading. We show that increasing the particle loading enhances the self pinning effect, thus enhancing printability, while the CRE can be suppressed by increasing the velocity ratio v_w/v_d. To ensure coverage of large areas, single lines must be connected, however the conventional line-by-line approach is insufficient for low viscosity colloidal suspensions due to capillary penetration of the previously printed line. Hereby, we present a “comb”-printing approach to overcome this issue and print coherent colloidal layers. Finally, we demonstrate that ceramic-based inverse opal photonic coatings are produced when the optimized templates are infiltrated via ALD, showing broadband omnidirectional reflection properties.

9:00 AM SF02.01.03
Energy Absorption Properties of 3D Printed Lattice Structures Ryan Nam[1], Michael Jakubinek[2] and Hani E. Naguib[1]; [1]University of Toronto, Canada; [2]National Research Council Canada, Canada

Novel lattice structure designs fabricated by additive manufacturing are promising in aerospace development in terms of lightweight alternatives to the current solutions. Cellular core sandwich structures offer many multifunctional advantages, such as high specific energy absorption capabilities and

flexural stiffness, and can be further tailored to enhance specific properties. Fused deposition modeling (FDM) of functionally graded lattices shows the potential to be used as a lightweight cellular core for sandwich structures due to their high specific energy absorption in quasi-static compression. Variations in the structural configuration and material composition of an architected core structure are performed to observe the differences in compressive behavior. By FDM printing a lattice composed of repeating unit cells with rows differing in the wall thickness and, consequently, the filled cell volume, the structural grading effects in the direction of compression is explored. Both discrete and continuous grading of the wall thickening were applied from the top to bottom lattice rows along the direction of applied compressive force and display differences in energy absorption properties. The material grading effects are characterized by using two distinct filaments to vary composition of the core structure and hence the material density and tensile modulus properties between the layers. The stress-strain behavior and values of the specific energy absorbed were calculated by examining the printed samples during a quasi-static compression load test. Greater specific energy absorption (energy per mass) was seen in the graded layer by layer design compared to the non-graded octet lattices. The multi-material grading arrangements significantly modified the onset location of structural collapse to influence the layer compression order. These behaviors demonstrate the possibility of 3D printing a lightweight sandwich core with tailorable compressive properties using a combination of material and structural grading.

9:15 AM SF02.01.05
Late News: Micro/Nanofibers-Based 3D Fibrous Scaffolds Using Additive Textile Manufacturing Huibin Chang, Qihan Liu, John Zimmerman, KeelYong Lee, Qianru Jin, Michael M. Peters, Michael Rosnach, Suji Choi, Sean L. Kim, Herdeline Ardoña, Luke MacQueen, Christophe Chantre, Sarah Motta, Elizabeth Cordoves and Kevin K. Parker; Harvard University, United States

There is growing interest to develop next generation of additive manufacturing platform that can rapidly produce micro/nanofibers and precisely control of the fiber alignment in fibrous 3D complex structure, which allows biomimetic materials for next generation philologically assays or customized fiber reinforced composite materials. However, reproducing micro/nano sized fibrous structure is difficult using existing technologies. For instance, approaches such as 3D printing are generally considered too slow for producing fibers in micro/nano size, while high-throughput nonwoven fiber deposition methods provide poor control over structural alignment and 3D geometry. Here we report a new form of additive textile manufacturing platform termed focused rotary jet spinning (FRJS) where micro/nanofiber formation and patterning process are independently controlled. We show that these deposited fibers can conform to various 3D geometries with controllable fiber alignment. This technology has potential in a range of applications, reaching from biomedical applications, fashion design to next-generation food packaging.

9:30 AM SF02.01.06
Probing Polycarbonate Welds Using a Novel Fracture Induced Test Method Ojaswi Agarwal[1], Zheliang Wang[1], Jonathan Seppala[2], Edwin P. Chan[2], Thao (Vicky) Nguyen[1] and Kevin Hemker[1]; [1]Johns Hopkins University, United States; [2]National Institute of Standards and Technology, United States

The Razorblade Induced Fracture Test (RIFT) is a mechanical test method in which a sharp blade is pressed into a sample to initiate and propagate a crack and used to determine the energy release rates (G_C) of soft polymers such as gels or food products [1, 2]. Its use in measuring G_C of stiffer polymers has been limited as the frictional component of the measurement becomes significant [3-5]. In this study we develop a cyclic RIFT test that can easily and repeatably probe narrow regions of the sample and simultaneously account for the frictional contribution to the measurement. We use this method to determine the strength of polycarbonate (PC) welds made using Fused Filament Fabrication (FFF). In conjunction with geometry and thermal characterization using micro-computed tomography (μ-CT) and infrared imaging (IR), we undertake a parametric study of how the thermal and flow history of the print affects the measured strength of the welds in the printed material. This information is compared to bulk PC made by injection molding [6-8].

In-situ birefringence measurements of the sample have shown a concentration of plastic deformation at the crack tip, and a non-negligible strain due to bending which is accounted for through parallel FE modelling. Ex-situ birefringence measurements have shown a small region around the crack tip where the plastic deformation localizes. The width of this region is limited to a single layer on either side of the strongest tested welds, decreasing in size as the welds get weaker . The radius of the region is approximately 0.3 mm while the calculated elastofracture length is much smaller at 11.8 μm. Preliminary results suggest that the frictional force component ranges from 35% to 45% of the measured cutting force. As expected, measured values of G_C for PC welds vary with printing conditions and with the measured thermal and flow history of the print. Increasing the welding increases the measured strength of the weld. The G_C for samples with longer welding times (printed at higher temperatures), approach that of injection molding bulk PC.

9:45 AM SF02.01.07
Decoupling the Effect of Geometry and Microtexture on the Mechanical Response of Additively Manufactured IN625 Thin-Walled Elements Arunima Banerjee[1], Jeff Rossin[2], William Musinski[3], Paul Shade[3], Marie Cox[3], Tresa Pollock[2] and Kevin Hemker[1]; [1]Johns Hopkins University, United States; [2]University of California, United States; [3]Air Force Research Laboratory, United States

Additively manufactured (AM) metallic components have highly anisotropic microstructures spanning multiple length scales. The relationship between microstructure and mechanical properties of printed structures is complicated by the introduction of additional design parameters, such as build orientation and geometric variations. This study was undertaken to decouple the contribution of microstructure and geometry on the mechanical response of thin-walled Inconel 625 T-elements fabricated by laser powder bed fusion. The T-elements were printed at either 40° or 90° inclinations from the build plate resulting in a 10% difference in the ligament widths. Milli-scale tests indicate that the 90° T-elements are stiffer in both the stress-relieved and the fully recrystallized states. However, the modulus along the loading direction determined from EBSD maps suggest the 40° T-elements to be stiffer in the stress-relieved case. The measured yield load difference between the recrystallized samples was in better agreement with the values predicted from beam theory.

10:00 AM BREAK

10:30 AM SF02.01.08
Late News: *In Situ* Evolution of Microtribology in Additively Manufactured 316L Steel by Selective Laser Melting Mohanad Bahshwan[1,2], Mark Gee[3], John Nunn[3], Connor Myant[1] and Tom Reddyhoff[1]; [1]Imperial College London, United Kingdom; [2]University of Jeddah, Saudi Arabia; [3]National

Physical Laboratory, United Kingdom

Consensus on the wear and friction performance of additively-versus-conventionally manufactured components has not been achieved; mainly because the tribological test set-ups thus far were not suited for investigating the underlying microstructure's influence on the tribological properties. As a result, utilization of additive manufacturing techniques, such as selective laser melting (SLM), for sliding components remains questionable. Here, we investigate the anisotropic microtribology of SLM 316L stainless steel via in situ SEM reciprocating scratch testing to highlight the microstructure's role. As-built 316L SLM specimens were compared against annealed wire-drawn 316L. We found that: (i) microgeometric conformity was the main driver for achieving steady-state friction, (ii) the anisotropic friction of the additively manufactured components is limited to the break-in and is caused by the lack of conformity, (iii) the cohesive bonds, whose strength is proportional with frictional forces, are stronger in the additively manufactured specimens likely due to the presence of dislocations and/or cellular structures, (iv) low Taylor-factor grains with large dimension stimulate microcutting in the form of long, thin sheets with serrated edges. These findings uncover some microstructurally driven tribological complexities when comparing additive to conventional manufacturing.

10:45 AM SF02.01.09
Assembly, Sintering and Characterization of III-V Nanoparticles for Electronics Applications Anthony S. Childress, Jared Cohen and Ahmed Busnaina; Northeastern University, United States

Additive manufacturing has the potential to make nanoscale electronics at a fraction of the cost required by current conventional fabrication. Through the directed assembly-based printing of nanomaterials, hundreds of steps of deposition and etching can be removed from the fabrication process. Previous research conducted at the NSF Center for High-rate Nanomanufacturing and other works have shown the effectiveness of the directed assembly processes that allow for high throughput and high precision at comparatively low cost. However, the assembly and sintering of semiconducting nanomaterials such as InP and GaAs poses a significant challenge to this endeavor. In this talk I will outline our recent results in the processing, assembly, and annealing of III-V semiconducting nanoparticles. Through high-speed ball milling, bulk particles of III-V semiconductors have been reduced to dimensions of less than 30 nm, after which they were formulated into a stable ink suitable for printing. A silicon wafer with a functionalized surface allows the precise assembly of nanoparticles through preferential adhesion of the ink. The particles are assembled as structures suitable for making transistors and measuring Hall and other electronics characteristics. Annealing the particles to make a continuous structure is critical for fabricating practical electronics, and it is this aspect which poses one of the greatest challenges due to the loss of the lighter elements (P and As) during annealing. This barrier is overcome through the use of small amounts of sacrificial particles during annealing, resulting in a continuous structure. Once the assembled particles are sintered, gold contacts (source and drain) are deposited for electronic characterization. The results from our work demonstrate the feasibility of printing III-V semiconductors for electronics applications.

11:00 AM SF02.01.10
Differences in Microstructures and Mechanical Properties of Ti-6Al-4V Fabricated by Selective Laser Melting with Pulse Width Modulation Under the Same Volumetric Energy Density and Duty Cycle Seunghwan Moon, Seungmuk Ji, Young-Shik Yun and Jong-Souk Yeo; Yonsei University, Korea (the Republic of)

Metal Additive Manufacturing (AM) is drawing attention to the application of biomedical implants because of its ability to fabricate customized precise structures readily than conventional casting methods. Powder Bed Fusion (PBF), which is implemented by irradiating powder particles with a heat source, provides sufficient mechanical property without post-processing in contrast to the other AM technologies. There are two types of heat sources that are used for PBF; laser and electron beam. The former is known as Selective Laser Melting (SLM) and the latter is Electron Beam Melting (EBM). Especially for SLM, a pulse laser can be used by modulating the power signal of a continuous-wave laser into a pulse shape. This process is called Pulse Width Modulation (PWM), which allows additional process control compared to a continuous-wave laser.

Volumetric Energy Density (VED), calculated by dividing laser power by the product of scan speed, layer thickness, and hatch spacing, is a concept that expresses the applied average energy on the unit volume of the specimen. In many cases, microstructures and mechanical properties of fabricated specimens with SLM can be described by VED, but there exist exceptions. This is because the degree that each process parameter contributes to the properties of the specimen is different.

In this study, we focus on the differences in microstructures and mechanical properties of the specimen fabricated using the same VED conditions, especially with PWM laser. Even if all the process parameters composing the concept of VED and the duty cycle (DC) of the PWM laser are the same, the microstructure and mechanical properties are still very different depending on the pulse width. The surface roughness is also changed according to the pulse width. Mechanical properties are measured by using the Vickers hardness test, and the porosity and roughness are compared using an optical micrograph. For microstructural analysis, electron back-scattered diffraction is measured on the transverse section of specimens. Based on the results from these measurements and the simulation of the thermal distribution obtained through the finite element method, the causes leading to the differences in microstructures and mechanical properties of specimens fabricated under the same VED and DC are analyzed.

This research was supported by the Ministry of Trade, Industry and Energy (MOTIE) and Korea Institute for Advancement of Technology (KIAT) through the International Cooperative R&D program (N0002624) and was also supported by the National Research Foundation (NRF) of Korea under the "Korean-Swiss Science and Technology Program" (2019K1A3A1A1406720011).

SESSION SF02.02: Additive Manufacturing Methods, Characterizations, and Mechanics II

1:30 PM SF02.02.01
Late News: A Study of Microstructure and Mechanical Properties in Additively Manufactured AlCuFeNiTi High Entropy Alloy Sandeep Khadka and Philip Yuya; Clarkson University, United States

An equiatomic AlCuFeNiTi high entropy alloy (HEA) was synthesized using pre-alloyed
powder by direct energy deposition (DED) on a Ti6Al4V substrate and characterized to provide

insight into its microstructural and nanoscale mechanical properties. Scanning electron microscope (SEM) and energy-dispersive X-ray spectroscopy (EDS) were performed to characterize the alloy's microstructure. Also, electron backscatter diffraction (EBSD) and X-ray diffraction (XRD) were carried out to understand the crystallographic information of the alloy. Nanoindentation technique was used to determine the reduced modulus and hardness. Microstructural characterization results show three distinct regions as Cu-rich, Fe-rich, and Al-Ti-Ni rich regions. The presence of these regions shows the variance of local composition within the alloy that influences its mechanical properties. The dendritic regions rich in Al, Ni, and Ti presented a hard zone, whereas the inter-dendritic regions rich in Cu and Fe showed a soft zone. XRD and EBSD analysis confirmed that the regions are a mixture of BCC and FCC phases. The alloy was determined to have a reduced modulus and hardness of 181±14.26 GPa and 9.03±2.42 GPa, respectively.

1:45 PM SF02.02.02
Late News: An Alternative Method for Accident Tolerant Fuel Cladding Using Swaging and Drawing Process at Room Temperature Jong Woo Kim[1], Young Ah Park[1], Jisu Na[1], Hyeongwoo Min[1], Yong Hee Kim[2] and Young Soo Yoon[1]; [1]Gachon university, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of)

At the time of the nuclear power plant accident in Fukushima of Japan, zirconium alloy (Zr-alloy) cladding reacted with high-temperature steam in Loss of Coolant Accident (LOCA) and a large amount of hydrogen gas was generated. [1] In order to solve these problems, the Accident-Tolerant Fuel (ATF) cladding is inevitably a hot topic, led to innovative designs, such as coated Zr-alloy, ceramic cladding and advanced steels. [2] Among others a variety of coating technology have been studied to satisfy the goal of improving ATF in a short term without replacing the existing Zr based alloys. However, it's not easy to deposit coating materials on long cladding, almost 4-meters. The development of the multi-walled swaging & drawing process using Stainless Steel 316 (SS316) tube on Zr-alloy cladding is very simple and can be performed at room temperature which can be mass-produced. However, thermal conductivity of SS316 is low and the thermal neutron absorption cross-section is more than 10 times larger than Zr-alloy. [3] Therefore, it should be used as thin as possible in SS316 tube. The SS316 tube about 100μm thickness was overlapped inside and outside of the Zr-alloy cladding and adhered using drawing process. The multi-walled cladding specimen was oxidized at 1200°C for 600s, in conditions of LOCA, and test shown increase the resistance to oxidation compared to commercial Zr-based alloy cladding. The interface between SS316 tube and Zr-alloy cladding was investigated by Optical Microscope (OM) and Scanning Electron Microscope (SEM). The multi-walled cladding was successfully fabricated using a drawing process, and it was proved that oxidation resistance was excellent through Energy Dispersive Spectroscopy (EDS) and mass change results. Based on the results, it is expected that better Accident-Tolerant Fuel (ATF) can be derived with the thin SS316 tube swaging and drawing process.

2:00 PM SF02.02.03
Late News: Effect of CrN Thin Layer Deposited by Sputtering Method on SS316L Structural Material for PMFR Unho Lee, Young Ah Park, Jisu Na, Jeong Hye Jo and Young Soo Yoon; Gachon University, Korea (the Republic of)

Recently, 4th generation nuclear power generator for Distributed Energy Resources (DERs) in Passivation Molten salt Fast Reactor (PMFR). However, the Interface of reactor vessel materials occurs corrosion by molten salt with Nuclear Fission Product (NFP) at operating temperature. Generators under conventional operating conditions have overcome their limitations and current models at 600 K to 700 K, 46 KCl-54 UCl (mol%) or 17.8 KCl-68.2 $MgCl_2$-14 NaCl (mol%) salts. Materials that overcome chemical stability, high corrosion, and temperature resistance for semi-permanent use should be selected. (NFP: Te, Nb, Zr). Penetrates into the grain boundary of the base material and acts fatally. Therefore, a non-reactive material, CrN, is coated to prevent corrosion decay accidents. The integrity behavior was confirmed through the combined Cr and CrN layer by PVD RF-Sputtering system. NFP adsorption and penetration analysis were performed by heating the specimen at the misch metal jig at 930.15K with 1atm. Through the nano-indenter-based scanning electron microscope (SEM) analysis, the adhesive strength of the 3μm thin film was confirmed, and the elastic modulus of 160GPa was confirmed. A corrosion current density plot was obtained through an immersion test to confirm the chemical stability of the grain boundary. Corrosion voltage section is improved over 0.5V. These results suggested that CrN as a Passivation Molten salt Fast Reactor (PMFR) base material with secured lifetime promises to be a suitable candidate.

2:15 PM SF02.02.04
Customizable Digital Manufacturing Method for Silicon Carbide Jatinder Sampathkumar[1], Nik Ninos[2], Gregory L. Whiting[1] and Nicole J. Labbe[1]; [1]University of Colorado Boulder, United States; [2]Calix Ceramics, United States

Silicon carbide (SiC) is a desirable ceramic for a wide range of applications due to its ability to withstand very high temperatures (>1500K), resistance to thermal shock, and inertness in corrosive environments. These characteristics make the material ideally suited for heat transfer devices, which often require small feature sizes such as aviation engine components and microfluidic devices. For these types of applications, conventional manufacturing processes are primarily used and involve rigid tooling and expensive fabrication techniques. These methods have limited small component silicon carbide manufacturing to relatively simple geometries, with more intricate configurations requiring specialized modifications which can be cost-prohibitive for low volume production and one-off prototype manufacturing. Furthermore, these processes are not amenable to iterative design changes. Additive manufacturing for silicon carbide, while presenting a more flexible processing method compared to other orthodox manufacturing routes, continues to be challenged by smaller form factors or with high feature resolution due to constraints imposed by the slurry and powder composition. High aspect ratio configurations with small feature sizes in the range of 100 to 500 microns prove particularly difficult with these manufacturing methods, requiring numerous post-sinter processing steps or bespoke tooling implements.
To address these shortcomings, this work describes a novel processing route that is iterable, has a high throughput, and is inexpensive for manufacturing small, high aspect ratio silicon carbide geometries. This fabrication sequence utilizes a hybrid manufacturing technique that harnesses the rapid iterability of additive manufacturing and combines it with the knowledge base that exists for conventional ceramic processing. This novel method involves a unique SiC precursor composition that is tailored to be compatible with multiple compaction techniques. The flexibility of polymer and metallic additive manufacturing is utilized to create multiple variants of the tooling required to produce these intricate high aspect ratio geometries at scale and reliably. Specialized compaction tooling to achieve the required green-state strength for compatibility with these small volumes is detailed. The capability of this processing technique is extended to other high aspect ratio structures and ceramic types, showcasing its broad applicability. Material characterization studies are presented to compare features of the sintered SiC geometries constructed using this process to typical fabrication methods.
A use case for this manufacturing technique is presented in the development and production of microfluidic reactor devices. SiC reactors that are straight

tubes with a 1mm inner diameter and 3cm in length featuring an internal constriction of 300 microns to stabilize the fluid flow were manufactured with our process, replacing the current tubular reactors of similar size produced using an extrusion process. An experimental evaluation of this new design in a combustion pyrolysis experiment is presented compared to the currently used SiC reactor geometry, highlighting improvements in material performance and the variation in results obtained due to the presence of an internal taper which stabilizes fluid flow within the reactor. This specific application showcases the adaptability of this method in producing small devices which can be iteratively modified based on the experimental requirement to meet the needs of small-scale experimental facilities.

2:30 PM SF02.02.05
Surface Force-Driven Direct Ink Writing of Polyelectrolyte Membranes Guy J. Cordonier, KmProttoy S. Piash, Oishi Sanyal and Kostas Sierros; West Virginia University, United States

A direct ink writing method for 3D printing low-viscosity inks has been developed and used to fabricate polyelectrolyte membranes. Poly(allylamine hydrochloride) and poly(acrylic acid) inks are deposited in a meandering pattern in a layer-by-layer fashion, forming films with thickness up to hundreds of nanometers. Additionally, films are formed using a traditional layer-by-layer dip coating methodology for comparison. The molecular weight of each polyelectrolyte and post-treatment is varied to change the properties of the resulting films. The films are characterized with scanning electron microscopy, atomic force microscopy, optical profilometry, contact angle, and water filtration.

Long-Term Stabilized Amorphous Calcium Carbonate—An Ink for Bio-Inspired 3D Printing Hadar Shaked and Boaz Pokroy; Technion-Israel Institute of Technology, Israel

Biominerals formed by organisms in the course of biomineralization often demonstrate complex morphologies despite their single-crystalline nature. This is achieved owing to the crystallization via a predeposited amorphous calcium carbonate (ACC) phase, a precursor that is particularly widespread in biominerals. Inspired by this natural strategy, we utilized robocasting, an additive manufacturing 3D-printing technique, for printing 3D objects from novel long-term, Mg-stabilized ACC pastes with high solids loading. We demonstrated, for the first time, that the ACC remains stable for at least a couple of months, even after printing. Crystallization, if desired, occurs only after the 3D object is already formed and at temperatures significantly lower than those of common post-printing sintering. We also examined the effects different organic binders have on the crystallization, the morphology, and the final amount of incorporated Mg. This novel bio-inspired method may pave the way for a new bio-inspired route to low-temperature 3D printing of ceramic materials for a multitude of applications.

Voxel 3D Printing and Computer Simulations to Prototype Bimaterial Attachments Based on Local Interface Patterning Quentin Grossman[1], Peter Varga[2] and Davide Ruffoni[1]; [1]University of Liège, Belgium; [2]AO Research Institute Davos, Switzerland

Joining materials with dissimilar properties is a challenging but ubiquitous task for load-bearing engineering and biological materials. Bimaterial interfaces are prone to stress concentration, which may trigger failure upon loading. Nature's materials feature several strategies to mitigate stresses at bimaterial junctions, making soft-to-hard attachments long lasting. Some biological materials, such as squid beak and byssus thread, display a gradual change in mechanical properties over a region spanning up to several millimeters, which is a length scale much larger than the soft and hard elementary constituents. Other biological interfaces, like the bone-tendon junction, lack long-range property gradients and the transition in mechanical behavior occurs over a micrometer-sized region. Here, failure resistance is obtained by introducing local interface patterning. Advances in multimaterial manufacturing are opening unprecedented possibilities to prototype new bioinspired solutions for bimaterial attachments. Using 3D printing is nowadays possible to assign location-specific material properties to individual voxels within a macroscopic object, enabling the fabrication of complex centimeter-sized heterogeneous structures, referred to as voxel-based materials, with properties tuned at the micrometer level. In this work, we combined voxel 3D printing and computer simulations to prototype bimaterial attachments based on local interface patterning at the mesoscale. We used a polyjet printer (Object 260, Stratasys), which deposits and UV-cures photopolymer droplets in a layer-by-layer fashion. Using different inks, the printer allows fabricating structures composed of individual stiff or compliant cuboid voxels having minimum dimensions of 40 x 80 x 30 µm. In a previous work we have shown that, owing to the printing process, the spatial transition in elastic properties across bimaterial interfaces can be fairly broad (around 150 µm) and larger than voxel size [1]. Here, we manufactured centimeter-sized bimaterial samples featuring voxels having side length of 420 µm. This dimension, higher than printer resolution, is chosen to minimize the impact of the interface, such that a voxel can retain its mechanical character. Samples were fabricated by assigning to the stiff voxels a rigid glassy polymer (Young's modulus of 2 GPa) and to the soft voxels a rubber-like material (Young's modulus of 40 MPa). We architectured bimaterial interfaces based on the general idea of introducing minimal interface patterning, i.e. the width of the perturbed region at the interface between stiff and complaint materials (mesoscale) was at least one order of magnitude smaller than sample length (macroscale). Stiff and compliant voxels were rearranged to form either geometrical patterns or compositional gradients. Starting from a flat interface, we considered chessboard, rectangular and triangular designs as well as gradients with different slopes. We performed failure tests to measure strength and fracture toughness. Our results indicated that minimal interface perturbation in the form of triangular patterns outperformed compositional gradients to enhance failure resistance. Finite element simulations were done to characterize stress concentration and spatial distribution of strain energy density (SED). Firstly, a mesh analysis underlined that at least 4 hexahedral elements were necessary to model individual voxels in case the two materials were assigned very dissimilar properties. More relevant, simulations highlighted that while a flat interface led to the smallest stress concentration in a defect-free case, in the presence of a locally damaged interface triangular patterns minimized stress localization and helped to redistribute SED away from the damaged region. Our results shall provide guidelines to improve failure resistance of bimaterial junctions using voxel-based interface patterning.

Functionally Graded Materials Fabricated by Site-Specific Texture Control During Laser Powder Bed Fusion Karl Sofinowski, Mallory Wittwer and Matteo Seita; Nanyang Technological University, Singapore

Due to the unique ability to manipulate the local solidification conditions point by point, additive manufacturing makes it possible to design materials with spatially varying microstructures. By controlling the distribution of these microstructures, we can design components with enhanced structural and functional properties. In this work, we use our recently published layerwise engineering of grain orientation (LEGO) technique to design functionally graded materials using blocks of discrete near-single crystal and gradient crystallographic textures. We apply our LEGO technique during laser powder bed fusion of stainless steel 316L to demonstrate the potential of site-specific texture control with two applications. In the first, we leverage the anisotropic chemical properties of 316L to create a new, high-throughput method for encoding data in metals. In the second, macro-scale "metamaterial" specimens that mimic grain-scale structures such as grain boundaries, twin boundaries, and triple junctions are examined with in situ mechanical testing. The techniques presented in this work may be further extended to control any material properties affected by crystallographic texture.

4:00 PM SF02.02.10
Late News: Mechanical Evaluation of Laser Powder Bed Fusion (LPBF) Process Based 3D Printed Parts Using Partially Pre-Alloyed Water-Atomized Iron Powder (Fe-1.50Cu-1.75Ni-0.50Mo) Taehyeob Im[1], Huengseok Oh[1], Jai-Sung Lee[1], Sebastian Meyers[2], Kopila Gurung[2], Brecht V. Hooreweder[2] and Caroline S. Lee[1]; [1]Hanyang university, Korea (the Republic of); [2]KU Leuven, Belgium

The demand for metal based additive manufacturing (AM) is exponentially increasing in the field of aerospace, automotive, medical, and other sectors. Accordingly, the metal 3D printing market is also increasing, while steel is the most used material among them. In metal 3D printing, the most widely used technology is laser powder bed fusion (LPBF) for which typically expensive gas-atomized (GA) powders are used due to their high quality, flowability, and purity, which enables the production of high quality parts. On the other hand, water-atomized (WA) powders with their irregular shape causing low powder flowability, with poor layer deposition quality and forming defects in final parts, generally are not favorable in metal AM. However, due to its economic advantage and straightforward fabrication process, vigorous research has recently been carried out to prove its applicability to 3D printing.
In this study, low alloyed steel powder inspired by the 'Distaloy series' of Hoeganaes was fabricated for AM part production and for evaluating the resulting mechanical properties. Nano-sized Cu-Ni-Mo metal compound was mixed with WA iron powder for low alloy steel powder fabrication. Here, the nano-sized metal alloy elements were homogeneously milled and mixed, to be added to the concave part of the WA iron powder while the commercial powder (Distaloy series) uses only micro-sized alloy elements. It was found that the developed partially pre-alloyed powder showed better flow properties than those of commercial powder.
This powder was used to produce cuboids by applying LPBF with a varying energy density window from 90 to 124 J/mm^3. The parts which had the relative density values of over 99 % can be obtained at a feasible range of laser power from 150 W to 225 W. Especially, the maximum relative density of 99.79% was achieved when producing parts at its laser power of 175 W, scan speed of 700 mm/s (108 J/mm^3) while observing pore structure and the melt pool structure. Moreover, hardness of the parts was measured to find out that the 3D printed parts under that processing window show uniform hardness values (217.1±4.7 HV) among parts with no pores observed while other parts which were manufactured outside the processing window showed non-uniform hardness values (210.0±15.2 HV). Finally, the tensile strength measurement results compared the sample fabricated using partially pre-alloyed WA iron powder with the parts made by raw WA iron powder. The tensile bars made by pre-alloyed powder had two times higher yield stress values [points of yield (pre-alloyed powder: 372.4 MPa, raw WA powder: 167.0 MPa), two times higher ultimate tensile stress (pre-alloyed powder: 460.9 MPa, raw WA powder: 207.3 MPa)] and three times higher strain values [points of ultimate tensile strength (pre-alloyed powder: 7.0%, raw WA powder: 2.6%), three times higher elongation to fracture (pre-alloyed powder: 11.7%, raw WA powder: 3.0%)] compared to those made by raw WA powder. Finally, it was found that the fabricated parts achieved their tensile test results which are comparable to the values [the yield stress (357.4 MPa), the ultimate tensile stress (459.6 MPa), the strain at the ultimate tensile strength (6.5%), the elongation to fracture (7.0%)] of the sample proceeded by GA stainless-steel powder. Therefore, the results show that the pre-alloyed WA iron powder can potentially be a promising material suitable for the LPBF process used for various applications.

SESSION SF02.03/SF03.01: Joint Session: Multifunctional Soft Composites

Temperature-Responsive Multistable Metamaterials Rui Yin, Lucia Korpas, Hiromi Yasuda and Jordan R. Raney; University of Pennsylvania, United States

The ability for materials to adapt their shape and mechanical properties to their environment is useful in a variety of applications, such as soft robotics and deployable structures. Liquid crystal elastomers (LCEs) have been widely explored in recent years due to their ability to controllably actuate in response to multiple external stimuli, such as heat and light. In this work we integrate LCEs with multistable structures to allow autonomous reconfiguration in response to temperature changes. To accomplish this, we integrate LCE-silicone bilayers as hinges in a kirigami-inspired multistable material based on a rotating squares mechanism. The bilayer hinges bend and soften as the temperature increases. By choosing geometric parameters for the hinges such that bifurcation points in the stability exist, a transition from mono- or tristability to bistability can be triggered by a sufficient increase in temperature, forcing rearrangements of the structural configuration in the heat-effected area as minima in the energy landscape are removed. Depending on the choice of energy landscape, these local structural reconfigurations may or may not propagate to the rest of the structure, analogous to the propagation of a phase transformation. These effects are relevant to applications smart interfaces, reconfigurable structures, and soft robotics.

Cellular Fluidics: Using Architected Lattices to Tune Multiphase Interfaces in 3D Nikola Dudukovic, Erika Fong, Hawi Gemeda, Joshua DeOtte, Maira Cerón, Bryan Moran, Jonathan Davis, Sarah Baker and Eric Duoss; Lawrence Livermore National Laboratory, United States

We present a novel platform based on capillary fluid flow in ordered three-dimensional open-cell lattices: cellular fluidics [1]. By designing the cell and lattice architecture, combined with additive manufacturing methods that provide access to length scales below 100 μm, we can fabricate complex polymeric 3D structures with deterministic porosity and advanced functionalities. This approach enables selective placement and direction of liquid flow into predetermined continuous paths through the structure and optimization of gas-liquid and liquid-liquid interfaces for multiphase processes. We demonstrate the application of such cellular fluidic devices for processes such as transpiration cooling and CO_2 capture. Further, we show that flowing the appropriate electroless plating solutions through the predetermined paths allows selective metallization in regions of interest in three dimensions, resulting in multimaterial heterostructures that can further be electroplated with different materials. Hence, this new platform is a promising tool for designing novel 3D microfluidic devices such as electrochemical reactors with control over multiphase transport processes.

11:00 AM SF02.03/SF03.01.03
Tissue-Adhesive and Stretchable Liquid Metal Antennas by Direct Silicone Printing on Elastomeric Thin-Film Substrates Kento Yamagishi, Wenshen Zhou, Terry T. Ching, Shao Ying Huang and Michinao Hashimoto; Singapore University of Technology and Design, Singapore

Flexible and stretchable antennas are important for devices that use wireless communication to address mechanical mismatches at the tissue-device interface. To mechanically comply with the curvature of the organs and match their motion, such devices typically featured thin designs to ease bendability and elastomer encapsulations to enhance stretchability. Emerging technologies of liquid metal-based stretchable electronics are promising approaches to improve the flexibility and stretchability of conventional metal-based antennas. However, existing methods to encapsulate liquid metal requires monolithically thick (at least 100 μm) substrates and the resulting devices are limited in deformability and tissue-adhesiveness. To overcome this limitation, we demonstrated fabricating microchannels by direct ink writing on a 7 μm-thick elastomeric substrate, referred to as Ecoflex microsheet, to obtain liquid metal microfluidic antennas that exhibited unprecedented deformability. The fabricated wireless light-emitting device was powered by a standard near-field-communication system (13.56 MHz) and retained a consistent operation under deformations including stretching (> 200% uniaxial strain), twisting (180° twist), and bending (3.0-mm radius of curvature) while maintaining a high Q factor (> 20). We also demonstrated suture-free conformable adhesion of the polydopamine-coated device to *ex vivo* animal tissues under mechanical deformations. This technology offers a new capability for the design and fabrication of wireless biodevices, which require conformal tissue-device integration. Liquid metal antennas would be used as a platform for various multifunctional wireless biodevices. DIW 3D printing technology can also offer integration of other functional components such as physical sensors, electrochemical sensors, and drug delivery systems. This technology paves the way towards minimally invasive, imperceptible medical treatments.

11:15 AM SF02.03/SF03.01.04
Innervated, Self-Sensing Liquid Crystal Elastomer Actuators with Closed Loop Control Arda Kotikian[1], Javier Morales[2], Aric Lu[1], Jochen Mueller[1], Zoey Davidson[1], John W. Boley[2] and Jennifer Lewis[1]; [1]Harvard University, United States; [2]Boston University, United States

Soft materials that exhibit self-sensing and programmable actuation are of great interest for applications ranging from robotics to adaptive structures. Liquid crystal elastomers (LCEs) are an emerging class of soft materials that exhibit reversible and large deformations with high energy density. These materials have been patterned into shape-morphing architectures with programmed director alignment via HOT-DIW, an extrusion-based 3D printing method (Kotikian et al, *Adv. Mater.* 2018; Kotikian & McMahan et al, *Sci. Rob*. 2019). Recently, we have further demonstrated the fabrication of innervated LCEs (iLCEs) composed of liquid metal (LM) cores surrounded by LCE shell features via core-shell 3D printing. iLCE actuation is programmed by Joule heating power and thermal response is measured and modeled. Importantly, iLCEs self-sense their own deformation during actuation, as strain correlates with resistance in unidirectional and 3D morphing structures. Due to their large concomitant changes in length and resistance and their high energy density, iLCE fibers and spiral architectures are capable of closed loop control, with regulation of actuation sequences even with large bias loads. Our multi-material 3D printing platform enables the rapid design and fabrication of soft functional materials with exquisite control over their composition, architecture, and performance.

11:30 AM *SF02.03/SF03.01.05
3D Printing of Dynamic Liquid Metals and Liquid Metal Composites Michael Dickey; North Carolina State University, United States

This talk will discuss the use of liquid metals for 3D printing. Gallium-based metal alloys have interesting properties including low-viscosity, low melting point, low toxicity, and negligible volatility. Despite the large surface tension of the metal, it can be molded, patterned and printed into non-spherical shapes due to the presence of a native oxide skin that is only a few nanometers thick. We have harnessed these properties to form a number of electronic devices encased in polymer matrices. The resulting structures take on the mechanical properties of the polymer and can therefore be soft, self-healing, and ultra-stretchable. The metal can be printed and then withdrawn from 3D printed structures as a sacrificial, fugitive ink to create microvasculature in polymer monoliths. In addition, it is possible to 3D print vasculature within polymeric materials printed using conventional 3D printing, and then back-fill the structures with liquid metal to add function in a post-processing step. The metals can be used for adding electrical conductivity as well as toughening. In addition, liquid metal can be mixed with uncured elastomers to tune the rheology to create printable inks. These inks can be cured to create self-encapsulated, stretchable conductors. Finally, we have recently demonstrated ways to treat 3D printed polymeric structures so that liquid metal can be injected and withdrawn on demand. This allows for reconfigurable and dynamic structures in which the conductors can be fully recovered. The challenge is to create a coating that can be deposited on the walls inside 3D printed parts without damaging the part. To address this, we have create a solvent-based coating that uses fumed silica to create slightly roughened surface to which the liquid metal does not adhere. This talk will discuss the key processing parameters to enable printing of metal, the applications of such printing, as well as future opportunities and challenges.

SESSION SF02.04: Multifunctional Soft Composites
Session Chairs: Kun Fu and Jordan Raney
Tuesday Afternoon, November 30, 2021
Sheraton, 3rd Floor, Commonwealth

1:30 PM *SF02.04.01
Additive Manufacturing of 3D Nano-Architected Metals, Oxides and Multifunctional Gels via Vat Polymerization Julia R. Greer[1,2], Amylynn Chen[1], Max Saccone[1], Carlos Portela[3], Daryl W. Yee[3] and Ryan Ng[1]; [1]California Institute of Technology, United States; [2]Kavli Nanoscience Institute, United States; [3]Massachusetts Institute of Technology, United States

Additive manufacturing (AM) represents a set of processes that enable layer-by-layer fabrication of complex 3D structures, with some advanced methods attaining nanometer resolution and the creation of unique, multifunctional materials and shapes derived from a *photoinitiation-based chemical reaction* of custom-synthesized resins and thermal post-processing. A type of AM, vat polymerization, has allowed for using hydrogels as precursors, and exploiting novel material properties, especially those that arise at the nano-scale and do not occur in conventional materials. The development of small-scale AM has revolutionized the production of complex parts for aerospace, military, automotive and medical applications, and is enabling major innovations in these areas. Shapes as complex as fractal trusses and as simple as cubes, with vastly multi-scale dimensions, from nanometers for nanophotonics to millimeters for sensors to centimeters for space-relevant technologies been demonstrated.
We present synthesis and fabrication of nano- and micro-architected materials using vat polymerization and 3D (two-photon and interference) lithography, and characterize their properties as a function of architecture, constituent materials, and microstructural detail. We focus on specific materials and architectures with unique properties: **(1)** Impact resistant nano-architected carbon, **(2)** Hydrogel-enabled AM of pure metals and alloys with micron and sub-micron dimensions, **(3)** Ligand exchange-based fabrication of 3D TiO_2 photonic crystals (PhCs), with critical feature dimensions between 150 and 600

nm, and (4) AM of Metallo-polyelectrolyte Complexes with stretchability up to 1000% and full recoverability, and (5) Hydrogels moisture-harvesting properties.

2:00 PM SF02.04.03
Tough, Fatigue-Resistant Soft Composites via Controlled Spatial Variation of Fiber Alignment Using Direct Write 3D Printing Chengyang Mo, Haiyi Long and Jordan R. Raney; University of Pennsylvania, United States

Stretchable electronics, tissue engineering, and soft robotics are a few of the many examples in which engineers require soft materials with higher toughness and better fatigue-resistance in order to prevent premature failure during demanding, repeated mechanical loading. One effective method to improve the toughness of soft materials is to embed stiff fibers in a soft matrix. We 3D print soft composites using direct ink writing (DIW). The composite material consists of polydimethylsiloxane (PDMS) reinforced with glass fibers (with diameter roughly 15μm). DIW processes result in alignment of fibers during printing, due to the shear field in the deposition nozzle. Hence, parts can be 3D printed with controlled spatial variations in fiber alignment, based on the print path and other parameters that affect the shear field in the nozzle. In this work, we first consider how the fiber-matrix bond influences the failure properties of the printed composite. We show that if the glass fibers are treated with acid prior to formulating the ink, the fiber-matrix bond is strengthened, and the toughness of the composite is greatly improved. Additional experiments are conducted to quantify the intrinsic toughness of the composite, and the effect of mechanical dissipation resulting from fiber-matrix debonding. We also measure the fatigue properties, which also show significant improvement after fiber treatment. Finally, we show that using bioinspired spatial variations in fiber alignment, such as in skin and artery, the composites are tougher and more fatigue resistant without further stiffening the material.

2:15 PM SF02.04.04
Freeform Polymer Precipitation (FPP) on Thermoplastics in Non-Newtonian Support Gels Rahul Karyappa and Michinao Hashimoto; Singapore University of Technology and Design, Singapore

Embedded 3D printing (e3DP) has demonstrated fabricating freeform structures of curable polymer resins in microparticulate hydrogels. This method is, however, not compatible with thermoplastics extruded at high temperature. This communication presents a unique approach to 3D-print thermoplastics in embedding media, termed freeform polymer precipitation (FPP). FPP is based on spatially controlled immersion precipitation of polymer inks patterned in microparticulate gels for various thermoplastics with additives. The embedding media offers unique dual functions: Bingham plastic to maintain printed structures, and nonsolvent for *in situ* precipitation of polymer inks. Polymer inks with a wide range of vapor pressure (0.04 – 60 kPa) and viscosity (0.1 – 1000 Pa.s) were demonstrated for FPP. Using acrylonitrile butadiene styrene (ABS) dissolved in acetone (20 – 60 w/w%) as a model ink, we identified the printing conditions to ensure vertical and lateral attachments of printed inks. The fabricated 3D objects were porous due to rapid phase separation induced by nonsolvent, which was controlled by the concentration of the polymer and the porogens in the inks. FPP offers a simple route to fabricate 3D freeform structures of thermoplastics with controlled internal porosity and should serve as a useful toolkit to 3D-print multi-functional materials such as polymer nanocomposites.

2:30 PM SF02.04.05
Metallizing Complex 3D-Printed Polymers with Electroless Deposition—The Design Rule Toolbox of Pretreatment Steps Megan Ellis[1], Shohini Sen-Britain[1], Jonathan Davis[1], Rohan Akolkar[2], Christine Orme[1] and Nikola Dudukovic[1]; [1]Lawrence Livermore National Laboratory, United States; [2]Case Western Reserve University, United States

Recent advances in additive manufacturing have allowed fabrication of high resolution, complex geometries with fine features from UV-curable acrylated polymers. Utilizing electroless deposition in conjunction with these manufacturing techniques allows us to leverage the aforementioned benefits and impart electrical and thermal conductivity, a basis for catalytic activity, and improved mechanical properties. Electroless deposition onto 3D-printed polymer acrylates is not well understood and frequently demands a trial-and-error approach to successful metallization of the surface. Plating of these polymer surfaces requires pretreatment steps; there is a lack of knowledge surrounding how these steps affect the coating adhesion and uniformity. Here, we present a systematic investigation into these pretreatment steps with the aim of leveraging quantifiable data to establish best practices. We characterize the effects of alkaline etching on surface roughness and surface chemistry through the use of optical surface topography measurements and ToF-SIMS, respectively. We utilized Quartz Crystal Microbalance to examine the absorption of Tin (sensitizer) and Palladium (activator) species on the polymer surface. The resulting adhesion strength of the plated metal was measured through peel testing and the coating uniformity was quantified with a coverage fraction parameter. We show that changes in surface roughness of the polymers during the etching step occur at several length scales and time scales, associated with uneven curing degrees in regions of oxygen-inhibited polymerization. We find that the surface concentration of adsorbed sensitizer and activator species is related to the surface concentration of hydrophilic groups produced in the alkaline etching step. We show that the adhesion and uniformity are a function of both surface roughness and surface chemistry. These findings facilitate design guidelines for electroless deposition on 3D-printed polymers, specifically UV-cured acrylates. Further, these design rules allow for a deeper understanding of the role mass transport plays in the metallization of multiscale three-dimensional architectures. This work performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344 within the LDRD program 20-ERD-056. LLNL-ABS-821864.

2:45 PM SF02.04.06
On-the-Fly Modulation of Grain Size in Sub-Micrometer Copper Wires Deposited by Electrohydrodynamic Redox 3D Printing Maxence Menétrey[1], Alain Reiser[2], Lukas Koch[1], Alla Sologubenko[1], Stephan Gerstl[1] and Ralph Spolenak[1]; [1]ETH Zürich, Switzerland; [2]Massachusetts Institute of Technology, United States

Additive manufacturing at the micro-/nano-scale has the potential of revolutionizing the conception of small-scale devices. Yet, a major challenge is currently encountered: combining high-resolution, geometry control, high-throughput together with multi-materials printing. Even more crucial towards real applications is the ability to synthesize device-grade materials [1].

In this contribution, we will show that electrohydrodynamic redox 3D printing (EHD-RP) can be used to locally optimize grain size in 3D printed wires, changing mechanical strength by a factor of 2. EHD-RP is an ink-free AM technique with multi-metal capabilities and offering sub-micron spatial and chemical resolution [2]. A unique feature of this synthesis technique (and all synthesis techniques in comparison to transfer techniques) is the possibility to locally tune microstructure by adjusting growth parameters. In this work, we show the different microstructures accessible by EHD-RP, showing potential for material optimization. To this end, we first map the microstructure and morphology of wires as a function of printing voltage. We then use detailed microstructure and elemental analysis by TEM and APT to elucidate the causal relationship between the printing voltage and the grain size, adding important understanding to the formation of the microstructure. The influence on materials properties is illustrated by micro-compression experiments showing the relationship between the grain size distribution and the materials' strength—the so-called Hall-Petch strengthening. Finally, we demonstrate the fast switching between the different regimes by fabricating nano-wires with sub-micrometer modulation in grain size, and thus local strength. Our work opens the door to the fabrication of small-scale metal 3D geometries with optimized microstructural distributions..

Additively Manufactured Spinodoid Metamaterials with Enhanced Toughening Mechanisms Somayajulu Dhulipala and Carlos Portela; Massachusetts Institute of Technology, United States

Research in the field of additively manufactured (AM) architected materials has enabled engineered materials with mechanical properties that were previously thought unattainable. For instance, a large part of the research has focused on the linear properties of truss-based lattices, demonstrating high stiffness- and strength-to-weight ratios. However, most truss-based lattice structures suffer from a bending-dominated response and stress concentrations at the sharp joints, the latter of which results in initiation and propagation of fracture. Spinodoid metamaterials have been proposed as an alternative to combat these stress concentrations due to their finite (low) curvature and bicontinuous morphologies. Furthermore, the mechanical properties of these spinodoid metamaterials can be tuned by introducing preferential interface directions which results in tailorable anisotropy.
In this study, we explore the effect of curvature and anisotropy on the strength and toughness of spinodioid metamaterials. The spinodoid morphologies are generated using a computational spinodal decomposition framework where tunable anisotropy is introduced by energetically penalizing preferential directions for interface formation, resulting in a mean curvature and Gaussian curvature distribution that is dependent on the direction of the surface normal. Using a two-photon lithography process we fabricate prototypes of these 50%-relative-density (i.e., fill fraction) anisotropic spinodoid morphologies, containing spatially varying curvature distributions, and perform in-situ nanomechanical uniaxial compression and bending experiments to determine their curvature-dependent stiffness, strength, and toughness. Complemented by finite element models of the as-fabricated morphologies, we demonstrate a relation between curvature distributions, the stress distribution, and the toughness of these metamaterials. Our findings present the potential of architected spinodoid metamaterials as a new class of additively manufactured lightweight materials with widely tunable properties such as fracture resistance, which may expand the property space of classical lattice-based AM materials.

4:15 PM SF02.05/SF03.03.02
StructureD Electrode Additive Manufacturing for Lithium-Ion Batteries Kun Fu; University of Delaware, United States

Current battery electrode manufacturing using slurry coating and drying to produce electrode films is energy and time-intensive, containing significant quantities of environmentally toxic solvents, and lacks processability that controls electrodes' thickness and geometric complexity. New manufacturing processes have been developed to produce electrodes with increased thicknesses and complex physical structures with improved performance and safety characteristics. A growing trend to rapidly create structured electrodes with programmable geometries, improved thickness, and multiscale structural details is using additive manufacturing, also known as 3D printing, as replacements for typical state-of-the-art ink casting. However, existing 3D printing strategies can only fabricate electrodes using ink-based slurries, which lack the capability of forming complex geometries or use a narrow range of UV-curable resins with insufficient ionic and electric transport capabilities. Therefore, a new electrode fabrication route is needed to improve structured electrode design and manufacturing flexibility.
In this talk, I will present a novel electrode processing route, Structured Electrode Additive Manufacturing (SEAM), which can rapidly fabricate ultra-thick structured electrodes with low tortuosity, mechanical robustness, and complex geometry, enabling LIBs to achieve high power and high energy at a low production cost. SEAM involves two innovations of dry electrode formation and the debinding/sintering process. The innovation in dry electrode formation is enabled by a high-loading dry-extrusion technique called Shear Assisted Particle Extrusion (SHAPE). SHAPE can manufacture thick electrodes using compositions close to commercial electrodes without using any solvents or the drying process, and it can orient geometrically anisotropic active materials (e.g., graphite flakes) along their longitudinal directions at high-pressure induced shear flow and deposition. The debinding/sintering process can remove polymer components in the electrode while retaining the original printed “green” geometry without structural collapse or failure. SEAM leverages the dry-extrusion additive manufacturing combined with a rapid debinding/sintering process to meet the geometric design and cost requirements for replacing slurry coating and drying techniques.

Bulk Ferroelectric Metamaterial with Enhanced Piezoelectric and Biomimetic Mechanical Properties from Additive Manufacturing Jun Li; University of Wisconsin--Madison, United States

Three-dimensional (3D) ferroelectric materials are promising electromechanical building blocks for achieving human-machine interfacing, energy sustainability, and enhanced therapeutics. However, current natural or synthetic materials cannot offer both high piezoelectric responses and desired mechanical toughness at the same time to meet the practicality. Here, a nacre-mimetic ferroelectric metamaterial was created with a ceramic-like piezoelectric property and a bone-like fracture toughness through a novel low-voltage-assisted 3D printing technology. The one-step printed bulk structure, consisting of periodically intercalated soft ferroelectric and hard electrode intercalated layers, exhibited a significantly enhanced longitudinal piezoelectric charge coefficient (d_{33}) of over 150 pC N^{-1}, as well as a superior fracture resistance of ~ 5.5 MPa $m^{1/2}$, more than three times higher than conventional piezo-ceramics. The excellent printability together with the unique combination of both high piezoelectric and mechanical behaviors allowed us to create bone-like structure with tunable anisotropic piezoelectricity and bone-comparable mechanical properties, marking a cornerstone toward manufacturing practical, high-performance, and smart biological systems.

4:45 PM SF02.05/SF03.03.04
Experimental and Numerical Investigation of Impact Absorbing Viscoelastic Truss Metamaterials Raphael N. Glaesener, Jan-Hendrik Bastek and Dennis M. Kochmann; ETH Zurich, Switzerland

Recent advances in the additive manufacturing of trusses made from viscoelastic base materials have created new opportunities for the design of time-

dependent metamaterial properties. Using compliant polymers as base material [1] to fabricate 3D periodic architected metamaterials facilitates high energy absorption capabilities and allows the engineering and tailoring of the topology to a specific impact situation. Such structures facilitate shock and impact absorbing capabilities that have great potential in blast-protection applications but also as protective sports gear. The dissipation of energy is induced solely by the viscous base material model instead of layer-wise plastic deformation and failure of beams [2], coming with the advantage of shape-recoverability [3] and thereby also reusability of the lattice after impact.

We use a linear viscoelastic constitutive model along with the co-rotational beam description by Crisfield [4], which captures large rotations. We solve linear momentum balance in a time-discrete fashion, based on a variational formulation employing variational constitutive updates for the viscoelastic material model, which results in a rate-dependent material response to be explored.
In addition to performing discrete numerical beam calculations, we include the viscoelastic beam model into the generalized continuum description of Glaesener et al. [5] and show a good match with the discrete formulation. The closed-form solution for the incremental update formulation, combined with the first-order homogenization approach at the microscale allows for an efficient computation of initial boundary value problems. Applying the linear viscoelastic material model to the investigation of non-catastrophic impact combines the study of history-dependent constituents with time-dependent load scenarios. We show that, for a given viscous base-material behavior, truss topology, and known impact velocity, the magnitude of damping (coefficient of restitution) upon impact can be computed. We present calculations for both the discrete and continuum framework, reporting good agreement with experimental observations.

Additive Manufacturing of Architected and Functional Materials Christopher M. Spadaccini; Lawrence Livermore National Laboratory, United States

In this presentation, we will cover some of the latest work in advanced and custom additive manufacturing processes for the fabrication of architected materials and functional devices. The concept of architected materials revolves around the notion that material properties are traditionally governed by the chemical composition and spatial arrangement of constituent elements at multiple length-scales. This usually limits material properties with respect to each other creating trade-offs when selecting materials for specific applications. For example, strength and density are inherently linked so that, in general, the more dense the material, the stronger it is in bulk form. We will review the latest in design methods such as topology optimization, as well as advanced additive micro- and nanomanufacturing techniques to create new material systems with previously unachievable property combinations. These processes include projection microstereolithography (PuSL), direct ink writing (DIW), and electrophoretic deposition (EPD) as well as new advanced concepts such as volumetric additive manufacturing (VAM), computed axial lithography (CAL), parallel two-photon polymerization, liquid metal jetting, and diode-based additive manufacturing of metals (DiAM). The performance of the resulting material constructs is fundamentally controlled by geometry at multiple length-scales, from the nano- to the macroscale, rather than chemical composition alone. We have fabricated and will review the resulting properties of these mechanical metamaterials in polymers, metals, ceramics, and combinations thereof. These new processes and concepts can also be applied to functional materials such as those for supercapacitor electrodes, optical components, and even for fluidic system such as the recently published cellular fluidics concept. A review of these functional systems will be followed by a brief discussion of future directions.

Multifunctional Artificial Artery from Direct 3D Printing with Built-in Ferroelectricity and Tissue-Matching Modulus for Real-Time Sensing and Occlusion Monitoring Jun Li; University of Wisconsin--Madison, United States

Treating vascular grafts failure often requires complex surgery procedures and associates with a high mortality rate. Real-time monitoring vascular system could enable quick and reliable identification of complications and initiate safer treatments in the early stage. In this work, electric field-assisted 3D printing technology was developed to fabricate *in situ*-poled ferroelectric artificial arteries that offered battery-free real-time blood pressure sensing and occlusion monitoring capability. The complex functional artery architecture was made possible by the development of a printable ferroelectric bio-composite which could be quickly polarized during printing and reshaped into devised objects. Synergistic effect from the ferroelectric potassium sodium niobate (KNN) particles and the ferroelectric polyvinylidene fluoride (PVDF) polymer matrix yielded a superb piezoelectric performance (bulk-scale d_{33} > 12 pC N^{-1}, confirmed by piezometer) on a par with that of commercial ferroelectric polymers. The sinusoidal architecture brought the mechanical modulus down to the same level of human blood vessels. The desired piezoelectric and mechanical properties of the 3D-printed artificial artery provided an excellent sensitivity to pressure change (0.306 mV/mmHg, R^2> 0.99) within the range of human blood pressure (11.25 to 225.00 mmHg). The high pressure sensitivity and the ability to detect subtle vessel motion pattern change enabled early detection of partial occlusion (e.g., thrombosis), allowing for preventing grafts failure. This work demonstrated a promising strategy of incorporating multi-functionality to artificial biological systems for smart healthcare systems.

SF02.06.03

Directed Assembly, Annealing and Characterization of III-V Semiconductors Jared Cohen, Anthony S. Childress and Ahmed Busnaina; Northeastern University, United States

As the demand for smaller feature size and lower cost integrated circuits, printed circuit boards, and other micro and nano-scale devices increases, newer and faster printing methods that retain the accuracy of previously used methods must be developed in order to address such challenges. Previous research conducted at the NSF Center for High-rate Nanomanufacturing and others have shown the effectiveness of directed assembly processes which allow for highly precise and comparatively low cost manufacturing. However, the printing of single crystals using nanoparticles for making semiconducting devices, such as transistors and diodes, has proven to be a significant challenge. We report in this poster experimental efforts to print III-V semiconductors that show promising results. The particle size was significantly reduced to the nanoscale utilizing both physical milling and chemical synthesis techniques. Nanoparticle suspensions were formulated to be used in our fast fluidic directed assembly printing process. We have shown that indium phosphide and gallium arsenide nanoparticles can be reliably and accurately assembled. After printing, the printed structures are annealed and the crystalline structure, material properties, and electrical properties are measured. This poster shows the results of sintering the printed semiconductor devices along with their electrical characterization to demonstrate the effectiveness of the methods developed. Our directed assembly method allows for reliable and accurate assembly of these semiconducting devices. This will enable faster, lower cost, and more sustainable prototyping and production of micro and nanoscale electronic devices which could revolutionize semiconductor fabrication as we know it.

SF02.06.05

Evaluation of Additively Printed Dielectrics for Fully Printed Carbon Nanotube Thin-Film Transistors Brittany N. Smith, Hope Meikle, Shiheng Lu and Aaron D. Franklin; Duke University, United States

Carbon-nanotube thin-film transistors (CNT-TFTs) have the potential for a wide variety of applications, such as chemical sensors and digital logic circuits, due to their high field-effect mobility and compatibility with versatile fabrication approaches. Aerosol jet printing is an additive, direct-write approach for integrating CNT-TFTs onto various substrates. Among all the layers making up a CNT-TFT, the gate dielectric is the most difficult to additively print owing to challenges in thickness scaling, pinhole formation, and reliance on high sintering temperatures. The most commonly used printed dielectrics include electrolytes and ion gels due to their high specific capacitance and compatibility with solution-phase dispersion into inks. Recently, crystalline nanocellulose (CNC) has been utilized as an electrolyte gate dielectric to realize a fully recyclable, printed CNT-TFT. In this work, we present a detailed evaluation and benchmarking of three additively printed gate dielectrics for fully printed, top-gated CNT-TFTs that operate at low voltage: an electrolyte consisting of elastomer PVDF-HFP; CNC with varying salt concentrations from 0% up to .5%; and an ion gel consisting of triblock polymer PS-PMMA-PS, ionic liquid EMIM-TFSI, and ethyl acetate in a 1:9:90 w/w ratio. Using a surface map of the transistor on/off-current ratio, we evaluate the dependence of gate location on device performance. Because electrolyte dielectrics are performance-limited by ionic diffusion rates, the impact of voltage sweep rate on switching characteristics, such as threshold voltage, subthreshold slope, and hysteresis, is examined. Further, electrical bias and mechanical stress testing are performed to determine the resilience of these dielectrics. This extensive evaluation of three leading options for additively printed dielectrics will aid in moving the field of printed electronics closer to application-ready devices with stable, low-voltage operation TFTs.

SF02.06.06

Controlled Nano-Porosity in Additively Manufactured Micro-Scale Ag Structures Nikolaus Porenta[1], Mirco Nydegger[1], Souzan Hammadi[2] and Ralph Spolenak[1]; [1]ETH, Switzerland; [2]Uppsala University, Sweden

For many industrial applications such as catalysis, sensing, optical elements and many more, complex three-dimensional micro-scale porous metal structures with pore sizes in the sub-micron scale are desirable. However the fabrication of such sophisticated small-scale structures is not an easy task. In recent years the field of additive manufacturing (AM) has received more and more interest as a very powerful tool for the production of complicated three-dimensional structures[1] One AM technique that has been shown to be able to produce complex structures with sub-micron resolution is electrohydrodynamic redox printing (EHD-RP)[2]. EHD-RP furthermore has multi-metal and multi-material capabilities.

In this contribution, we will describe a fabrication process that can be used to readily produce nano-porous Ag structures on the micro-scale utilising the multi-metal capabilities of EHD-RP. Aqueous Ag-Cu salt solutions were used as printing solutions to produce small-scale metallic structures. Porosity in these structures was then achieved by selectively etching away Cu. In this work we show that by varying the composition of the printing solutions used, precise control over the ratio of Ag to Cu in the as-printed structures was achieved. Utilising this control of the chemical composition we were able to tune the porosity as well as the pore size of the dealloyed structures. Being able to precisely tune the porosity of micro-scale three-dimensional structures, as demonstrated in this work, opens up many new possibilities in the field of optical meta-materials especially focused on sensing applications. The high local control given by EHD-RP combined with the porosity control described here could also be used to fabricate structures with locally varying mechanical properties.

Modification of Regolith for Lunar Habitat Development—A Preliminary Assessment of Novel Additives for NASA Formulated Simulants to Generate 3D Printable Concrete K. Shipps[1], B. Chadwick[2], M. Tittemore[3], B. Wan[1], C. Dilman[1], T. Trinh[1], L. Baglio[1], H. Talbot[3], M. McCuish[1], A. Perticone[1], D. Rodriguez[1], A. DaSilva[1], S. Abbas[1], Douglas X. Shattuck[4,3] and Markus J. Buehler[4]; [1]Malden Catholic High School, United States; [2]Concord-Carlisle High School, United States; [3]St. Joseph School, United States; [4]Massachusetts Institute of Technology, United States

In 2015 NASA began issuing challenges for the development of innovative technologies that would support human colonization of the moon and Mars by 2050. Subsequently, our students began with concepts and images developed at MIT as part of the initial Habitat Challenge [1]. From there, the team, including middle and high school students, their advisors, MIT researchers, and grad students, hypothesized that the most efficient and sustainable means of structural development would be to use the indigenous materials: silicon-rich basaltic and calcium-rich plagioclase regolith with water-ice discovered at the poles. In addition, we assume NASA's Challenge to biologically harvest solar energy to produce organic binders will be successful and provide additional structural constituents.
Our research focused on evaluating the structural capacity of a lunar regolith analogs [2] and their ability to withstand compression and impact forces. For this work we evaluated Lunar Highland Simulant (LHS-1) and Lunar Mare Simulant (LMS-1) prepared by Exolith Lab at the University of Central Florida. Commercially available stone-dust with similar geologic properties was also used as a lunar analog. Published works suggests that albumin may serve as an effective binder while other authors suggest chitin may be effective [3,4]. For this investigation commercially available chicken egg albumin (egg white) and chitosan (commercially available chitin) were among the materials evaluated. Water was used as a non-binding control. In addition, samples of fine

fractions were vitrified using a glass-manufacturing kiln.
Each regolith sample was mixed with varying amounts of binding agent, formed in 5 cm cube molds, pressed, smoothed, and allowed to cure for 24 hours, 7 or 14 days. Afterward, each sample was non-destructively tested with commercial compression hammers. The results were compared to terrestrial construction standards and are being presented.
Based on our observations, we believe lunar regolith may become a viable construction material, but additional work will be necessary to produce a binding material that will be suitable for building sound, impact-resistant dwellings. In addition to reinforcing concepts developed during research, this activity dramatically demonstrates the links among elementary and secondary school learning, academic research, and the private sector that supports them.

Printing of Flexible Electronic Components Using Directed Fluidic Assembly Jonah Yu[1,2], Ahmed Abdelaziz[1,2] and Ahmed Busnaina[1,2]; [1]Northeastern University, United States; [2]Nano OPS Inc., United States

As the demand for smaller and more reliable mass-produced electronic devices grows, the directed assembly of electronic devices as additive manufacturing technique provides a promising potential solution to achieve mass production with low fabrication costs. This technique is proved to be capable of directly printing conducting, semi-conducting, as well as insulating materials using variety of liquid dispersions within micro to nano-scale resolution. Moreover, this technique is additive, more efficient, and cheaper than many other conventional subtractive techniques. Conventionally, in order to print basic electronic components such as resistors, capacitors and inductors on different substrates, high vacuum vapor deposition, ink jet printing, and etching techniques are implemented. However, these techniques require high energy consumption, poor printing resolution, and incompatibility with many substrates. Here, we utilized the directed fluidic assembly technique to monolithically print basic electronic components on a large scale with high printing resolution and large production throughput. Using this technique, we tackled different obstacles simultaneously. First, the process can be applied to wide range of substrates, which allows these circuit components to be dynamically integrated into other systems that may have not been previously compatible. Second, unlike other traditional printing processes, this process is considered conservative, thus minimizing the fabrication cost significantly. Third, basic electronic components can be easily controlled by adjusting thickness and structure dimensions down to several microns. Our results, show two basic printed electronic components, these are thin film resistors and micro-scale capacitors, which're printed monolithically on a flexible PET substrate. The resistors values showed wide resistance range of 1-10 KΩ using metallic conducting ink and 10 KΩ to 25 MΩ using ceramic composite dispersion. The achieved capacitance of the printed capacitors was between 80-100 pF which can be adjusted by varying the electrodes surface area and the spacing between the printed electrodes. We believe that this fluidic directed assembly will pave the way for the mass production of basic circuit components at lower time and energy costs than normally possible with conventional fabrication techniques.

SF02.06.12

Late News: An Automated Process for Eliminating Racial and Gender Bias in Respiratory Protective Equipment Enabled by Additive Manufacturing Shiya Li[1], Samuel Willis[1], Mohanad Bahshwan[1,2], Jacob Tan[1], Joseph Folkes[1], Livia Kalossaka[1], Usman Waheed[1] and Connor Myant[1]; [1]Imperial College London, United Kingdom; [2]University of Jeddah, Saudi Arabia

Various studies highlighted the failure of generically designed respiratory protective equipment (RPE) in fitting female and black, asian, and minority ethnic (BAME) users. As a result, many of those users' lives were put at risk during the COVID-19 pandemic. Employing additive manufacturing (AM) techniques for producing custom-fit RPE may overcome this problem if the laborious barriers in computer-aided design (CAD) creation can be overcome. Here we propose a process for producing custom fit RPE based on a single input containing the user's 3D facial scan captured via smartphone depth-sensitive camera. Through a combination of rigid and non-rigid iterative close point transformations, the coordinates of key landmarks were extracted to generate a custom-fit RPE via a CAD API. Subsequently, the goodness of fit was measured between each of the generated RPE and the raw facial scan using Euclidean distance. We evaluated the process for 207 submissions from users of different demographics, out of which 180 submissions were successfully processed (87.0%) with an average runtime of 3.33 minutes per scan. Furthermore, it was found that goodness of fit from the process-generated RPE was independent of age, race, gender, and Body Weight Index. The results demonstrate the viability of combining automated CAD generation with AM for producing inclusive wearable devices.

Keynote: Machine Learning-Based Design of Metamaterials and Soft Robots Xuanhe Zhao; Massachusetts Institute of Technology, United States

How to design metamaterials and soft robots to achieve a set of specific properties is an inverse problem facing the challenges of non-existent or non-unique solutions. The design of extreme properties such as the Hashin–Shtrikman (H-S) bounds of moduli and strengths makes the challenges even more daunting. Existing methods such as the trial-and-error approach have proven to be inefficient for such designs. Here we propose an initio approach to the design of metamaterials and soft robots to achieve multiple extreme properties simultaneously. The ab initio method is based on a combination of crystallography for structural symmetries, simulations to generate data, and machine-learning algorithms to exploit the data for designs. We demonstrate the concurrent designs of multiple extreme properties of architecture materials such as moduli, strengths, negative Poisson's ratios, and thermal conductivity. We will further discuss the implications of our ab initio method for material and structural designs in general.

11:00 AM SF02.07.01

Explainable AI for Investigating Replication of Subject Expertise in AM (A Quantitative Approach to Explainable AI in AM) Jennifer Ruddock[1,2], Robert Weeks[3], Ezra Ameperosa[2], Jeannette Geisler[1,2], James Hardin[2], J. D. Berrigan[2] and Jennifer Lewis[3]; [1]UES, Inc, United States; [2]Air Force Research Laboratory, United States; [3]Harvard University, United States

With the growth of machine learning techniques and their more direct societal use, the need for interpretability and transparency of how these algorithms make their decisions also grows. This understanding instills trust and helps to engineer more robust algorithms and data treatments by ensuring that the algorithm is picking up on features that a human would deem important, as opposed to correlated or contextual features, or even machine-specific features that would not transfer across users and systems. Here, we use Layerwise Relevance Propagation (LRP) to examine the results of convolutional neural networks used to estimate the rheological properties of inks printed by direct ink write 3D printing. LRP is often used to assign relevance to pixels in image classification. In this study, we look at the changes in relevance for image regression analysis. In particular, ink properties such as the yield stress, rate index, and consistency index of an ink can be determined from the sharpness of printed corners and the width of deposited filaments. We determine how well these algorithms predict these properties and compare them to direct measures of width and curvature, while also drawing relations to the pixel relevancy values and locations. We bring a quantitative approach to LRP in understanding print morphologies in AM.

11:15 AM SF02.07.02
Topology Optimization of a Bi-Material Composite Using Genetic Algorithm-Augmented Finite Element Method (GA-AFEM) Mehrzad Soltani, Yunwei Xu and Yijie Jiang; University of North Texas, United States

These days, topology optimization designs via pixelized/voxelized heterogenous material programming to achieve desired mechanical properties are of interest. Synergy between soft and stiff components in heterogenous materials leads to delocalization of stress field throughout the composite and thus advanced mechanical properties, such as high toughness and damage tolerance. The enormous possible combinations of two materials and design of crack path via displacing fracture-prone stress concentration areas make finding the optimum designs challenging, where advanced computer-aided and machine learning-aided designing strategies are needed. In this study, we investigate a genetic algorithm (GA) guided material programming strategy to get a robust model with optimum toughness to moderate catastrophic failure of bi-material systems. The GA is a stochastic global search algorithm mimicking biological evolution. In GA, the design space is pixelized and each pixel is treated as a gene by assigning one type of materials. An augmented finite element method (A-FEM), which is a numerical efficient cohesive zone model (CZM) type method, is used to perform the tensile and fracture simulations to evaluate fitness score of each design. We leverage the GA operator of crossover to create a new generation of designs by switching parts of pixels based on the objective function of previous generation. A mutation ratio, which randomly changes pixels, is used to avoid local maximum to find the global optimization. We develop a dynamic selection of the mutation ratio regarding the fitness scores by generations to further enhance the efficiency of GA searching. Finally, samples are fabricated by 3D printing and tested by tensile experiments to validate the materials designs. The GA-AFEM method can be further applied for different loading conditions (impact, bending) and combinations of other materials.

11:30 AM SF02.07.03
Programmable Microbial Ink for 3D Printing of Functional Living Materials Avinash Manjula Basavanna[1,2,3], Anna Duraj-Thatte[1,2,3], Jarod Rutledge[1], Jing Xia[4], Shabir Hassan[4], Arjirios Sourlis[1], Andrés Rubio[4], Ami Lesha[4], Michael Zenkl[4], Anton Kan[1], David Weitz[4], Yu Shrike Zhang[4] and Neel Joshi[3]; [1]Wyss Institute Harvard University, United States; [2]Massachusetts Institute of Technology, United States; [3]Northeastern University, United States; [4]Harvard University, United States

3D printing technology has been recently utilized to print microbial cells for biotechnological and biomedical applications. Typically, microbes are embedded in well-established bioinks to print 3D architectures. In contrast to existing approaches, we have designed and developed the world's first bioink, termed as Microbial Ink that is produced entirely from the genetically engineered microbes by a bottom-up approach. The shear-thinning property of the Microbial Ink coupled with its high viscosity, high yield-stress and shape fidelity facilitated the extrusion-based 3D printing into multi-layered architectures. The Microbial Ink was further programmed by using rationally designed genetic circuits in microbial cells to produce; 1) Therapeutic Living Material – On demand secretion of an anticancer drug, 2) Sequestration Living Material – Selective removal of toxic moieties and 3) Regulatable Living Material – To control the number of cells by inducing cell death. This work enables unprecedented avenues to manufacture macroscopic Functional Living Architectures and showcases advanced capabilities of Living Materials Technology.

11:45 AM SF02.07.04
Conformable and Robust Force Sensors to Enable Precision Joint Replacement Surgery Liam Ives[1], Alizée Pace[1], Fabian Bor[1], Qingshen Jing[1], Thomas Wade[1], Jehangir Cama[2], Vikas Khanduja[3] and Sohini Kar-Narayan[1]; [1]University of Cambridge, United Kingdom; [2]University of Exeter, United Kingdom; [3]Addenbrookes Hospital, United Kingdom

The correct balance of forces on weight-bearing joints such as the hip and knee during joint replacement surgeries is essential for implant longevity. Minimising implant failure and the corresponding need for expensive and difficult revision surgery is vital to both improve patient quality of life and lighten the burden on overstretched healthcare systems. This is increasingly important, for example, in total hip replacements, where the average age of patients is decreasing; these implants must survive greater activity levels and correspondingly higher stresses than those typically found in older, less active patients. However, force balancing during total hip replacements is presently entirely dependent on surgical skill, as there are no sensors capable of providing quantitative force feedback within the small and complex geometry of the hip joint. Here, we solve this clinical unmet need by presenting a thin, conformable and flexible microfluidic force sensor, whose use can be easily incorporated into the standard surgical process. Such sensors were fabricated using a combination of stereolithography 3D printing and aerosol-jet printing. Using precise mechanical testing and finite element modelling, we calibrate the sensors and optimise their design and materials choices. We incorporated our novel sensor into a model hip implant geometry and, with a bespoke mechanical testing rig, determined that these sensors are operational and highly sensitive at force ranges typically achieved during hip implant positioning in surgery. We anticipate that these sensors will be used in the clinic to guide implant positioning and thereby increase the lifetime of existing hip replacements, and more generally represent a powerful new surgical aid for a range of orthopaedic procedures where force balancing is crucial.

SESSION SF02.08/SF03.06: Joint Session: Biomimicry, Bioinspirations, and Bioelectronics

1:30 PM SF02.08/SF03.06.01
3D-Printed "Growing" Cardiovascular Implants for Pediatric Patients with Congenital Heart Defects Fanzhen Ding[1], Runhan Tao[1], Emilio Bachtiar[1,2] and Sung Hoon Kang[1]; [1]Johns Hopkins University, United States; [2]Duke University, United States

3D printing has been actively studied for patient-specific devices due to its advantage for low-cost customization and rapid prototyping. However, most 3D printed devices have fixed shapes and properties, which are not suitable for situations where we need dynamic changes, especially medical implants that require surgery for replacement. Right ventricle–to–pulmonary artery (RV-PA) conduits are used as a surgical palliative treatment for various congenital heart diseases. Due to the growth of the infant or child, these conduits require replacement as they cannot grow, which involves several major open-heart surgeries.

To address this issue, we have investigated 3D-printed RV-PA conduits that "grow" through self-unfolding mechanisms triggered by flow and pressure change associated with growth so that fewer surgeries are required from infancy to adulthood. We will present our results for design of self-adaptable implants, followed by experimental results of testing 3D printed implant devices using an in-vitro testing set-up. The results showed that our self-adaptable implants can autonomously change shapes to accommodate the growth of children. We anticipate that our approaches and findings can contribute to improving patient welfare by customized designs with growth potential based on patient anatomy, which can minimize the number of required surgeries and associated danger, trauma, and expenses.

Molecular Engineering of Liquid Crystalline Elastomer Inks for Additive Manufacturing of Biologically Relevant Actuators Grant E. Bauman, Joselle M. McCracken and Timothy White; University of Colorado Boulder, United States

Recent innovations in additive manufacturing of liquid crystalline elastomer (LCE) inks via direct ink write (DIW) have produced actuators capable of programmable performance based on the tailorable actuation temperatures of their constituent inks. Approaches to date utilize polymer network optimization to control actuation onset temperatures and overall strain of DIW LCE. Here, we describe a molecular engineering approach to 3D printed LCE devices that are capable of producing high strains at or below body temperature and room temperature. To do so, we utilize the LCE mesogen C6BAPE in DIW LCE formulations, which we have previously shown to substantially reduce actuation temperature (T_{NI}) and increase rate of actuation. The rheological and phase transition properties of C6BAPE-based DIW LCE inks are explored to minimize smectic character conferred by C6BAPE and to maximize actuation output across a range of low temperatures. Resulting materials have been demonstrated with T_{NI} that are responsive across biological temperature ranges that may enable numerous biomaterial application opportunities.

2:00 PM SF02.08/SF03.06.04
Additive Manufacturing of Hydrogel Bioelectronic Interfaces Tao Zhou, Hyunwoo Yuk and Xuanhe Zhao; Massachusetts Institute of Technology, United States

Bioelectronic interfaces require intimate and prolonged functional communication with soft, wet, and dynamic biological tissues or organs. However, conventional bioelectronic devices based on engineering solids are dissimilar to biological tissues in their mechanical and chemical properties, and therefore, can face limitations in long-term functional interfacing and biocompatibility due to unfavorable foreign body responses. Clearly noticeable in the progressive advances in bioelectronic interfaces in the recent decades, bioelectronic interfaces have been continuously innovated in both designs and materials to achieve tissue-matching properties to minimize foreign body responses while providing desired electrophysiological functionalities such as recordings and stimulations. Owing to the unique tissue-matching properties, hydrogels have been one of the most promising materials to provide biocompatible long-term interfacing with biological tissues. In this talk, we introduce our recent advances on the 3D-printed hydrogel bioelectronic interface consists of highly stretchable and soft hydrogels. The unique set of 3D-printable hydrogel inks allows facile and flexible one-step additive manufacturing of bioelectronic interfaces with diverse designs. To validate tissue-matching properties and biocompatibility of the 3D-printed hydrogel bioelectronic interfaces, we perform systematic mechanical and electrical characterizations and *in vivo* evaluations based on rat models. The resulted hydrogel bioelectronic interfaces will not only provide a promising platform for bioelectronic devices and treatments but also inspire the future development of functional hydrogel devices and machines.

3D Printed Porous Molds for the Fabrication of Biomimetic Vascular Constructs Terry T. Ching[1,2], Jyothsna Vasudevan[1,2], Shu-Yung Chang[1], Hsih Yin Tan[2], Chwee Teck Lim[2], Javier Fernandez[1], Jun Jie Ng[2], Yi-Chin Toh[3] and Michinao Hashimoto[1]; [1]Singapore University of Technology and Design, Singapore; [2]National University of Singapore, Singapore; [3]Queensland University of Technology, Australia

Anatomically and biologically relevant vascular models are critical to progress our understanding of cardiovascular diseases (CVDs) that can lead to effective therapeutics. Recent advances in 3D printing employ techniques such as sacrificial molding, direct ink writing, coaxial bioprinting, embedded bioprinting to 3D-print the intricate vascular architecture. Despite advances in the 3D-bioprinting, however, there is yet a single fabrication technique that (1) enables a wide array of anatomical mimicry (*i.e.*, freestanding, branching, multilayered, perfusable, mechanically stretchable), and (2) enables customizability of the employed bioinks (*i.e.*, improving compatibility with relevant cell types and mimicking the mechanical properties of native vessels). In this work, we highlight a technique capable of fabricating anatomical accurate vascular models (*i.e.*, freestanding, branching, multilayered, perfusable, mechanically stretchable) with the option of customizing the bioink blend to improve compatibility with relevant cells and the mechanical properties. Briefly, this fabrication technique relies on a two-part mold that was 3D-printed using porous hydrogels (*i.e.*, poly(ethylene glycol) diacrylate (PEGDA) hydrogel). These molds can be designed with desired shape (i.e., bifurcating, construction) or derived from computerized tomography (CT) scan of native vasculatures. Before casting, the molds were then soaked in calcium chloride solution to allow the calcium ions to diffuse into the PEGDA matrix. When alginate-containing precursor solution was perfused into the mold cavity, the calcium ions in the PEGDA matrix diffused radially inwards. The diffusion of calcium ions into the mold cavity prompted ionic crosslinking of the alginate in the precursor, forming a tubular construct. To prevent the further curing of alginate, a buffer solution was perfused through the mold to remove the uncrosslinked alginate-containing precursor. Finally, the vessel construct was removed from the mold and exposed to ultraviolet (UV) light to photo-crosslink the photocurable monomer (*e.g.*, gelatin-methacryloyl (GelMA)) present in the precursor. Applying our proposed technique, vessel constructs with anatomically accurate geometries (i.e., constructions, bifurcation) and mechanical stress (*i.e.*, cyclical motion) were readily fabricated. Our technique also permitted the fabrication of multilayered architecture mimicking native blood vessels. Importantly, we successfully fabricated cell-laden vessel constructs with smooth muscle cells and endothelial cells in a multilayer arrangement. Lastly, we demonstrate the capability of our platform to simulate the insertion of a drug-eluting stent, highlighting a possible preclinical model to test future percutaneous coronary interventions. Overall, we developed a fabrication technique capable of fabricating a freestanding cell-laden hydrogel vascular model with high anatomical relevance: freestanding, branching, multilayered, perfusable, mechanically stretchable. Furthermore, the hydrogel composition of the vessel wall can be specifically tuned for mechanical and biological functions. We believe that these vasculature models with increases biomimicry can benefit future research in mechanistic understanding of CVD progress and the development of therapeutic intervention.

3D Printing Bionic Devices Michael C. McAlpine; University of Minnesota, United States

The ability to three-dimensionally interweave biological and functional materials could enable the creation of devices possessing personalized geometries and functionalities. Indeed, interfacing active devices with biology in 3D could impact a variety of fields, including biomedical devices, regenerative biomedicines, bioelectronics, smart prosthetics, and human-machine interfaces. Biology, from the molecular scale of DNA and proteins, to the macroscopic scale of tissues and organs, is three-dimensional, often soft and stretchable, and temperature sensitive. This renders most biological platforms incompatible with the fabrication and material processing methods that have been developed and optimized for functional electronics, which are typically planar, rigid, and brittle. A number of strategies have been developed to overcome these dichotomies. Our approach is to utilize extrusion-based multi-material 3D printing, which is an additive manufacturing technology that offers freeform, autonomous fabrication. This approach addresses the challenges presented above by (1) using 3D printing and imaging for personalized device architectures; (2) employing 'nano-inks' as an enabling route for introducing a diverse palette of functionalities; and (3) combining 3D printing of biological and functional inks on a common platform to enable the interweaving of these two worlds, from biological to electronic. 3D printing is a multiscale platform, allowing for the incorporation of functional nanoscale inks, the printing of microscale features, and ultimately the creation of macroscale devices. This blending of 3D printing, functional materials, and 'living' inks may enable next-generation 3D printed devices.

4:00 PM SF02.09.01
Versatile Additive Manufacturing of Metals and Alloys via Hydrogel Infusion Max Saccone[1], Daryl W. Yee[2], Rebecca Gallivan[1], Kai Narita[1] and Julia R. Greer[1]; [1]California Institute of Technology, United States; [2]Massachusetts Institute of Technology, United States

Additive manufacturing (AM) of metal components has emerged as a uniquely powerful tool for rapid prototyping and creating parts with complex geometries. We explore AM enabled by vat polymerization, typically used to produce polymers and ceramics, for the fabrication of metals and metal alloys. This technique can simultaneously achieve high resolution and high throughput, making it a promising candidate for practical industrial use.

We developed a general method for the fabrication of a wide variety of metals and alloys with complex shapes and overall dimensions of several mm via vat polymerization AM and subsequent post-processing and thermal treatment. This streamlined technique makes use of a single resin composition and a single set of processing conditions during the vat polymerization process, followed by infusion of appropriate metal precursors into a hydrogel structure. Heat treatment in oxidizing followed by reducing atmospheres converts the polymer/precursor matrix into the target metal. Unlike previous vat polymerization strategies which have target materials or precursors incorporated into the resin during the printing process, this method does not require re-optimization of resins and resin curing parameters when the target material is changed.

We report photoresin design and post-processing strategies to show how to use this technique to easily fabricate a range of AM metal and alloy structures. As a proof of concept, we fabricated octet lattice architectures with beam diameters on the order of 50 μm from several materials including copper, nickel, silver, cobalt, cupronickel alloys, and tungsten. We characterize these materials to show the unique microstructures enabled by our technique and link them to mechanical properties measured by nanoindentation. Our approach represents a paradigm shift in vat polymerization AM of functional materials by reducing the experimental burden on resin design and allowing the target material to be selected after the structure is fabricated.

Expanding Available Polymeric Materials for Powder Bed Fusion via Rational Control of Liquid-Liquid Phase Separation Kaizhong Guan, Akan George and Mark Dadmun; University of Tennessee, United States

Powder Bed Fusion (PBF) is an important process in polymeric additive manufacturing. However, there exist limited polymers available for PBF, where most efforts use nylon to create object using PBF. In an effort to expand the polymers available for PBF and to provide additional insight into the sintering process, we have utilized a relatively facile method, thermally induced phase separation (TIPS), to synthesize polypropylene (PP) powders for PBF. More specifically, using TIPS, polymeric microspheres from PP with molecular weights of 12k, 250k and 340k, and their blends, have been formed. Specific conditions of the TIPS process, including polymer concentration and precipitation temperature were controlled to fabricate spherical PP powders with smooth surface morphologies, and appropriate particle size that is suitable for PBF (between 45μm and 100μm). Interpretation of the temperature, solution concentration, and molecular weight dependence of particle size that emerge from the TIPS process provides important fundamental understanding into the phase separation processes that govern particle formation. This in turn offers insight that will enable the rational design of thermodynamic conditions required to create polymer powders that are suitable for powder bed fusion for a broad range of polymers using the TIPS process.
At the same time, coalescence in PBF occurs in stationary particles, and thus the rate of weld formation is related to the zero-shear viscosity of the polymer melt. Given the fundamental importance of polymer diffusion in particle coalescence in PBF, we are interested in examining the impact of polymer molecular weight, and thus zero-shear viscosity, on the success of the fabrication of structures by PBF. The production of PP powder that is suitable for PBF with varying molecular weight provides an experimental system to examine this relationship, which is underway. Thus, we will discuss how the TIPS process opens clear routes to fabricate PBF powders with controlled zero-shear viscosity, providing pathways to examine and more thoroughly optimize the complexities of the coalescence process in PBF printing.

4:45 PM SF02.09.04
Additive Solution-Processed Iridescent Metal-Dielectric-Metal Structural Color Weijie Feng and L.Jay Guo; University of Michigan, United States

Thin metal-dielectric-metal (MDM) structure, a simple Fabry-Perot cavity, is highly desirable for structural color applications due to its simple structure and ability to reflect strong visible colors. However, conventional fabrication methods typically require high vacuum processes such as physical vapor deposition, magnetron sputtering, which significantly limits their practical use, especially for large-scale production due to the high cost and long processing time. Herein, we developed a series of solution-based methods for thin layer deposition of MDM structural color aiming at similar quality to cost-ineffective vacuum processes. We chose Cu-SiO_2-Cu as our model system due to its easy accessibility and low cost. Electroless plating of copper is implemented for the top and bottom metal while an electrochemical-assisted sol-gel process is adopted for the middle silica deposition. A systematic investigation is carried out for each deposition layer to ensure good film quality as well as its compatibility with all previous layers. Precise control of the silica precursor concentration, deposition time, deposition potential, and pH allow for a wide dielectric (SiO_2) thickness range, from sub-100nm up to 400nm thickness. Due to the low refractive index of silica, attractive iridescent structural colors are produced. The spectroscopic and morphological qualities of these solution-deposited structural colors are then compared with conventional vacuum-deposited samples for color performance. Subsequent work will utilize solution-based thin film deposition methods to deposit conformal thin-film structural color on curved surfaces, which is considered difficult for conventional deposition methods. Further exploration of solution-based deposition of other thin metals and dielectrics depositions will be carried out to expand the material library. We believe that these solution-based thin film-based methods can advance practical implementations of structural color fabrication.

5:00 PM SF02.09.05
Manifold Learning Between Geometric Defects and Electromagnetic Performance in Additivity Manufactured Devices Deanna Sessions[1], Venkatesh Meenakshisundaram[2], Andrew Gillman[3], Alexander Cook[4], Kazuko Fuchi[5], Gregory Huff[1] and Phil Buskohl[3]; [1]The Pennsylvania State University, United States; [2]UES, Inc., United States; [3]Air Force Research Laboratory, United States; [4]NextFlex, United States; [5]University of Dayton Research Institute, United States

Additive manufacturing enables game-changing fabrication capabilities for customized, low-cost, and multi-functional devices. However, process-specific fabrication anomalies can result in non-intuitive variations in geometry and function, especially for electromagnetic applications. To address this challenge, we implemented a machine learning methodology to map between geometric variances and their impact on electromagnetic performance, and further characterized the underlying defect mechanisms of the print. Using a direct-write additive manufacturing approach with a conductive Ag thermoplastic polyurethane ink, we printed a frequency selective surface (FSS) consisting of ~4000 Archimedean spirals in a hexagonal-packed array. Each spiral was optically imaged and then simulated as a FSS in a computational electromagnetic solver, which resulted in a paired geometric and electromagnetic performance dataset. Dimensionality reduction was applied to both datasets, which revealed 6 distinct classes of geometry defects and a strong dependence of the electromagnetic data manifold on the resonance frequency of the FSS. To map between the two domains – geometry and electromagnetic performance – convolutional neural networks were used to predict electromagnetic performance from images of the spiral geometry. Two convolutional neural networks (CNN) were explored: one using the image-derived geometric description, and one using the geometric description plus surface current information from the simulation. Network latent space dimensional analysis showed that the neural networks organized the geometric input information according to both geometric and electromagnetic values even in the case with no seeded electromagnetic information. Collectively, these results highlight the potential of CNNs to serve as low-cost surrogate models for in-line feedback predictions of electromagnetic performance from as-printed geometry, and highlight the utility of manifold learning techniques to provide a lens into the mechanisms and distribution of defects in additive manufacturing processes.

5:15 PM SF02.09.06
Extreme Mechanics Enabled by Additive Manufacturing—From Extreme Extensibility to Supersonic Impact Mitigation Carlos Portela[1], Widianto Moestopo[2], Julia R. Greer[2], Dennis M. Kochmann[3] and Keith Nelson[1]; [1]Massachusetts Institute of Technology, United States; [2]California Institute of Technology, United States; [3]ETH Zürich, Switzerland

Advances in additive manufacturing (AM) have enabled the fabrication of novel materials with high stiffness & strength and simultaneously low weight, but realizations of these lightweight materials beyond this quasi-static and small-deformation regime have remained scarce. For instance, few additively manufactured materials can achieve extreme deformations without accumulating permanent damage, and their stiff mechanical properties prevent their application in regimes where compliance is required (e.g., tissue engineering). At the other extreme, little is known about these materials' performance under dynamic stimuli such as impact. To enable emerging applications of additively manufactured materials, new design and fabrication paradigms are required to achieve materials beyond the classical small-deformation parameter space.

To this end, we employ a two-photon lithography process to fabricate two types of material systems that independently achieve (i) extreme extensibility (and compliance), and (ii) extreme impact mitigation. First, we present a novel design paradigm for AM-materials that consists of 'woven' monolithic fibers which bypasses the need for nodes or joints between structural elements. Performing in situ nanomechanical experiments, we demonstrate that woven architecture gives rise to compliant mechanical properties, extensibility of up to twice the elastic strain limit of the constituent material, and cyclic compression to 35% strain with minimal damage accrual. Second, we present additively manufactured carbon materials with nanoscale features (consisting of 13,500 unit cells) that attain extreme energy dissipation upon supersonic microparticle impact. Here, we subject polymeric precursor micro-architected materials to a pyrolysis process of 900C in vacuum, resulting in isotropically shrunk carbon nano-architected materials. Using a laser-induced particle impact technique, we showcase the potential for architected materials at the nanoscale to serve as lightweight shielding materials, dissipating up to 70% more energy than Kevlar for the same mass-normalized impact conditions. Together, these works showcase new design paradigms and mechanical property spaces capable of opening new frontiers for additively manufactured materials.

SESSION SF02.10: Multifunctional Structures I

10:30 AM SF02.10.01
Two-Photon Fabrication of 3D Nanoporous Structures with Enhanced Mechanical Properties Using Nanocluster-Based Photoresists Qi Li, John Kulkwsk, David Doan and Wendy Gu; Stanford University, United States

Currently there is still a pressing need to develop new printable resins which are comparable with the state-of-the-art micro-/nano- printing techniques for a fast 3D fabrication of desired structures (for example, hierarchical nanoporous structure) with high shape-fidelity and improved properties. Herein, we report a new type of resin solution for the efficient fabrication of 3D metal-carbon hierarchical nanoporous structures which utilizes the atomically precise metal nanoclusters as two-photon initiators, nano-porogens and Reinforcing fillers for enhanced mechanical properties. Our resin shows high fabrication efficiency and high shape fidelity for various complex 3D metal structures with line widths down to ~200 nm can be obtained. Furthermore, 3D nanoporous metal-carbon structures are obtained after annealing and improved mechanical properties are obtained based on the nanoindentation and micro-compression testing. Overall, this work provides a new resin solution which utilizes the unique light-matter interactions and intrinsic chemicalphysics properties of ultrasmall metal nanoclusters for the efficient nanoscale 3D printing with high-fidelity and improved properties achieved in the final structures.

10:45 AM SF02.10.02
Additive Manufacturing of 3D Micro-Scaffolds with Computationally-Predicted Anisotropic Stiffnesses Weiting Deng[1], Siddhant Kumar[2], Alberto Vallone[3], Dennis M. Kochmann[3] and Julia R. Greer[1]; [1]California Institute of Technology, United States; [2]Delft University of Technology, Netherlands; [3]ETH Zürich, Switzerland

Cell viability, proliferation, and tissue formation are significantly influenced by the physical cues of local microenvironments, i.e., extracellular matrix (ECM) elasticity directs stem cell differentiation. Proper scaffold design would help identify the mechanisms of cell-ECM interactions in three-dimensional environments. A key unsolved challenge has been the lack of quantifiable mechanical cues that could guide the fabrication of physiologically relevant scaffolds with high architectural complexity and anisotropy. To date, matching the mechanical property landscape within a scaffold has relied on trial-and-error techniques and topology optimization, which are computationally and experimentally expensive, sensitive to the initial guess, and incapable to explore the entire design space.

In this work, we fabricated and characterized biomimetic 3D scaffolds with tunable anisotropic stiffness predicted by an artificial intelligence-enabled model. We generated spinodal-like topologies via a machine learning-based technique and fabricated the computed structures out of IP-Dip photoresist with critical dimensions of 2.3μm and overall sample dimensions of 70μm ×70μm ×70μm using two-photon lithography (TPL). The SEM images of the samples showed that they could geometrically resemble the porous structure of natural tissue environments, for example trabecular bone. Quasi-static uniaxial compression experiments, conducted at a strain rate of to a strain of 10^{-3} s^{-1}, revealed the normalized elastic moduli of the samples in e_1, e_2, and e_3 directions as 1.000 ± 0.097, 0.354 ± 0.042, and 0.619 ± 0.100, respectively. The results matched closely with the numerically computed prediction that the normalized elastic moduli of the sample in e_1, e_2, and e_3 would be 1.000, 0.360, and 0.621.

Through these experiments and computations, we successfully demonstrate that this spinodoid model can accurately predict direction-dependent stiffnesses, with high tunability and flexibility, rendering it possible to systematically investigate ECM environments in various tissues. This approach could help expand the parameter space of mechanobiology research.

11:00 AM SF02.10.03
Additively Manufactured Complex Reactors for Carbon Utilization Jacquelynn Garofano[1], Mehdi Mortazavi[2], Seyed Niknam[2] and Dongsheng Li[3]; [1]Connecticut Center of Advanced Technology Inc, United States; [2]Western New England University, United States; [3]Advanced Manufacturing LLC, United States

The objective of this research work is to design, develop and fabricate microchannel reactor with complex features using additive manufacturing (AM) for carbon capture and utilization. Fabrication parameters of selective laser melting were optimized to improve fabrication quality. The designs were optimized based on simulation results from computational fluid dynamics. AM technologies will provide an opportunity for enhanced design and superior heat transfer performance. In this study, innovative Manifold-microchannel reactor or heat exchanger (MMHX) are designed and fabricated starting from the study of fluid flow in single channel reactor to multichannel with complex features and configurations. An experimental instrument was designed to measure pressure drop and heat transfer in AM designed MMHXs with a wide range of Reynolds numbers. Measurement results demonstrated that in some scenarios adding more internal features, i.e. increasing design complexity, does not necessarily improve the MMHX performance. This fluid flow study provides a guidance for additively manufactured MMHXs design optimization from experimental perspective. The reactors were loaded with catalyst to hydrogenate carbon dioxide into methanol. The effect of twist angle of the channels on carbon utilization efficiency and selectivity were investigated preliminarily. Further study on balancing conversion efficiency with pressure drop due to complexity will be investigated.
MMHX studied here has become a favorite topic in various fields ranging from air conditioning to aircraft gas turbine engines. In essence, high manufacturing cost has emerged as the major drawback in broad applications of MMHXs. The possibility of cost-effective manufacturing has generated wide interest in applying additive manufacturing (AM) for fabricating MMHXs. The methodology established in this study will contribute to the development of other reactors using similar additive manufacturing methods.

11:15 AM SF02.10.04
Failure Mechanisms of Nano-Architected Nanocrystalline Zinc Oxide Rebecca A. Gallivan[1], Zachary Aitken[2], Yong-Wei Zhang[2] and Julia R. Greer[1]; [1]California Institute of Technology, United States; [2]Institute of High Performance Computing, A*STAR, Singapore

The advances in additive manufacturing at the nanoscale drive the need to understand the role of microstructure and size effects in mechanical properties of constituent solids. Nanomechancial studies have shown the emergence of size effect in mechanical properties of materials, with small-is-stronger behavior in single crystals, smaller-is-weaker in nanocrystalline metals, and suppression of brittle failure in amorphous metallic glasses. In addition to this size effect that emerges in samples with sub-micron extrinsic dimensions, the intrinsic length scale of material microstructure also dictates the dominance of different deformation and failure mechanisms. While heavily studied in metallic systems, a dearth of studies exists on the contribution of nanocrystallinity and nanostructuring in ceramics.
Using a Photopolymer Complex Synthesis additive manufacturing technique, we created nanocrystalline zinc oxide (ZnO) pillars with diameters ranging from 250nm to 3μm and heights of 600nm to 9μm. We achieve these structures by first patterning zinc ion-containing aqueous photoresins using two-photon lithography and subsequently calcining them at 500°C to produce pure nanocrystalline ZnO. Through in-situ micro-compression experiments we show three distinct failure behaviors based on structure size: 1) splitting via crack propagation 2) shear off events and 3) non-catastrophic deformation of the structures. These three regions can be described through the energetic competition of different failure mechanisms, similar to those in metal and metallic glasses. TEM analysis of the microstructure and Molecular Dynamics simulations of nanocrystalline ZnO provide insights into the deformation mechanisms and help establish the link between the microstructural features and failure behavior. Investigation of this system highlights the interplay between traditional weakest link failure theory and stochastic localization of stress within the microstructure. Through these studies we show the effect of extrinsic size on failure behavior in nanocrystalline ZnO, reveal the role of intrinsic length scales in deformation and failure mechanisms, and lay the foundation for fundamental insight to designing metal oxide nano-architectures from a microstructural viewpoint, as well as emphasize the importance of microstructural investigation in micro- and nano-sized additively manufactured materials.

11:30 AM SF02.10.05
Multimaterial Design of Programmable Shape Memory Alloy-Based Smart Structures via Topology Optimization Ziliang Kang[1], Pascal Zehnder[2], Felix Jensch[3], Markus Bambach[2] and Kai James[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]ETH Zürich, Switzerland; [3]Brandenburg University of Technology Cottbus - Senftenberg, Germany

Shape memory alloy (SMA)-based smart structures have been long-awaited for comprehensive computational design tools. Generally, SMA-based smart structures are developed based on experimental or empirical designs. Their configurations vary drastically from application to application, and are limited in ability to achieve multifunctionalities with simple, generic geometries. Via the technique of topology optimization, we propose a computational design framework that enables programming the stimuli-responsive behaviors of SMA-based smart structures with multiple material candidates. Specifically, the proposed framework is able to program the target thermomechanical performance of the structure into its material distribution, by modeling nonlinear phase transformation of SMAs coupled with transient thermal conduction. The proposed design framework allows for achieving multifunctionalities such as bending, inchworm-like crawling, and twisting with simple geometries. Further, we study laser powder bed fusion (LPBF)-based 3D printing techniques to realize our designs. A series of 3D printed sample designs enabled by the framework including SMA-based stents and grippers are then discussed.

11:45 AM SF02.10.06
Transforming 3D-Printed Mesostructures with Nanoscale Conductive Metal Oxides Julia Huddy, Md Saifur Rahman, Andrew B. Hamlin, Youxiong Ye and William J. Scheideler; Dartmouth College, United States

Additive manufacturing (AM) excels at fabricating structural materials in complex geometries, but electronics integration could transform these *parts* into *sensors* and *systems*, expanding 3D printing far beyond prototyping. Here we present a method for engineering conductive 3D mesostructures via low-temperature atomic layer deposition (ALD) and industrial microstereolithography (μSLA). μSLA was used to produce a range of 3D structures (cubes, spheres, etc.) composed of internal octet lattices (10 - 200 μm critical features) having ultrasmooth surface morphology, (r_q < 40 nm) enabling 3D deposition of ZnO, ZnO:Al, and SnO_2 films leveraging an Al_2O_3 seed layer to prevent growth inhibition.

Uniform growth of ultrathin layers (7 nm – 100 nm) was achieved over a wide range of temperatures up to the polymer T_g , allowing control of the films' semiconducting or degenerate behavior and yielding resistance from 100 Ω to 100 kΩ for per dimensionless cubic volume. XRD studies of the 3D oxide coatings reveal the ability to grow both amorphous and crystalline films matching those of 2D ALD films. Similarly, XPS and EDS studies indicate the similar atomic composition of coatings on 3D polymers and 2D substrates. However, despite their similar material characteristics these 3D networks show significantly enhanced conduction vs. 2D films, stemming from their high surface area and parallel 3D conduction paths. This allows precision geometrical manipulation with μSLA to enhance volumetric conductance and engineer electronic transport in novel 3D devices. This process has significant and broad implications for designing 3D electronics that bridge the gap between nanoscale materials and 3D-printed mesostructures.

SESSION SF02.11: Multifunctional Structures II
Session Chair: Sung Hoon Kang
Thursday Afternoon, December 2, 2021

1:30 PM SF02.11.01
Custom 3D Beauty Masks—An Additive Technology Approach to Deliver Fully Tailored Consumer Goods Products Scott Stanley; The Procter & Gamble Company, United States

We have been investigating additive manufacturing across a range of applications in the consumer goods space at P&G. One commercial interest lies in creating tailored, personalized products. In this talk, I will review additive manufacturing technology approaches we have explored in the beauty products category, specifically, custom 3D beauty masks. I will cover scanning approaches, resolution requirements, a manufacturing path for creating custom shaped objects, application of custom chemistries and the benefits associated with custom shape applicators and chemistries. Our approach utilizes a combination of 3D scanning, additive manufacturing (3D printing) of disposable molds, thermoforming replicates, custom laser cutting, and custom application of chemistries to create a scaled approach of creating fully tailored, customized offerings. I also will cover business model considerations for offering such products and share some future directions of this research. I hope that this work serves as an example and case study of how additive manufacturing technologies can be applied in the consumer goods space and open the door for partnerships.

1:45 PM SF02.11.02
Hierarchical Co-Assembly-Enabled 3D-Printing of Porous Materials Chenfeng Ke; Dartmouth College, United States

Natural materials are inherently constructed hierarchically from the molecular-level to the macroscale, which often possess light-weight porous scaffolds (e.g. bone), outstanding mechanical properties (e.g. shells and skins), as well as stimuli-responsive behaviors (e.g. muscles). My research group aims to develop 3D-printing materials that emulate natural systems' multiscale and multifunctional integration across the nano-to-macroscale.
Currently, there is an emerging need to introduce smart molecular systems that lack the necessary molecular features for direct ink writing technique. This roadblock severely limits the number of smart materials available for 3D printing. To address this problem, my research group has developed a general method to integrate a variety of inorganic and organic molecules as functional 3D-printing inks through the introduction of micellar-based supramolecular templates.[1] In our hierarchical co-assembly enhanced direct ink writing design, molecular monomers and supramolecular templates co-assembled via multivalent noncovalent interactions to form a viscoelastic ink. After 3D printing, the molecular monomers and supramolecular templates in the 3D-printed monolith co-assembled in a holistic manner, affording monoliths with hierarchically ordered superstructures. In this process, a localized re-configuration of monomer and template was critical to maintaining the self-standing macroscale structure. Subsequent chemical crosslinking and template removal stapled these assembled molecular monomers together at the macroscale to afford the desired functional monoliths. 3D-printed mesoporous silica monoliths with a surface area of 304 m^2/g were successfully fabricated. We further demonstrated that a molecular pillar insertion resulted in a macroscopic size expansion in the 3D-printed BTA monolith. The co-assembly process not only enhances the printing resolution by up to one order of magnitude but also enables precise spatial control of nanoscale features, such as molecular assembly, over a large scale. In the next step, we expanded this co-assembly-enabled 3D-printing method to fabricate highly ordered covalent organic frameworks (COFs) with imine and β-ketoenamine linkages.[2] The supramolecular template was introduced to coassemble with imine precursors in an aqueous environment. By limiting the degree of imine polycondensation during COF formation, co-assembled 3D-printable hydrogels were formed. After the removal of the template followed by an amorphous-to-crystalline transformation, the assemblies

were converted to the first set of single- and multi-component 3D-printed covalent organic framework monoliths, possessing high crystallinity and large surface areas, as well as robust mechanical stability.

2:00 PM SF02.11.03
Mechanical Properties of Micrometer-Size Foam-Like Auxetic Structures Ming Wang and David Harding; University of Rochester, United States

Applications for polymer structures made using the two-photon polymerization additive manufacturing method, which produces structures with submicrometer resolution, are primarily optical or biological. Mechanical applications are less prevalent, partially because the structures' properties depend on the processing parameters and structural design, and these are less extensively studied. This study investigates the performance of millimeter-size cellular auxetic structures (~0.2 g/cm^3) subjected to impulse loadings at room and cryogenic temperatures (295 K and 130 K, respectively). Auxetic structures are an example of a metamaterial that is ideally suited for the deterministic production methods of additive manufacturing and can be purposely designed for specific applications.

The stress–strain relationship, creep behavior, and recovery response of structures made from a proprietary thermoset acrylate resin (IP-S^{TM}) under static and dynamic loading is reported. Different auxetic structures were designed using two finite-element programs, NX7.5 and ANSYS, to calculate the stress/strain distribution in the structure for different loads and to produce stereolithographic files for use with a commercial laser writer (Nanoscribe GmbH). These structures were tested using a thermal mechanical analyzer (PerkinElmer) at 295 K and 130 K, at loads ranging from 10^5 to 10^6 Pa, and at different cyclic frequencies. The compression modulus and strength of the best-performing structure were 2.5X and 2X higher, respectively, at 130 K and at 295 K. The maximum strain the structure could withstand under cyclic loading and recover was 2% and 0.8% at 295 K and 130 K, respectively; the maximum strain it could withstand before crushing irretrievably was 18%. The corresponding energy dissipated as strain is calculated to be ~86 J/kg.

This material is based upon work supported by the Department of Energy National Nuclear Security Administration under Award Number DE-NA0003856, the University of Rochester, and the New York State Energy Research and Development Authority.

Additive Manufacturing and Characterization of Microstructures Using Two-Photon Polymerization for Use in Cryogenic Applications Sherman Peek, Jacob Ward, Stephen Bankson, Archit Shah, John Sellers, Mark Adams and Michael Hamilton; Auburn University, United States

Additive manufacturing technologies and techniques are becoming a more mainstream approach to prototyping, small-scale manufacturing, and one-off manufacturing especially in microelectronics and medical sciences. Two primary criteria are necessary for implementation of additive manufacturing techniques: resolution and scalability. One method of additive manufacturing that addresses these criteria is direct writing of three-dimensional structures by way of two-photon polymerization. Two-photon polymerization has the potential of being an incredibly useful tool for micro/nanofabrication due to the ability to fabricate with sub-wavelength resolution; however, the technique requires additional exploration. The equipment required to achieve two-photon polymerization provides the benefit of high resolution and is becoming more accessible for research groups lending to scalability through parallelization.

In this work, we demonstrate a process to additively fabricate microstructures on diced silicon chips with oxide. We describe the process of creating the polymerized resin as well as its application onto the target substrate. Parameters of the laser system are described. Pre-fabrication adhesion layers are also discussed and post-write procedures are described. Characterizations of the load shear failure mode at room temperature and post cryogenic thermal cycling at temperatures as low as 77 K are presented. Cryogenic thermal cycling shown in this work was accomplished by direct submersion in liquid nitrogen to assess the worst-case degradation due to thermal shock. A discussion of experimental results and a comparison of room temperature and thermal cycle data is provided. The reliability of the structures demonstrated in this work show promise for additional exploration for more complex structures at cryogenic temperatures.

2:30 PM SF02.11.05
Inkjet-Printed Polymeric Dampers for MEMS Application Prisca Viviani[1], Martina Scolari[2], Ilaria Gelmi[2], Laura Castoldi[2] and Luca Magagnin[1]; [1]Politecnico di Milano, Italy; [2]STMicroelectronics, Italy

Over years, additive manufacturing has gained growing interest and attention in applications where customization and cost-effectiveness are strategic features. In this frame, Ink-jet printing (IJP) has emerged as a potential process to be flanked by traditional microelectronics material deposition method, where less exigent restraints on resolutions are required. However, high resolution in the micrometric range can be achieved, making this technique attractive for microfabrication. Indeed, many devices feature microfabricated parts, as Micro-electro-mechanical systems (MEMS). Compared to more traditional surface patterning techniques, IJP is a contact-less, mask-less droplet-based technique able to deposit functional materials onto specific substrates. The possibility to finely control the thickness, by tuning the number of printed layers, combined with minimum material waste reveal the great versatility of this fabrication technique. However, major challenges of IJP are found on two levels. One is the long-term cartridges durability, as nozzle clogging is prone to occur. On the other hand, IJP requires precise ink rheological properties to guarantee flow under the application of a shear stress: low viscosity (i.e. 2-20 cP) and surface tension (i.e. 25-50 mN m^{-1}) [1,2].

IJP is also considered to be a key technology regarding polymers deposition. In particular, polymers are optimal candidate materials for vibration damping applications. Vibrations often represent a problem due to undesired motions and stresses, that can lead to fatigue, failure, degradation and reliability loss for a wide range of structures in microelectronics. As MEMS devices consist of mechanical parts, they are prone to experience harsh undesired vibrations too. There are two material classes for vibration control mechanism: active and passive damping. The most common passive damping material are Viscoelastic materials (VEMs), combining properties of elastic and viscous materials, where damping occurs by energy dissipation due to friction among oligomers chains under cyclic deformation. VEMs may be used as discrete dampers, absorbers or the surface of the structure can be fully or partially covered. As a matter of fact, a common viscoelastic treatment to control vibrations in a structure is the Free-layer damping (FLD) approach. The damping material is deposited on the structure surface, creating a damping layer. When the structure is deflected, vibrations are damped because of the energy dissipated following of the compression/extension of the damping material [3,4].

The aim of this work is to propose a simple VEM deposition through IJP on top of a spring in the MEMS device, exploiting the FLD approach. First, an extensive material selection has been performed to individuate an adequate polymeric material, with low elastic modulus that would not alter spring properties. The characterization of the optimized ink in terms of physical properties, to understand ink printability through considerations regarding the

Ohnesorge diagram, will be presented. A jetting characterization will also be presented, evaluating the printability assessment as a function of the ink droplet speed. Eventually printed pattern characterization will be discussed either in terms of surface profilometry, microscopy and vibration damping ability.

Large-Scale Transparent and Flexible Electronics Based on SWCNTs Enabled by Directed Fluidic Assembly Ahmed Abdelaziz, Jonah Yu and Ahmed Busnaina; Northeastern University, United States

Over the past two decades, single-walled carbon nanotubes (SWCNTs) attracted a lot of interests due to their outstanding electronic, physical, and structural properties. Which make them extremely promising candidates for high performance integrated circuits. On the other hand, the expanding of microelectronic large area sensors arrays, smart labels, and RFID tags enhanced the motivation of implementing these SWCNTs integrated circuits onto flexible and transparent substrates. However, large scale SWCNT development has been facing numerous challenges attributed to the difficulty of achieving homogeneously distributed nanotubes across large substrate surface area, as well as the complexity of the fabrication process, that in many cases affects the nanotubes stability as well as the maximum fabrication yield. Here, we report the fabrication of transparent large scale SWCNTs transistors and logic circuits on a four-inch scale wafer flexible substrate. Our approach implements directed fluidic assembly method to directly print SWCNTs over large scale on flexible and transparent substrates. This facilitates the fabrication of SWCNTs with high device density and yield without affecting the nanotubes stability compared to other fabrication techniques such as transfer printing or dry etching. Following this approach, the field effected transistors are fabricated with density of 1250 transistors per cm^2, with a yield of 97 %, whereas the on/off ratios for the fabricated devices was $0.5x10^5$ in average. This technique also allows the fabrication of various flexible integrated logic circuits using SWCNTs such as NOR gates, NAND gates, and inverters. We believe that this fabrication approach will be of a significant value in the development of flexible electronics for different application such as sensing, computing, and communications.

3:00 PM SF02.11.07
Dynamic Behavior of Additively Manufactured Polymeric Microlattices Thomas Butruille and Carlos Portela; Massachusetts Institute of Technology, United States

Ultralight mechanical metamaterials enabled by additive manufacturing (AM) have previously achieved density-normalized strength and stiffness properties that are inaccessible to monolithic materials, but the majority of this work has focused on static loading while the mechanical properties of these metamaterials under extreme dynamic loading conditions has remained largely unexplored. Properties such as energy absorption and the ballistic limit of these additively manufactured materials are of high interest for protective applications and recent works on their dynamic response have demonstrated the benefit of architecture for impact mitigation. Despite these promising results, limitations of current additive manufacturing processes at the macroscale have made thorough investigations of impact both time- and cost-inefficient, particularly if separation of scales between the periodic building block and the impactor is required.

Here, we use two-photon lithography as a rapid prototyping technique for microscopic polymeric microlattices, to systematically study their response to projectile impact. We fabricate lattice architectures of different morphologies (i.e., kinematically rigid and non-rigid architectures), with beam diameters ranging from ~1.0 to ~1.5 μm and unit cells of 7.5 μm, and we qualitatively and quantitatively characterize their response to microparticle impact. We employ the laser-induced particle impact test (LIPIT) method to accelerate ~30 μm-diameter microparticles to velocities of up to 800 m/s, and use ultra high-speed imaging of the impact process to measure impact energetics. To isolate the effect of architecture, we maintain a constant relative density (i.e., fill fraction) across prototypes and probe them with a range of impact energies. Lastly, we analyze our experiments in a dimensionless framework that allows application of these results to metamaterials at larger scales. This investigation provides a framework for the rapid design and characterization of future AM metamaterials for a variety of energy mitigation applications.

8:00 AM *SF02.12.01
High-Area Rapid Printing (HARP)—A Dead Layer-Free Approach to High Throughput 3D Printing Chad Mirkin, David Walker and James Hedrick; Northwestern University, United States

We report a stereolithographic three-dimensional printing approach for polymeric components that uses a mobile liquid interface (a fluorinated oil) to reduce the adhesive forces between the interface and the printed object, thereby allowing for a continuous and rapid print process, regardless of polymeric precursor. The bed area is not size-restricted by thermal limitations because the flowing oil enables direct cooling across the entire print area. Continuous vertical print rates exceeding 430 millimeters per hour with a volumetric throughput of 100 liters per hour have been demonstrated, and proof-of-concept structures made from hard plastics, ceramic precursors, and elastomers have been printed. This novel High-Area Rapid Printing (HARP) methodology works in the presence or absence of O_2, which expands the scope of resin materials that can be utilized for both prototyping and manufacturing.

8:30 AM SF02.12.05
Designing Direct-Ink-Write Structures for Specific Mechanical Responses Ilse Van Meerbeek, Todd H. Weisgraber, Ward Small and Jeremy Lenhardt; Lawrence Livermore National Laboratory, United States

This talk presents a method that uses simulation to explore the large design space of direct-ink-write (DIW) structures. Research has shown that we can design porous, elastomeric structures whose mechanical responses are specifically tailored to a given application; however, without complete information

about the design space, we are limited in what mechanical responses we can achieve. We used this method to expand our knowledge of the DIW design space by examining helicoidal structures in compression. We defined a parameter set and performed 90 simulations. The results suggest that changing the angle of rotation between layers (while keeping other parameters fixed) can increase the stress in compression by up to 300%. This raises the question: what other parameters can we define, and what effect will they have on the stress response? Porous elastomers are used for stress mitigation, in medical devices, and in soft robotics, all of which could benefit from precisely tuned mechanical responses. This method can facilitate optimizing for such applications.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. LLNL-ABS-823652

8:45 AM SF02.12.04

Late News: Enhancement of Tensile Toughness of poly(lactic acid) (PLA) Through Blending of an Alkyl-Branched Polydecalactone-Grafted Cellulose Graft Copolymer Woojin Lee[1], Jinsu Park[1], Jae W. Chung[2] and Seung-Yeop Kwak[1,3,4]; [1]Seoul National University, Korea (the Republic of); [2]Soongsil University, Korea (the Republic of); [3]Research Institute of Advanced Materials (RIAM), Seoul National University, Korea (the Republic of); [4]Institute of Engineering Research, Seoul National University, Korea (the Republic of)

Bio-polymers and bio-degradable plastics have attracted a considerable attention in scientific and industrial fields as a solution for alleviating pending issues regarding petrochemical-based plastic wastes, carbon dioxide emissions, and depletion of fossil resources. Poly(lactic acid) (PLA), an aliphatic polyester generally derived from bio-resources such as plant starches including corn, cassava, and sugarcane, is one of the most essential bio-polymers for various industrial applications. However, it is well known that the applications of PLA are considerably limited when compared to the typical petrochemical-based polymers owing to its inherent characteristics such as brittleness. Accordingly, increasing the toughness of PLA, i.e., concurrently increasing both the tensile stress and elongation at break, remains as a major challenge. In this present study, the fully bio-based PLA blends with polydecalactone (PDL)-grafted cellulose copolymer (CgPD) were fabricated to enhance the tensile toughness of the PLA matrix. As a toughness enhancer, the CgPD was synthesized via the direct ring-opening polymerization (ROP) of ε-decalactone (ε-DL), which is known as renewable and bio-degradable alkyl-branched lactone derivatives. The blending ratio was controlled by varying the amount of CgPD from 1 wt% to 10 wt% relative to that of PLA matrix, and the formation of thermoplastic film was performed by solution casting and subsequent melt-quenching methods under 4500 psi at 190 °C. The prepared bio-blends were found by FT-IR and solid-state ^{1}H NMR to be physically intact and miscible at the sub-twenty-nanometer scale. The WXRD and DSC analyses indicated that the addition of the alkyl-branched CgPD imparts a more structurally disordered PLA mesophase state to the prepared PLA_CgPD bio-blends. UTM analysis was used to characterize the macroscopic mechanical properties of the PLA_CgPD bio-blends. Both the tensile strength and elongation properties were simultaneously improved with the addition of 1 wt% CgPD loading amount to PLA (PLA_CgPD1). This study experimentally demonstrates that the enhanced mechanical properties of PLA_CgPD1 are closely related to the existence of more ordered PLA mesophases induced by the introduction of an optimal amount of CgPD additive into the PLA matrix. Consequently, the proposed strategy in this study presents the possibility of designing a fully bio-based polymeric blend materials with exceptionally improved mechanical properties.

9:00 AM SF02.12.06

Recycling of Additively Manufactured Bio-Based Composites Katherine E. Copenhaver, Xianhui Zhao, Tyler Smith, Matthew Korey, Meghan Lamm and Soydan Ozcan; Oak Ridge National Laboratory, United States

As demand for high-performance composite materials rises, their management at end-of-life (EOL) must be considered more carefully. Bio-based polymers and composites have gained interest as global environmental awareness has heightened and governments and industries alike have put forth efforts to lower their carbon footprint. Identifying efficient routes for recycling of bio-based composites and establishing their application space after reprocessing will make these materials even more environmentally friendly. Additive manufacturing (AM) has also gained attention as a low-waste and highly flexible technique in which bio-based polymers and composites can be readily used. High-throughput, large area AM is a relatively new and fast-growing area of research, and the recyclability of these parts is important to establish considering the scale of parts and amount of material used. As such, the effect of recycling on additively manufactured poly(lactic acid) (PLA)/wood flour (WF) composites was studied. Parts were printed on the Big Area Additive Manufacturing (BAAM) system at Oak Ridge National Laboratory. The parts were size reduced using a water jet cutter and fed into a shredder/granulator. The obtained granulate was then fed directly back into the BAAM for reprinting without the need for repelletization. The thermomechanical performance of virgin and recycled parts was then characterized and compared in order to determine the impact of mechanical recycling on PLA/WF parts produced by AM. Mechanical recycling and direct reprinting of EOL AM parts was demonstrated as a cost-effective pathway for converting used bio-based composites into new products.

9:15 AM SF02.12.07

Late News: Fabrication of a Stretchable Cellulosic Material with Internally- and Externally Dual-Plasticized Structure Woojin Lee[1], Jinsu Park[1], Jae W. Chung[2] and Seung-Yeop Kwak[1,3,4]; [1]Seoul National University, Korea (the Republic of); [2]Soongsil University, Korea (the Republic of); [3]Research Institute of Advanced Materials (RIAM), Seoul National University, Korea (the Republic of); [4]Institute of Engineering Research, Seoul National University, Korea (the Republic of)

In recent years, environmental issues regarding the disposal of conventional synthetic plastics derived from petrochemical resources have emerged as a major issue. Thus, the development of bio-based plastics has received significant scientific interest over the past decades. Among the various natural resources, cellulose, which constitutes the main skeletal component of plants, is the most abundant natural polymer on the planet. However, it is well known that cellulose has a low solubility in most organic solvents, in addition to a poor melt processability owing to their intrinsic supramolecular hydrogen bonding properties and chain rigidity. Therefore, it is necessary to the develop of methodology capable of controlling molecular structure, flexibility, and stretchability of cellulose by imparting an effective plasticizing structure.
In this study, we developed a highly stretchable internally- and externally-plasticized (i.e., dually-plasticized) cellulose, which is composed of a polydecalactone-grafted cellulose copolymer (CgPD) and a hyperbranched polycaprolactone external plasticizing additive (HPC). To investigate the effect of branching structures of polycaprolactone-based external plasticizing additives on the plasticization capability, a linear polycaprolactone (LPC) and a star-shaped polycaprolactone (SPC) plasticizing additives were prepared as control groups to HPC. It is observed that dipolar interactions existed between CgPD and external plasticizing additives in the dually-plasticized cellulosic materials (i.e., CgPD_LPC, CgPD_SPC, and CgPD_HPC). Especially, among the dually-plasticized cellulose samples, the CgPD_HPC exhibited the lowest apparent activation energy (E_a= ~128.8 kJ mol^{-1}) required to achieve the sufficient plasticizing behavior, which resulted in an enhanced elongation at break value (ε = ~136%) compared to those of the CgPD (ε = ~75%), whereas CgPD_LPC and CgPD_SPC displayed severely deteriorated values (ε = ~25 and ~59%). This deterioration of mechanical properties may be attributed to the induction of structural discontinuity derived from the recrystallized polycaprolactone in the dually-plasticized celluloses. Therefore, it can be concluded that the highly-branched architectures as well as the structural uniformity between the internal- and external-plasticizing components play a critical role in determining the plasticization behavior.

9:30 AM SF02.02.07
Morphological Simulation for Material Design of Uniform Droplet-Sprayed Mg Alloys in Additive Manufacturing Charalabos C. Doumanidis[1], Yiliang Liao[2], Nikolaos Kostoglou[3], Hiroki Fukuda[4] and Claus Rebholz[5]; [1]BRAC University, Bangladesh; [2]Iowa State University, United States; [3]Montanuniversitat Leoben, Austria; [4]Fukuda Metal Foil & Powder Co Ltd, Japan; [5]University of Cyprus, Cyprus

This work introduces a morphological simulation of rapid solidification process deposited structures on 2-D planar sections, modeled as Apollonian packs of generalized ellipsoidal domains growing out of nuclei and dendrite arm fragments. The model employs descriptions of the dynamic thermal field based on superposed Green's/Rosenthal functions with source images for initial/boundary effects, along with alloy phase diagrams and classical solidification theory for nucleation and fragmentation rates. Initiation of grains is followed by their free and constrained growth by adjacent domains, represented via potential fields of level set methods, for effective mapping of the solidified topology and its metrics, i.e. apparent grain size and fractal dimension of densely-packed domains. The model parameters are calibrated and its predictions are validated against micrographs of three Mg-Zn-Y alloys deposited by uniform droplet spraying for additive manufacturing.
Further evolution of this real-time computational model and its application as a process observer for feedback control in 3D printing processes, as well as for off-line material design and optimization, is also summarized.

Impact of Novel Post-Processing Techniques on the Corrosion Response of L-PBF 316L Stainless Steels Stephanie Prochaska[1,2] and Owen Hildreth[1]; [1]Colorado School of Mines, United States; [2]US Bureau of Reclamation, United States

Post-processing of additively manufactured (AM) 316L stainless steel parts printed via laser powder bed fusion (L-PBF) is required for removing support structures and to improve surface finish. Various novel processes have been recently developed to remove supports and/or improve surface finish on the entire part without requiring intensive manual labor. One technique, a self-terminating etching process, removes supports and smooths surfaces; another technique that improves surface finish involves a stepwise application of a chemical conversion coating and subsequent mechanical removal of material. The corrosion response of AM 316L stainless steel parts having undergone these novel processes is not fully understood. This puts into question their ability to be reliably used in real-world environments and limits their practical application. To date, most corrosion studies of L-PBF 316L materials have been limited to parts in the as-built condition, with preliminary data showing that L-PBF 316L stainless steel's corrosion response differs significantly from conventionally manufactured counterparts. Additionally, the corrosion response of L-PBF specimens has been found to change based on print orientation with respect to the build platform and also vary with post-processing heat treatments that impact microstructure. This work evaluates AM 316L stainless steel samples in the as-built condition and after they have undergone post-processing techniques to show how printing parameters, build orientation, and novel post-processing treatments impact corrosion response. Electrochemical data was combined with metallographic analysis to connect corrosion mechanisms to the underlying microstructure and, ultimately, the processing conditions.

10:45 AM SF02.13.02
Ultra-Sonic Fatigue Testing—A Rapid Testing Method for Additively Manufactured Metal Alloys Christopher Macey, Jarid Barthold-Robinson and William Gabler; Shimadzu Scientific Instruments, Inc., United States

Rapid prototyping using additive manufacturing techniques has increased the need for faster methods to characterize the fatigue behavior of 3D-printed alloys. Fatigue testing instruments utilizing ultra-sonic (20kHz) sample resonance enable testing to 10^7 cycles in about 10 minutes versus over 10 hours using standard instrument designs. Ultra-sonic fatigue measurements also allow sample testing to extremely high cycles (10^{10}) in a reasonable timeframe allowing insight to material failure behavior beyond the traditional "fatigue limit" of 10^7 cycles.
This paper reviews the experimental considerations necessary for successful USF measurements and provides examples of USF measurements of 3D printed alloys.

11:00 AM SF02.13.03
3D and 4D Printing of Smart and Nanostructured Polymer Thermosets—Shape Memory and Light-Weighting Properties Rigoberto C. Advincula[1,2,3]; [1]Case Western Reserve University, United States; [2]The University of Tennessee, Knoxville, United States; [3]Oak Ridge National Laboratory, United States

There is high interest in smart and nanostructured materials based on the use of chemical and nanoparticle additives that enable structure-composition-property correlation towards their targeted application. 3D printing enables a convergence of optimized materials and geometrical design which can be further fine-tuned by the effective use of the 3D printing parameters: flow, slicing, temperature, adhesion, etc. There is the possibility of using artificial intelligence and machine learning (AI/ML) methods including simulation to optimize these properties such that valuable feedback can be obtained for optimized processing both during and post-printing. Herein, we focus on developing thermoset polymer materials to enable high performance for thermo-mechanical properties and eventual light-weighting applications. These include the following projects: 1) Thermoset elastomers based on VSP process emulsions, 2) Shape-memory polybenzoxazine materials that are highly stable, and 3) High-performance epoxy-carbon fiber materials and ideal light-weighting properties. The focus on thermosets enables materials development independent of melt-processability and using of photo-curing methods enabling the use of both chemical and physical crosslinking for curing modes. The VSP methods when applied at room temperature followed by post-printing curing methods including thermal treatment enable a more versatile method compared to high-performance polymer (HPP) FDM 3D printing methods.

11:15 AM SF02.13.04
Irregular Mechanical Metamaterials Using Liquid-Solid Scaffolds for Enhanced Impact Energy Absorption Zongling Ren[1], Robert Green-Warren[2], Assimina Assimina Pelegri[2], Jonathan Singer[2] and Jae-Hwang Lee[1]; [1]University of Massachusetts Amherst, United States; [2]Rutgers, The State University of New Jersey, United States

Disordered or irregular microstructures may demonstrate extraordinary mechanical characteristics when short-range phenomena, including interfacial (2D)

and nanoscale confined (3D) interactions, are tailored to govern the overall collective characteristics. Since the lack of lattice symmetry and statistical isotropy can allow scalable additive manufacturing as well as defect insensitivity in manufacturing, irregular metamaterials have been gaining greater attention in recent years. Because the range of mechanical exchanges is highly localized for the mechanical stimuli of high strain rates (HSRs), the irregular mechanical metamaterials can be more effective compared to ordinary regular mechanical metamaterials.
In this respect, we have investigated irregular solid-liquid hierarchical structures having characteristic lengths ranging from micro to nanometers. In their two-step additive manufacturing processes, first, polystyrene spherical nano-shells are stacked with uniform thicknesses using self-limiting electrospray deposition (SLED). Second, the nanoscale interstitial space of the PS structure are subsequently backfilled with weakly-crosslinked polydimethylsiloxane to introduce nanoscale interactions found between solid and viscous liquids to the system. To observe HSR viscoelastic responses of the microstructures, a single silica microsphere (approximately 20 μm diameter) is accelerated up to 500 m/s incident to the sample using laser-induced projectile impact test (LIPIT). Kinetic energy dissipation of the speeding microsphere during its collision with the metamaterial is quantified from the ultrafast stroboscopic microscopy. The correlations of the energy dissipation with a projectile's impact energy and viscoelasticity of the PDMS filler are demonstrated and compared with low-strain-rate indentation results. This study provides an understanding of the role of solid-liquid interactions within irregular solid nano-scaffolds materials under HSR inelastic deformation conditions.

11:30 AM SF02.13.05
Role of Substrate Surface Oxide and Temperature on the Bonding Characteristics of Al6061 Microspheres at Ultra-High Strain Rates in Cold Spray Process Swetaparna Mohanty[1], Carmine Taglienti[1], David L. Arellano[1], Victor K. Champagne[2] and Jae-Hwang Lee[1]; [1]University of Massachusetts Amherst, United States; [2]United States Army Research Laboratory, United States

Cold spray is a deposition process of solid powders and is employed in the additive manufacturing process to fabricate parts and structures below the powders' melting temperatures. Supersonic velocity impacts of microparticles to target substrates in this process results in the microparticles experiencing high-strain-rate microscopic ballistic collisions. At these high speeds, the kinetic energy of the particles leads to extreme plastic deformation of the interface of the microparticle and the target substrate, which eventually enables solid-state consolidation. Study of impact dynamics, bonding mechanism, and critical velocities of these microparticles helps us better understand the cold spray process.
It has been generally understood that the parameters influencing the critical velocity and bonding mechanism include the presence of an oxide layer and the temperature at which the collision events take place. In this study, as a model system, the dynamic behavior of polycrystalline aluminum 606l T6 alloy (Al 6061) microparticles (~ 20 μm diameter) after impact on a target substrate at ultra-high strain rates are quantified by using a micro-ballistic method: advanced laser induced projectile impact test (α-LIPIT). The controlled parameters in these highly controlled experiments are impact speed (0-1,000 m/s), temperature (room temperature-300°C), and substrate oxide film thickness (10-20 nm additional oxide layer prepared using atomic layer deposition). Individual particle's deformation characteristics are systematically studied with electron microscopy and focused ion beam milling. The precisely simulated microscopic collision events establish a quantitative relationship between the high-strain-rate dynamic response of the microparticles and the control parameters.

11:35 AM SF02.13.06
Toward Optimum Processing Parameters for Direct Laser Writing—A Molecular Dynamics Simulation Approach Elaheh Sedghamiz, Modan Liu and Wolfgang Wenzel; Karlsruhe Institute of Technology, Germany

Three-dimensional direct laser writing (3D-DLW) is an indispensable tool to high accuracy structuring and fabricating of 3D micro- and nano-objects via polymerization processes induced by direct laser writing. Over the past decade, this technology has become a well-established lithography tool for fabricating 3D geometries directly on functional substrates. This capability provided the possibility for a wide range of applications in photonics, microfluidics, mechanical microstructures, and cell scaffolds.
As the dimensions of the printed structures shrink, it remains a challenge to control the stiffness and resolution of the fabricated structure by changing the many conditions influencing direct laser writing. We, therefore, developed a nanoscale simulation approach as an alternative to physical experiments to optimize the 3D writing process and reduce the number of experiments. This approach enables a systematic study of how various writing parameters affect the structure and stiffness of the fabricated polymer network. We employ a coarse-grained molecular dynamics (CG-MD) approach to simulate direct laser writing of 3D polymer networks from a monomer pool, where monomers react irreversibly according to reaction rate constants, which results in 3D objects being printed voxel by voxel.
Simulations show that the degree of monomer conversion increases with higher laser power or, correspondingly, higher exposure times and saturates towards high writing powers/ high exposure times. Nonetheless, the laser power has a more pronounced effect on the degree of monomer conversion and mechanical properties than the exposure time. Furthermore, we study the relationship between mechanical strength, the porosity of the polymer network, and the mixture ratio of the radical quencher into the resins. We propose the optimum writing condition including the oxygen quenching effect to fabricate polymer networks of high resolution with acceptable mechanical stability. This approach allows us to tune the writing conditions of the 3D printed objects exploiting the fine interplay between laser power, exposure time, oxygen quenching to meet the requirements for different applications.

11:40 AM SF02.06.11
Late News: (Garcia High School Student) Optimizing the PP/PS Blends for Polymer 3D Printing Forest Ho-Chen[1], Emma Savov[2], Shuhe Liu[2], Yu-Chung Lin[3] and Miriam Rafailovich[3]; [1]George school, United States; [2]Mainland Regional High School, United States; [3]SUNY Stony Brook University, United States

Polypropylene (PP) is a widely used plastic, due to its superior mechanical properties and resistance to corrosion. Processing of PP using classical extrusion is well established but using PP as filaments for 3D printing has proven challenging. One problem, common in general to semi-crystalline polymers, is warpage which is exacerbated by the lack of adhesion to the base plate and makes printing of larger structures difficult. Polystyrene is another common polymer with good chemical corrosion resistance, which is easy to extrude, but very difficult to print. Its high melting point, makes it brittle, resulting in filament breakage and clogging of the nozzle mechanism during printing. Here we demonstrate that blends of PP and PS can overcome these problems to produce filaments that are ductile and print structures that resist warping and maintain structural accuracy. Furthermore, it has been shown that PP allows high loading of graphene nanoplatelets, GNP, while still retaining ductility [kai]. Printing with PP/GNP produced highly oriented layers, with high electrical conductivity, but the warpage persisted, and only narrow interconnects were easily produced.
Here we show that blends of these polymers could be made, extruded into filaments, which are then easily printed and could produce large multilayer structures. Blends of PP and PS, with 80/20, 70/30, and 60/40 ratios, were produced via melt mixing in a Brabender twin-screw extruder, where torque was monitored, and drawn into filament using a Filabot extruder. Samples were printed for tensile and Izod impact testing, as well as temperature and frequency rheological measurements. Measurement of G' and G''at T=200C, showed shear thinning behavior, which is advantageous for nozzle extrusion followed by rapid thickening to maintain accuracy. Tensile data indicates that the impact toughness of 80/20 PP/PS was significantly higher than the rest. Filaments were also produced where the PP phase was loaded with up to 20 weight percent GNP, and the electrical and thermal conductivity properties were compared to those obtained from pure PP with comparable loading, where large differences were observed between the perpendicular and parallel

orientations relative to the extruded control samples. Correlation with TEM images of the blend morphology and in operando x-ray scattering of the printing process will be presented.

Emergence of Multi-Material Volumetric Additive Manufacturing—Overprinting and Particle Inclusion Hayden Taylor, Joseph Toombs, Chi Chung Li, Sui Man Luk, Weisa Wang, Ingrid Shan, Vishal Bansal and Alexander Watson; University of California, Berkeley, United States

Volumetric additive manufacturing (VAM) describes a developing class of 3D printing methods in which a photosensitive precursor material is transformed into a solid object via highly parallelized illumination. Computed axial lithography (CAL) is a specific VAM process in which a rotating volume of material is illuminated with a time-evolving light pattern such that the cumulative light dose is tomographically synthesized and can be controlled in three dimensions. Where the light dose exceeds a material-dependent threshold, the material is transformed into a solid object. Unlike conventional photopolymer additive manufacturing, CAL is layer-free, which brings several advantages. Here, we describe two ways in which the unique characteristics of CAL are enabling multimaterial objects to be prototyped.

Firstly, because the entire volume of the target object is exposed simultaneously, pre-existing solid objects can be immersed in the precursor material and "overprinted" with a polymeric geometry, analogously to overmolding or insert molding in thermoplastic injection molding. We have evaluated ways of strengthening the bond between CAL-printed polymer geometries and metallic objects, including silane-based coupling agents and cross-pattern knurling, the latter of which was found to increase the shear strength of the printed bond by approximately a factor of two. We also describe a specialized algorithm to generate illumination patterns that compensate for the occlusion of light by the object. This algorithm is shown to improve the accuracy of 3D dose reconstruction during overprinting, compared to ignoring the occlusion of light. We discuss the application of overprinting to microfluidic devices incorporating CAL-printed hydrogels.

Our second multimaterial process innovation exploits the fact that in CAL there is no relative motion between the precursor material and the fabricated object during printing. Thus freed of the limitations of hydrodynamic stresses, CAL can access a wider range of higher-viscosity or thermally pre-gelled precursor materials without sacrificing processing speed. We can harness this advantage to process dispersions of solid particles with exceptionally high volume fractions and associated high viscosities. We discuss approaches to modeling the propagation of light through these precursor materials, and the prospects for processing dispersions of fibers using CAL.

Three-Dimensional Printing of Glass Micro-Optics Using Liquid Precondensed Tetramethoxysilane Oligomers Piaoran Ye[1], Zhihan Hong[1], Rongguang Liang[1] and Douglas A. Loy[2,1]; [1]The University of Arizona, United States; [2]University of Arizona, United States

To meet the increasing needs of high-precision glass micro-optics and address the major limitations of current three-dimensional (3D) printing optics, we have developed a liquid, solvent-free, silica precursor and two-photon 3D printing process. The printed optical elements can be fully converted to transparent inorganic glass at the temperature as low as 600 °C with the shrinkage of 17%. We demonstrate the complete process chain, from material development, printing process, and performance evaluation of the printed glass micro-optics. 3D printing of glass micro-optics with isotropic shrinkage, micrometer resolution, low deviation peak-to-valley value (<100 nm), and low surface roughness (< 6 nm) is achieved. The reported technique will enable the rapid fabrication of complex glass micro-optics previously impossible using conventional glass optics fabrication processes.

BCC High Entropy Alloy with High Strength in High Temperature Environments for Additive Manufacturing Kazuhiro Abe, Tomonori Kimura and Kazuya Shinagawa; Materials Processing Research Department CTI - Production Engineering and MONOZUKURI, Japan

New high temperature materials exceeding Ni-base superalloys are highly demanded because it can realize higher burning efficiency in turbines or internal combustion engines by improving temperature resistance of heat resistant parts. Although Ni-base superalloys has excellent high temperature properties up to 1000°C, improvement is needed for their use at higher temperatures due to their melting temperatures and γ'-solvus. As a breakthrough solution, high entropy alloys(HEAs), which are composed of multi-principal elements, are highly attracted because of their several unique properties [1]. Among them, refractory high entropy alloys(RHEAs), which are based on refractory metals such as WNbMoTaV and WNbMoTa, are known as alloys with excellent high-temperature strength because of high melting temperature [2]. Also, additive manufacturing for RHEAs has been reported, and thus they are promising for new structure materials [3]. However, most of RHEAs with outstanding high-temperature strength are low ductility at room temperature and they have higher density than conventional Ni-based alloys. They are large obstacles to make RHEAs in practical use.
The purpose of this study is development of alloys with both high strength and low density for additive manufacturing. We focused on the elements with both high melting temperature and low density compared with Ni, and the properties of VNbMoCrTi alloys and VNbMoCrTiC alloys were investigated. VNbMoCrTi alloys and VNbMoCrTiC alloys ingots were prepared by arc-melting under an Ar atmosphere. Specimens cut from the ingots were solution treated at 1300°C for 24 hours under vacuum followed by furnace cooling. All ingots were characterized by scanning electron microscopy(SEM) and energy dispersive X-ray spectroscopy(EDX). The phase structure was analyzed by X-ray diffractometer(XRD). Density of each specimen were measured by Archimedes method. The high-temperature strength was evaluated by the compressive test.
From the SEM observation of VNbMoCrTiC alloys, homogenized body centered cubic(BCC) matrix phase with carbide were confirmed after heat treatment. Also, EDX results indicated that carbide is mainly composed of TiC. XRD pattern showed the peak derived from BCC phase and carbide, and these results agree with EDX results Besides, VTiNbMoCrC alloy showed the yield stress of 780MPa at 1000°C regardless of lower density compared with Ni-based alloys.

Self-Terminating Etching Method for Support Removal of Additively Manufactured GRCop Sanaz Yazdanparast, Subbarao Raikar and Owen Hildreth; Colorado School of Mines, United States

Selective Laser Melting (SLM) is an emerging manufacturing technique that enables fabrication of parts with complex geometries and excellent mechanical properties. However, metal SLM components require expensive and difficult post-processing steps to remove supports and improve surface finish. To address this issue, this work presents a new self-terminating etching process to simplify the post-processing of copper alloy components fabricated using SLM. This process was performed on two advanced copper alloys; GRCop-84 and GRCop-42 that are interesting materials in aerospace applications due to their excellent thermal and mechanical properties. The self-terminating etching process contains two main steps: 1) altering the chemical composition of the outer surface of a metal by a proper sensitizing agent, and 2) dissolution of the resultant corrosive region by wet chemical etching. We demonstrate that iodine can be used to "sensitize" the surface of copper alloy components by forming soluble metal iodide salts that can be then dissolved in acetonitrile. Using this technique, a pre-defined amount of copper is removed from all interior and exterior surfaces resulting in separation of the component from the support. In addition, the surface roughness measurement shows an improvement of surface finish of GRCop by 70 % after 4 iodization-dissolution cycles.

2:15 PM SF02.14.06
Evaluation of the Infill Design on the Tensile Response of Metal Parts Produced by FFF Process Using Digital Twin Reconstruction Method Saleh Atatreh, Mozah Alyammahi, Hayk Vasilyan, Rahmat Agung Susantyoko, Tawaddod Alkindi and Oginne Lapuz; Dubai Electricity & Water Authority, United Arab Emirates

Additive Manufacturing (AM) technologies have evolved significantly. The applications of AM have expanded from rapid prototyping to a larger scale, such as the construction of buildings and the mass production of spare parts. The world's first 3D-printed laboratory has been constructed in Dubai in 2017, aligned with Dubai's strategy to be a leading hub of 3D printing technologies by 2030. AM has various advantages, such as reduced material usage, geometric freedom, and automation that will shape the future of the manufacturing industries.

AM technologies can be classified into material extrusion, binder jetting, and powder bed fusion (PBF), direct energy deposition (DED), and other technologies. Each of the above classifications can be sub-categorized based on feedstock material and sub-processes. With the rapid expansion of AM applications, feedstock materials have developed noticeably: from polymers and ceramics to metals and composites. Selective Laser Melting (SLM) is the most common method within PBF to fabricate metal parts. Electron Beam Additive Manufacturing (EBAM) is adopted for DED of metals.

The progress in developing new AM feedstock material has empowered the exploration of other technologies to manufacture metal parts, such as Material Extrusion. The flexibility in choosing the feedstock material is an advantage for the technology that facilitated its growth by users around the globe in research and industry. Fused Filament Fabrication (FFF) is one of the most common and cost-effective material extrusion AM technologies. FFF applications include rapid prototyping and the production of high-performance functional parts. The feedstock material is shaped in a wire form that is utilized through a filament. It passes through a nozzle that heats and extrudes it layer by layer over the print bed, following a predefined path determined by the G-code. Different terms have been used in the industry and literature that refer to metal fabrication through FFF, such as metal FFF, Bound Powder Extrusion (BPE), Atomic Diffusion Additive Manufacturing (ADAM), and Metal Fused Filament Fabrication (MF^3). The process of manufacturing metal parts with FFF consists of 3 main steps: printing, de-binding, and sintering.

It is critical to understand how different printing parameters and other factors along the process of metal FFF can affect the mechanical properties of the parts. Understanding the different characteristics of such parts is considered essential to expand the applications of this process and understand the economic and environmental impacts.

This paper attempts to explore the different characteristics of the parts produced via metal FFF, which includes the mechanical properties of two metals: 17-PH stainless steel and copper. The study will also investigate the porosity of these parts, cost analysis, weight, and environmental impact.

Two comparison models are designed to validate the results: experimental 3D Printed and numerical Finite Element Analysis (FEA) for the same. For the experimental test, two sets of each metal material are manufacture using FFF through the Markforged Metal X system. One set is fabricated with solid infill, while the other has triangular infill. Each set consists of four identical "dog bone" specimens. The dimensions and test conditions were set according to ASTM F3122 and ASTM-E8 standard. A uniaxial tension test will be conducted using Instron 3367 tensile testing machine. For the numerical FEA Analysis, the Digital Twin reconstruction method will be used where an explicitly generated CAD Model is made using an Additive Reconstruction Tool with the G-Code as input to simulate the solid layer by layer and obtain a digital equivalent of the 3D Printed part in CAD Software. A Scanning Electron Microscope (SEM) will be used to investigate the parts' internal structure and average pore size. The porosity will be characterized through density comparison and analyzing pore distribution.

2:30 PM SF02.01.04
Analysis of Additively Manufactured Material Using Thermomechanical Simulation and X-Ray Diffraction Trupti S. Mali, Todd Letcher and Anamika Prasad; South Dakota State University, United States

Additive Manufacturing (AM) is an emerging and highly promising technology for manufacturing metal-based complex geometries for specialized applications such as aerospace, defense, medical implants, and in-space manufacturing, among others. However, the structural and property impact of additive manufacturing processes on manufactured parts remains to be fully explored. For example, the repeated thermal cycles during layer-by-layer deposition can create uneven material properties and residual stresses. These localized residual stresses may result in material failure during use. Also, minor changes in input parameters such as powder size, laser power, and laser scan speed can significantly impact the final quality of the deposit. A critical study of the relationship of input parameters with residual stresses and part performance is necessary for designing post-processing heat treatment and broader acceptance of AM process.
The finite element analysis (FEA) is an effective tool to analyze the impact of AM input parameters on the final performance of manufactured parts, resulting in a significant saving on cost and time compared to production and experimental analysis. Hence, to generate design guidelines for AM processes, we analyze residual stress patterns on the directed energy deposited (DED) thin-wall structure in as-built and post-treated conditions. The computational results are compared and contrasted against the X-ray diffraction (XRD) study of AM. The simulation is performed in ABAQUS (Dassault Systemes, USA) using an integrated thermomechanical analysis step with temperature-dependent material properties. The materials properties for the simulation were used from tensile and fatigue tests data available in literature for AM copper alloy (GRCop-42), a material developed for NASA rocket propulsion application. A plot of the effect of input parameters such as laser power and scan speed on the residual stress changes is presented, along with simulation validation through comparison with the experimental residual stresses XRD data. The simulation stress distribution implicates the agreement with experimental analysis. Also, it exemplifies the use of the thermomechanical model to guide parameter space for the AM.

Optimization of Additive Manufactured Housings for IoT Devices in an Alpine Environment Thomas Schmiedinger, Markus Ehrlenbach and Christian Schmid; University of Applied Sciences Kufstein, Austria

Common housings for Internet of Things (IoT) sensors consist of a polymer like acrylonitrile butadiene styrene (ABS). The primary function of these objects is to protect the electronics from environmental influences e.g., water. Due to the exposed location of IoT sensors, especially in alpine regions, the housings are important for a proper and long-term function of the sensor. Beside protection, additional features like insulation properties are important too, for ensuring sensor functionality. The insulation aspect of common IoT housings has been realized by adding insulation material in addition to the housings. Additive manufacturing may enable a combined design approach in fulfilling mechanical and thermodynamical requirements at the same time. The aim of the paper is to describe and investigate different designs for additive manufacturing which combine insulation properties without affecting structural stability of housings for IoT devices in alpine regions.
Finite element analysis simulation models for IoT housings are used to determine the thermodynamical and structural properties of different materials and designs. Selected designs are fabricated and tested in a climate chamber regarding insulation and mechanical properties.
The approach of design for additive manufacturing enables an integration of different functionality (e.g., thermal and mechanical function) into the designed part. The insulation property of additive manufactured housings for IoT devices exhibit a significantly higher insulation ability in comparison to common housings of IoT devices. This approach enables highly innovative housings which can withstand the harsh environment in alpine region.

Additive Manufacturing of Thermosetting Resins via Direct Ink Writing and Radio Frequency Heating and Curing Anubhav Sarmah, Ava Crowley, Suchi K. Desai, Gabriel Zolton and Micah J. Green; Texas A&M University, United States

Direct Ink Writing (DIW) is an extrusion-based additive manufacturing method where the print medium is a liquid-phase ‘ink’ dispensed out of small nozzles and deposited along digitally defined paths. Conventional DIW methods for thermosetting resins rely on the use of viscosifiers, novel crosslinking chemistries, and/or long curing schedules in an oven. Here, we demonstrate the use of a co-planar radio frequency applicator to generate an electric field which can be used to rapidly heat and cure DIW-printed, nano-filled composite resins. This method avoids the need of an oven or post-curing step. The proposed process consists of a layer-by-layer, print-and-cure cycle which allows for printing of high-resolution, multi-layer structures. Every extruded layer is partially cured using RF before depositing the next layer; this allows the printed part to maintain structural integrity without buckling under its own weight. The process enables both increased throughput and decreased touch time relative to traditional part manufacturing. Commercial epoxy resin with varied nano-filler loadings were examined as DIW candidates. Rheological characterization was used to assess both curing kinetics and printing behavior. After printing, the thermo-mechanical properties, surface finish, and shape retention of RF-cured samples were evaluated and found to be comparable against samples conventionally cured in an oven. This method of manufacturing establishes RF heating as a suitable alternative to conventional methods, facilitating rapid, free-form processing of thermosetting resins without a mold.

Abstract

This study focuses on the fabrication of a porous superhydrophobic membrane for oil/water separation. The membrane, made from nanosilica-containing poly(vinylidene fluoride-co-hexafluoropropylene) (PVDF-HFP), was prepared by direct ink writing. The as-prepared membrane displayed anti-wetting property and superoleophilicity, allowing oil to pass, but not water, through its openings. Such surface characteristics are mainly attributed to the synergistic effect of hierarchical surface roughness created by the silica nanoparticles and low surface energy inherent to PVDF-HFP. Combined with mechanical robustness and high thermal stability, the nanosilica-filled fluoropolymer membrane is practically useful in solving industrial problems concerning water contamination and oil spill response.

Keywords: superhydrophobicity; superoleophilicity; fluoropolymer; silica; oil/water separation

4:45 PM SF02.15.05
***Operando* X-Ray Characterization of Temperature Profiles and Phase Evolution Along Building Direction During Laser 3D Printing of Ti Alloys** Ming Chen[1], Marco Simonelli[2], Steven Van Petegem[1], Yau Yau Tse[3], Dario Ferreira Sanchez[1] and Helena Van Swygenhoven-Moens[1]; [1]Paul Scherrer Institute, Switzerland; [2]The University of Nottingham, United Kingdom; [3]Loughborough University, United Kingdom

The high temperatures and rapid cooling rates during laser powder bed fusion make it difficult to characterize the thermal cycles the material undergoes during printing. Such information is however crucial for understanding the evolving microstructures, especially, when the material undergoes phase transformations during thermal cycling. We recently demonstrated an *operando* X-ray diffraction technique to measure temperature and phase evolutions in a newly deposited layer during laser powder bed fusion (L-PBF) of Ti-6Al-4V (*Hocine et al., Materials Today, 34, 2020*). Here, the o*perando* X-ray diffraction experiments are carried out on thin walls of Ti-6Al-4V-3Fe and Ti-6Al-4V. Temperature profiles and cooling rates are derived from X-ray diffraction patterns measured in transmission mode for multiple layers below the surface while the laser rescans the surface. Microstructures are further characterized by transmission electron microscopy (TEM) and energy dispersive X-ray (EDX) spectroscopy. The powders used were prepared by

decorating a pre-alloyed Ti-6Al-4V powder with pure Fe particles using a simple mixing method (*Simonelli et al., Materials Characterization, 143, 2018*). It is known that minor addition of Fe can stabilize the β-Ti phase at ambient temperature. The present study shows that Fe is heterogeneously distributed after printing and that the β-Ti phase is stabilized where the Fe concentration is highest. During remelting the surface layer, temperatures above the β transus (1252 K) are reached in at least 3 layers below that newly printed layer. Furthermore, during remelting of the upper layer, the Fe distribution is homogenized. The evolution of the β phase during thermal cycling is discussed in terms of the temperature profiles and cooling rates in multiple layers along the building direction.

Shape-Reconfigurable and Recyclable 4D Plastics for Wearable and Adaptive Device Platforms Kiesar Sideeq Bhat, Wen See Tan, Amelia Lee, Rui Yuan Han, Mike Regan and Juha Song; Nanyang Technological University, Singapore

The increased demand for wearable devices such as smartwatches, shoes, and even masks, amid the pandemic, has led to an increased demand for customized and adaptive materials, specifically for use on the human body. One such material is smart materials with an intrinsic shape memory effect to morph into another shape when an external stimulus is applied. The fabrication of such materials through additive manufacturing is known as 4D printing. However, such 4D printing is limited to materials with intrinsic shape memory effects, which are usually expensive and limited. Thus, herein, we proposed a new smart material platform where a conventional non-smart thermoplastic material with pre-programmed structure induces reversible 4D effect through local heat generation associated with selective Joule heating mechanisms. Through multi-material printing capability of a Multi-Jet Fusion printer, we successfully fabricated polyamide-12 (PA-12) with embedded heat channels. Through a designed 3D structure and silver-polymer composition variation, resistance gradient was induced at selective local regions where Joule heating considerably occurred. 3D finite element analysis (FEA) modeling was conducted in parallel to experiments, and the simulation results showed good agreement with the experimental observation, validating the underlying mechanism of this 4D system. Through parametric studies with various structural and material parameters, those 4D systems can be tuned depending on operation conditions. We also demonstrated the applicability of this system through a proof-of-concept product, adaptive mask frames that could be conformed depending on the contour of a human face. This 4D system was also durable and reversible, showing consistent performance over multiple loading cycles. In conclusion, this study demonstrated that common thermoplastics with embedded heat channels can be used as a new type of smart material systems, creating a new material category, “4D plastics”. We envisage that this system can be applied to build wearable wearable devices, customized clothing and shoes, military weapons, and medical instruments where adaptability, conformity and rigidity are required.

5:15 PM SF02.15.07
Effect of Laser Remelting Processing on Microstructure and Mechanical Properties of 17–4 PH Stainless Steel During Laser Direct Metal Deposition Zhiyuan Yu; Shanghai Jiao Tong University, China

Laser direct metal deposition (DMD) is an efficient and flexibility additive manufacturing technique which has broad application prospects, but limited due to varieties of defects and anisotropy. Laser remelting (LR) is a process that the same slice data is scanned secondly without powder deliver after each layer is deposited, and it is often used during selective laser melting. Herein, LR process has been applied during the DMD process of a 17-4 PH steel to enhance the densification level and relieve the mechanical anisotropy. It is found that thermal history, porosity and microstructural evolution are shown to be dependent on the LR energy density. Moreover, the roughness of top surface of the deposited layer and intralayer porosity decrease with increase of laser remelting energy density. While for interlayer defects, there is an optimal LR energy density corresponding to the lowest interlayer porosity. Furthermore, LR process can enhance the holding time at high temperature, even sometimes heat the sample above Ac_1, resulting in change in contents of austenite and carbide. In addition, LR process greatly dilutes the pre-solidified texture. It was also proved that the flat defects in-plane to the interlayer and the anisotropy of the crystallographic orientations are extremely harmful for the mechanical isotropy of the DMDed samples. Finally, sample manufactured with laser remelting at 15.0 J/mm^2 has the lowest porosity and random crystallographic orientations resulting in near isotropous tensile strength, but the contribution of laser remelting to eliminate anisotropy in elongation is limited because of the interlayer defects.

5:30 PM SF02.15.08
Development of a Nanocomposite Conductive Photocurable Resin for the Production of MEMS Through Stereolithography Raffaella Suriano, Filippo Iervolino and Marinella Levi; Politecnico di MIlano, Italy

In recent years, additive manufacturing has become an attractive technology that offers many advantages over the other widespread subtractive methods. The most evident advantage is the possibility to make any object, virtually without any geometrical limitations.[1] Among the additive manufacturing processes, stereolithography enables the manufacturing of small items with miniaturized features and extraordinary precision. For these reasons, the production of MEMS (microelectromechanical system)-based sensors by stereolithography could be a valid alternative to the existing silicon-based technologies, even though it is diametrically opposite to current technologies, which allow the production of huge amounts of identical objects, i.e. mass production. Oppositely, stereolithography enables mass customization thanks to the production of objects which can be different from each other and completely customizable.[2]
In this work, a commercial resin was used and fully characterized, because its formulation, as well as its physical and mechanical properties, were unknown. The high precision of stereolithography, together with the thermal stability of the resin, were exploited to produce customized MEMS-like sensors. However, stereolithography is suitable only for photo-curable materials called photopolymers. They are usually insulating materials, which should be coated with metallic layers either by inkjet printing or by electroless deposition and subsequent wet metallization, to add electrically conductive patterns to the 3D printed objects.[3] In this work, carbon nanotubes (CNTs) were added to the photocurable resin to obtain a photocurable conductive nanocomposite aiming to create electrically active parts in MEMS-like sensors. Furthermore, different types of CNTs were investigated: (i) pristine CNTs; (ii) amino-functionalized CNTs; and (iii) silver-decorated ones. The addition of CNTs to obtain an electrically conductive photocurable material has been revealed to be effective. The enrichment of the matrix with a CNT content greater than 0.1 wt% led to improve the conductivity of the material by 5-to-6 orders of magnitude. Using a 0.5 wt% CNT concentration, the material showed a conductivity equal to 3.9 10^{-4} S/cm. This result could be increased by 2.4 times using CNTs functionalized with NH_2 due to their more homogenous dispersion in the matrix and by 10.8 times by using CNTs decorated with silver nanoparticles. Even higher values could be obtained by better controlling the synthesis of Ag-MWCNTs to deposit much smaller nanoparticles. However, a custom-made formulation for the resin can be developed in the future to tune some properties such as stiffness and viscosity.

A Fabrication Method of 3D Printing Alumina Ceramic with Complex Structure Yiran Ma and Yuxiang Zhang; Northwestern Polytechnical University, China

Ceramics are characterized with high hardness, brittleness and heat resistance, the applications of which are restricted by traditional fabrication processes. Additive Manufacture (AM) can be innovatively applied to direct manufacture of ceramic structures, hence the relatively labour-saving fabrication of 3D ceramic parts in contrast with the conventional methods. DLP (Digital Lighting Process), as one of the AM techniques, is capable to fabricate alumina ceramics with complex structures through mask-image-projection, which ensures the precision and improves the efficiency of manufacture.
In this research, alumina ceramic with complex structures was obtained by DLP with a high resolution and applicable mechanical properties. A long-time stable ceramic suspension with high ceramic powder content was firstly obtained, which achieved the mass fraction of 70%. Then optimized parameters of the UV-curing process ensured the resolution of the complex structure. The two-step sintering method was adopted to optimize the sintering process in order to reduce defects and improve density. The complex ceramic structure with high resolution showed an average flexural strength of 220MPa and a relative high density, with potential applications of aerospace, tissue engineering, machinery manufacture and so on.

Yuxiang Zhang and Yiran Ma contributed equally to this work.

SESSION SF02.16: Additive Manufacturing Techniques, Characterizations, and Applications VII

8:00 AM SF02.16.01
Preventing Premature Failure and Circumventing the Strength-Ductility Trade-Off of Additively Manufactured Materials Jurgen H. Eckert[1,2], Zhi Wang[3] and Konda Gokuldoss Prashanth[4,1]; [1]Austrian Acad of Sciences, Austria; [2]Montanuniversitaet Leoben, Austria; [3]South China University of Technology, China; [4]Tallinn University of Technology, Estonia

Additively manufactured metallic materials exhibit excellent mechanical strength. However, they often fail prematurely owing to external defects that act as sites for crack initiation. Cracks then propagate through grain boundaries and/or cellular boundaries that may contain brittle second phases. In this work, the premature failure mechanisms in selective laser melted (SLM) materials are studied. A submicron structure is introduced containing semicoherent precipitates distributed in a discontinuous but periodic fashion along the cellular boundaries. Alternatively, martensitic phases are used to create alloys with modulation of phases and different strengthening mechanisms. The observed hierarchical microstructure combining different phases spanning over different length scales, consisting of remelted zones and track core regions at the macro-scale, regions with elongated columnar grains and equiaxed grains at the micro-scale, martensitic laths at the submicron-scale, and a high density of dislocations and stacking faults at the nano- and atomic scale leads to outstanding tensile properties of as-prepared and annealed samples. The mechanisms determining the strength and ductility are discussed in terms of the hierarchical microstructure and internal defects. The cellular structure with a high density of dislocations along their boundaries and the martensitic structure are the reasons for strengthening, while the hierarchical microstructure helps to obtain appropriate ductility. Furthermore, martensitic transformation induced plastic bending of residual FCC plates helps to balance the different plastic strains within the heterogeneous structure. This work provides a material design approach for creating hierarchically structured additively manufactured materials with improved strength-ductility tradeoff provided that premature failure is alleviated.

8:15 AM SF02.16.02
Development and Characterization of a Personalized 3D-Printable Bioactive Splint Christian Schmid[1], Leif Steuernagel[2], Markus Ehrlenbach[1] and Thomas Schmiedinger[1]; [1]University of Applied Sciences Kufstein Tirol, Austria; [2]Clausthal University of Technology, Germany

A challenge of combined traumata is, that these situations may require contradictory interventions. Open fractures or fractures in combination with burns requires on one hand a stabilization of the fracture and on the other hand a treatment of the superficial injury. Common therapeutical approaches may lack the ability, to fulfill both requirements at the same time.
The aim of the paper is to develop and characterize a 3D-printable bioactive splint. This bioactive device ensures splintage in combination with the healing stimulation of superficial injuries (e.g. skin abrasion, burn). By creating a digital model of the affected body part, an individualized splint can be realized. Stimulants for healing support are transported through a permeable membrane. This membrane enables an exchange of stimulants to the affected region. The University of Applied Sciences Kufstein develop the design of the splints. A digital model of the affected body part is generated by 3D-scanning. The resulting point cloud of the surface is used for designing the splint. Reservoirs for healing stimulants are added at the individual positions. Standardized connectors are used for enabling the application of standardized medical devices. Polymeric filament blends are fabricated by Technical University of Clausthal. The filaments are processed on a material extrusion machine.
The fabricated bioactive splint enables a personalized design. This approach can support the therapy of combined traumata by resolving contradictory requirements, thus, the approach may have a positive effect on the healing duration.

8:30 AM SF02.16.03
Tailoring Thermal Post-Treatments for Additively Manufactured Nickel Superalloy Alloy 718 Sneha Goel[1,2], Uta Klement[3] and Shrikant Joshi[2]; [1]Paul Scherrer Institute, Switzerland; [2]University West, Sweden; [3]Chalmers University of Technology, Sweden

Electron beam melting (EBM) is a powder bed fusion (PBF) based additive manufacturing technology which has been gaining increased popularity for manufacturing complex customized parts for various sectors such as aerospace, medical etc. An interesting candidate to process using EBM technique is Alloy 718, which is a nickel-based superalloy extensively used in aerospace sector. Irrespective of the choice of processing conditions, EBM processed Alloy 718 is almost always subjected to thermal post-treatments to resolve challenges associated with formation of detrimental defects and/or phases, microstructural inhomogeneity, as well as to achieve the required mechanical response for demanding applications. However, the post-treatment (hot isostatic pressing, HIP and heat treatment, HT) procedures employed are those typically used for castings. This is also reflected in the ASTM F3055 standard for PBF Alloy 718, which appears to adopt the long time-temperature schedules applied for castings. However, this procedure might not be most appropriate and perhaps excessive for EBM Alloy 718 builds.

Therefore, the objective of this study was to investigate the possibility of shortening the duration of post-treatment from the typically long protocols suggested in the above ASTM standard. Results from a detailed study of microstructure evolution during post-treatment revealed possibility of significantly reducing the time for post-treatment. A pathway for further shortening the post-treatment by combining different post-treatment steps into one uninterrupted HIP cycle was also explored. The above results were further substantiated by the mechanical response of EBM Alloy 718 builds subjected to varied post-treatment protocols. Furthermore, such a shortened protocol was found to be robust when applied to EBM builds with distinctly different starting microstructures.

8:45 AM SF02.16.05
Quantitative Percussion Diagnostics for Evaluating Porosity and Roughness of Cold Sprayed and Laser Deposited Materials Mahsa Amiri[1], Grant A. Crawford[2] and James C. Earthman[1]; [1]University of California, Irvine, United States; [2]South Dakota School of Mines and Technology, United States

Quantitative percussion diagnostics (QPD) is a has been used successfully in a number of applications for non-destructive evaluation of structural integrity. This technique involves a rod that is actuated to tap on a specimen with a given kinetic energy. The resulting mechanical response of the specimen as a function of time is measured using a piezoelectric force sensor and the mechanical energy returned to the rod is then analyzed. Because contact with the specimen is on the order of a few hundred microseconds, QPD can be used in situations and for specimen conditions (e.g. high temperature) that are not feasible for other nondestructive testing methods. The objective of the present study was to evaluate the use of QPD for characterization of defects in specimens fabricated using two additive manufacturing methods, i.e. cold spray deposition and laser powder directed energy deposition (LPDED). Cold spray specimens were produced using commercially pure nickel with varied process conditions including gas type (i.e. helium and nitrogen) and deposition rate. In addition, a Ti-6Al-4V specimen was manufactured using LPDED with varying porosity content. All specimens were characterized using both QPD and destructive methods (i.e. cross-sectional metallography) to compare results for observed defect characteristics. Cold spray specimens exhibited a lower energy return when they contained more porosity and/or surface roughness. Microscopic plastic deformation at highly porous surfaces was indicated during percussion testing that reached a saturation level after repeated percussion. Overall, the results showed that QPD can effectively evaluate cold spray and LPDED specimens for porosity and surface roughness.

9:00 AM SF02.16.07
Direct Observation of Crack Formation Mechanisms with *Operando* Laser Powder Bed Fusion X-Ray Imaging Steven Van Petegem[1], Hossein Ghasemi Tabasi[2], Charlotte de Formanoir[2], Jamasp Jhabvala[2], Samy Hocine[1], Eric Boillat[2], Navid Sohrabi[2], Federica Marone[1], Helena Van Swygenhoven[1] and Roland Logé[2]; [1]Paul Scherrer Institute, Switzerland; [2]EPFL, Switzerland

Laser powder bed fusion (L-PBF) is a versatile additive manufacturing process that can print geometrically complex metal parts for a variety of applications. However, poor control of defect formation during processing hampers its widespread industrial adoption. Many materials suffer from a high crack susceptibility during L-PBF, which results in degraded mechanical properties, and is an obstacle to the certification of critical parts.

The CM247LC nickel-based superalloy is a gamma-prime-strengthened Ni superalloy, which is of particular interest due to its excellent mechanical, creep, wear, and oxidation properties at both ambient and elevated temperatures. However, this alloy contains high amounts of Al and Ti and is considered vulnerable to cracking due to $L1_2$ Ni_3(Al, Ti) precipitation. In literature, several mechanisms are reported to be responsible for cracking during the manufacturing of CM247LC alloy.

In order to unveil those cracking mechanisms, we employ, for the first time, high-speed synchrotron X-ray imaging in combination with a miniaturized L-PBF set-up that reproduces real processing conditions (Hocine et al. Materials Today 34 (2020) 30-40). This unique setup provides *operando* imaging of crack formation during L-PBF. These measurements are complemented by post-mortem inspection of crack morphology and analysis of the chemistry around the cracks. Furthermore, finite elements simulations were performed to obtain the evolution of the local temperature during printing. The simulations are validated by *operando* X-ray diffraction-based measurements (Hocine et al. Additive Manufacturing 24 (2020) 101194) . The results provide, for the first time, direct evidence of the occurrence of solidification and liquation cracking in CM247LC.

9:15 AM SF02.16.08
Changes on Textural Properties of Additively Manufactured IN718 During High Temperature Homogenization Process Selda Nayir[1], Bertrand Max[2], Simon Perusin[2] and Todd A. Palmer[1]; [1]The Pennsylvania State University, United States; [2]IRT Saint Exupéry, Institut de Recherche Technologique, France

Heat flow direction during Additive manufacturing plays an important role while shaping the textural properties of the build samples. The grain structure of nickel-base alloys fabricated using powder bed fusion additive manufacturing processes display a preferred orientation along heat flow direction that usually overlaps with building direction. These highly oriented grains with strong orientational dependencies can cause anisotropy in the properties of the final components. Age-hardenable nickel base alloys, such as IN718, undergo a series of high-temperature post-process heat treatments in order to obtain their strength. However, the effectiveness of these high-temperature heat treatments in altering the grain structures and removing the preferential grain orientations is not well established. Through a series of high-temperature heat treatments at temperatures between 1050C and 1200C, the evolution of the as-deposited grain structure across different orientations with respect to the build direction was evaluated. Surface textures along the build direction rotated from a prominent [001] to [011] direction while the texture perpendicular to build direction remained unchanged along the [011] with increasing temperatures and times. At the same time, the grain sizes and morphologies changed along this same direction transitioned from elongated to equiaxed grains, matching those observed on the plane normal to this orientation.

9:30 AM SF02.01.11
3D Printed Surface Topography to Achieve On-Demand Wettability and Separation Bingchen Wang[1,2], Cliff Kowall[1] and Lei Li[1]; [1]University of Pittsburgh, United States; [2]University of Wisconsin–Madison, United States

The biomimetic superhydrophobic and superoleophobic surfaces require the microscale and nanoscale hierarchical surface textures, combined with coatings with low surface energy. While it has always been difficult and expensive to fabricate the superwetting surfaces with well-controlled textures via conventional manufacturing techniques, 3D-printing serves as a time-efficient and cost-efficient alternative. Here, a novel microscale re-entrant surface topography is successfully fabricated by two-photon polymerization (2PP) 3D-printing. On-demand wettability of various liquids has been achieved on the single re-entrant surface. For a given liquid, the re-entrant angle can be precisely manipulated to be either smaller than the liquid CA on the flat surface to achieve dewetting, or larger than the liquid CA on the flat surface to achieve wetting. The 3D-printable microscopic repeating re-entrant surface, which is difficult to make by conventional techniques, has been demonstrated to further enhance the desired on-demand surface wettability. Moreover, efficient on-demand separations of liquid mixtures with high flux are enabled by the 3D-printed separation membranes with the repeating re-entrant structures, which is critical for wastewater treatment in the chemical industry.

SESSION SF02.17: Additive Manufacturing Techniques, Characterizations, and Applications VIII

10:30 AM SF02.17.01
FFF 3D Printing of Filled Thermoplastics and Thermoreversible Thermosets Luis Arciniaga, Piaoran Ye, Krishna Muralidharan, Barrett G. Potter, David S. Margolis, John A. Szivek and Douglas A. Loy; The University of Arizona, United States

In order for 3d printing to realize its potential for distributed manufacturing, it must be possible to make parts with acceptable mech. properties, use local materials, and recycle or rework printed materials. Fused Filament Fabrication (FFF) printing of thermoplastics is generally limited by poor adhesion between layers in prints. Composite filaments for FFF are difficult to make and use due to the challenges in mixing highly viscous molten thermoplastics with filler and the inflexibility of the resulting filled filaments. Soln. processing of thermoplastics facilitates homogeneous incorporation of filler, but introduces addnl. process steps, creates a solvent waste stream and potentially degrades composite performance through plasticization by residual solvent. Thermoreversible thermosets provides a soln. to all of these problems. These highly cross-linked resins have thermal weak-links that break apart at higher temps. and can reform to re-establish crosslinks once the temp. is reduced. The most common weak-link is the Diels-Alder cycloadduct of maleimides and furans that form at room temp. and exhibit a reversion temp. of 100°C. In our study, we have prepd. and mech. tested composites based on PLA, ABS, TPU, and bismaleimide-tetrafurfuryl thermoreversible thermosets with silica, silicate minerals, and tricalcium phosphate.

10:45 AM SF02.17.02
Design of Soft Homocomposite Silicone Gels for 3D Printed Architectures with Magneto-Capillary Reconfiguration Lilian B. Okello[1], Sangchul Roh[2], Joseph B. Tracy[1] and Orlin D. Velev[1]; [1]North Carolina State University, United States; [2]Cornell University, United States

This talk will present the design of a new class of smart elastomeric architectures that undergo complex reconfiguration and shape change in applied magnetic fields. These magnetoactive soft actuators are fabricated by 3D printing with Homocomposite Thixotropic Pastes (HTPs) of capillary ink consisting of silicone microbeads, liquid silicone and water [1,2] Superparamagnetic and ferromagnetic nanoparticles are embedded inside the microbeads before curing to render the resulting ink magnetically active without compromising its mechanical properties. The mechanical stability of the printed and cured structures as well as their extensibility to attain maximum possible actuation distance is achieved by optimizing the HTPs material moduli. We will discuss how the magnetic particle loading into the microbeads, volume of liquid polymer precursor used for capillary bridging and controlled level of polymer crosslinking, can be adjusted to fabricate 3D printed structures which are very soft, yet strong enough to withstand many cycles when actuated by external magnetic fields. We will show that the printed meshes and strands are much softer and more flexible than those fabricated by merely reducing crosslink density of bulk PDMS. This ultrasoft material is biocompatible and has tunable mechanical characteristics, which make it suitable for biomedical and soft robotics applications. The HTP 3D printing method makes possible the fabrication of soft architectures with different actuation modes, such as isotropic/anisotropic contraction and multiple shape changes [3]. The cyclic actuation of these objects can be modulated to mimic the pumping mechanism like that seen in heart and lung muscles, while the moduli can be tuned by design to match that of live tissues. Specifically, magneto-capillary actuators can be reversibly laterally contracted and expanded by controlling the normal magnetic field applied from below the vessel. Similar architectures that reconfigure in magnetic fields in response to external stimuli could find a broad range of applications, such as making 2D auxetic materials, soft actuators and soft robots with non-contact actuation.

Hierarchically Structured Composite Fiber for Thermal Regulated Textiles and Beyond Weiheng Xu, Dharneedar Ravichandran, Sayli Jambhulkar, Yuxiang Zhu and Kenan Song; Arizona State University, United States

Multilayered polymer nanoparticle composite (PNC) has shown potential in enhancing thermal and electrical properties. Most widely used manufacturing techniques include layer-by-layer coating, filtration, and ice-templating. Here, we introduce a new scalable manufacturing technique including both forced assembly and dry-jet-wet fiber spinning processes. Multipliers were designed and fabricated with metal 3D printing. The resulting continuous fiber, approximately 100 µm in diameter, consists of 4 to 512 alternating layers of composite A and composite B. Depending on the fabrication process, each layer's thickness can be controlled from a few micrometers to hundreds of nanometers. To demonstrate the fiber's potential as a thermally regulated textile, boron nitride (BN) and polyvinyl alcohol (PVA) were chosen as materials A and B. The alternating structure enabled continuous pathways of confined BN for high thermal conduction within flexible PVA matrices. By changing A and B materials, alternating layers of porous structure also showed excellent mechanical stability and thermal insulting behavior. Through varying the material selection for A and B, including nanoparticle and polymer, this fabrication technique can be applied to numerous applications with multilayered structures.

11:15 AM SF02.17.04
Multichannel-Electrochromic Data Transmission Analyzed by Computer Vision for Smart Contact Lens on 3D Printed Template Moobum Kim, Jeonghun Yun, Jia Li, Yeongae Kim and Seok Woo Lee; Nanyang Technological University, Singapore

In the 4th industrial revolution, the market size of wearable devices is growing dramatically with the recent advances in the smart healthcare system. Users receive the notification from the device by sound or vibration when the real-time sensor detects a sudden change in vital signal or danger from the surrounding. In the wearable device market, wristwear and eye-headwear take more than 60% of the whole market of wearable devices. Among them, the market size of the smart contact lens can be extended with the advantage of important and diverse vital signs from eye and tear. Examples of those elements involve ions, such as sodium and potassium, organic molecules, such as glucose, and biomolecules. However, in the past research, wireless communication was used to transfer the data from the sensor in the smart contact lens. Also, it required a complex circuit containing an antenna and receiver inside and outside. In previous our group's research, the only single channel was suggested with a limited amount of data transmission for electrochromic data transmission.
Here, a multi-channel electrochromic data transmission system on the 3D printed template is suggested. 3D printer was used to manufacture the template

having eight channels in one procedure instead of a complicated and multi-step process. A 3D printed template provided more strength to sustain unintended bending or folding of contact lenses. The device was made with eight electrochromic channels and one reference electrode. The color of each electrode was changed between blue and transparent. Electrochromic channels were used to transfer the diverse and complex signals to the user. 256 (28) different signals can be expressed theoretically at least, and the number of signals has the potential to be increased by controlling the color change in three or four steps. Also, the Prussian Blue (PB)'s electrochromic performance was characterized, and various color-changing combinations were realized as an 8-bit barcode pattern by controlling each channel's voltage. For example, 10110001 was changed to 11110001 for transferring different signals to the user. Furthermore, the video of eight-channel color change was taken, and color change patterns were recognized by video processing using Python with OpenCV, one of the libraries in Python to solve the computer vision problems.

11:30 AM SF02.17.05
Polymer-Assisted 3D Printing of Magnetocaloric Cooling Devices Vaibhav Sharma, Lilly Balderson, Radhika Barua, Ravi L. Hadimani and Hong Zhao; Virginia Commonwealth University, United States

As the key component of a magnetic refrigerator, magnetocaloric regenerators (also known as heat exchangers) consist of magnetocaloric materials (MCM) with voids and channels to enable efficient heat transfer to a heat-exchanger fluid. To date, research efforts to produce magnetocaloric regenerators are mainly focused on packed particle beds and plane plates that can be stacked and separated by spacers to provide channels for the heat-exchanger fluid. Both structures possess inherent processing challenges that reduce their performance once integrated into a device. Powder bed fusion-based additive manufacturing methods, such as selective laser sintering, on the other hand, are expensive; and the melting and re-crystallizing of the magnetic particles changes the magnetic and crystalline phases and induces defects in the printed structures.

To address these unique challenges, in this work, we have fabricated magnetocaloric cooling devices using a polymer-assisted 3D printing process followed by a two-stage sintering post-treatment. The printing ink consists of magnetocaloric particles, a sacrificial polymer binder, and a tri-solvent system. Preliminary experiments were conducted using magnetocaloric nanoparticles of nominal composition, $La_{0.6}Ca_{0.4}MnO_3$. The solvents modulate the rheology of the printing ink to facilitate the 3D printing process. The polymer binder (polyethylene glycol or PEO) holds the 3D printed magnetic materials in place after solvent removal. A low-temperature sintering process removes the polymer binder, and a high-temperature sintering process fuses/bonds the magnetic particles inside the printed 3D architectures. Thermogravimetric analysis (TGA) is used to determine the processing condition of the sintering. Results indicate that the magnetocaloric response, i.e., the magnetic entropy change upon application or removal of a magnetic field, exhibits a small difference between the unprocessed MCM powders and the 3D printed devices, which demonstrates the effectiveness of this fabrication process. Compared to other metal additive manufacturing methods, this approach eliminates the complexity of powder handling, expensive laser or e-beam systems, and extremely delicate green parts for powder removal (e.g., binder jet 3D printing). With the inherent advantage of creating spatially designed channels and structures, this polymer-assisted 3D printing scheme provides a promising additive manufacturing platform for high-performance magnetocaloric cooling devices.

11:45 AM SF02.17.06
Late News: In Operando X-Ray Diffraction Studies of Metal Additive Manufacturing Adrita Dass and Atieh Moridi; Cornell University, United States

Understanding the dynamic solidification behavior during metal additive manufacturing (AM) is essential as it directly influences final microstructures, defects and therefore mechanical properties of the part. Many efforts in this domain are based on numerical and computational approaches. Some studies focus on experimental determination of these parameters using in operando monitoring including pyrometry or IR imaging, which fail to provide sub-surface information.
Novel in-operando synchrotron x-ray experiments at different spatial and temporal resolutions provide an unprecedented opportunity to develop a new understanding of the underlying physics of the AM process and solidification in cooling rates applicable to beam-based AM. Here we demonstrate a novel approach using in operando synchrotron x-ray diffraction to analyze the solidification process by tracking the evolution of the mushy zone during a single line scan of Inconel 625. Using this approach, we calculate the melt pool and mushy zone dimensions, along with real-time cooling rates, all by virtue of tracking real-time changes in lattice parameters. Finally, our work aims to establish a link between the transient ‘mushy zone’ formed during solidification for prediction of defects inside the final microstructure of the AM parts. Results are corroborated with microscopy analysis of the printed structures and show good agreement. Future experiments to study material behavior during extreme heating and cooling rates of AM process will be discussed as a tool to develop new materials for AM.

12:00 PM SF02.17.07
Late News: 3D- Printing of Li-Ion Conductive Oxide Solid Electrolytes Erika Ramos; Lawrence Livermore National Laboratory, United States

Significant advances in battery technology requires electrochemistry that goes beyond conventional Li-ion batteries to further boost energy density and increase safety. All-solid-state lithium battery (ASSLB) technology, with the integration of solid-state electrolytes (SSEs), has the potential to provide higher energy density, better safety, and longer cycle life. Significant progress has been made for ASSLBs by the development and optimization of SSEs that can provide efficient Li-ion conduction while mitigating the problems of leakage and high flammability associated with the organic liquid electrolytes currently used in commercial Li-ion batteries. Among the different chemistries employed as inorganic SSEs, e.g., sulfides and halides, oxides are considered promising SSE candidates for ASSLBs due to their chemical stability and ionic transport properties. Among the reported inorganic solid Li-ion conductive oxides, the garnet-like $Li_{6.4}La_3Z_{1.4}Ta_{0.6}O_{12}$ (LLZTO) cubic structure has received increasing attention due to its chemical stability against lithium metal, high lithium ion conductivity (10^{-3} S/cm at 25°C) and wide electrochemical window.

ASSLBs are difficult to process by traditional manufacturing strategies due to the brittleness of SSE ceramic materials, poor solid-solid contact (SSE/electrodes), and electrolyte-electrode stability issues; as a result, battery performance is far from ideal. The advancement in novel manufacturing techniques such as 3D printing has enabled the assembly of electrodes and SSE materials in more complex geometry configurations, with intimate solid-solid contact and lower interfacial resistance. Particularly, direct ink writing (DIW), is the most widely used additive manufacturing method due to its low cost, easy operation, and broad applicability. Here, we developed different ink formulations with desired rheological properties that enable DIW 3D printing of the LLZTO solid electrolyte with varying features. Different additives such as Al_2O_3, SiO_2, and Li_3BO_3 and post-sintering approaches were investigated to boost the LLZTO’s density and improve battery performance. These inks were used to 3D-print different patterns, which after sintering revealed thin, nonplanar, intricate architectures composed of LLZTO SSE. Using the herein developed 3D-printing ink formulations to further study and optimize electrolyte structure and properties could lead to the advance of batteries with low cell resistance and higher energy and power density.

12:15 PM SF02.17.08
Automated Support Removal and Surface Finishing for Additively Manufactured Ti-6Al-4V Subbarao Raikar, Steven DiGregorio, Robert Hoffman and Owen Hildreth; Colorado School of Mines, United States

The advent of 3D printing has widened the design space and complexity of parts/assemblies manufactured using Ti-6Al-4V (Ti64) alloy. The complex designs manufactured using additive manufacturing (AM) inevitably have sacrificial support structures that are challenging or inaccessible to remove using traditional methods, i.e., milling, electrical discharge machining, or using a rotary tool. The removal of supports accounts for almost 50 percent of the post-processing cost. With a high demand for one-of-a-kind parts in the medical and aerospace industries, there is a need to develop faster, cheaper, and scalable ways to remove supports. This work introduces a novel, self-terminating etching process for support removal for AM Ti64 parts. During heat treatment, a corrosion agent is diffused into the part to a depth equal to at least half of the support thickness. The corrosion products formed during the heat treatment are then dissolved chemically. The etching solution dissolves only the corrosion products and not the base metal. The effect of the process on the surface finish and the mechanical properties is studied in this work, along with the process kinetics. This work also describes a COMSOL Multiphysics simulation developed to study the impact of part geometry and position on the support removal process. In summary, a novel approach to remove supports from additively manufactured Ti64 parts is demonstrated to decrease costs and further expand the design space for additively manufactured Ti64 parts.

12:20 PM SF02.17.10
3D Printed Schwarzites for Nanoplastics Water Remediation Raphael M. Tromer[1], Bramha Gupta[2], Rushikesh Ambekar[2], Partha Ghosal[2], Rupal Sinha[2], Abhradeep Majumder[2], Partha Kumbhakar[2], Pulickel Ajayan[3], Douglas S. Galvao[1], Ashok Gupta[2] and C S. Tiwary[2]; [1]Universidade Estadual de Campinas, Brazil; [2]Indian Institute of Technology Kharagpur, India; [3]Rice University, United States

Nanoplastics contamination has increasingly become one important environmental problem because of their presence in rivers and oceans, toxicity and difficulty in separation and removal. Here we report the development of a 3D printed water filter system [1], which is topologically based on schwarzites, which can perform as an efficient nanoplastic scavenger. Schwarzites are mathematical, 3D porous solids with periodic minimal surfaces having negative Gaussian curvatures. The atomic-scale models obtained from molecular dynamics simulations are converted into .stl format. This approach has been proved effective to other classes of 3D printed materials [2-4]. The FlashForge Adventure 3 Printer (Fused Deposition Modeling) was used to fabricate the water filters. The ABS (acrylonitrile butadiene styrene) filament used to print the filter was melted in the extruder at 210 °C and extruded through a nozzle onto the heated bed. The proposed filtration mechanism of surface-charge-based water cleaning was further validated using ab initio and molecular dynamics simulations. The fabricated filters proved to be effective in removing nanoplastics from samples from various sources, such as sea, river, and pond. These new classes of 3D printed water filters represent a significant low-cost, energy-efficient, and feasible advanced system to address the problem of nanoplastics water remediation.

12:25 PM SF02.06.01
Textile Force Sensitive Resistors by Inkjet Printing for Wearable Tactile Sensors Beomjun Ju, Inhwan Kim, Braden Li, Caitlin Knowles, Amanda Mills, Landon Grace and Jesse Jur; North Carolina State University, United States

Pressure sensors for wearable healthcare devices, particularly force sensitive resistors (FSRs) are widely used to monitor physiological signals and human motions. However, current FSRs are not suitable for integration into wearable platforms and are expensive to process. This work presents a novel technique for developing textile force sensitive resistors (TFSRs) using a combination of inkjet printing of metal-organic decomposition silver inks and heat pressing for facile integration into textiles. The TSFR structure consists of a thermoplastic polyurethane (TPU) membrane sandwiched between two nonwoven textiles with inkjet printed electrodes. The insulating void between the top and bottom electrodes creates an architectured piezoresistive structure. The structure functions as a simple logic switch where under a threshold pressure the electrodes make contact to create conductive paths (on-state) and without pressure returns to the prior insulated condition (off-state). The TFSR can be controlled by arranging the number of layers and hole diameters of the TPU spacer to specify a wide range of activation pressures from 4.9 kPa to 7.1 MPa. For a use-case scenario in wearable healthcare technologies, the TFSR connected with a readout circuit and a mobile app shows highly stable signal acquisition from finger movement. According to the on/off state of the TFSR with LED bulbs by different weights, it can be utilized as a textile switch showing tactile feedback. When integrated with a physical device or object, the sensor design has a high potential for registering tactile interaction as a means to quantify health-related behaviors such as medication adherence or use of a self-monitoring device.

SESSION SF02.18: Additive Manufacturing Techniques, Characterizations, and Applications IX

Tuesday Afternoon, December 7, 2021
SF02-Virtual

1:00 PM *SF02.18.01
Robotic Metamaterials: Additive Fabrication for Multi-Materials and Multi-Functionalities Xiaoyu Zheng; University of California, Los Angeles, United States

Material properties are governed by their chemical composition and intrinsic crystalline structures. This fundamentally limits material properties and their applicability creating trade-offs for selecting materials for product applications, from structural components to antennas and robots.

Metamaterials represent the concept of utilizing artificial material building blocks to create desirable properties and behaviors derived from three-dimensional architectures and compositions. Additive manufacturing is widely used to construct complex 3D objects and architectures made of metal, plastic, or ceramics from a digital computer model. However, it is presently difficult to combine different materials (structural, dielectric, conducting and ferroelectrics) to create a complex device with multiple functionalities.
In this talk, I will outline a suite of new material processing and additive fabrication routes to rapidly assemble complex topology, multi-scale features and multi-material attributes. I will present high speed printing techniques that enable the rapid patterning of a variety of structural, electronic and ferroelectric materials into complex architectures, not limited by tool-path, embedding and wiring requirement. Attention is focused on how these additive manufacturing techniques, combined with computations and artificial intelligence, unlock new material discovery and design freedoms, which leads to new classes of structural and ferroelectric materials, where presently unachievable mechanical and energy conversion behaviors can be created. Next, I will present future device architectures derived from these artificial building blocks, from materials for energy absorption, wave guiding, to smart transducers and autonomous micro-robots.

1:30 PM SF02.18.02
Adaptive Auger Extrusion-Based 3D Printing of Ceramics with In-Line Viscosity Monitoring Chao Liu and Junjun Ding; New York College of Ceramics at Alfred University, United States

Ceramics are extensively used in applications due to their excellent mechanical and chemical performance, such as outstanding compressive mechanical strength, high thermal stability, and corrosion resistance. Extrusion-based 3D printing methods are promising for digitally manufacture ceramics due to ease of use, good adaptability to different materials, and high solid loading of slurries. The auger extrusion method, extruding the slurry by a screw, not only provides accurate control of the slurry flow including consistent flow rate and precise start and stop, but also possesses the ability of mixing multi feedstocks into a homogeneous slurry before being extruded. The viscosity of the slurry determines the printability of the slurry in the auger extrusion-based 3D printing process. However, little research has focused on the in-line measurement of the slurry viscosity and a feedback system to self-control the viscosity of the slurry. In this work, we fabricate alumina parts using an adaptive auger extrusion-based 3D printing system with an in-line viscosity monitoring and feedback system. A high viscous alumina feedstock and a low viscous ink are fed into the barrel and mixed by the auger screw. The viscosity of the mixed slurry is calculated with an in-line capillary rheometer using measured pressure drop after extrusion. Based on the measured in-line viscosity, the slurry is adaptively controlled by adjusting the feeding ratio of two ceramic feedstocks with different rheological properties. This work enables a speedy development of printable ceramic slurries and provides a quality control in the extrusion-based 3D printing of ceramics.

1:45 PM SF02.18.03
Flexible Core-Shell Fiber Supercapacitors Manufactured by Coaxial Extrusion Printing Yuqi Gao and Junjun Ding; New York State College of Ceramics, United States

Energy storage devices have a spreading application in various fields, such as soft robotics, human motion monitoring, and smart textiles. Fiber-shaped supercapacitors are especially attractive as an energy storage unit in these applications due to their excellent flexibility. However, fabricating robust fibers with large yields remains a challenge.
In this work, we prepare flexible core-shell fibers via coaxial extrusion printing. Specifically, an extrusion system with a custom-designed core-shell nozzle is used to extrude two separate slurries at the same time. Carboxymethylcellulose sodium salt (CMC) slurry with controlled rheological properties is extruded from the outer channel, while the graphene oxide (GO) slurry is extruded from the inner channel simultaneously. The freeze-drying processing protects GO sheets from agglomeration, providing more efficient chemical reduction. The reduced GO (rGO) sheets are separated and expanded to fill in the CMC sheath, which eliminates the shrinkage of the shell structure and delamination between the CMC sheath and rGO core after drying. CMC is designed as a sheath to package the inner conductive rGO core, as well as a separator to avoid short circuits between two electrodes. We study the influences of the freeze-drying process on the fiber microstructures, and explore the slurry design, fiber quality, reduction condition, and electrochemical performance. The core-sheath structure endows the fiber-shaped supercapacitors with robustness and flexibility. The fabrication method realizes more efficient conducting networks, allowing scalable manufacturing of the core-shell microfiber electrodes.

Late News: Exploiting Lack of Fusion Defects for Microstructural Engineering in Additive Manufacturing Jenniffer Bustillos and Atieh Moridi; Cornell University, United States

Rapid cooling rates and stochastic interactions between the heat source and feedstock in additive manufacturing (AM) result in strong anisotropy and process-induced defects deteriorating the tensile ductility and fatigue resistance of printed parts. We show that by deliberately introducing a high density of lack of fusion (LoF) defects, a processing regime that has been avoided so far, followed by hot isostatic pressing, we can print Ti-6Al-4V with reduced texture and exceptional properties surpassing that of wrought, cast, forged, annealed, and solution-treated and aged counterparts. Such improvement is achieved through the formation of low aspect ratio α-grains around LoF defects upon healing, surrounded by α-laths. This occurrence is attributed to surface energy reduction and recrystallization events taking place during healing of LoF defects. Using an adaptive domain misorientation approach of electron backscattered diffraction, we resolve the heterogenous distribution of strains in the duplex microstructure in the form of complex dislocation cells, and sub-grains. Our approach to design duplex microstructures is applicable to a wide range of AM processes and alloys and can be used in the design of damage tolerant microstructures.

2:15 PM SF02.18.06
Late News: Fabrication of Nanostructured, Phase Separated, Liquid Crystal-Silicone Polymer Networks Using Direct Ink Writing Jay M. Taylor, Paul V. Braun and Ralph Nuzzo; University of Illinois at Urbana-Champaign, United States

The ability to control the nanoscale internal structures of soft polymers networks during fabrication is challenging. When done, these materials have interesting mechanical, optical, and physical properties. Herein, using direct ink writing, phase separated liquid crystalline networks are 3D printed that exhibit oriented, phase-separated molecular structure. The liquid crystalline domains within the printed material are aligned in the print direction and feature a nanoscale lamellar structure that impacts the materials mechanical and optical properties. At temperatures above the phase transition of the liquid crystal, its nanostructure deteriorates resulting in material softening and loss of optical birefringence. Upon cooling, the nanostructure reforms and its properties return. As a result of the oriented structure, when the printed material is submerged in solvents that swell the liquid crystalline phase, the material expands preferentially in its printed direction. This expansion results in a reconfiguration of the materials structure that can be controlled by adjusting its print direction and orientation during fabrication. The results and strategies presented herein, will be of interest to those studying how additive manufacturing can be used to design polymers with aligned and oriented structures.

Late News: Direct Ink Writing of TiO2-based Foams in Microgravity Conditions for Lunar Habitation Applications Ellena D. Gemmen, Samuel

Cyphert, Guy J. Cordonier and Kostas Sierros; West Virginia University, United States

With the increasing interest in long-term human habitation of space on the lunar and Martian surfaces for both research and commercial interests, there is a growing need for cutting-edge, versatile materials that can be modified to be used for more than a single purpose. TiO_2 based foam and microemulsion inks have been shown to have many advantageous properties, including: photocatalyzation with the UV spectra, filtration, habitat repair/reinforcement, and solar cell creation.
In this report, the first successful 3D printed metal oxide nanoparticles aqueous-based foams performed in microgravity are recorded. While undergoing parabolic flight and simulating microgravity in an aircraft, a Direct Foam Writing (DFW) method was used to print TiO_2 foam in line patterns onto glass substrates. Initial characterization of the foam's properties is stated. The printed foam's cross-sectional area, contact angle of DI water, and surface roughness is affected by microgravity as compared to Earth gravity, displaying less deflation and lower amount of spread after being deposited on the substrate.
As a result of the experiment's success, the WVU Microgravity Research Team plans to test the viability of two additive manufacturing techniques; Cold Spray Additive Manufacturing (CSAM) and spray atomization of a TiO_2-based foaming microemulsion.

SESSION SF02.19: On-Demand
Sunday Morning, December 5, 2021

Grayscale Digital Light Processing 3D/4D Printing—A Novel Method to Create Functional Parts Liang Yue, Xiao Kuang, Xiaohao Sun, Stuart M. Montgomery and Hang (Jerry) Qi; Georgia Institute of Technology, United States

Digital light processing (DLP) based 3D printing is an additive manufacturing method that utilizes light patterns to photopolymerize a liquid resin. Typical DLP method uses a digital micromirror device (DMD) to control light pattern at the resolution around 20-50 microns and cure a thin resin in 1-5s. DLP thus has the advantage of high speed and high resolution. However, conventional DLP method is not suitable for multimaterial printing because it uses a single vat of resin. In recent years, our group has explored using light grayscale (or light intensity) to control local properties of printed parts to achieve multimaterial-like printed parts. The advantage of this grayscale DLP (g-DLP) method is that it still uses a single resin vat and thus retains the advantages of conventional DLP printing. In this talk, we will first present a few examples of how to use grayscale light together with novel resins to achieve multimaterial functional parts, including 4D printing of inflatable structures, 3D printing of cold-draw shape memory polymers, etc. Second, As the graded light intensity can create concentration gradients of the different chemical species during photocuring, the spatial resolution as well as the physical property resolution in g-DLP printing can be affected. We will briefly present a reaction-diffusion model coupled with radiative transfer to analyse the effects of component diffusion and its impact upon the resulting mechanical property resolution on a sub-pixel and macro scale. Third, the capability of spatially control mechanical properties offers a vast design space for 4D printing to create shape-changing devices. We present our recent efforts of using evolutionary algorithm and machine learning to rapidly explore the design space and to obtain optimized design. This new design paradigm seamless connects design concepts to the 3D printed shape changing devices. Finally, we will briefly discuss the future work in the g-DLP method.

SYMPOSIUM SF03

3D Printing of Functional Materials and Devices
November 30 - December 8, 2021

SESSION SF03.02: Soft Robotic Matter
Session Chairs: Arda Kotikian and Ryan Truby
Tuesday Afternoon, November 30, 2021
Sheraton, 3rd Floor, Fairfax

2:00 PM SF03.02.01
Stretchable HAXEL Arrays Made by Multi-Material Additive Manufacturing Giulio Grasso[1], Samuel Rosset[2] and Herbert Shea[1]; [1]EPFL, Switzerland; [2]The University of Auckland, New Zealand

Soft electrostatic actuators stand out from other classes of compliant transducers thanks to their combination of fast response, high strain, and high power density. Hydraulically-Amplified Taxels (HAXELs) consist of planar polymer pouches filled with dielectric oil, with electrodes patterned on the periphery of both surfaces, and a central stretchable region. Applying a voltage between the electrodes generates an electrostatic pressure that pulls the electrodes together in a zipping motion, thus displacing the fluid towards the center of the actuator, creating a raised bump.
We present the design, fabrication and characterization of stretchable, ink-jet printed, HAXEL arrays. Using additive manufacturing (AM) allows the fabrication of fully-integrated actuators whose design can be rapidly changed. Three inks were developed for a commercially available printer (Jetlab 4XL from MicroFab Inc.). A solution of polydimethylsiloxane (PDMS) and solvent is dispensed in order to deposit 30 µm thick stretchable dielectric layers. 5 µm thick electrodes are patterned by using a suspension of carbon black particles combined with silicone polyglucoside. Fluidic channels and cavities are obtained by printing sub-3 µm thick sacrificial layers from ethyl cellulose. Printing HAXELs requires patterning a stack of at least 6 layers. The sacrificial layer, which defines the fluidic circuit, extends to the edge of the printed structure, where PDMS tubes are temporarily connected. The sacrificial material is removed by injecting ethanol, which is then replaced by a dielectric oil (Envirotemp FR3) at the desired pressure. The HAXELs are finally sealed, and the filling tubes removed.
We printed and tested 2x2 arrays of 5 mm wide square HAXELs. Each actuator is obtained by printing a 100 µm thick stack of the functional materials on a 150 µm thick PDMS substrate. Actuators are less than 1 mm thick after filling with dielectric fluid. We observe 250 µm of free displacement and 30 mN blocked force at 4 kV voltage. These actuators will be integrated into stretchable haptic feedback systems. Inkjet printing enables easily tailoring the geometry of the device to adapt to different location on the body, and to different morphologies between users.

2:15 PM SF03.02.02
Fluidically Innervated Architected Materials for Soft Robot Proprioception Ryan L. Truby, Lillian Chin and Daniela Rus; Massachusetts Institute of Technology, United States

Designing soft sensorized robots with distributed sensing capabilities is essential for addressing long-standing challenges in soft robot control. However, progress in designing soft sensorized robots has been limited due to the inherent multi-material manufacturing challenges of fabricating such devices and the disadvantages posed by many sensing strategies with soft conductive materials. We present a strategy for creating soft sensorized robots through the fabrication of fluidically innervated, architected materials. These structures are 3D printed with distributed, embedded networks of open fluidic channels. The fluidic channels are connected to pressure transducers, which provide an analog voltage corresponding to changes of pressure within the deforming networks. Importantly, our manufacturing method involves one single material: structure, actuation, and sensing capabilities are seamlessly integrated through printed architecture. Here, we first demonstrate our methods for fluidic sensing on well-studied lattices printed from elastomeric and flexible polyurethanes. We then design and characterize fluidically innervated handed shearing auxetics (HSAs), which we use in examples of electrically-driven soft sensorized robots. Finally, we showcase the importance of robust, reliable sensory feedback in an HSA-based soft robotic system that learns its configuration via deep learning. Overall, our methods represent a simple, single-material strategy for sensorizing soft robotic materials that we anticipate will help expedite efforts in the design, fabrication, and control of autonomous soft machines.

2:30 PM SF03.02.04
Late News: On-Board Timing, Memory, and Sensing in Autonomous Cell-Sized Robots Enabled by a Simple Memristor-Based Circuit Friendly to Additive Manufacturing Jingfan Yang[1], Albert T. Liu[2,1,3], Thomas A. Berrueta[4], Ge Zhang[1], Allan M. Brooks[1], Volodymyr Koman[1], Sungyun Yang[1], Xun Gong[1], Todd Murphey[4] and Michael Strano[1]; [1]Massachusetts Institute of Technology, United States; [2]Stanford University, United States; [3]University of Michigan–Ann Arbor, United States; [4]Northwestern University, United States

Micrometer-scale robots capable of navigating enclosed spaces and remote locations are approaching reality, with a rich literature emerging on externally actuated and supervised agents. To accelerate the advancement of micron-sized robots with greater autonomy, alternatives to conventional top-down lithography, particularly those amenable to assembly by additive manufacturing, are desired for rapid prototyping and access to novel materials. Building upon experimental findings that memristive networks can be rapidly printed on substrates and lifted-off as single, intact microparticles, we herein introduce an alternative design paradigm based on arrays of two-terminal memristive elements that enables autonomous use of memory, sensing, and actuation in robots at the micron scale. The design's simple circuit topology permits the use of facile technologies – such as printing, stamping, and colloidal self-assembly – as well as diverse materials including polymers, bio- and nanomaterials. We validate several memristor-based designs representing key building blocks towards robot autonomy: tracking elapsed time, detecting and timestamping a rare event, continuously cataloguing time-indexed data, as well as accessing the collected information for a feedback-controlled response as in a robotic glucose-responsive insulin for diabetes treatment, as a test problem. Our computational results establish a novel actionable framework for microrobotic design whereby tasks that normally require complex microelectronic circuits can be achieved with self-assembled and printed memristor arrays within single microparticles.

2:45 PM SF03.02.05
Late News: Silicone-Based Support Material for Precision 3D Printing of Soft Silicone Senthilkumar Duraivel and Thomas E. Angelini; University of Florida, United States

Soft silicone structures are difficult to fabricate using the conventional FDM approach to 3D printing. Without adding rheological modifiers silicone inks, printed features will sag and spread upon deposition from the nozzle. Embedded printing into jammed support materials helps to overcome this challenge by trapping the silicone ink in space as it is printed, eliminating the need for ink additives. However, previously developed support materials for 3D silicone printing exhibit a large interfacial tension against silicone inks, creating instabilities that break up fine features and setting a minimum feature size. These instability-driven breakups can be prevented by developing a jammed support material that is chemically similar to silicone oil. Such a material would enable 3D printing of high-resolution structures having fine feature sizes. In the work presented here, we developed a silicone oil-based support material having tunable rheological properties that can be optimized for embedded 3D printing of soft silicone. We show that by practically eliminating interfacial tension between silicone ink and the silicone-based support material, features as small as 8 microns in diameter can be fabricated; these fine features are indefinitely stable over time. Using this new material we are able to fabricate robust, accurate, and complex structures like a model brain aneurysm for surgical simulation and a functional tri-leaflet heart valve model for potential biomedical applications.

3:00 PM *SF03.02.06
Scalable and Printable Granular Actuators Sophia Eristoff, Sang Yup Kim, Lina Sanchez-Botero, Trevor Buckner and Rebecca Kramer-Bottiglio; Yale University, United States

Soft robots have garnered interest due to their potential ability to change shape in response to changing tasks or environments, be robust to impacts and

falls, conform to the human body without restriction on the natural mechanics of motion, and grasp delicate and diverse objects. Fluidic actuators, which are controlled by the influx of circulating fluids, are the most common artificial muscle technology employed in the soft robotics literature. However, fluidic actuators typically require actuator-source tethering, limiting the mobility of the robot, especially for micro-scale systems. Alternatively, stimuli-responsive materials have been proposed to realize untethered, micro-scale actuation. Such stimuli-responsive materials include hydrogels and shape-memory polymers, among others. However, these material-based actuators are often slow or only expand or contract axially, preventing use in applications that require volumetric expansions.
To address such limitations of existing actuating materials, actuators based on the liquid-to-gas phase change of solvent inclusions encapsulated in a hyperelastic matrix have been realized. These phase-changing inclusion composites fill a gap in the field of material-based actuators by inducing rapid volumetric expansion similar to fluidic actuators, without being tethered to an external fluid source. However, phase-changing inclusion composites have never been demonstrated in micro-scale actuation spaces and generally are not amenable to printing, given the high content of low-viscosity liquid solvent in the mixtures.
In this talk, we will present granular actuators composed of volumetrically expanding grains as a new class of actuator to unlock scalable and printable actuation. A single grain consists of multiple solvent cores encapsulated in a hyperelastic silicone shell (Ecoflex 00-30). At elevated temperatures, the encapsulated solvent vaporizes and increases the internal pressure of the hyperelastic shell, inducing volumetric expansion of the grain. The grains are independently capable of rapid, high-force actuation, and are also easily arranged into granular assemblies to form larger-scale bulk actuators. Finally, the use of grains suspended in a carrier solvent or resin enables compatibility with granular self-assembly and 3D printing techniques, offering the potential to print volumetrically expanding actuators into freeform patterns across scales.

SF03.04.01
Ductile All-Ceramic Composites with High Thermal Shock Resistance Jason Hoffman-Bice, Grace Goddard and Randall M. Erb; Northeastern University, United States

Ductile all-ceramics composite materials are at the forefront of the next generation of materials. Typically, engineering ceramics are brittle across working temperatures and do not allow for any deformation, let alone extreme ductility. The ability to have an all-ceramic, with typical ceramic characteristics, that can have ductile behavior, under relatively low temperatures, and maintain structural integrity without catastrophic failure is a unique characteristic that is experimentally explored in this work. Further, thermally conductive filler particles in a ceramic matrix has the potential to provide unique thermal management opportunities for high-powered electronics or hypersonic aircraft. In order to fabricate these materials, a previously developed 3D printing technique is used to align the micro-particles to produce the green-body part, and then run through a sintering process to produce the all-ceramic composite. This work also explores the materials thermal shock resistance that is believed to be directly correlated to the alignment patterns of the microstructure, and the thermal conductivity of the platelets distributed throughout the dominant ceramic matrix. Therefore, the work presented here demonstrates the feasibility of a highly-ductile all-ceramic composite, at relatively low temperatures, that demonstrates good thermal shock resistance.

SF03.04.02
Coaxial Core-Shell Direct Ink Writing of Flexible Sensors Derrick Banerjee[1], John Burke[1], Han Mei[2], Chih-Hung Chang[2], Edward M. Sabolsky[1] and Kostas Sierros[1]; [1]West Virginia University, United States; [2]Oregon State University, United States

Direct ink writing of 3D structures has many advantages, specifically in this study is the ability to print multiple materials with tailored functionalities in a controllable and single-step process. It further allows for net shape printing in ambient conditions of a wide range of materials normally incompatible with each other or with other printing systems. In this work, custom-designed coaxial nozzles have been 3D printed using a stereolithography printer. These nozzles were then used to co-extrude conductive ink cores within shells of ambient or UV-cured elastomeric shells. Initially, conductive fibers were printed to study the interfaces, curing, and electro-mechanical properties of the dual ink system. Further, the core-shell fibers were printed into strain gages and incorporated within direct ink written 3D soft robotic pneumatic actuators. Infrared spectroscopy, nuclear magnetic resonance, and optical and electron microscopy were performed to further characterize the printed structures.

SF03.04.03
Development of Nanocoated Filaments for 3D Fused Deposition Modeling of Antibacterial and Antioxidant Materials Adnan Memic, Rayan Qurban, Tuerdimaimaiti Abudula, Mazin Zamzami, Ammar Melaibar, Numan Salah and Mohammed Shaaban Abdulwahab; King Abdulaziz University, Saudi Arabia

There is a technological need for materials with improved functionalities to propel new biomedical applications. Some of the outstanding challenges could be solved using three dimensional (3D) printing. However, there is a pressing need for new generation of biomaterials that have unique properties. Combining nanomaterials with natural and synthetic polymers could yield biomaterials with improved propertesi including the ability to better recapitulate complex architecture, better match native mechanical properties of tisses and even guide the formation of functional tissues. To accomplish some of these goals we have engieered dual nanocoated (Zinc and Silver) filaments using polybutylene succinate (PBS) and lignin as the base polymer blend. We show that this combination of polymers and coating provides strain specific antibacterial activity and antioxidant properties while improving the rheological and physical properties of the composites filaments. Taken together these nanocoated filaments could propel several biomedical applications including aiding design of bracing materials.

SF03.04.04
High Resolution 3D Printed Anion Exchange Membranes—Expanding the Design Space of Electrochemical Reactors Auston Clemens, Megan Ellis, James S. Oakdale, Nikola Dudukovic, Sarah Baker and Eric Duoss; Lawrence Livermore National Laboratory, United States

Electrochemical reactors and separation devices are predominantly planar in nature and limited to basic design space and inability to optimize complex

reactor designs. An explicit limiting component are ion exchange membranes (IEMs) that control transport of selective ions across a physical boundary. IEMs are typically manufactured by evaporation casting ionomers into thin flat sheets; however, three-dimensional ion exchange membranes have the potential for significant improvement in optimized mass transport properties, antifouling capabilities, as well as increasing active interfacial surface areas for membrane electrode assemblies. Here, we present a photocurable anion exchange membrane (AEM) formulation that can be 3D printed with ~100 um resolution using micro-stereolithography. We optimize the printable formulation by characterizing the ion exchange capacity, ion conductivity, water uptake and dimensional stability as a function of the composition. Printed 3D structures are investigated and operated in diffusion dialysis acid recovery flow cells for continuous recycling of metal contaminated acid. This technology has the potential to enable customizable manufacturing of membrane electrode assemblies for CO_2 electrolysis, unlocking control over structures across multiple length scales to optimize for desired reduction products. This work is performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344 within the LDRD program 19-SI-005. LLNL-ABS-823498.

SF03.04.05

Designing 3D Printed Micro-Actuators for Functionalized Fiber Optics Adia Radecka[1], Alyssa Bradshaw[1], Georgia Kaufman[2], Rebecca R. Tafoya[2], Michael Gallegos[2], Tim Dallas[3], Holly Golecki[1] and Bryan Kaehr[2,4]; [1]University of Illinois at Urbana-Champaign, United States; [2]Sandia National Laboratories, United States; [3]Texas Tech University, United States; [4]Center for Integrated Nanotechnologies, United States

The ability to capture, manipulate and release microscale objects using autonomous systems can enable widespread applications—from microsurgery and selective cell extraction to the assembly of complex microdevices. Microelectromechanical (MEMs) grippers fabricated using semiconductor techniques provide precise and reliable gripping mechanisms but are intrinsically planar and require direct electrical contacts for operation. With continuing development of smart and environmentally responsive materials compatible with 3D printing, cue-driven micro-grippers with high spatial and temporal precision can give rise to biocompatible devices. In this work, we investigate 3D printing of microgrippers based on traditional MEMs designs as well as non-planar, bioinspired architectures. Our aim is to develop robust micro-grippers integrated into imaging/optogenetic devices at the scale of single fiber optics and individual biological cells to enable micro-surgical applications. Using multiphoton lithography, we fabricate multimaterial actuators that incorporate inert skeletal components with hydrogel actuators. We evaluate the response time, accuracy and cyclability of grippers that use temperature and pH responsive hydrogels. Following this optimization, we designed microgrippers that incorporate a photothermal transducer within a thermally responsive gel actuator fabricated on the tip of a 200-micron diameter core fiber. By incorporating 3D printed micro-optics (lenses and reflectors), we show that gripper components can be actuated individually via site-specific photothermal transduction. This work provides a foundation to integrate stimuli responsive mechanical functions with micro-scale optical devices.

SF03.04.06

Hybrid Fabrication of Multimodal Intracranial Probes for Neural Recording and Local Drug Delivery Johannes Gurke[1], Alejandro Carnicer Lombarte[1], Tobias Nägele[1], Sam Hilton[1], Roberto Pezone[1,2], Emil J. W. List-Kratochvil[3] and George G. Malliaras[1]; [1]University of Cambridge, United Kingdom; [2]Delft University of Technology, Netherlands; [3]Humboldt-Universität zu Berlin, Germany

New fabrication approaches for mechanically flexible materials hold the key to advancing the applications of bioelectronics in fundamental neuroscience and the clinic. By combining the high precision of thin film microfabrication with the versatility of additive manufacturing, we demonstrate a straight-forward approach for the prototyping of intracranial probes capable of multichannel local field recordings and convection-enhanced drug delivery. The process makes use parylene-based arrays of neural recording electrodes and a commercial vat polymerizable elastomer, combining to produce a flexible implant. The mechanical and electrical properties of the implant are characterised, and its function is validated in an in vivo rodent model. We show that the implant can modulate neuronal activity in the hippocampus through local drug delivery, while simultaneously recording brain activity by its electrodes. Chronic implantation tests show good implant stability and minimal tissue response one week post-implantation. Our work shows the potential of hybrid neuronal probes combining different manufacturing technologies and paves the way for a new approaches to the development of multimodal probes.

SF03.04.07

High Conductivity Copper Ink-Based 3D Printed Flexible Sensors Saurabh V. Khuje and Shenqiang Ren; University at Buffalo, United States

Recent advancements in the field of flexible electronics, for instance, smart wearables, soft robotics and health monitoring devices has garnered immense attention in the domain of stretchable chemical and physical sensing methods. Amongst the plethora of sensors available, temperature and pressure sensors have been extensively investigated for fulfilling the demand of flexible, light-weight and disposable sensors demonstrating high sensitivities. The sensors of the former category can be utilized for structural-health monitoring, whereas sensors from the latter category can be utilized for pulse monitoring and provide vital information regarding the arterial physical situation of the body in a non-invasive way. A printed and built-in geometry with a capability of detecting stimuli such as temperature, pressure, etc. over a wide range are highly sought-after characteristics for any sensor. These smart components are manufactured using a combination of conductive copper inks and an extrusion-based direct-ink writing technique, onto flexible substrates. The sensors exhibit high sensitivities and show resistance to mechanical stimuli of bending. These demonstrations enunciate the capability of additive manufacturing techniques for flexible electronics.

SF03.04.08

Towards Multi-Material Small-Scale Additive Manufacturing—Fabrication of Semiconducting ZnO and Insulating MgO Microstructures and Their Integration with Metallic Cu by Electrohydrodynamic Redox 3D Printing Mirco Nydegger[1], Alain Reiser[2] and Ralph Spolenak[1]; [1]ETH Zürich, Switzerland; [2]Massachusetts Institute of Technology, United States

Combining the unprecedented design freedom in microscale additive manufacturing with the ability to control the chemical nature of each printed voxel could unlock unique possibilities for tailoring mechanical, chemical, electrical, optical and magnetic properties of inorganic microstructures.
A current challenge in the field of micro- and nanoscale additive manufacturing is to provide what microfabrication needs: the fast and reliable deposition of a wide range of device-grade materials, from insulators to semiconductors and metals [1]. In addition, on-the-fly switching between different materials classes remains a crucial, yet unsolved problem. Electrohydrodynamic redox 3D printing (EHD-RP) is a novel small-scale additive manufacturing technique, that offers a resolution of 250 nm with feature sizes down to 120 nm [2]. The ink-free approach, based on the on-demand generation of metal ions, enables the local modification of the chemical composition in a voxel-by-voxel fashion. However, so far only the deposition of metals was demonstrated.
We will focus on the challenges involved in expanding the materials range of EHD-RP from Cu and Ag to a wide range of metals, semiconductors and insulators. In particular, the deposition of Zn structures and their subsequent thermal oxidation to semiconducting ZnO will be presented. Together with an analysis of its structure, its optical properties will be assessed by photoluminescence spectroscopy. In addition, the direct deposition of insulating structures will be demonstrated on the example of MgO and first results towards their integration with printed metal conductors will be shown.
In summary, we outline a route towards establishing electrohydrodynamic redox 3D as a toolbox for the manufacturing of multi-material microelectronic devices.

SF03.04.10
A Thin-Film Flexible Inkjet Printed Lithium-Ion Battery Exploiting Innovative MXene Material as Current Collector Prisca Viviani, Eugenio Gibertini and Luca Magagnin; Politecnico di Milano, Italy

The Internet of things (IoT) market is a new groundbreaking field that has gained great attention both from the academic and industrial point of view. Progress in this field is deeply interconnected to the possibility of integrating smart devices with everyday objects and instruments, so that they are able to collect process and elaborate data without the need of human input. Therefore, always more demanding energy storage devices able to power such smart objects are needed. However, rigid, conventional batteries, as well as their respective fabrication processes, find limited applications when dealing with wearable electronics. Specifically, one of the major limitations of conventional batteries is, indeed, their rigidity and inadequate mechanical. When patterned electrodes or unconventional substrates are involved, new fabrication strategies are required to overcome limitations of traditional slurry coating electrode processing [1,2].

In this context, printing of batteries can be framed as a potentially innovative fabrication technique able to combine the benefits of thin-film technology, as for the lightness, mechanical flexibility, easiness of integration, and those typical of Additive manufacturing (AM), as for the long-term production low costs, scalability and versatility, easy processability and reproducibility. Among the technologies belonging to the AM class, Inkjet printing (IJP) is a solution-based mask-less additive technique able to deposit layers of different materials by propelling droplets of ink onto various substrates. When dealing with thin-film batteries, IJP is preferable over other printing techniques for several reasons, above all the limited material waste, as it is possible to finely control the position of the droplets, and the higher resolution this technique can provide [3]. However, a challenging aspect is related to the material processing, as specific ink physical properties need to finely be tuned to achieve a printable suspension.

Despite being a strategic solution for patterned flexible electrodes fabrication, to date poor attention has been driven toward a systematic study of how IJP could be possibly applied to Lithium-ion batteries (LIB) fabrication. In addition to this aspect, printing current collectors represents the main obstacle to obtain a fully inkjet printed LIB. An emerging class of material with outstanding electrical, electrochemical and rheological properties is represented by 2D transition metal carbides/nitrides, known as MXenes. $Ti_3C_2T_x$ is the most studied, due to its extremely high conductivity (> 15 kS cm^{-1}) and hydrophilicity, allowing to produce a safe, non-toxic aqueous ink, without the need of any surfactant or additive to control the stability [4]. The combination of these properties allows to easily print an extremely conductive current collector.

The aim of the work is the fabrication of a thin-film flexible inkjet printed battery exploiting aqueous-based LTO and LMO inks, used as anode and cathode, respectively, and MXene-based current collector. An extensive inks characterization will be presented in terms of viscosity, surface tension and mean zeta potential, to understand the inks stability and printability. Morphological and electrical analysis of the printed substrates, combined with an in-depth electrochemical characterization in order to understand the battery performance, will be discussed.

SF03.04.11
Direct Handwriting of High-Performance Perovskite/Polymer Composite-Based Optoelectronic Devices on Paper, Textile and Other Unconventional Substrates Junyi Zhao[1], Li-Wei Lo[1], Haochuan Wan[1], Zhibin Yu[2] and Chuan Wang[1]; [1]Washington University in St. Louis, United States; [2]Florida State University, United States

Owing to its unique properties such as tunable bandgap and strong optical absorption, perovskite material holds great potential and has drawn extensive research interest for a wide range of optoelectronic applications including solar cells, photodetectors (PDs), and light-emitting diodes (LEDs). In most reported work, the perovskite-based optoelectronic devices are constructed in a multilayer structure on rigid indium-tin-oxide (ITO) glass substrate with a vacuum-evaporated metal top electrode. In this work, we report a unique approach for direct handwriting of high-performance hybrid organic-inorganic perovskite LEDs and PDs on unconventional substrates (paper, textile, three-dimensional surfaces) using a regular ballpoint pen filled with formulated electronic inks. This novel and alternative fabrication strategy allows high-performance LEDs and PDs to be easily fabricated by any untrained individuals in a time-efficient (the whole device can be made within a few minutes) and cost-effective manner. This is especially useful for early-stage demonstrations or application with less stringent requirement on resolution, as well as science popularization and education purposes.

More specifically, the fully-handwritten perovskite LEDs and PDs employs a simple sandwich structure, consisting of a composite transparent bottom electrode of poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) and poly(ethylene oxide) (PEO), a composite active layer of methylammonium lead tribromide ($CH_3NH_3PbBr_3$) and PEO, and a silver nanowire (AgNW) top electrode. With the addition of polymer into the perovskite precursor, the voids between crystals can be eliminated to obtain a uniform and compacted functional layer. The multicolor perovskite-LEDs exhibit emission covering the whole visible range, especially the green emission with a low turn-on voltage of 2.3 V and high brightness of greater than 600,000 cd m^{-2}. Furthermore, this direct handwriting approach is also extremely versatile for use on various cellulose and fabric substrates and on curved and irregular surfaces that cannot be accomplished via conventional coating and deposition approaches. By integrating the perovskite-based LEDs and PDs, a handwritten sensor patch capable of measuring photoplethysmogram (PPG) waveforms from humans has also been demonstrated. This work demonstrates the great promise of using handwritten perovskite optoelectronic devices for emerging wearable health-monitoring applications.

SF03.04.13
Late News: Stencil Printed Micro Li-Ion Batteries for Autonomous Microsystems Anju Toor and Ana C. Arias; University of California, Berkeley, United States

The rapid growth of the electronics industry has resulted in a sustained need for portable electronics. Significant effort has been directed towards developing miniaturized devices for applications in wireless sensor networks, biomedical sensors, actuators, and wearables. Due to a rise in the popularity of the Internet of Things (IoT), demand for “autonomous wireless sensors” has increased. These devices can be used for smart building control, industrial process automation, factory automation, and many other applications. Such devices require integrated power sources to provide stable current supply and to deliver high peak currents on the order of ~1-10 mA while occupying small areas (< 1 cm2). Recent work has shown that except for the power supply, all the components needed for standards-compatible wireless communication can be integrated onto a single silicon chip with a wirebond antenna. Printing the

power supply directly on such a chip at wafer-scale would be a low-cost, small-volume solution.

For miniature or scaled-down Li-ion batteries, there are three key battery configurations that have been adopted, thin-film, thick-film, and 3D architectures. Typically, thin-film batteries suffer from insufficient power and capacity per unit footprint area to allow the operation of microelectronic devices. Thick-film battery configurations employ printing processes such as stencil printing[1], laser-direct write technique (LDW)[2,3] etc. to allow the fabrication of porous structured thick-film electrodes without requiring any lithographic patterning. 3D battery architectures involve 3D electrodes in several forms such as arrays of microrods/microtubes synthesized by templating method, honeycomb-like and sponge-like. However, the fabrication of 3D battery architectures is often quite complex and restricted to very few cathode and anode materials. One promising approach to develop high capacity miniature/micro Li-ion batteries is to employ printing methods such as stencil and screen printing to deposit thick, high capacity electrodes[1]. Printing methods also provide the flexibility to customize battery active area as per the device layout and size requirements.

This work demonstrates stencil-printed high-capacity Li-ion micro-batteries fabricated in Silicon for IoT applications. The battery consists of synthetic graphite and lithium cobalt oxide (LCO) as the respective anode and cathode layers printed on thin evaporated current collectors. For the fabrication of batteries, LCO is printed in a 225 um deep, 25 mm^2 Si cavity and the graphite electrode is printed on a glass substrate. Once printed, the batteries are assembled and packaged using an airtight seal (Torr Seal) in a glovebox and tested in air. This work investigates the electrochemical limitations of Li-ion batteries as the active areas are scaled-down. The influence of the electrode film thickness on the battery performance is studied. The batteries demonstrate an areal capacity as high as ~7.2 mAh/cm2, capacity retention >80% and columbic efficiency > 97% under 30 charge/discharge cycles. Our experiments show that a 25 mm2 battery can power a wireless transceiver chip, SCμM [7] that consumes a baseline current of 650 μA with a peak current as high as ~4 mA.

Jet Printing of Benzocyclobutene-Based Inks as Polymeric Adhesive Materials Filippo Iervolino[1], Raffaella Suriano[1], Martina Scolari[2], Ilaria Gelmi[2], Laura Castoldi[2] and Marinella Levi[1]; [1]Politecnico di Milano, Italy; [2]STMicroelectronics, Italy

Polymeric adhesive materials are widely used in the electronic industry for applications such as wafer bonding, 3D integration and packaging. One of the most used materials is benzocyclobutene (BCB). BCB is a thermosetting polymer that can be processed as polymer solution, also called ink. Usually, BCB is processed with spin-coating. However, spin-coating alone does not allow to fabricate complex patterns and it needs to be coupled with a lithographic process. Moreover, lithography is challenging when high topographies need to be fabricated [1].

To overcome this issue, jet printing technologies can be used. Jet printing is a direct ink writing additive manufacturing technology based on the emission of material in form of droplets [2]. It is a non-contact and maskless technology. Two of the most used jet printing technologies are drop-on-demand inkjet printing and aerosol jet printing. Inkjet printing is characterized by the selective emission of droplets obtained by a thermal or a piezoelectric actuator [3]. Aerosol jet printing, instead, is based on the emission of a focused nebulized ink, i.e., the aerosol, onto a substrate [4]. Both inkjet and aerosol jet printing present common advantages, such as the high versatility, high scalability, and the possibility of printing a wide variety of functional inks, e.g., polymeric, metallic and ceramic inks [5]. The main advantage of aerosol jet printing over inkjet printing is the possibility of using inks with a much wider range of viscosity, i.e., up to 1000 mPas instead of 20-30 mPas. However, aerosol jet printing has some drawbacks such as overspray and ink stability [6].

Here, we present the fabrication of BCB-based inks by inkjet printing and aerosol jet printing. For inkjet printing, we use a drop-on-demand system with a piezoelectric actuator. For aerosol jet printing, a pneumatic system is used allowing to print inks with a relatively high viscosity. Careful ink formulation is carried out for inkjet printing to have printable inks. Indeed, inks having a viscosity of ~5 mPas exhibit a stable jetting. For aerosol jet printing, instead, we evaluate the effect of different polymer dilutions. We show aerosol formation and printing of BCB-based inks with a viscosity up to ~400 mPas. Moreover, the other physical properties of the inks that have an influence on the printing process are characterized. Then, we print simple geometries to perform an in-depth characterization of the printing parameters. The feasibility of printing complex patterns is also presented. A comparison between inkjet printing and aerosol jet printing is proposed, with particular interest in the difference of the morphology of the printed patterns. On one hand, we observe that aerosol jet printing exhibit a higher versatility being possible to print pattern having a thickness ranging from 1 μm to 30 μm. On the other hand, inkjet printing shows a better reproducibility for complex geometries and better edge sharpness. Finally, adhesive properties of the printed materials are characterized.

Design and Applications of Printable Two-Dimensional Material Inks Mark C. Hersam; Northwestern University, United States

Two-dimensional (2D) materials have emerged as promising candidates for next-generation electronics [1] and quantum technologies [2]. With properties ranging from insulating (e.g., hexagonal boron nitride) to semiconducting (e.g., transition metal dichalcogenides) to conducting (e.g., graphene), nearly any electronic device can be fabricated by properly assembling 2D materials into heterostructures [3]. While device prototypes have been demonstrated on idealized research-scale samples, scalable manufacturing remains a challenge for 2D materials. In parallel, the field of printed electronics has made significant progress towards roll-to-roll additive manufacturing based on organic and nanoparticle inks. This talk will explore recent work aimed at uniting these efforts by designing electronic inks that combine the superlative electronic properties of 2D materials with the scalable manufacturing of printed electronics. To achieve this objective, multiple design goals have been concurrently pursued including exfoliation (i.e., optimizing yield, throughput, and flake size), ink formulation (i.e., engineering solvents and stabilizing surfactants and polymers for aerosol, inkjet, gravure, screen, and 3D printing), printed structure morphology (i.e., controlling film morphology and microstructure following printing via solvent evaporation, solvent additives, and curing conditions), and control of interfacial properties (i.e., minimizing interfacial resistance in conductive inks, maximizing capacitance in dielectric inks, and maximizing mobility for semiconductor inks). By achieving high levels of 2D material ink homogeneity and printing fidelity, a variety of high-performance applications have been achieved including photodetectors, optical emitters, supercapacitors, batteries, and sensors [4-7].

3D Printing Glass with Metastable Silicates Devon Beck, Paul Miller, James Mcrae, Bradley Duncan and Melissa Smith; Lincoln Laboratory, Massachusetts Institute of Technology, United States

Additive manufacturing of glass allows the fabrication of complex structures and geometries that traditional approaches cannot achieve. However, current strategies for 3D printing glass require thermal processes over 1000 °C to produce functional parts. We describe the development of low temperature process to 3D print glass and multimaterial composite glasses based on metastable silicate chemistry. The direct-write deposition process occurs at room temperature and the curing process only requires 250 °C to achieve a stable glass structure. The properties of the printed glass can further be tailored in a plug-and-play fashion by introducing functional filler materials such as conductive particles. This straight-forward strategy will enable the fabrication of a wide variety of microfluidic, electronic, and radio frequency devices with higher thermal stability without the need for extensive thermal processing.

4:45 PM SF03.07.05
3D-Enhanced Multimodal Sensing with Ultrathin Conductive Oxides on Polymer Scaffolds Md Saifur Rahman, Julia Huddy, Andrew B. Hamlin and William J. Scheideler; Dartmouth College, United States

We present a strategy for transforming 3D-printed polymer lattices into a versatile technology platform for multimodal electronic sensing. This method exploits nanometric ALD coatings of ZnO and ZnO:Al deposited directly onto the 3D printed polymer scaffold structures. We demonstrate that these conductive octet lattices can be designed for electronic multifunctionality, demonstrating 3D-enhanced chemical, thermal, mechanical, and fluid sensing. These applications leverage the synergistic effects of ultrathin semiconducting and conducting coatings with an increased surface-to-volume ratio due to the microscale pores of the 3D lattice.
The 3D sensors show a 100X enhanced response over 2D films when applied as low power, (10-50 nW) room temperature gas sensors for volatile organic compounds (VOCs). Leveraging the ultrathin deposition capability, 3D sensors with varying ZnO coatings (11 - 60 nm) were fabricated to enhance sensitivity, achieving thicknesses near the Debye Length to induce surface-dominated electrostatic interactions with physiosorbed gas molecules. The tunable electrical conductivity of these structures also facilitates a variety of thermophysical response mechanisms, including rapid air temperature sensing enabled by the low thermal mass resulting in millisecond response time. We explore self-heating functionality at the mW level and utilize geometric control of convective heat transfer to perform thermal anemometry over a 100X range of air velocities. Finally, the 3D scaffolds were also implemented using deformable polymer lattices that allow these oxide-coated structures to function as kPa-level mechanical pressure sensors operating up to 3% overall strain, overcoming the inherent mechanical limitations of ceramic materials.
This ability to engineer electronic transport in additive manufactured mesoscale structures offers huge potential for microelectronics integration and provides a glimpse of how 3D design can fundamentally enhance the performance of biosensors, actuators, and microelectromechanical systems.

5:00 PM SF03.07.06
Quantum Tunneling of Charge Carriers in 3D Printed Graphene Functional Devices Jonathan H. Gosling[1,1], Feiran Wang[1], Gustavo Trindade[1,1], Graham Rance[1], Oleg Makarovsky[1], Nathan Cottam[1], Zakhar Kudrynskyi[1], Alexander Balanov[2], Mark Greenaway[2], Ricky Wildman[1], Richard Hague[1], Christopher Tuck[1], T. Mark Fromhold[1] and Lyudmila Turyanska[1]; [1]The University of Nottingham, United Kingdom; [2]Loughborough University, United Kingdom

The unique structural and electronic properties of 2D materials can be exploited for use in transformative optoelectronic applications. However, devices are usually bespoke structures that require the sequential deposition of exfoliated 2D layers. Therefore, there is a need for scalable manufacturing techniques capable of producing high-quality large-area devices comprising multiple 2D materials. The 3D printing of inks containing 2D material flakes provides a promising solution. It has been demonstrated that inkjet-printing can be used to manufacture devices incorporating 2D materials. However, a greater understanding of the electronic transport phenomena and structural properties of such devices is still needed. Here, detailed electrical and structural characterization is reported and explained by comparison with charge transport modeling which includes inter-flake tunneling transport and percolation network dynamics. Results reveal that the electrical properties are strongly influenced by flake density and complex meandering electron trajectories, which form in the presence of disorder and can traverse several printed layers. Controlling such trajectories is essential for printing high-quality devices that exploit the properties of 2D materials. We use inkjet-printed graphene to form the conductive channel of a fully inkjet-printed field effect transistor and to provide Ohmic contacts on an InSe phototransistor. This is the first time that inkjet-printed graphene has successfully replaced single layer graphene as a contact material for 2D metal chalcogenides.

SESSION SF03.08: Emerging Processes
Session Chairs: Daryl Yee and Minxiang Zeng

10:30 AM SF03.08.01
Interfacial Photopolymerization (IPP) Additive Manufacturing of Linear Chain Polymers Cecile Chazot[1], Megan A. Creighton[2] and John Hart[1]; [1]Massachusetts Institute of Technology, United States; [2]Drexel University, United States

Photopolymerization additive manufacturing (AM), particularly stereolithography (SLA) and Digital light processing (DLP) is widely adopted due to its high resolution, simplicity, and the broad range of mechanical properties available from photopolymer resins. However, the technique is currently restricted to crosslinked polymers, resulting in challenges in both post-processing and recycling of printed parts that are absent when considering thermoplastic AM techniques. Here, we present a new process called interfacial photopolymerization (IPP) which enables photopolymerization AM of linear chain polymers. In IPP, a polymer film is formed at the interface between two immiscible liquids, each containing one type of reactive species. We demonstrate the integration of IPP in a proof-of-concept projection system and discuss how the reaction parameters affect printing resolution and final polymer properties. We also present a macrokinetics model to deepen understanding of the transport and reaction rates involved in IPP and evaluate the resolution of the printing process.

10:45 AM SF03.08.02
Late News: Integrating Non-Transparent Materials with Direct Laser Writing to Create Functional Microdevices Meng Li[1], Zemin Liu[1], Xiaoguang Dong[1], Ziyu Ren[1], Wenqi Hu[1] and Metin Sitti[1,2,3]; [1]Max Planck Institute for Intelligent Systems, Germany; [2]ETH Zürich, Switzerland; [3]Koç University, Turkey

The development of miniaturized 3D devices with programmability and high performance is key in paving the way towards building next-generation smart micro-systems to revolutionize healthcare, data storage, and human-machine interface. Integrating advanced functionalities, heterogeneous properties and complex 3D geometries is challenging in the micro-scale. Among all the fabrication techniques, 3D printing is the most advantageous in shaping 3D geometries with automated processes of large flexibility and design freedom. Two photon polymerization direct laser writing (2PP-based DLW) has risen as a promising technique for printing arbitrary 3D architectures with a resolution down to hundreds of nanometers.
However, functional composite inks that are compatible with 2PP-based DLW usually suffer from poor performance, due to their low loading fractions of the functional dopants. Because of the intense near-infrared laser beam needed for the 2PP 3D lithography, highly light absorptive materials are intrinsically not suitable for the DLW process—bubbles generated locally will destruct the printed structure, and not enough transmitted light can reach the desired printing depth. Such exemplary materials are composites doped with micrometer-size particles and non-transparent particles (such as carbon nanomaterials, magnetic particles, metallic particles) and highly photoactive materials (such as gold nanoparticles, photothermal dyes). Researchers have used different methods to incorporate DLW-incompatible materials with printed 3D architectures, such as coating, electroplating, surface modification, and molding. Every fabrication technique has its own advantages to meet the requirements of specific applications, but it also has its own limitations. For example, the coating method functionalizes the architectures in a 2D manner, lacking 3D space selectivity; electroplating and surface modification have a limited selection of compatible materials; molding a single material gives an isotropic property lacking advanced programmability.
We present here multistep-molding-integrated direct laser writing that is able to integrate those incompatible functional materials into high-resolution and complex 3D geometries, to create various microdevices with unique functionalities. Metachronal wave motion, fluid mixing, function reprogramming, structural reconfiguring, multiple degrees-of-freedom rotations, and stiffness-tunable double-layer mechanical bits are exemplary demonstrations of the versatility of this fabrication routine.

11:00 AM *SF03.08.03
Conformal Geometry and Multi-Material Additive Manufacturing Through Freeform Transformation of Building Layers Jigang Huang, Henry O. Ware, Rihan Hai, Guangbin Shao and Cheng Sun; Northwestern University, United States

3D printing or additive manufacturing is the process for building complex geometries via successive addition of materials based on a digital model. However, the traditional 3D printing processes employing planar-layer printing strategy have rather limited flexibility in customization and multi-materials integration. Originally developed for the sole purpose of rapid prototyping, the planar-layer printing process slices the digital models along the z-axis to generate a set of horizontal build layers in x-y plane. Those layers are sequentially stacked from bottom-up to create the physical replica of the digital model. After more than three decades, this standard procedure remains the would-be choice in most of the commercial 3D printers possessing 3-Degree of freedom (DOF) Cartesian motion. Despite its popularity, the limited 1-DOF stage motion along z-axis imposes serious constraints in 3D printing complex geometries. Recognizing how multi-axis machines are capable of producing freeform geometries with better quality and efficiency as compared to the 3-axis machines, there is a growing interest in exploring the new slicing and printing strategy beyond the 3-DOF Cartesian motion. Methods that employed high-DOF stage motion have also investigated in enabling conformal 3D printing on non-planar surfaces and support-free 3D printing. Recently reported computed axial lithography (CAL) method prints entire complex objects via angular accumulation of dynamically evolving light pattern in a cylindric coordinate system. All these methods demonstrated the ability to handle complex geometries with improved speed and surface finishing. Inspired by these most recent studies, we went a step further by allowing freeform manipulation of each build layer during the layered manufacturing process.

We show here untethering the build layer fabrication from unidirectional stage motion unlocks the means to reconstitute the 3D objects with added manufacturability such as custom design transformations, conformal geometry, and multi-material integration. The newfound fabrication flexibility allows us to executes full degree-of-freedom (DOF) transformation (translating, rotating, and scaling) of each individual building layer while utilizing continuous fabrication techniques. Transforming individual building layers within the sequential layered manufacturing process enables dynamic transformation of the 3D printed parts on-the-fly, eliminating the time-consuming redesign steps. Preserving the locality of the transformation to each layer further enables the discrete conformal transformation, allowing objects such as vascular scaffolds to be optimally fabricated to properly fit within specific patient anatomy obtained from the Magnetic Resonance Imaging (MRI) measurements. The manufacturability of the 3D printing process is further augmented with the use of the high-precision 6-axis robotic arm. It allows us to perform manufacturing tasks other than 3D printing, such as rinsing the samples mid-printing process. Finally, exploiting the freedom to control the orientation of each individual building layer, we further establish multi-materials, multi-axis 3D printing capability for integrating functional modules made of dissimilar materials in 3D printed devices. This final capability we demonstrate through 3D printing a soft pneumatic gripper via heterogenous integration of rigid base and soft actuating limbs. Although the reported method primarily focusing on the continuous stereolithography process, the underlying principle can be applied to other 3D printing process, with the potential to ease the burden towards the envisioned multi-process 3D printing.

11:30 AM SF03.08.04

Gas-Phase 3D Printing of Functional Materials David Munoz-Rojas; LMGP Grenoble INP/CNRS, France

Spatial Atomic Layer Deposition (SALD) is a recent approach 100 times faster than conventional ALD, even at atmospheric pressure. Previous works exploited these assets focussing on high-rate, large-area deposition for scaling-up into mass production. Conversely, this work shows that SALD indeed represents an ideal platform for area-selective deposition of functional materials by proper design and miniaturization of close-proximity SALD heads. In particular, the potential offered by 3D printing is used to fabricate low-cost customized close-proximity heads, which can be easily designed and modified to obtain different deposition areas, free-form patterns, and even complex multimaterial structures. Finally, by designing a miniaturized head with circular concentric gas channels, 3D printing of functional materials can be performed with nanometric resolution in Z. This constitutes a new gas-phase 3D printing approach. Because the process is based on ALD reactions, conformal and continuous thin films of functional materials can be printed at low temperatures and with high deposition rate in the open air. Our approach represents a new versatile way of printing functional materials and devices with spatial and topological control, thus extending the potential of SALD and ALD in general, and opening a new avenue in the field of area-selective deposition of functional materials.

3D Printing of Inorganic Thermoelectric Materials Jae Sung Son, Fredrick Kim, Seungjun Choo, Jungsoo Lee and Seong Eun Yang; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Heat is omnipresent in natural and artificial environments, more than 60% of which is dissipated. Thermoelectric (TE) power generation can provide a unique solution to convert this dissipated, wasted heat into useful energy, that is, electricity. Generally, TE conversion efficiency depends on the material properties and design of the module structure. However, despite the development of highly efficient TE materials, module engineering is rather less advanced and is still fabricated by the traditional multi-step process of materials synthesis, dicing, and assembly, restricting the available design of modules to that of planar structures. At this moment, three-dimensional (3D) printing technology can maximize the flexibility in the design and fabrication of TE modules into more efficient structures. Furthermore, the printing process can significantly reduce the processing cost for the fabrication of TE modules owing to lower energy input and a simplified assembly process. Herein, I present the development of the 3D printing process applied to a range of different TE materials of Bi_2Te_3, BiSbTe, PbTe, and Cu_2Se-based inorganic alloys. Surface states of TE particles were precisely optimized with the controllable charge states in the presence of anionic inorganic binders, achieving the suitable viscoelasticity of the TE inks to the extrusion-based 3D printing. The geometrically designed 3D-printed TE materials were assembled into power generating systems, in which high efficiencies of energy conversion were achieved by the optimization of heat transfer.

2:00 PM SF03.09..02
High-Throughput Additive Manufacturing Toward Material Design and Discovery Minxiang Zeng and Yanliang Zhang; University of Notre Dame, United States

The discovery of new materials and their compositional/microstructural optimization holds the key to next-generation technologies in areas such as sustainable energy and environmental mitigation. Highly universal, fast, and controllable manufacturing method with the ability to generate a large number of sample features is therefore becoming progressively more important. Here we report a high-throughput combinatorial printing (HTCP) technique capable of integrating multiple nanoscale materials in a single nozzle and varying the material compositions on the fly, generating chemically heterogeneous films in a gradient manner (compositional density>10^4/cm^2). Leveraging aerosol-based mixing and deposition, the proposed HTCP approach demonstrates the on-demand control on the compositional/structural arrangements with programmable accuracy. Due to the vast tolerance of ink particle size and morphology, the HTCP successfully fabricates intriguing matter with gradient compositions and complex structures by integrating a wide range of nanoparticles, including 0D nanosphere, 1D nanowire/nanorods, and 2D nanoplates/nanosheets. Furthermore, we demonstrate a fascinating variety of printing strategies including combinatorial doping, alloying, chemical reaction, and compositional microstructuring, expanding the application space for the HTCP method. As a proof of concept, HTCP has been used to investigate the role of doping level in thermoelectric (TE) materials, which helps to identify a high-performance n-type TE composite. The ability to combine the top-down designing freedom of additive manufacturing with bottom-up molecular control over material composition and structure promises almost infinite possibility of heterogeneous material library which is inaccessible from conventional manufacturing approaches, offering a new pathway toward the design and discovery of next-generation materials and composites for broad applications.

2:15 PM SF03.09..03
Inkjet Printing of Organic Electronics on 3D Objects Marc Steinberger, Andreas Distler, Hans Joachim Egelhaaf and Christoph J. Brabec; I-Meet Institute Materials for Electronics and Energy Technology, Germany

Inkjetprinting of organic electronics is an emerging field of interest in current research. The flexibility of the production process allows the production of organic photovoltaic with different shapes, colors and on several different 2D substrates. Here we show the first time all inkjet printed organic solar cells and OLEDs on a 3D object using a 5-Achs automated robot system. The ink engineering process was guided by the optimization towards stable inks that can be deposited on curved substrates with different printing distances. To overcome shunting issues a method for planarizing different substrates on 3D was developed using different polymer coatings. A successive study on performance dependence of print distance was performed in order to achieve full automation of the printing process. On top live time studies of fully printed solar cells on 2D and 3D were performed.

2:30 PM SF03.09..04
***In Situ* Materials Synthesis for Vat Photopolymerization of Functional Metal Oxides and Metals** Daryl W. Yee[1] and Julia R. Greer[2]; [1]Massachusetts Institute of Technology, United States; [2]California Institute of Technology, United States

Additive manufacturing (AM) is one of the most powerful manufacturing tools available today. Its layer-by-layer approach to fabrication enables greater flexibility in the use of topology to design functional materials with significant improvements in performances and/or previously impossible functionalities. Vat photopolymerization (VP) stands out amongst the various AM techniques as its ability to achieve high volumetric throughputs and resolutions allows it

to be applied in a variety of different settings, from fabricating nanophotonic devices to shoe soles. However, a key limitation of VP is the limited number of functional inorganic materials that are compatible with it. While composite resins with inorganic fillers and hybrid inorganic-organic resins have been developed to allow VP of these inorganic materials, they are often challenging to use, have poor resolutions, or are limited in the compositions achievable.

In this presentation, we will discuss the use of in-situ materials synthesis as an alternative materials development approach for VP that can address some of the current challenges associated with VP of functional inorganic materials. By printing a 3D object that contains the necessary reagents for the in-situ synthesis of the desired material, i.e. printing a "chemical reactor", we can adapt the extensive materials synthesis reactions already developed for use with VP. As a demonstration of this "chemical reactor" framework, we show how in-situ combustion synthesis can be used with various VP processes for the fabrication of various functional metal oxides and metals.

Central to this approach is the fabrication of metal-ion containing 3D hydrogels which are then thermally treated to yield either 3D metal oxide or metal structures. These homogenous hydrogels are facile to prepare and compositionally versatile, circumventing the issues associated with the state of the art in metal oxide and metal VP. Using this system, we fabricated zinc oxide structures with sub-micron features using two photon lithography and demonstrated their piezoelectric properties via in-situ compression experiments. Lithium cobalt oxide materials were also fabricated using digital light processing (DLP) printing and showed efficient performance as a lithium ion battery cathode over greater than 100 cycles. An array of micro-architected metals such as copper, silver, and cupronickel alloys were also fabricated with DLP printing, which could be used for thermal management applications.

This work highlights the use of polymer chemistry and materials science in expanding the range of materials that can be made via additive manufacturing. The ability to fabricate these functional 3D materials in a facile and versatile way has the potential to open up the field of smart devices and change how we design them.

2:45 PM SF03.09..05
3D Printing of the Half-Heusler Alloy $Nb_{1-x}CoSb$—A Case for Ternary Thermoelectric Materials Muath Al-Malki, G. J. Snyder and David C. Dunand; Northwestern University, United States

The continuous development of thermoelectric materials in the past decades led to the improvement of the dimensionless figure of merit and ultimately the overall device efficiency. However, synthesis and manufacturing of electronic materials in general, and thermoelectric materials particularly, requires delicate attention to attain the planned electronic and thermal properties. Furthermore, most of the conventional synthesis techniques, such as the hot pressing, limit the shape of the synthesized material; restricting them from being used in wide range of applications, including wearable devices. The literature of 3D printing of thermoelectric materials, so far, is limited to binary materials (Bi_2Te_3,PbTe,..). We are showing here the case for 3D printing of the half-Heusler alloy $Nb_{1-x}CoSb$, in which we tackle the problems of secondary phases formation, porosity control and the relation of all that to the transport properties. This should bridge the gap towards printing other ternary and quaternary thermoelectric materials.

Printable Energy Storage and Soft Robotic Components for Soft Electronics Andrew Fassler[1,2], Ryan Kohlmeyer[1,3], Greg Horrocks[1], Eliot Gomez[1,2], Shiwanka Wanasinghe[4], Alex Flynn[1,2], Obed Dodo[4], Jessica Sparks[4], Luke A. Baldwin[1], Christopher Tabor[1], Dominik Konkolewicz[4], Carl Thrasher[1] and Michael F. Durstock[1]; [1]Air Force Research Laboratory, United States; [2]UES, Inc., United States; [3]Xerion Advanced Battery Corp., United States; [4]Miami University, United States

Soft electronics and soft robotics aim to bridge the gap between functional, high performance, electronic devices & systems and our compliant, organic, human-centric environment. It involves the development of active and responsive electronic materials, devices, and systems in a form factor that is soft, flexible, stretchable, and mechanically robust. The use of 3D printing and direct write techniques offers some distinct advantages with respect to the fabrication of soft robotic components of increasing size and complexity, as well as in the heterogeneous integration of functional components such as distributed power sources and electronic components and interconnects. In particular, the development of flexible, printable, and mechanically robust energy storage devices is a key and oftentimes limiting requisite for many of these applications due to the fact that common battery materials and manufacturing methods are often incompatible with 3D printing and soft electronics. We demonstrate control of 3D printed batteries and energy storage components using a variety of printing approaches, including aerosol jet and direct ink write, combined with a mixed solvent, phase inversion approach to deliver porosity control, high resolution feature sizes, and high temperature performance. Additionally, advances in materials and design approaches are propelling the field of soft robotics at an incredible rate, however current methods of fabrication remain cumbersome and struggle to incorporate desirable geometric complexity at large scale. By developing a 3D printable, tunable, self-healing elastomer system, we demonstrate a soft robotic manufacturing approach that combines the advantages of 3D printing (e.g. vat photopolymerization) together with modular soft robotics whereby smaller subcomponents can be printed and subsequently self-healed together to form integrated parts.

3D Printing of Perovskite Nanopixels for Ultrahigh-Resolution, Multi-Level Anticounterfeiting Displays Mojun Chen and Ji Tae Kim; The University of Hong Kong, Hong Kong

The manufacture of pixels is a core task in optoelectronics and hybrid perovskites are emerging as a promising material candidate due to their strong, tunable, and high-color-purity luminescence. A number of lithographic or printing methods have been devised to fabricate perovskite pixels in thin-film forms. However, downsizing a thin-film pixel to the nanoscale loses its brightness, which remains a longstanding issue.
Here, we show that 3D layout of perovskite nanopixels offers an effective route to improve the brightness without sacrificing the lateral resolution [1]. Our nanoscale 3D printing approach that is based on femtoliter meniscus-guided crystallization [2] enables the fabrication of freestanding metal halide perovskite color nanopixels with programmed dimensions and placements. This approach provides outstanding lateral pixel dimensions such as a diameter of ~ 550 nm and a pitch of ~ 1.3 μm (pixel density > 19,500 ppi). Furthermore, on-demand control of the vertical pixel dimension by our 3D printing enables a couple of remarkable achievements: (1) enhancement and balancing of nanopixel brightness (tens of times brighter than a thin-film pixel) and (2) data encryption into nanopixel height for multi-level anticounterfeiting which is not easily accessible by high-magnification optical microscopy with

limited depth-of-field. This 3D printed nanopixel scheme is general and could be applied to diverse optoelectronic materials. In this talk, we will present our results and discuss the prospects of our work for potential applications in smart optoelectronic devices.

Water-Based and Defect-Free 2D Material Inks for Printed Electronics Cinzia Casiraghi; University of Manchester, United Kingdom

Solution processing of 2D materials [1] allows simple and low-cost techniques, such as ink-jet printing, to be used for fabrication of heterostructure-based devices of arbitrary complexity. However, the success of this technology is determined by the nature and quality of the inks used.
Our group has developed highly concentrated, defect-free, printable and water-based 2D crystal formulations, designed to provide optimal film formation for multi-stack fabrication [2]. I will give examples of all-inkjet printed heterostructures, such as large area arrays of photosensors on plastic [2], programmable logic memory devices [2], capacitors [3] and transistors on paper [3,4]. Furthermore, inkjet printing can be easily combined with materials produced by chemical vapor deposition, allowing simple and quick fabrication of complex circuits on paper, such as high-gain inverters, logic gates, and current mirrors [5].

Impact of Complexing Agent Evaporation on the Morphology and Media Resistivity of Printed Reactive Silver Inks Steven DiGregorio[1], Michael Martinez-Szewczyk[2], Subbarao Raikar[1], Avinash Mamidanna[1], Mariana Bertoni[2] and Owen Hildreth[1]; [1]Colorado School of Mines, United States; [2]Arizona State University, United States

3D printing of conductive inks is poised to revolutionize the microelectronics industry. However, some new technologies use thermally sensitive substrates that are not compatible with the high sintering temperatures (~ 200 °C) of metal nano-particle conductive inks. Reactive inks are an emerging technology that can solve this problem due to their ability to form highly conductive features at low temperatures (~ 90 °C). The underlying kinetics of reactive inks systems is crucial for designing high-performance inks but is not well understood. This work elucidates the impact of reaction kinetics on the morphology and the media resistivity of reactive silver inks (RSI) printed via direct ink writing. We introduce a new RSI system consisting of silver acetate, formic acid, and ethylamine, whose silver reduction mechanism is predominantly thermal. Comparing this new ink to an ink whose reduction mechanism is predominantly evaporative shows that thermal reduction produces dense bottom-up silver growth, and evaporative reduction produces highly porous silver morphologies. Decreasing the vapor pressure of the complexing agent or increasing the substrate temperature leads to more thermal reduction and, therefore, denser morphologies with lower media resistivities.

Inkjet-Printed Functionalized Surface Enhanced Raman Scattering (SERS) Sensors for Improved Detection of Narcotics Li-lin Tay and John Hulse; National Res Council Canada, Canada

Recent advances in Inkjet-printing of advanced materials have provided a versatile platform for the rapid development and prototyping of sensor devices. We have recently demonstrated inkjet-printed surface enhanced Raman scattering (SERS) sensors on flexible substrates for the detection of small chemical molecules. (Tay et al., J Raman Spectrosc., 2021, 52, 563-572) These flexible SERS sensors have good batch-to-batch uniformity and many advantages for performing point-of-sampling testing such as liquid or aerosol filtration and swabbing capabilities. These simple sampling and separation attributes make these inkjet-printed paper-based sensors ideal for field applications. The SERS effect relies upon the electromagnetic field enhancement that results from coupling of plasmonic nanostructures (e.g. silver or gold nanoparticles). SERS exploits the unique vibrational signature of an analyte molecule and in practice, it is often coupled with spectral recognition software for the detection of molecules of interest. Most SERS sensors are fabricated as non-functionalized plasmonic nanostructures in a single device. Because SERS is an optical near-field effect, it works best with molecules that have good binding affinity towards the plasmonic surfaces (such as thiols). SERS detection of non-binding molecules such as cannabinoids or other narcotics with poor affinity towards the plasmonic surfaces performs poorly. This can be improved through the use of surface functionality to help sequester or attract the molecules of interest to the plasmonic surfaces. The functionalization concept has been applied in SERS detection for a number of years. However, its applications have been limited typically to optimization of functional groups to target one particular chemical analyte, for example, the use of alkylthiol to improve glucose SERS sensing. (Lyandres et al., Anal. Chem., 2005, 77, 6134-6139) Once the surface has been functionalized and tailored for one specific analyte, it can often render the entire surface in-accessible for other molecular analytes. For example, a gold nanoparticle surface functionalized by halide ions (Cl- or I-) is often no longer active for detection of thiol species, despite the strong affinity of thiolated species towards gold surfaces. This problem can be overcome through the use of inkjet-printed SERS devices. With inkjet printing, multi-functionalized SERS active surfaces can be prepared in a single device thus retaining the performance of multiple types of functionalization in a single device. In this presentation, we will demonstrate the optimization of functionalized plasmonic ink formulation, inkjet-printing conditions and integration of multi-functional SERS active sites in a single sensing device. We will discuss the performance of differently functionalized SERS devices for the detection of narcotics.

9:05 AM *SF03.10.06
In-Space Manufacturing to Support Human Spaceflight Jessica Koehne; NASA Ames Research Center, United States

As human spaceflight pushes beyond Low Earth Orbit (LEO), resupply of consumables becomes a significant challenge. One solution to this problem is In-Space Manufacturing (ISM), the capability to perform on-demand manufacturing and repair of consumables in an in-space environment. ISM offers significant flexibility to missions as it allows for a high degree of tailorability and reduction in launch mass. Leveraging advancements in fabrication, repair and recycling, ISM provides a highly sustainable and affordable solution to exploration mission operations and logistics. In this talk, advances in printed

electronics and sensors, ranging from nanomaterial ink development and hands-free fabrication methodologies to devices will be presented. Applications presented will include sensors for crew health monitoring along with supporting electronics. In the future, these devices will be fabricated and characterized on the International Space Station and the approach will be evaluated for future in-space manufacturing to support human spaceflight.

SESSION SF03.11: Engineering Complex Structures by 3D Printing

Stereolithography-3D Printed Hierarchically Porous Carbon Microarchitectures for Structurally Robust Energy Storage Akira Kudo[1], Jiuhui Han[1] and Mingwei Chen[2,1]; [1]Tohoku University, Japan; [2]Johns Hopkins University, United States

3D printing has become one of the most attractive fabrication techniques in materials science and engineering, offering its immense degree of freedom in designing complicated architectures with feature sizes smaller than millimeters or even micrometers. As the designed architectures can control the physical and chemical properties of the materials, 3D printing thrusts creating innovative multifunctional materials.
In this presentation, we employed stereolithography (SLA) 3D printing to fabricate hierarchically porous carbon microarchitectures that integrate structural robustness and energy storing functionality. By using photocurable resin mixed with magnesium oxide (MgO) nanoparticles as a porogen, an LCD (liquid crystal display)-SLA 3D printer successfully replicated the 3D-modeled microarchitectures. After pyrolysis in vacuum at 1000degC and removal of MgO nanoparticles in heated hydrochloric acid, we obtained fully-carbonized simple cubic lattices that retained the architected micropores (<200μm) and stochastic nanopores (<40nm) developed in the individual structural elements. While showing ~300m^2/g of the specific surface area, supercritical liquid or other complicated setups were not required for drying. The obtained structures demonstrated a combination of mechanical robustness and functionality as a supercapacitor in a single body. Further optimization of both microarchitectures and nanoporosity will lead to a highpower energy device embedded in structural components.
Out results can present a novel configuration of structural capacitors and/or batteries different than ones using carbon fibers, benefitting from the capability of 3D printing.

10:45 AM SF03.11.02
Direct 3D Printing of High-Aspect-Ratio Metallic Nanoprobes for Scanning Microscopy Heekwon Lee and Ji Tae Kim; The University of Hong Kong, Hong Kong

Over the past 40 years, the scanning probe microscope (SPM), a class of Nobel-Prize-winning techniques, has become a routine and essential imaging tool for exploring not only surface topography but also material properties at the nanoscale. The core feature of SPM is a “nanoprobe” typically made up of a sharp tip mounted on a cantilever.

Recently, high-aspect-ratio (HAR) nanoprobes have ushered in a new era in SPM characterization. First, the HAR probe enables full-profile topography of deep and narrow 3D nanodevices, e.g., fin-based multigate transistors (FinFETs), photonic metamaterials, and neuromorphic circuitries. Second, the HAR probe geometry is quite effective in amplifying the chemical imaging contrast in tip-enhanced-Raman spectroscopy (TERS), as it provides enough space to separate the light excitation region from the Raman scattered region on the probe. However, the technological challenges associated with the fabrication of HAR nanoprobes such as high-cost, labor-intensive, and low- throughput remain unresolved.

Here, we have developed a one-step, on-demand, material-saving benchtop 3D printing method to fabricate metallic HAR atomic force microscope (AFM) probes for deep 3D imaging [1]. This method exploits electrohydrodynamic (EHD) nano-dripping to fabricate a freestanding silver nanowire (AgNW) with an aspect ratio over 30 directly on a cantilever. Our 3D printing approach offers the benefits associated with unprecedent simplicity in the probe’s dimension control, material selection, and regeneration, which are not easily attainable in the traditional lithographic approach. Moreover, our 3D printed tip delivers a high fidelity in deep-trench imaging better than a standard pyramidal tip and comparable to commercial HAR probes, yet at a fraction of their cost.

Furthermore, 3D printing has the potential to produce/customize diverse classes of functional nanoprobes, as recently demonstrated scanning 3D thermocouple networks for mapping microscale temperature fields in three-dimensions [2]. In this talk, we will present the experimental results including 3D printing of functional nanoprobes and discuss prospects of our work for potential applications in nanomaterial characterization and sensing.

KEYWORDS:3D printing; electrohydrodynamic nano-dripping; nanowire probe; 3D deep AFM imaging

BackBot—Insect Inspired Underwater Miniature 3D printed Robot with Self-Regulation of Catalytic Driven Buoyancy Dror Kobo and Bat-El Pinchasik; Tel Aviv University, Fleischman Faculty of Engineering, Israel

Backswimmers (family Notonectidae) are aquatic insects known for their ability to hang upside-down at the water-air interface, due to their superhydrophobic legs.[1] They can, however, also regulate their buoyancy underwater through controlling the size of a bubble attached to their abdomen.[2,3] They do that by controlling the amount of oxygen attached to haemoglobin cells. In this way, they reach neutral buoyancy without the need to swim actively.
With the miniaturization of robots, interfacial phenomena become prominent in terms of stability, adhesion and arts of locomotion.[4] While interfacial phenomena may hinder locomotion and complicate the development of small robots, it can also be used in order to facilitate the performance of specific tasks, as exhibited in nature, and promote the development of robotic insects and insect-inspired devices. This is especially important in underwater robotics, where energy consumption and hydrodynamics challenge the miniaturization of robots.
In this study, a 3D printed backswimmer-inspired miniature robot is developed. A mat of gas bubbles is created and autonomously controlled, in order to

regulate the buoyancy of the robot. The bubbles nucleate and grow using a catalytic mechanism underwater. Water from the environment split into oxygen and hydrogen micron-sized bubbles on small (2 cm) comb-like electrodes, in response to voltage. In order to release bubbles and regulate the buoyant forces, three mechanisms for bubble release are investigated: rotational, linear and pulse mechanism. An undesirable outcome of the bubble release rotational mechanism is rotational motion of the robot to the opposite direction, due to conservation of angular momentum. In the case of the pulse driven release mechanism, high-energy consumption is recorded, in comparison to the other release mechanisms. Therefore, the linear mechanism is the most useful for bubble release in terms of power consumption and motion control. Through a control loop, the nucleation, growth and release of bubbles are self-regulated, allowing the robot to achieve neutral buoyancy without any further energy consumption, in an autonomous fashion. The development of this device lays the ground for investigating interactions between autonomously moving underwater miniature robotic swimmers.

11:15 AM SF03.11.05
Direct Printing of Functional 3D Objects Bhavana Deore[1], Katie Sampson[1], Thomas Lacelle[1], Rony Amaya[2], Joseph Hyland[2], Hendrick W. de Haan[3], Patrick Malenfant[1] and Chantal Paquet[1]; [1]National Research Council Canada, Canada; [2]Carleton University, Canada; [3]University of Ontario Institute of Technology, Canada

3D printing is an emerging additive manufacturing technology poised to transform both design and manufacturing due to its ability to customize design and generate structural complexity not possible using traditional manufacturing processes. Commercial examples of 3D printed objects using monolithic materials, such as GE's fuel nozzle, illustrate early success of this technology by enabling new designs and significantly reducing the number of parts and supply chain required for manufacturing. However, only marginal progress has been made to demonstrate multi-material printing and as such it remains a low technology readiness level research endeavour at the moment with enormous potential for innovation and commercial impact. Multi-material 3D-printing would increase the complexity and enable the fabrication of complete devices in a single printing process combining materials with different properties (structural, functional, conductive, etc.). Through novel chemistries, and the exploitation of controlled self-assembly, various functions (e.g. electrical, optical, magnetic, mechanical) may be introduced into objects as they are being constructed/printed. 3D spatial segregation of materials within the object will be controlled from the nano-scale to the macro-scale, carefully tuning bulk and surface properties, yet breakthroughs in many aspects of material science will be required to achieve this level of control. These "smart multifunctional objects" are intended to be adaptive and responsive (i.e. intelligent) and enable applications that cannot be easily addressed using other forms of fabrication. This is a leap beyond traditional assembly. Success will provide breakthroughs in robotics and IoT via new form factors with optimized mechanical properties, embedded sensors and antennas for wireless communication. In this presentation, we demonstrate a strategy to generate functional objects by vat polymerization 3D printing that relies on controlled phase separation. Using photoresins comprising of judiciously selected components, the diffusion of phase separating components are modulated via the kinetics of gelation and network entrapment to yield spatial control over material placement. This methodology yields a rich selection of morphologies with distinct functional surfaces that provide direct access to 3D printed smart objects such as sensors and wireless applications.

11:30 AM SF03.11.06
Microextrusion of Energy Storage Materials for Custom-Form Lithium Batteries Jorge A. Cardenas, John P. Bullivant, David Ashby, Eric Allcorn, A. A. Talin, Adam W. Cook and Katharine L. Harrison; Sandia National Laboratories, United States

Additively manufactured custom-form batteries can maximize practical energy densities in applications where power sources must be more efficiently packed into a given space. Conversion cathodes paired with lithium metal further enable high energy density batteries. Carbon monofluoride (CF_x) and iron disulfide (FeS_2) are two conversion cathode materials of broad interest where little to no work has been carried out on the development of microextrusion methodologies for these materials. Meanwhile, silica sol based ionogels have been shown as a promising solution-deposited solid-state electrolyte, though no work has been carried out on the printing of this material for custom-form cells. In this work we demonstrate and optimize the printing of CF_x and FeS_2 cathode systems in custom-form lithium batteries, where the impact of ink solid composition on rheology, custom-form shape retention, cell capacity, rate, and cyclability is investigated. Additionally, the microextrusion of silica-based ionogels is demonstrated for the first time, where it is used with conversion or intercalation chemistries in custom-form cells. For the FeS_2 material system, it is found that ink solid compositions between 40-50% w/w are needed to adequately retain shape in custom-form configurations while maintaining up to 450 mAh/g cell capacity over 10 charge/discharge cycles. For the CF_x material system, ink solid compositions between 30-40% w/w are needed for shape retention in custom-forms and low process variance while cells discharge at capacities above 600 mAh/g at rates greater than C/25. Overall, this work demonstrates the microextrusion of energy storage materials for custom-form lithium batteries, which are of broad interest generally and for Sandia related applications where practical energy densities in a given system must be maximized. Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

11:45 AM *SF03.11.07
Next Generation Bioelectronic and Biosensing Devices via Nanoparticle 3D Printing Rahul Panat[1], Azahar Ali[1], Sandra Ritchie[1], Hailey Gordon[1], Chunshan Hu[1], Mark Nicholas[1], Bin Yuan[1], Sanjida Jahan[1], Sadeq Saleh[1], Eric Yttri[1] and S.J. Gao[2]; [1]Carnegie Mellon University, United States; [2]University of Pittsburgh Medical Center, United States

In this research, we develop a nature-inspired droplet-based nanoparticle 3D printing method that creates highly complex three-dimensional architected structures and use them to make a new class of biomedical devices. Fluid dynamics of aerosol microdroplets is used to stack nanoparticles in 3D space without any support materials to create such structures. First, we use this technique to realize a regenerable biosensor that detects COVID-19 antibodies and antigens within 10 seconds! This is the fastest detection time yet reported in literature and will have a significant positive impact on the course of the current pandemic. Several fundamental problems related to deformation during nanoparticle sintering were solved during this research. Second, we use 3D printing to create fully customizable brain-computer interfaces (BCIs) having recording densities of thousands of electrodes/cm2, which is 5-10x higher than the current state-of-the-art BCI technologies. Recording of action potentials from the brain of anesthetized mice was achieved with a high signal to noise ratio. Lastly, we also demonstrate highly flexible 3D printed cardiac biomonitors that lead to minimal patient discomfort. Our research thus focuses on advancing microfabrication via 3D printing and using the same to realize next-generation biomedical devices for the benefit of public health.

8:00 AM SF03.12.01
Freeform Embedded 3D Printing and Pressurized Thermo-Curing Platform for Customized Acrylic Biomedical Implants Qian Shi[1,2], Wen See Tan[1] and Juha Song[1]; [1]Nanyang Technological University, Singapore; [2]Xi'an Jiaotong University, China

Poly (methyl methacrylate) (PMMA) is a synthetic polymer commonly used for medical implants in cranioplasty and orthopaedic surgery owing to its good mechanical properties, optical transparency, and minimal inflammatory responses. Recently, the development of 3D printing opens new avenues in fabrication of patient-specific PMMA implants for personalized medicine. However, challenges are confronted when introduction of medical-grade PMMA resins to a conventional 3D printing process due to its dynamic viscosity and poor self-supportability during printing. In addition, the intrinsically exothermic polymerization of PMMA creates voids and pores within the printed product due to locally trapped MMA gas to which is often attributed poor mechanical performance and resultant opaqueness. Therefore, in this study, a freeform embedded 3D printing platform is proposed, followed by the pressurized thermo-curing for fabrication of customized PMMA implants with improved strength and transparency. An alginate-based supporting matrix is used to structurally support the extruded liquid acrylic resin during both 3D printing and post-curing processes; moreover, the autoclave reactor enclosing the alginate matrix and as-printed PMMA is utilized to generate temperature-dependent hydrostatic pressure, which serves for suppressing bubble formation and densifying polymerised PMMA during the post-curing. The 3D printed PMMA shows almost comparable mechanical behavior to that of PMMA from a conventional casting method because of well-densified uniform microstructures. Also, *in vitro* cytotoxicity results confirm that 3D-printed PMMA is as biocompatible as casted PMMA. As proof-of-concepts, various complex structures are also fabricated through this 3D printing and post-curing platform. We envisage that the proposed freeform 3D printing platform in conjunction with the pressurized post-curing method can also allow fabrication of various liquid resins such as epoxy resins and their composites besides acrylic resins.

8:05 AM SF03.12.02
3D Printed Magneto-Active Fibrous Scaffolds for Skeletal Muscle Regeneration and Stimulation Miguel Castilho[1,2], Ouafa Dahri[3], Gerardo Cedillo[1], Joost van Duijin[1], Joao Meneses[4], Joana Silva[4], Andre Pereira[4], Fernao Magalhaes[4], Jos Malda[1], Niels Geijsen[3] and Artur Pinto[4]; [1]UMC Utrecht, Netherlands; [2]Technische Universiteit Eindhoven, Netherlands; [3]Leiden University Medical Center, Netherlands; [4]Faculdade de Engenharia da Universidade do Porto, Portugal

Introduction
Skeletal muscle comprises the majority of tissue in the human body. It is essential to keeping posture, balance and mobility but also has crucial functions in many physiological and metabolic processes. Gene mutations leading to muscular dystrophies, such as Duchenne Muscular Dystrophy (DMD), have a major impact on patients' lives causing progressive disability and, ultimately, death due to cardiac or respiratory failure. Current therapeutic methods against DMD are very limited, including corticosteroids with severe side effects and experimental stem cell based therapies [1]. Despite great promise, this latter method has been restricted by the absence of 3D matrices that promote myofiber alignment and, importantly, support and stimulate muscle contractile force during regeneration. Furthermore, magnetic fillers embedded into 3D matrices can be used to externally induce cyclical deformation over implanted scaffolds to activate mechanotransduction pathways that will improve tissue regeneration. [2] In this work, we hypothesized that iron-modified reduced graphene oxide (rGO-Fe) with magnetic responsive properties can be processed by melt electrowriting (MEW) – a unique technique for the fabrication of highly ordered scaffolds with ultra-fine fibers – once mixed with polycaprolactone (PCL), and that well-organized fiber scaffold architectures can guide myofiber growth and remotely stimulate muscle contraction.
Materials and Methods
Composites of medical grade PCL and rGO-Fe were prepared by melt blending (rGO-Fe loadings between 2-20 wt%), and their processing compatibility was systematically investigated according to key MEW parameters. Fabrication of well-organized fibrous scaffolds with different laydown microstructures (square, hexagonal and auxetic) and macrostructures (straight and circular) was explored. The effect of rGO-Fe content and MEW processing parameters on fiber scaffold morphology, magnetic properties and mechanical performance was studied. Finally, fiber scaffolds were seeded with an immortalized mouse myoblast cell line (C2C12), encapsulated in an extracellular matrix-like hydrogel, to ensure uniform cell distribution within the fiber scaffold. Cell survival, morphology, tissue structure and functionality were studied after 7 and 14 days in culture.
Results and discussion
Well-organized scaffolds (microfiber diameter=10-15 µm) composed of rGO-Fe/PCL blends with square, hexagonal and auxetic microstructures were successfully manufactured for the first time using MEW. The smallest pore resolution achievable was 300 µm, for a scaffold thickness of 300 µm and 2 wt% rGO-Fe. Both hexagonal and auxetic architectures allowed for better deformation recoverability and approximately a 10-fold increase in applied strain with respect to conventional square fiber architectures. Additionally, above a rGO-Fe content of 10 wt%, scaffolds allowed for in-plane and out-of-plane deformation of near to 10% in the presence of magnetic stimulation. All scaffolds were cytocompatible, and hexagonal constructs showed enhanced myofiber alignment and organization with respect to square fiber architectures.
Conclusion
In summary, the present study demonstrated for the first time that highly ordered microfiber scaffolds based on rGO-Fe/PCL blends can be reproducibly produced and that these organized constructs are promising candidates to guide skeletal cell growth, stimulate contraction and (potential) regeneration under externally controllable magnetic triggering.

3D Printing of Antibacterial Polymer Devices Based on Nitric Oxide Release from Embedded S-nitrosothiol Crystals Wuwei Li[1], Yuanhang Yang[1], Christopher Ehrhardt[1], Nastassja Lewinski[1], David Gascoyne[2], Gary Lucas[2], Hong Zhao[1] and Xuewei Wang[1]; [1]Virginia Commonwealth University, United States; [2]Momentive Performance Materials, United States

Drug-eluting polymer devices play a pivotal role in combating foreign body reactions and infections associated with the functional devices. We report here a one-step 3D printing strategy to create drug-eluting polymer devices with a drug-loaded bulk and a drug-free coating. The spontaneously formed drug-free coating is crucial to biomedical applications because it drastically reduces the surface roughness and also functions as a protective layer to suppress the burst release of drugs. A moisture cured silicone is used as the printing ink that can be extruded based on its shear-thinning property and quickly vulcanize upon exposure to ambient moisture to retain the fidelity of the 3D printed patterns. S-nitrosothiol type nitric oxide (NO) donors in their crystalline forms are selected as model drugs because of the potent antimicrobial, antithrombotic, and anti-inflammatory properties of NO. Direct ink writing of the homogenized polymer-drug mixtures results in devices with very rough and ill-defined surfaces because of the exposed S-nitrosothiol microparticles. By further addition of a low-viscosity silicone (polydimethylsiloxane) into the ink, the low-viscosity silicone diffuses outwards upon deposition to form a drug-free outermost layer without compromising the printing integrity. S-nitroso-N-acetylpenicillamine (SNAP) embedded in the printed silicone matrix releases NO under physiological conditions from days to about one month. The micro-sized drug crystals are well preserved during the ink preparation and printing processes, which is one reason of the sustained NO release. Preliminary biofilm and cytotoxicity experiments confirm the antibacterial property and safety of the printed NO-releasing devices. This additive manufacturing platform does not require dissolution of drugs and involve no thermal or UV

curing processes, and therefore, offers unique opportunities to produce drug-eluting silicone devices in a customized manner.

8:15 AM SF03.12.04
Cellulose Nanocrystals-Based All-3D Printed Piezoelectric Nanogenerator for Mechanical Energy Harvesting Application Kuntal Maity, Anirban Mondal and Mrinal Saha; University of Oklahoma, India

Rapid development of wearable electronics, accessible and environmentally sustainable energy generation has attracted an extensive attention in next generations. In this context, piezoelectric materials have the ability of generating electric signal when it is subjected to certain mechanical stimuli, such as stress, elongation, tension, vibration, etc.[1] It has been found that different types of piezoelectric materials are reported so far, for example, as a semiconductor (ZnO, ZnS, GaN, etc.), ceramics (PZT, $BaTiO_3$, $NaNbO_3$, $KNbO_3$, KNN, $ZnSnO_3$, etc.), polymers (PVDF and its copolymers, polyamides, etc.) and some natural materials (bones, hairs, collagen fibrils, peptide, cellulose, sugar cane, etc.).[2] Among them, natural piezoelectric materials possess several advantages over the other class of piezoelectric materials. For example, cellulose, a novel piezoelectric polymer is almost endlessly available polymeric raw material that exhibits fascinating natural structure and also treated as eco-friendly and biocompatible product. In addition, cellulose is also utilized for versatile sensing applications and easily obtained from various plants as micro-fibrils consist of glucose−glucose linkages with linear chains. On the other hand, the advancement of three-dimensional (3D) printing technology has recently attracted a great deal of attention as the 3D printing enables the fabrication of materials with intricate macroscopic shapes and controlled microstructures and properties.[3] Cellulose nanocrystals (CNCs) have recently received significant attention due to its high Young's modulus, high strength, light weight, low density, sustainability, biocompatibility, biodegradability, recyclability, and abundance nature. As a result, it is conceivable and advantageous to substitute traditional 3D printing thermoplastics with cellulosic materials such as CNCs. In addition, the choice of electrodes and their compatibility with 3D printed surface remain challenging tasks, particularly when device performance, durability and implant ability are considered.
Here we present an all-3D printed piezoelectric nanogenerator (PNG) based on CNCs by direct-ink write (DIW) process for energy harvesting from various types of mechanical vibrations. We achieved the all-3D printed multilayer structure where active piezoelectric ink CNC is printed in between two printed electrodes (top and bottom). For electrode printing, the conductive ink is developed using the carbon nanotube (CNT) into CNCs matrix. Interestingly, we address the electrode compatibility issue by keeping the same polymer matrix (CNCs here) through the whole structure and subsequently enhancing the interface compatibility of the piezoelectric active layer and the electrode layers. Noteworthy that, for distinct electrode and piezoelectric material, mechanical pressure imparting leads to the delamination of the interfacial layer due to the mismatch of Young's modulus, and results in the degradation of PNG performance. The crystallinity of the printed CNC was determined from X-ray diffractometry (XRD) spectra. The Fourier transform infrared spectroscopy (FT-IR), Raman spectroscopy are used to examine the vibrational bands of CNC and CNT. The surface morphology is characterized by Field emission scanning electron microscope (FE-SEM) images. The mechanical properties are done by stress-strain testing. Owing to excellent electrode contact-adherence, the PNG exhibits an effective conversion of mechanical energy of human finger movements into electrical energy (~10 V). Importantly, the fatigue test under continuous mechanical impact (over 1000 cycles) shows great promise as a highly durable mechanical energy harvester. Thus the all-3D printed PNG will play an essential role in future self-powered electronics.

3D Printing of Living Materials Andre R. Studart; ETH Zurich, Switzerland

Exploiting microorganisms to fabricate engineered living materials has gained impulse in recent years due to the sustainable nature of biological processes and the possibility to add living functionalities to synthetic materials, including self-healing, self-regeneration and adaptation. In this talk, I will show how 3D printing can be used to leverage the metabolic activity of microorganisms and create a new generation of complex-shaped living materials. To this end, biocompatible hydrogels are thoroughly designed to enable loading with selected microorganisms and printing using the extrusion-based Direct Ink Writing technique. By formulating inks with suitable rheological properties and appropriate culture media, it is possible to control the geometry of the printed object and promote the proliferation and growth of material-forming microorganisms within the deposited structures. Using selected examples, I aim to demonstrate that the achieved shape programmability and tailored spatial distribution of microorganisms makes 3D printing a powerful tool for the manufacturing of functional living materials.

8:50 AM SF03.12.06
All-Organic Flexible Nanogenerator with 3D Printed Ferroelectrets and Fabric Electrodes Ningzhen Wang[1], Kerry L. Davis[1], Robert Daniels[1], Mohamadreza Arab Baferani[1], Michael Sotzing[1], Chao Wu[1], Reimund Gerhard[2], Gregory Sotzing[1] and Yang Cao[1]; [1]University of Connecticut, United States; [2]University of Potsdam, Germany

Ferroelectrets with internal polarized pores are an appealing solution for self-powered sensors and wearable energy harvesting devices due to its flexibility and strong piezoelectric response. Additive manufacturing, or 3D printing, enables the designability of pore structures and the piezoelectric performance of ferrroelectrets to be optimized further than traditional manufacturing methods. Our previous investigation found that the compressible fabric-based electrodes and the outer surface of the ferroelectret film can form an additional electro-electret and can significantly contribute to the overall piezoelectric performance. In this work, polypropylene (PP) ferroelectrets with different kinds of porous structures (ellipsoid, hexagon, triangle, spherical protrusions) were fabricated by 3D printing and polarized through corona discharge. The all-organic ferroelectret nanogenerator (FENG) was then assembled after applying the electrodes of poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS)-coated Spandex fabric. It was found that the PP ferroelectret with spherical protrusions on the surface, which is the optimal balancing in film thickness, porosity and elastic modulus, shows the best short-circuit current and open-circuit voltage under the same compressive condition. The performance of the all-organic FENG was demonstrated by charging several capacitors and lighting up the light emitting diodes (LEDs) successfully. The 3D-printed porous structures would be conducive for studying the charge storage mechanism of ferroelectrets due to the pores' regularity and designability. Moreover, because of its easy integration with clothing, shoes, carpets, *etc.*, the all-organic FENG with fabric electrodes would be a competitive candidate in wearable electronics field.

9:05 AM SF03.12.07
3D Bioprinted Functional Surgical Mesh for Soft Tissue Repair Crystal S. Shin[1], Aparn Adumbumkulath[2], Remya Ammassam Veettil[1], Richard Lee[1], Pulickel Ajayan[2] and Ghanashyam Acharya[1]; [1]Baylor College of Medicine, United States; [2]Rice University, United States

A hernia is a common soft tissue injury resulting from a weak or defective abdominal wall, causing protrusion of the intra-abdominal contents. Surgical implantation of a prosthetic mesh is the most common hernia repair technique to support and reinforce the abdominal wall. Over 400,000 incisional hernia repair surgeries are performed annually in the US. However, surgeries involving prosthetic meshes induce local inflammatory responses leading to the

formation of visceral adhesions, hardening, and gradual shrinking of the implanted meshes, which require additional surgeries. Hence, there is a critical need for a soft tissue repair scaffold to minimize post-surgical complications.
This study presents the development of a 3D-bioprinted functional biomaterial-based surgical mesh (Biomesh) that modulates local inflammation. We designed and fabricated Biomesh to yield a soft, pliable, and mechanically strong mesh by in situ phosphate crosslinking of polyvinyl alcohol. The crosslinking of hydroxyl groups with phosphate groups gives a negative surface zeta potential of Biomesh. We showed that the negatively charged Biomesh "captured" positively charged pro-inflammatory cytokines such as IL-1β, IL-6, and TNF-α via electrostatic interactions. We also reported that in a rat ventral hernia model, the implantation of Biomesh modulated inflammation in the surgical site and prevented visceral adhesions even after 8 weeks compared to the polypropylene mesh implant. Thus, this study successfully demonstrated the therapeutic efficacy of Biomesh as an intrinsically inflammation-modulating surgical mesh without the need for anti-inflammatory agents for soft tissue repair surgery.

9:20 AM SF02.08/SF03.06.03
Wearable, 3D Printed, Personalized, Wireless and Battery-Free Tools for Chronic Recording of Biosignals Philipp Gutruf; University of Arizona, United States

The concept of digital medicine, which broadly deals with streams continuous information from the body to gain insight into health status, manage disease and predict onset health problems, is currently only gradually developing.[1][2] Key technological hurdles that slow the proliferation of this approach are means by which clinical grade biosingals are continuously obtained without frequent user interaction.[3] To overcome these hurdles, solutions in power supply and interface strategies that maintain high fidelity readouts function chronically are critical. Current approaches for high fidelity recordings typically rely on adhesive interfaces that are subject to epidermal turnover, limiting sensor lifetime. Additionally, they rely on electrochemical power supplies which are subject to frequent recharge, add bulk and weight, require user interaction and introduce motion artefacts. Here we introduce a new class of devices that overcomes the limitations of current approaches by utilizing digital manufacturing to tailor geometry, mechanics, electromagnetics, electronics, and fluidics to create unique personalized devices optimized to the wearer. These elastomeric, 3D printed and laser structured constructs, called biosymbiotic devices, enable adhesive-free interfaces and the inclusion of high performance, far field energy harvesting to facilitate continuous wireless and battery-free operation of multimodal and multi device, high-fidelity biosensing in an at-home setting without user interaction.

SESSION SF03.13: 3D Printing Functional Composites and Devices
Session Chairs: Sohini Kar-Narayan and Ethan Secor
Wednesday Morning, December 8, 2021
SF03-Virtual

10:30 AM SF03.13.02
Additive Manufacturing of Functional Emulsions Aaron Haake[1], Ravi Tutika[2], Michael D. Bartlett[2] and Eric Markvicka[1]; [1]University of Nebraska Lincoln, United States; [2]Virginia Tech, United States

Elastomer composites with embedded liquid phase fillers are an emerging material architecture for creating highly functional elastomer composites that are soft, elastically deformable, and exhibit unique combinations of electrical, thermal, and mechanical properties. The material architecture consists of a functional emulsion of liquid phase fillers, such as liquid metal microdroplets, dispersed in an uncured hyperelastic polymer that can be cured into an elastomer composite. These functional emulsions are typically manufactured in bulk using replica molding or soft lithography techniques that results in primarily spherical inclusions with little control of shape, orientation, or spatial placement. Here, we will introduce a new additive manufacturing process to actively tailor the liquid inclusion microstructure of functional emulsions throughout a manufactured part to control the electrical, thermal, and mechanical properties of soft elastomeric composites of complex geometry. The material microstructure is actively tailored through a direct ink write alignment processing technique and the creation of a new emulsion ink that is suitable for additive manufacturing. The programmed inclusion shape and orientation is characterized as a function of material properties and processing parameters. Individual printed filaments and printed sheets are experimentally characterized for mechanical and functional properties. Finally, the ability to print sheets and multilayer parts with varying material microstructure is demonstrated. This manufacturing method for processing functional emulsions provides new opportunities to create soft elastomer composites with directly tunable and addressable material properties and performance.

10:35 AM SF03.13.04
Effects of Extrusion-Based Additive Manufacturing on Thermoelectric Transport in Elemental Ni and Bi Victoria J. Stotzer, Christian Apel, Ashley Paz y Puente and Sarah J. Watzman; University of Cincinnati, United States

Conventional synthesis and manufacturing of thermoelectric materials is often tedious, time-intensive, and expensive with severe limitations in terms of resultant sample geometry and size. While traditional growth techniques have been used for many years in the field, as the interest in thermoelectric devices and environmental efficiency has increased, the wastefulness of the process has become abruptly apparent. Recently, popularity has grown for using additive manufacturing methods in materials science fields, offering the potential to decrease fabrication time and cost for both samples and devices. Nevertheless, success in additive manufacturing has been majorly limited to metals and polymers, while the manufacture of thermoelectric semiconductors has identified current limitations [1]. These limitations include the need for post-processing that often leads to pore formation and decreased adhesion [1]. Additionally, current work has not extensively studied how additive manufacturing techniques alter thermoelectric transport. In this work, we approach the problem starting with Ni, whose thermoelectric properties are well known [2], albeit less compelling than those of Bi2Te3 and other conventional thermoelectric materials. Specifically, we focus on the particle-laden ink extrusion printing process, which has proven successful with producing bulk Ni samples [3]. This process contributes to the formation of micro and macro cracks and pores in bulk samples. Through altering printing parameters and sintering techniques, we study the microstructure of printed samples with a specific focus on densification, composition, and pore and crack concentration. Then through comparison of the temperature dependence of thermopower, electrical resistivity, and thermal conductivity in the printed samples to those made using traditional crystal growth techniques, including dense and porous polycrystalline samples, the effects of the particle-laden ink extrusion printing processing on thermoelectric transport properties can begin to be made clear. This information is then used to inform the extension of the particle-laden ink extrusion printing technique to more efficient thermoelectric materials, in this case starting with Bi, which are more demanding in their

manufacturing requirements. Bi makes an ideal starting point due to the well-known transverse thermoelectric transport properties. Pure Bi has also not previously been printed using extrusion based additive manufacturing; therefore, we present a newly-developed low-temperature method.

10:40 AM SF03.13.05
Smart Viscoelastic Materials via Viscous Solution 3D Printing (VSP) Methods—From Elastomers to Metals Fabrication Rigoberto C. Advincula[1,2,3]; [1]Case Western Reserve University, United States; [2]The University of Tennessee, Knoxville, United States; [3]Oak Ridge National Laboratory, United States

3D Printing methods have enabled rapid prototyping and production of parts and OEMs that have been considered a paradigm shift in several industries. In the area of polymers, thermoplastics, thermosets, and elastomers based on their thermo-mechanical properties have been matched with their processability. However, it is not as simple as the classification into these groups when it comes to their intended applications and the development of new properties. There are a number of choices for 3D printing methodologies (FDM, SLA, SLS, VSP)
which can make use of blended or formulated compositions. However, this talk will focus on a class of viscoelastic materials that can be 3D printed even at room temperature. This will be exhibited in the following examples: 1) Elastomeric foam materials from plastics based on polyurethane, 2) Silicone materials with high electrical and thermal conductivity, and 3) Metals from bio-based sustainable viscoelastic materials. The design of the materials and the geometry are very important and must be matched with the 3D printing parameters. The utilization of rheological and viscoelastic materials studies is important prior to the study as these emphasize shear thinning behavior, sufficient yield stress, and thixotropic behavior to achieve high fidelity with the CAD design.

10:55 AM *SF03.13.06
Printing Methods for Flexible and Conformal Wearable Sensors Ana C. Arias; University of California, Berkeley, United States

Wearable sensors are increasingly prevalent in health monitoring and human–machine interface applications as a result of improvements in their size and comfort. Flexible and printed electronics have enabled the fabrication of wearable sensors that can mechanically bend and conform to non-planar and dynamic surfaces of the human body, allowing physiological signals of low bandwidth to be measured. Hybrid systems that combine flexible sensors with rigid computational components on a separate substrate have also been developed. To provide a real-time analysis of physiological signals, wearable biosensors can implement machine-learning models for signal processing. Traditionally, skin bioelectrodes have relied on wet electrodes, metal or composite electrodes coated in an electrolytic gel, applied by trained professionals. These wet electrodes ensure consistent electrode-skin contact but are susceptible to impedance mismatch related noise and interference as they dry out. In addition, the skin preparation required for wet electrodes (often lead to skin-irritation and hair loss. We have developing methods for 3D printed dry electrodes that are optimized for different sensing locations. In this talk I will discuss several fabrication methodologies and materials used for skin conformal sensors, including dry electrodes. These electrodes exhibit high effective surface areas and when compared to wet electrodes of the same area, they express comparable electrode-skin impedances. Applications in electrocardiography (ECG), electromyography (EMG), and electroencephalography (EEG) will also be discussed.

11:25 AM SF03.13.07
Polymer and Nanoparticle Composites in Layered Nanostructures Kenan Song, Weiheng Xu, Sayli Jambhulkar, Dharneedar Ravichandran and Yuxiang Zhu; Arizona State University, United States

Layer-structured composites have broad applications in structural systems, thermal insulation, microelectronics, optics, and biomedical devices. The design and assembly of layered structures containing polymer and particle materials have been challenging in sub-microscale. The bottleneck is the lack of appropriate manufacturing compatible with soft matter and nanomaterials. This research will demonstrate three examples in 1D, 2D and 3D structures containing polymer and nanoparticle layers for different applications.

The first example was the use of polymer-nanoparticle interphase design to achieve 1D fibers. As well known that polymer fibers of microscale with continuous nanoparticle distribution are difficult to process due to the stiffness mismatching between polymers and nanoparticles. This example will demonstrate unique fiber spinning that blends polymers and nanoparticles at different layers. The soft macromolecules and rigid particles will be stacked along the radial or the fiber axis for enhanced mechanical, electrical, and thermal properties. The unique material system of composite fibers were used as piezo- and chemi-resistive sensors.

The second example exhibited a thin composite film on compliant structures for thermoelectric generators (TEGs). The stacking of 2D films contained conjugating polymers in-situ polymerized at the presence of nanoparticles. During the processing, the polyaniline molecules were found to coat evenly on carbon nanotubes and led to high electrical conductivity, power factor, and enhanced mechanics. Thus, these compressed films were exhibited on compliant structures and used as wearable devices for human body heat collection. The generated electricity was for powering wearable sensors in detecting human movement and health conditions.

The third demonstration utilized layer-by-layer-based deposition techniques. Both additive manufacturing (e.g., 3D printing) and coating methods were used on the same processing platform. One dimensional carbon nanofibers (CNF) and 2D MXene particles were used as examples to be selectively deposited on polymer surfaces with pre-printed patterns. The control of the surface patterns and the nanoparticle assembly conditions (e.g., thermodynamic parameters, nanoparticle interactions, solid-liquid-air contact lines, etc.) led to selective deposition and preferential alignment of nanoparticles. As a result, the conductive paths on the substrate were developed to be anisotropic; following this characterization, the multifunctional sensitivity to strain, temperature, chemical liquids and volatile organic compounds (VOCs) were also displayed.

11:40 AM SF03.13.08
Hybrid Printing of Wearable Piezoelectric Sensors Yipu Du[1], Ruoxing Wang[2], Minxiang Zeng[1], Mortaza Saeidi-Javash[1], Wenzhuo Wu[2] and Yanliang Zhang[1]; [1]University of Notre Dame, United States; [2]Purdue University, United States

Piezoelectricity provides an ideal electromechanical mechanism with emerging applications in wearable devices due to its simplicity and self-powered nature. However, the 3D printing of piezoelectric devices still faces many challenges, including material printability, high energy poling process, and low dimensional accuracy. This study demonstrates, for the first time, a tellurium nanowire-based poling-free piezoelectric device fabricated by a hybrid printing method. The home-built hybrid printer consists of an extrusion printing head for structural material fabrication and an aerosol jet printing head for functional material fabrication. The aerosol jet printed tellurium nanowire demonstrates piezoelectric properties without the need for any poling or post-

printing processing due to the unique properties of the tellurium nanowires coupled with the aerosol jet printing process. The sliver nanowire electrodes printed by aerosol jet printing demonstrate excellent conductivity and stretchability without the need of sintering. The extrusion method is employed to print the silicone films which serve as the stretchable substrate and the electrical insulation layers between the printed tellurium and silver. The fully printed, sintering-free and poling-free, and stretchable piezoelectric device opens enormous opportunities for facile integration with a broad range of printed electronics and wearable devices.

SESSION SF03.14: On-Demand
Sunday Morning, December 5, 2021
On-Demand

8:00 AM SF03.04.09
Customized 3D Printer Filament with Metalized Ceramics Antwine McFarland, Anusha Elumalai and David K. Mills; Louisiana Tech University, United States

Halloysite nanotubes (HNTs) are naturally occurring clay nanotubes having 50 nm external diameters, 15 nm luminal diameters, and 500-1500 nm lengths on average. *Halloysite* is a two-layered aluminosilicate, chemically similar to kaolin, and has a predominantly hollow nanotubular structure in the submicron range. HNTs typically display an inner diameter ranging from 15–50 nm, an outer diameter from 30–50 nm, and a length between 100–2000 nm. HNTs exhibit vigorous activity, especially when coated with metal, and have found industrial uses due to their properties as a filler leading to strength reinforcements. We created a new nanocomposite 3D printer filament designed to manufacture replacement parts in a matter of hours, not days, using a 3D scanner and a commercially available 3D printer. Our composite consists of HNTs and nylon (6 and 12). Our lab analysis (3-point bed test, crystallinity measurements, elasticity, hardness tests) of this printer filament products showed significant increases in mechanical strength. In addition, DSC analyses showed enhancement of the nanocomposite filament's thermal resistance. Fused depositional modeling (FDM) or high-intensity laser-powered projector printing (LAPS) were used to design and print high-end, high-performance devices, parts, and tools. Regardless of which nylon type or a blend of nylon, the addition of HNTs significantly reinforced the material properties of 3D printed parts and tools. 3D printed constructs showed a higher bend capacity, increased hardness, and elasticity while keeping the inherent native properties of nylon. The filaments are the most costly to produce. The application of nylon with additives 3D printing will enable 3D printed devices, and parts produced on-site. Examples include anti-icing gasket, O-rings, sump cover, non-critical components, and standard requirements such as surface toilet cover, door handles, and light switches. These devices can be custom-fitted, produced on-demand, and in a rapid manner. The complexity of design, internal or external architectures, does not significantly challenge the fabrication of high-quality finished parts. Accordingly, this technology can move beyond its original low-volume, high-value market niches toward economical and sustainable manufacturing on an industrial scale.

8:05 AM *SF03.02.03
Printing Programmable Materials Skylar Tibbits; Massachusetts Institute of Technology, United States

Programmable Materials are physical materials that can be embedded with information and capabilities like logic, actuation, or sensing.We are now able to design and fabricate these material compositions through new forms of 3D and 4D printing. In this talk we will present the fundamental principles for programmable materials through material properties, geometry, activation energy and physical transformation. We will then explore various material properties and fabrication processes that enable new programmable behaviors and functionality in our built environment. By taking advantage of these new material behaviors and emerging fabrication processes we are now able to create higher performing products which tap into natural forces like moisture, light, temperature, or pressure to become highly active and tuned to their environment.

1:30 PM SF04.01.02
3D Printing of Corn-Based Natural Fiber Composites via Direct Ink Writing Md Nurul Islam and Yijie Jiang; University of North Texas, United States

Natural materials and composites are receiving increased attention for sustainable manufacturing. They are renewable, biodegradable, and inexpensive. Manufacturing using natural resources into mechanically-robust materials alleviates environmental concerns associated with the use of petroleum-based materials. Cellulose fibers have been used as fillers in polymer matrices to make composites. However, the hydrophilic cellulose fiber are incompatible with synthetic hydrophobic polymers[1], leading to poor interfaces between fillers and matrix. In addition to traditional manufacturing, additive manufacturing enables the customized and precision fabrication of composites with the control of internal microstructures[2,3]. Although there are emerging researches using natural materials into 3D printing[4,5], limitations on printable materials and their mechanical robustness exist.
In this study, we develop 3D printable biocomposites entirely from corn byproducts and waste. We extract cellulose microfibers from corn husks by alkalization, delignification and high-speed homogenization. FTIR spectrum reports the effective removal of hemicellulose and lignin from corn husk. The extracted cellulose fibers (60 um in length and 10 um in diameter) are distributed into compatible matrices derived from corn starch to formulate 3D printable biocomposites. Ink preparation is tailored with water content and thermal treatment to achieve desired rheological properties for direct ink writing (DIW) 3D printing and tunable mechanical properties for the printed samples. The printed triangular cellular architectures using composites (10 wt% fiber) show 2 and 1.5 times increase in stiffness and strength, respectively, over the pure starch. Besides, preheating time substantially affects the mechanical properties of the printed biocomposites. The specific young's modulus and specific strength increase 159.8% and 160% for 14 minutes preheating at 120^0C compared to 6 minutes preheated samples, correlating to the microstructures evolution at different preheating times. The results indicate a comparable mechanical performance compared with other 3D printed thermoplastics. The manufactured biocomposites consist of purely natural components will have potential applications in medical and food area.

1:45 PM SF04.01.03
Multifunctional Polyethylene Based Composite Material for Space Applications Lembit Sihver[1,2,3], Cody Alison Paige[4] and Svetlana V. Boriskina[4]; [1]Cosmic Shielding Corporation, United States; [2]Technische Universität Wien, Austria; [3]Chalmers University of Technology, Sweden; [4]Massachusetts Institute of Technology, United States

To enable the planned rapid growth of both government and private operators in space, including satellites, space tourism and manned missions to the Moon and to Mars, a realistic and holistic approach to radiation risk reduction is needed. In deep space, ionizing radiation from Galactic Cosmic Rays (GCRs) and Solar Energetic Particles (SEPs) from the sun pose a critical threat to both humans and electronic equipment. GCRs provide a chronic, slowly varying, highly energetic background source of High-Z high-Energy (HZE) particles, while the Sun's activity varies with an 11-year cycle during which the Sun produces Solar Wind (SW) at varying intensities and unpredictable bursts of Solar Particle Events (SPEs). SPEs can be a nightmare for the astronauts and cause acute radiation damage, while GCRs can cause long term damage including cancer, cataracts, central nervous system and cardiovascular system damage, fibrosis, neurodegeneration, digestive diseases, and immunological, endocrine, hereditary effects, and cognitive impairment.

The GCRs and SPEs can also cause degradation of micro-electronics, optical components and solar cells. Spacecraft electronics are especially susceptible to radiation effects that emerge from interactions with HZE particles, but highly energetic gamma photons, neutrons and protons can also damage electrical components. Since the exposure of humans and electronics to GCRs and SPEs in deep space, and on the surface of the Moon and Mars, will cause huge radiation risks, it is very important to apply the best possible protection for both humans and electronics. Currently, the only proven and practical countermeasure to reduce the exposure to GCRs and SEPs is passive shielding. It is well known that low atomic number (Z) materials are most effective for shielding in space, and liquid hydrogen has the maximum theoretical performance as a shielding material. Hydrogen is not, however, a practical shielding material, being a low temperature liquid associated with practical handling problems and explosion risks. Hydrogen concentrated in specially engineered and doped polyethylene based composites, however, is ideal for stopping primary cosmic and solar radiation, as well as secondary neutrons created when the primary particles are impinging on the spacecraft. Low atomic number (Z) materials also produce less electron-positron pairs and Bremsstrahlung than materials with higher Z, such as aluminum alloys, which are used in conventional satellites and spacecraft.
Additives can improve the flame retardancy and inhibit the release of toxic gases as well as absorption of neutrons created when HZE particles hit the shielding and other components of the spacecraft. The material can also be produced for protection against micrometeoroids, debris, extreme temperature variations and protection against atomic oxygen present at low Earth orbit (LEO).

We will present the basic physics, as well as simulated and experimental properties of a 3D printed specially engineered and doped polyethylene based composite, which can be manufactured with different degrees of flexibility, stiffness and thermal conductivity. We have demonstrated that hierarchical engineering of PE materials and composites enables drastic modification of their light absorption, thermal emission, heat, and moisture transport properties [1,2]. The material can therefore be used for many different applications, ranging from radiation shielding of components inside a satellite or spacecraft, to a construction material for satellites, to spacecraft and space habitats, and components in intravehicular (IVA) and extravehicular (EVA) spacesuits.

2:00 PM SF04.01.04
Fatigue Damage Reversal in Self- Healing Vitrimer and Its Composites Mithil Kamble, Nikhil Koratkar and Catalin R. Picu; Rensselaer Poly Institute, United States

Thermosetting polymeric composites which are ubiquitous in structural applications due to their superior strength and stiffness compared to their thermoplastic counterparts. These superior properties are principally imparted by dense and permanent crosslinking present at the molecular network level. However, as thermosets are subjected to fatigue loading, they accumulate damage in terms of ruptured crosslinks which eventually result in catastrophic failure. Vitrimers provide an advantage relative to the standard thermosets in that the network is transient and damage introduced by excessive loading may heal. In this work we explore the ability of the vitrimer to repair damage introduce during fatigue loading. We work with a vitrimeric system based on epoxy resin and adipic acid, with a suitable catalyst. The system has stiffness and strength comparable to those of conventional epoxies. We demonstrate that the vitrimer can be periodically healed by heating at temperature between Tg and Tv. Further, we develop and test a carbon fiber vitrimer composite which can be similarly healed by periodic healing. Such composites can pave the way for next generation of structural components which are recyclable and have longer service lifespans.

The Role of Pulsed Lasers in Progress of 3D Assembly and the Materials Used Jayant Saksena[1], Binod Subedi[1], Roger Narayan[2] and Douglas B. Chrisey[1]; [1]Tulane University, United States; [2]North Carolina State University, United States

Direct writing describes any technique or process capable of depositing, dispensing, or processing, including removal of, different types of materials over various surfaces following a present computer-generated pattern. Indeed, 3D assembly involves the confluence of information, energy, and materials in different and often novel platforms. This presentation will describe the unique role that materials play in present day pulsed laser and photonic processing of 3D hierarchical assemblies ranging from mesoscopic passive and active electronics and engineered tissue constructs to nanometric control of surfaces for energy storage and conversion. In all cases there is a need to refine and optimize the aforementioned confluence to have better control over the function of the final product. The energy supplied by pulsed lasers and photonic processing can be used to simply heat materials to high temperatures almost instantaneously allowing for rapid synthetic transformations or to initiate photolytic processing such as in Click Chemistry. In all cases there is the absorption of light, electronic excitation, and followed by the relaxation of excited states into the desired material phases as well as shapes and sizes. Therein the photon-material interaction plays a paramount role and the energy attributes of intensity, wavelength, pulse width, and repetition rate make this route to processing very powerful. The distinctive control of pulsed lasers and photonic processing make this approach to processing materials for 3D assembly especially enabling and amenable to roll-to-roll manufacturing.

Polymeric Nanoclay Scaffold Blocks with BMP Coatings for Enhanced Long-Term Bone Regeneration Kalpana Katti, Krishna Kundu and Dinesh R. Katti; North Dakota State University, United States

Often, the time required to regenerate bone in nonunion bone defects using tissue-engineered scaffolds is too long for practical clinical relevance. Hence we have designed novel interlocking blocks using 3D printed miniature molds to fill large bone defects. The scaffold blocks are fabricated using nanocomposite polymer materials with amino acid-modified nanoclays. In addition, these blocks are coated with bone morphogenic proteins (BMP-2 and BMP-7) to initiate and speed up bone growth. On seeding the scaffolds with a combination of human mesenchymal stem cells and osteoblasts, the BMP-coated scaffolds exhibit a much higher formation of the extracellular matrix formed within three days. We also observe enhanced osteogenic differentiation of MSCs at the interfaces between the blocks and the formation of bone mimetic fibril-like collagen. We also observe that the interlocked assembly of the scaffold blocks maintains the mechanical integrity of a single cylindrical scaffold. We also report long-term bone growth over a period of up to 9 weeks on the scaffolds. The coating of scaffolds with BMP-2 and BMP-7 increases cell viability on the scaffold interlocking blocks. We also observe increased intracellular ALP levels in interlocking blocks coated with BMPs indicating enhanced osteogenic differentiation of MSCs. Further immunocytochemistry and FTIR experiments indicate the formation of bone mimetic fiber-like collagen formation and increased ECM formation in the BMP-coated scaffolds. The role of BMPs on long-term bone growth is significant. The degradation in material properties of a hydrated scaffold over a period of 0 to 9 weeks is compared with increasing mechanical properties of the cell-seeded scaffold with the formation of ECM using the nanomechanical investigation of elastic modulus of the scaffolds. The changes in mechanical properties are consistent with the gene expressions indicative of enhanced osteogenesis in the scaffold blocks. Thus, here a novel BMP-coated interlocking blocks system is presented for accelerated bone growth.

Late News: 3D Printable PLA/PP/WO3 Nanocomposites Mohammed L.M.Shaath[1] and Mohamed Ansari Mohamed Nainar[1,2]; [1]Universiti Tenaga Nasional, Malaysia; [2]Institute of Power Engineering, UNITEN, Malaysia

3D printable materials reinforcement and fabrication processes have attracted many scientists and researchers, as most industries and consumers require tailored materials specifically suitable for their needs. These materials are usually chosen for their specific characteristics and attributes, which can enhance the desired characteristics or reinforce the polymer, while fabricating the materials by physical blending then by extruding it into filaments with a specific dimensions. In this study a method for the preparation of 3D printing wire rods of Poly (lactic acid) (PLA) / polypropylene (PP)/ Tungsten tri-oxide (WO_3) nanocomposite with up to 10wt% of WO_3 constitution was developed. The results showed that the interfacial compatibility of WO_3 and PLA was improved by adding 20wt% of PP. The addition of nano sized WO_3 with PLA greatly increased the tensile strength of the PLA composites and addition of PP has enhanced the elasticity of the composites. Moreover, morphological studies revealed the brittle behaviour of the PLA/WO_3 composites has shifted to ductile behaviour by the influence of PP phase in the nanocomposite.

Keywords: Poly (lactic acid) (PLA), Tungsten-trioxide (WO_3), polypropylene (PP), nanocomposites, 3D printing (3DP)

Magnetorheological Elastomers Using Hybrid Magnetic Particulate and Magnetic Annealing for Fused Deposition Modeling Sarah Ziemann, Nathan Fischer, Jimmy Lu, Alex Robinson, Thomas J. Lee and Brittany Nelson-Cheeseman; University of St. Thomas, United States

Magnetorheological elastomers are smart materials that are magnetoactive, meaning they can deform and change shape based on the application of a magnetic field. These magnetic elastomers perform best in soft robotics and biomedical applications when they have increased anisotropy, or different properties along different axes. Magnetic annealing and the use of hard magnetic particulate are common ways to increase the anisotropy- and thus performance- of magnetic elastomers. To further increase this anisotropy, one can utilize fused deposition modeling (FDM), also known as 3D printing. FDM generates different underlying infill patterns within the sample, creating meso-scale anisotropy [1]. FDM of magnetic elastomers has recently been shown to control the magnetic anisotropy within these materials [2]. To create added micro-scale anisotropy by aligning magnetic particulate within the sample, magnetic annealing is used during extrusion of the elastomer filament. Hard or permanent magnets can be oriented using an external alignment field, and strontium ferrite is particularly interesting because it costs less than other rare-earth magnets (or materials). Previous studies in this group have focused on carbonyl iron, a soft or impermanent magnet that showed a large amount of magneto-action, though small changes in its properties after magnetic annealing. Strontium ferrite shows a smaller magnitude of magneto-action in comparison to carbonyl iron, but it has more distinct anisotropy effects after magnetic annealing. Combining these two magnetic particulates into one hybrid composite elastomer filament leverages these trade-offs, creating innovative and emergent mechanical, magnetic, and magnetoactive properties. Our thermoplastic magnetic elastomer composite is created using solvent-casting techniques with 15 vol% $SrFe_{12}O_{19}$ particulate, 10 vol% $SrFe_{12}O_{19}$/5 vol% carbonyl iron, and 5 vol% $SrFe_{12}O_{19}$/10 vol% carbonyl iron. The material is then extruded into FDM filaments. During the extrusion process, some filament of each different chemical composition is magnetically annealed in an axial applied field created by NdFeB magnets, while other filament extruded without magnetic annealing acts as the control. Mechanical stress vs. strain curves of the extruded filaments are acquired using an MTS tensile testing machine. Magnetic hysteresis loops are measured using a vibrating sample magnetometer (VSM). In order to determine the relative level of magnetic anisotropy within the samples due to these factors, hysteresis loops with the field applied parallel and perpendicular to the axis of extrusion are compared to one another. Magnetoactive testing is used to measure the mechanical deflection angle as a function of the strength of a transverse applied magnetic field. Understanding the mechanical, magnetic, and magnetoactive properties of these magnetorheological elastomers provides insight into how magnetic anisotropy can be controlled by a combination of hard and soft magnetic particulate, magnetic annealing, and FDM for optimized performance.

SF04.02.03
Tuning the Mechanical Properties of Nanoglass-Metallic Glass Composites with Brick-and-Mortar Designs Suyue Yuan and Paulo Branicio; University of Southern California, United States

We use molecular dynamics simulations to characterize the mechanical behavior and failure mechanisms of $Cu_{64}Zr_{36}$ metallic glass-nanoglass (MG-NG) composites. The composites are designed with a brick-and-mortar arrangement consisting of a soft and highly ductile NG matrix and a strong MG second phase. The results show that the best compromise of mechanical properties is reached at a 30/70% volume fraction of the MG/NG phases, when the ultimate strength of the NG is distinctly improved from ~1.8 to ~2.0 GPa without inducing localized plasticity. In addition, MG bricks arranged in a staggered way can further synergize the mechanical properties of the two phases by effectively distributing the stress load, hindering the buildup of local stress hotspots, and preventing the generation of critical shear bands.

SF04.02.04
Composite Aerogels of Cellulose/Poly(Lactic Acid)(PLA) Made by Directional Freezing Yejin Park and Jonghwi Lee; Chungang University, Korea (the Republic of)

Cellulose is the most abundant natural polymer on the planet. Despite its high heat resistance and high toughness, it is insoluble in many solvents, making its fabrication process difficult. Poly(lactic acid) (PLA), a biodegradable polymer made from corn or sugar cane, is made by polycondensation of lactic acid or ring-opening polymerization of lactide. PLA has poor foam processability because of its low melt viscosity. In this study, a cellulose/PLA composite is prepared with wood-like vertically aligned pore structures to overcome the weak mechanical properties of foam. Cellulose was dissolved in an alkaline solution of NaOH and urea at a low temperature. This solution is frozen by a liquid nitrogen reservoir followed by ice removal with cryogenic ethanol. Cellulose aerogel is made by exchanging solvents from ethanol to water and then freeze drying. Finally, PLA solution is infiltrated into the dried cellulose aerogel to create PLA-cellulose aerogel composite. NaOH-urea solution can be frozen at low temperatures, especially using the liquid nitrogen reservoir. Etching ice with ethanol retains the cellulose structure created during freezing. The temperature gradient freezing method creates honeycomb-shaped holes aligned vertically like a tree. The aerogel composite is made of cellulose and PLA using infiltration method. The porosity of aerogel is calculated by the ethanol replacement method. In this way, the porosity of cellulose and cellulose/PLA is about 80% similar. Cellulose/PLA aerogel composite has a higher modulus and stress-to-break than the control cellulose aerogel in compression tests, due to the thin PLA continuous phase. Because both PLA and cellulose are biodegradable, cellulose/PLA composites have great potential to be used in future eco-friendly applications.

Design and Fabrication by 4D Printing of Multilayered Tissue Engineering Scaffolds with High Elasticity and Good Shape-Morphing Ability Shangsi Chen and Min Wang; Department of Mechanical Engineering, The University of Hong Kong, Hong Kong

The injuries and defects of uterus, especially impaired endometrium, can cause abnormal menstruation, recurrent miscarriage and pregnancy complications and may lead to absolute uterine factor infertility (AUFI). The inability to achieve pregnancy usually has a severe impact on couple's physical and mental health. Conventional gynecological treatments including hysteroscopic adhesiolysis, intrauterine devices (IUDs) intervention and hormone therapy can relieve patients' symptoms to some extent and partially restore uterine structure but they do not recover the function of fertility for patients. The anatomical

structure of the uterus consists of three layers: perimetrium, myometrium and endometrium. The myometrium comprising smooth muscle cells is very elastic and the endometrium has a significant regeneration capability. Current studies start to employ tissue engineering scaffolds to repair uterine defects. For example, natural polymers such as collagen, hyaluronic acid and gelatin and synthetic polymers such as poly(lactic acid) (PLA) and poly(lactic-co-glycolic acid) (PLGA) have been used for uterine scaffolds. Although, those biomaterials are biocompatible and biodegradable and have been widely used in the tissue engineering field, their lack of good elasticity restricts their ability to simulate myometrium functions. In this study, a multilayered scaffold with high elasticity and good shaping-morphing ability was designed to mimic the anatomical structure of the uterus and was fabricated by combining 3D printing and electrospinning techniques. First, highly elastic thermoplastic urethane (TPU) and poly(D,L-lactide-*co*-trimethylene carbonate) (PDLLA-*co*-TMC) were melted and blended at high temperature. The blends were then 3D printed into scaffolds with different hierarchical structures in accordance with a CAD model. The TPU/PDLLA-*co*-TMC scaffolds were prepared to as a substitute for the uterine myometrium layer. Therefore, the elastic properties of printed scaffolds were studies through tensile testing. Additionally, the glassy transition temperature of TPU/PDLLA-*co*-TMC blends was investigated. The shape-morphing ability of 3D printed TPU/PDLLA-*co*-TMC scaffolds was investigated by immersing the scaffolds in a water bath at 37 degrees Celsius. Subsequently, a layer of electrospun PLGA/polydopamine (PDA) hybrid fibers was fabricated on the surface of 3D printed TPU/PDLLA-*co*-TMC. In this electrospun nanofibrous layer, 17beta-estradiol (E2) was loaded in PDA particles. The incorporation of E2 in PDA particles could solve the E2 insoluble problem and also preserve its bioactivity. Previous studies showed that E2 could promote endometrium regeneration by augmenting the function of angiogenetic growth factors, e.g., vascular endothelial growth factor (VEGF) and human basic fibroblast growth factor (hFGF). The controlled and sustained E2 release was studied in different pH solutions (pH4.5, 7.4 and 9.0) and under different NIR laser (808nm) irradiation energy. Finally, the last layer from a gelatin methacryloyl (GelMA)/gelatin (Gel) bioink encapsulated with human bone marrow derived mesenchymal stem cells (hBMSCs) was printed on the electrospun PLGA/PDA layer. *In vitro* biological behaviors such as cell viability and cell proliferation on 3D printed GelMA/Gel were evaluated. The effects of released E2 on cell survival and differentiation were also studied. The multilayered tissue engineering scaffolds made by 4D printing and electrospinning possess hierarchical structures to bio-mimic native structures of the uterus and have the potential for uterine regeneration.

3D Printing of Hard Materials for Surfboards Marc In het Panhuis; University of Wollongong, Australia

Surfing is an iconic sport that is extremely popular in coastal regions. Current surfboard fin manufacturers produce high end products using an expensive injection moulding process to create hydro-foil shaped fins. This process, however, does not allow for easy customisation or rapid prototyping.

I will discuss the development of surfboard fins (a hard material) using a performance feedback loop. This loop involves the unique combination of computational fluid dynamics, computer aided design, 3D printing of hard materials, stiffness/flex testing, ocean testing (surfing the waves), embedded sensors / wearables and surfers' perceptive experiences.

I will finish my talk with our progress on measuring the mechanical flex behaviour of surfboards, including modal (vibration) analysis and (what we call) 'fingerprint' analysis.

8:45 AM SF04.03.03
Graphene-Based Nanocomposite Materials and 3D Printing—Nanostructuring for Improved Mechanical Properties and Electronic Applications Rigoberto C. Advincula[1,2,3]; [1]Case Western Reserve University, United States; [2]The University of Tennessee, Knoxville, United States; [3]Oak Ridge National Laboratory, United States

The use of 2D nanomaterials including graphene for improving electrical and thermal conductivity properties in thin-film devices and sensors is well-studied. There is also high interest in using these materials for anti-microbial properties in coatings and formulations. However, there is high interest in the use of these materials in fabrication methods based on 3D printing. The 2D and high aspect nature of the nanomaterials enable nanostructuring of the nanocomposites for improved transport and stress or residual stress mitigation. Other than their known contribution to electrical and thermal conductivity they also enable stimuli-responsive properties in 3D fabricated objects and function. To this goal, this talk will focus on emphasizing the unique properties of graphene materials and their incorporation in 3D printed materials using FDM, VSP, SLA, and SLS Methods. In this talk, we will demonstrate the nanostructuring of graphene materials for 3D printing in the following projects: 1) FDM of polyurethane nanocomposites, 2) SLA 3D printing, and the use of post-processing thermal curing for highly improved thermo-mechanical properties, 3) Plastic motor based on emulsions coating on SLS 3D printed powders. On these demonstrated projects it is important to emphasize the use of integrated spectroscopic and microscopic characterization to correlate with structure-composition-property relationships.

9:00 AM SF04.03.05
3D Printing DIY Thermoset Elastomeric Adhesives and Formulated Nanocomposites Fazley Elahee[1], Chase P. Breting[1], Matthew Yang[1], Zane J. Smith[2], Lihan Rong[1], Tania E. Ceniceros[3], José B. Cruz[3] and Rigoberto C. Advincula[2]; [1]Case Western Reserve University, United States; [2]The University of Tennessee, Knoxville, United States; [3]CIMAV-Unidad Monterrey, Mexico

Commercial thermoset elastomers are widely available at lower costs compared to prepolymer formulations. They are classified as do-it-yourself (DIY) home improvement and repair materials. They are based on a wide array of chemistries and have been found to have rheologies very suitable for AM. We hereby investigated their 3D printability using direct ink writing (DIW) methods. The materials are divided into two main classes: silicone (three materials) and non-silicone (six materials) with hybrid chemistries and composites.They were characterized by: functional identification using GC-MS pyrolysis, rheology, cure behavior, cured Shore A hardness, 3D printability, TGA, thermal conductivity, dielectric, and mechanical properties. Corresponding ASTM standard test methods were also used and the results are reported. We also investigated the addition of nanoparticles to develop new properties out of the typical DIY function. Dispersion of nanoparticles is achieved using high-frequency ultrasonication techniques. Methods to incorporate nanoparticles into commercial thermoset elastomers is described. Nanoparticles include carbon nanotubes (CNT), graphene oxide (GO) and a 50/50 composite blend of CNT and GO up to 2% by weight. Reported results highlight the advantage in thermal and electrical conductivity.

9:15 AM SF04.03.06
Development of Highly Conductive Printable Material by the Combination of Fused Filament Deposition and Laser Sintering Remi Rafael and Paddy K. L. Chan; Hong Kong University, Hong Kong

3D printing has significantly participated to a general acceleration of research activities by providing a rapid and economical source of completely personalized parts. Besides being the central focus of some publications thanks to the novel design strategies enabled by additive manufacturing technologies, the holders, adaptors and other mechanical supports are innumerable. However, printed parts are often relegated to purely mechanical functions due to the difficulties to print multi-materials and the restrictions associated with functional (and in particular conductive) material.
In this work, we aim at developing a hybrid 3D printer and a new composite material to print both conventional Fused Filament Deposition (FFD) filaments and a highly conductive material. FFD of conductive materials is limited by the necessarily thermoplastic properties of the filament used. Since

no currently existing material is at the same time highly conductive and thermoplastic, a trade-off is obtained with composite materials using conductive particles inside a thermoplastic matrix. The composites use high aspect ratio particles to form conductive path by percolation, but the maximal particle loading is limited by the mechanical properties of the filament. As a result, the high loading leads to embrittlement and lowers the printability of the filament. Furthermore, the matrix material present at the junction between particles strongly impacts the contact resistance. Electrify, the most conductive filament currently available on the market still has a conductivity of 0.006 Ω cm (too high for advanced PCB applications) and suffers from high contact resistance and high price (196USD/100g).
To remedy this limitation of the maximal loading of particles in the printed material, here we propose a two-step printing process comprised of the FFD of a composite material, followed by a step of laser sintering to remove (evaporate) the thermoplastic matrix material and sinter the conductive particles together. This process is repeated for each layer to produce fully 3D PCB-like structures. To achieve this, we developed both a hybrid 3D printer based on economical desktop 3D printer and laser engraver parts, and a composite filament based on PLA and copper microparticles. The detailed electrical and mechanical characterizations of the printed conductive materials will be presented.

9:30 AM SF04.03.07
Late News: Two Photon Polymerization of Microstructured and Nanostructured Medical Devices Roger Narayan; North Carolina State University, United States

Two photon polymerization involves the use of ultrashort (e.g., femtosecond) laser pulses to selectively polymerize photosensitive resins; this technique has been used for 3D printing of medical devices with microscale and/or nanoscale features. The two photon polymerization technique involves near simultaneous absorption of two or more photons from a Ti:sapphire or fiber laser within a small volume over a short time period. The nonlinear nature of two photon absorption enables 3D printing of structures, including medical devices, which contain features below the diffraction limit. Several kinds of photosensitive resins, including polymers and polymer-ceramic hybrid materials, may be processed into medical devices with two photon polymerization. Recent medical uses of two photon polymerization have included processing of drug delivery devices, scaffolds for tissue engineering, and transdermal sensors. In vitro and in vivo evaluation of two photon polymerization-fabricated medical devices will be considered. Our results indicate that two photon polymerization is an important technique for creating microstructured and nanostructured medical devices.

10:30 AM SF04.04.01
Influence of Sintering Temperature and Print Orientation on Copper Printed with an FDM Printer Using Bound-Metal Filament Ahron Wayne; Lawrence Technological University, United States

3D printing of thermoplastics has become a mainstay of modern engineering research and development, enabling industry, universities, and even individuals the ability to rapidly manufacture and iterate upon computer-aided designs. 3D printing of metals, however, has continued to remain out of reach except for those able to bear the exceptional start-up and operational costs of existing solutions, such as powder bed fusion or metal injection molding (MIM). One solution that has the potential to reduce costs is the MIM-like process of using an organic binder mixed with powdered metal to produce a feedstock (filament) that can be printed using any conventional fused-deposition-modeling (FDM) 3D printer; the result after debinding and sintering is a pure metal part. We report here an even more accessible variant of this process we have improved upon to create 3D-printed copper parts. The process utilizes a purely thermal, as opposed to chemical debinding step, and the addition of carbon produces a locally favorable gaseous environment during sintering without the use of vacuum or outside injection of protective gas. The influence of printing orientation and sintering temperature on the microstructure and mechanical properties of printed and sintered copper parts was investigated. Higher sintering temperatures resulted in stronger and denser parts but with increasingly anisotropic shrinkage. Parts sintered at 1074 C showed comparable tensile strength and ductility as copper produced using the powder bed fusion process. Printing orientation was found to play a major role in the strength of unsintered parts, but this effect diminished to undetectable levels after sintering. Microstructural analysis showed the presence of carbon in both the printed part interior and exterior; this presence of carbon and its role in the densification process was discussed. The process shows promise for rapid, inexpensive turnaround of 3D printed copper parts for applications without the strict requirements of both strength and 3D intricacy.

10:45 AM SF04.04.01
Enhancing Strength and Ductility of AlSi10Mg Fabricated by Selective Laser Melting by TiB_2 Nanoparticles Yakai Xiao, Yi Wu, Zhe Chen and Haowei Wang; Shanghai Jiao Tong University, China

Nanoparticles are known to play a crucial role in helping achieve excellent mechanical properties in advanced metal matrix composites fabricated by emerging selective laser melting (SLM) technology. Despite this, the understanding of their impacts on the evolution of microstructure and mechanical properties remains nebulous. In the present study, we adopted the SLM process to fabricate *in-situ* nano-TiB_2 decorated AlSi10Mg composites with alternative TiB_2 nanoparticle contents (0, 0.5, 2, 5, 8 wt.%) to investigate the effects of introduced nanoparticles on the SLM processability, microstructures, texture evolution and mechanical properties. Results show that nearly fully-dense TiB_2/AlSi10Mg composite samples can be manufactured at the optimized SLM processing parameter due to the enhancing SLM processability by nano-TiB_2 particles. Besides, increasing the nano-TiB_2 addition can gradually transform the coarse columnar grain structure with <100> fiber orientation texture to fine equiaxed grain structure without preferred crystallographic texture due to the heterogeneous nucleation effect of nano-TiB_2 particles. The elongated cellular sub-structure transforms to the equiaxed cellular sub-structure without obvious directionality. The dislocation density of the TiB_2/AlSi10Mg composites is higher than that of the alloy due to the mismatch of the thermal expansion coefficient between TiB_2 particles and a-Al matrix. Additionally, the microhardness, tensile strength and ductility can be improved simultaneously by the addition of nano-TiB_2 particles. With increasing TiB_2 nanoparticles content, the tensile strength and microhardness increased in a stepwise manner while the ductility increased first and then decreased. Moreover, the SLMed TiB_2/AlSi10Mg composites have superior tensile properties comparing to the previous SLMed AlSi10Mg alloy and their composites with the addition of other particles. The underlying mechanisms of strengthening are mainly attributed to grain boundary strengthening, dislocation density strengthening, load-bearing transformation strengthening, and Orowan strengthening. Meanwhile, the enhancing ductility in the composites is mainly attributed to higher relative density due to better SLM processability, less strain localization due to modified grain structure, high dislocation plasticity due to the intragranular nanoparticles. This study sheds light on SLM-produced nanoparticles decorated aluminium composites for the production of advanced materials.

11:00 AM SF04.04.02
Protonation and Weakening of Epoxy Resin Under Wet Conditions from First-Principles Calculations Shuji Ogata and Masayuki Uranagase; Nagoya Institute of Technology, Japan

Adhesive bonding using epoxy resin is a key industrial manufacturing process of joining materials. Recently, advanced technologies requiring extensive use of adhesive bonding, such as multi-material design with proper mixing of metals and polymers for lightweight automobile bodies, tight packing of electronic components requiring rapid heat dissipation, and additive manufacturing for novel materials, have become increasingly popular. However, a significant challenge facing adhesive bonding is the weakening or lost of adhesion under damp conditions. For instance, the adhesion strength between aluminum and epoxy resin decreases by 30–50% under wet conditions. This study proposes, for the first time, a proton-related mechanism for the moisture-induced breaking of epoxy resin from the extensive first-principles calculations.

We investigated the cohesive failure of epoxy resin prepared using amine-based curing agents by DFT-based free energy calculations. To this end, we performed the thermodynamic integration of the DFT energy difference between the deprotonated and original states through the artificial process of gradually transformation of the target proton into a dummy atom having zero charge to calculate the free energy of protonation. We thereby found that the amine group of the epoxy resin is protonated at equilibrium depending on the location of the amine group when the epoxy resin is embedded in water under standard conditions.

Next, we calculated the bond breaking barrier energies of the principal groups of the epoxy resin under both dry and wet conditions. Concerning the ether group, the energy barrier to C-O bond breaking is reduced from 2.86 eV under dry conditions to 2.30 eV under wet conditions because of the dissociation of H2O. The energy barrier for breaking the amine group decreases from 2.30 to 1.94 eV under dry and wet conditions, respectively, because of the protonation of the amine group, but the dissociation of H2O does not lower the transition state barrier energy further. We thereby show that the bond breakage of the protonated amine groups is the principal process causing the weakening of epoxy resins under wet conditions.

11:15 AM *SF04.04.03
Composites and Hybrids for 3D Printing in Tissue Engineering Min Wang; Department of Mechanical Engineering, The University of Hong Kong, Hong Kong

3D printing provides a powerful manufacturing platform for different industries and has been increasingly used in the tissue engineering field. 3D printing technologies includes an array of technologies: liquid-based, filament- or paste-based, and powder-based technologies. Using smart materials and with innovative designs, 4D printing produces dynamic structures that can change their shape, property, and/or function under external stimulus/stimuli. Using inks that contain living cells, 3D/4D bioprinting creates living structures for different purposes (cancer tissue models, tissue engineering, organ-on-a-chip, etc.) in the biomedical field. 3D printing technologies greatly improve our ability to fabricate a variety of complex and customized biomedical products accurately, efficiently, economically and with high reproducibility. However, finding or developing suitable biomaterials appears to be a bottleneck for the advancement of 3D/4D printing in biomedical engineering (J.Lai, C.Wang, M.Wang, “3D Printing in Biomedical Engineering: Processes, Materials and Applications”, *Applied Physics Review*, Vol.8 (2021), DOI:10.1063/5.0024177). Different 3D printing technologies have different requirements for the materials/inks to be used, and in most situations these requirements are highly demanding. The requirements for 3D printing materials/inks in tissue engineering include printability, biocompatibility, biodegradation properties, and mechanical properties of printed products. Biocompatibility is of paramount importance for a material in tissue engineering applications but it becomes highly important only when the material can be 3D printed where 3D printing is employed for structure formation. We have investigated / are investigating several 3D printing technologies, such as selective laser sintering (SLS), cryogenic extrusion 3D printing, and digital light projection (DLP), for fabricating advanced tissue engineering scaffolds and cell/scaffold constructs for the regeneration of bone, osteochondral tissue, blood vessel, etc. For example, for 3D printing of bone tissue engineering scaffolds via SLS, calcium phosphate (Ca-P)/ poly(hydroxybutyrate–co-hydroxyvalerate) (PHBV) nanocomposite was developed (B.Duan, *et al.*, “Three-dimensional Nanocomposite Scaffolds Fabricated via Selective Laser Sintering for Bone Tissue Engineering”, *Acta Biomaterialia*, Vol.**6** (2010), 4495–4505). For cryogenic extrusion 3D printing of scaffolds for osteochondral tissue regeneration, beta-tricalcium phosphate (beta-TCP)/poly(lactic-*co*-glycolic acid) (PLGA) nanocomposite was used (C.Wang, *et al.*, “Cryogenic 3D Printing of Heterogeneous Scaffolds with Gradient Mechanical Strengths and Spatial Delivery of Osteogenic Peptide/TGF-beta1 for Osteochondral Tissue Regeneration”, *Biofabrication*, Vol.12 (2020), 025030). For shape-morphing scaffolds, beta-TCP/poly(D,L-lactide-*co*-trimethylene carbonate) (PDLLA-*co*-TMC) nanocomposite was developed (C.Wang, et al., “Advanced Reconfigurable Scaffolds Fabricated by 4D Printing for Treating Critical-size Bone Defects of Irregular Shapes”, *Biofabrication*, Vol.12 (2020), 045025). For obtaining complex shape-morphing structures, alginate (Alg) and methylcellulose (MC) blends were investigated (J.Lai, *et al.*, “4D Printing of Highly Printable and Shape-morphing Hydrogels Composed of Alginate and Methylcellulose”, *Materials & Design*, Vol.205 (2021), 109699). This talk will give an overview of our work in developing different materials for 3D/4D printing in tissue engineering. It will provide design guidelines and practical approaches in developing composites and hybrids for biomedical 3D/4D printing.

11:45 AM SF04.04.04
Design and Fabrication by Digital Light Processing of Biphasic Calcium Phosphate Tissue Engineering Scaffolds Yue Wang[1,2], Jiaming Bai[2] and Min Wang[1]; [1]Department of Mechanical Engineering, The University of Hong Kong, Hong Kong; [2]Department of Mechanical and Energy Engineering, Southern University of Science and Technology, China

Tissue engineering provides new vital means for human body tissue/organ repair. Tissue engineering scaffolds give temporary structural support to cells for their attachment, growth, and proliferation until the body has restored the mechanical and biological properties of the host tissue. However, the fabrication of tissue engineering scaffolds with controlled porous structures (pore shape, pore size, porosity, etc.) and desired external morphologies (shape, dimensions, etc.) is still a challenge. Digital light processing (DLP) is now recognized as a powerful 3D printing technology which can process ceramics into complex and interconnecting porous structures with high precision and resolution. Biphasic calcium phosphate (BCP), a physical mixture of hydroxyapatite (HAp) and beta-tricalcium phosphate (beta-TCP), is a promising bioceramic for bone tissue regeneration owing to its proven biocompatibility, osteoconductivity, possible osteoinductivity, and controllable biodegradation rates. But fabrication of BCP bioceramic scaffolds via DLP is rarely reported. In this study, a comprehensive investigation was conducted to assess and optimize DLP fabrication to produce high-performance porous BCP scaffolds. First, equal amounts of nano-sized HAp and beta-TCP powders were mixed using a planetary mill. The BCP powders were then formulated with photosensitive resins to prepare BCP slurries. In this step, different dispersants were used and compared for powder surface modification, aiming to decease bioceramic nanoparticle agglomeration and to achieve stable BCP slurry with high solid loading and low viscosity. The relationships between solid loading and slurry viscosity, DLP energy dose and cure depth and the optimal concentration of photo-initiator were systematically investigated so as to obtain the optimal processing parameters. Second, thermogravimetric analysis (TGA) was performed on DLP-formed green bodies to determine the debinding and sintering strategy for obtaining crack-free BCP porous scaffolds with desired biological and mechanical properties. Furthermore, the effects of sintering temperature (1100 - 1300 degree Celsius) on the shrinkage, phase stability, mechanical properties and biological properties of BCP scaffolds were investigated. Fourier transformed infrared spectroscopy (FTIR), X-ray diffraction (XRD), mechanical testing (compression tests and hardness testing) and surface roughness measurement were conducted for scaffold samples. Finally, BCP scaffolds with different designed pore morphologies, pore sizes

and porosities were made via DLP and sintering using optimized processing parameters. The results showed that scaffolds sintered at 1300 degree Celsius had the best mechanical properties and the lowest surface roughness. Cell attachment and proliferation experiments indicated that DLP-formed BCP scaffolds had good cell viability. Also, the optimized DLP process demonstrated the DLP capability to fabricate complex tissue engineering scaffolds with great freedom and high accuracy. This study has therefore shown great potential of DLP for constructing complex bioceramic scaffolds and possibly other devices for biomedical applications.

Late News: Fabrication, Processing and Characterization of Copper Nanoparticle Deposited Graphene Sheet Embedded Carbon Fiber Composite Vishwas S. Jadhav and Ajit Kelkar; North Carolina Agricultural and Technical State University, United States

Due to high stiffness and strength per unit mass, carbon fiber composite became more popular during the last few decades. The low conductivity of carbon fiber composite made aeronautical structures more vulnerable to withstand lighting strikes and unable to prevent electrostatic accumulation. To overcome this, typically different nanofiller are used in conjunction with conventional carbon fiber composites. Due to the high aspect ratio, extraordinary mechanical and electrical properties of nanomaterials, nanoengineered composites are becoming popular. In the present research work Graphene sheet (GS) of 120 µm thick, fabricated from 2D Graphene nanoplatelets, was incorporated into carbon fiber composites to enhance the electrical and mechanical properties of the composite laminate. Preliminary studies indicated that GS embedded composite laminates degraded the mechanical properties instead of enrichment due to weak graphene epoxy bonding. To improve the bonding in addition to vertical, horizontal, and square grids spiked roller was used to make holes in the GS. The utilization of the graphene grid helped to boost the graphene-epoxy bonding as well as mechanical properties. GS added at the mid-plane was expected to send the strong electric signal but in reality, the strength of the signal was not strong. To overcome the issue of weak bonding and electrical conductivity, a chemical deposition method was used to deposit copper nanoparticles on a Graphene sheet. The electrical conductivity of copper deposited GS was evaluated using Jandel four-point tester. Dynamic Mechanical Analysis (DMA) was carried out to evaluate and compare thermomechanical properties of copper deposited Graphene, plain graphene sheet reinforced composite and bare composite. Fragile interface observed due to weak plain GS- epoxy bonding resulted in degraded mechanical properties. The effect of copper nanoparticles deposited on the GS helped to enhance the bonding. Glass transition temperature (T_g), storage, and loss modulus, in addition to Electrical conductivity, were evaluated and compared. Scanning electron microscopy was used to evaluate and compare bonding at the mid-plane of the laminate. Overall study indicates that the copper deposited GS into carbon fiber composites would help to enhance the strength, stiffness, and conductivity of the carbon fiber-reinforced composite laminate.

Light-Induced Levitation of Ultralight Carbon Aerogels via Temperature Control Reo Yanagi, Ren Takemoto, Kenta Ono and Tomonaga Ueno; Nagoya University, Japan

The weight reduction of materials is crucial for building a resource- and energy-conscious society, realizing comfortable living spaces, and space exploration. Porous materials, such as aerogels, facilitate the fabrication of materials with density less than that of air. Owing to their high electrical, thermal, and mechanical properties, carbon aerogels have been studied for use in many applications. The lightest carbon aerogel, discovered to date, has a density of 0.16 mg cm^{-3}, as reported by Sun et al. in 2013 [1]. The density of this aerogel is approximately 1/6 of the density of air at room temperature; however, it does not levitate in air. This is because there are many pores in the ultralight aerogel that are filled with air, and therefore the apparent density is the sum of those of the material and inner air, thereby making it heavier than air. Many studies have been conducted on ultra-lightweight materials; however, the attempts to make them levitate in air have been very few and limited. If ultralight materials can levitate in air, they will behave as if they are defying gravity, providing new values to our lives. In recent years, research on carbon aerogels with a three-dimensional geometric structure designed using 3D printing technology has also been conducted to expand the applications of carbon aerogels further. This technology makes it possible to create aerogels that retain specific mechanical properties in a density range approaching air density by realizing complex geometric structures.
In this study, we show ultralight carbon aerogels that can intermittently levitate in air for a long time according to Archimedes' principle. Ultralight carbon aerogel**s** fabricated with CNTs can be easily heated by light, and the temperature can be controlled. A carbon aerogel, with density that is less than that of air, is heated using a halogen lamp. As a result, the air inside expands to reduce the air density inside the aerogel, thereby creating a state in which the sum of the densities of the aerogel and inner air is less than that of the surrounding air. This allows the material to levitate due to buoyancy.
Ultralight aerogels, composed of CNTs and cellulose nanofibers (CNFs), were produced with a prepared density of 0.25, 0.50, 0.75, and 1.0 mg cm^{-3}. UV-visible/near-infrared spectroscopy (UV-vis/NIR) measurements using an integration sphere show that the diffuse reflectance of all samples is between 0 % and 4 % in the wavelength range of 350–2500 nm. The ultralight aerogel fabricated showed a heat capacity of approximately 9.3×10^{-4} to 2.7×10^{-3} J K^{-1} cm^{-3} per unit volume in the temperature range of 20–200 °C. The small heat capacity across the entire temperature range suggests that the aerogel could be heated instantaneously using a small amount of energy.
The levitation experiment was conducted by heating the ultralight aerogel with a 90 W halogen lamp in an acrylic cylinder whose bottom was covered with an aluminum lid placed in a container filled with liquid nitrogen. When the lamp was turned on, the aerogel was heated and began to levitate. A cylinder surrounded the aerogel, and the bottom was covered with an aluminum lid such that it was not affected by the updraft caused by the liquid nitrogen. The aerogel levitated as long as it remained exposed to light from the lamp. To confirm that the ultralight aerogel was heated by the halogen lamp and levitated via buoyancy according to Archimedes' principle, the densities of the aerogel (ρ_a) and ambient air (ρ_m) during levitation were calculated and compared. All the data obtained from the calculation results are near the line where $\rho_a = \rho_m$, indicating that air buoyancy levitates the ultralight aerogel, according to Archimedes' principle, when heated by the halogen lamp.

Engineering Bottom-up Fabrication of Functional Multi-Material Nanostructures Created Through Evaporation Induced Self-Assembly of Nanocolloidal Droplets Shadi Shariatnia, Dorrin Jarrahbashi and Amir Asadi; Texas A&M University, United States

Achieving desired performance from self-assembly of nanoparticles (NPs) is very challenging due to the stochastic nature of interactions among the constituent building blocks. Self-assembly of Nano-colloids through evaporation of particle-laden droplets can be exploited to fabricate tailored nanostructures that add functionality and engineer the properties of the manufactured components. The particle-particle and particle-solvent interactions, as

well as the forces arising from the evaporation of the solvent are the main driving factors that define the formation of the final nanostructure. In this study, we introduce a nanoparticle-agnostic approach that allows the fabrication of multi-material nanostructures with precisely engineered patterns. Evaporative droplets of aqueous suspensions of Carbon Nanotubes (CNTs), Graphene Nanoplatelets (GNPs), and Boron Nitride Nanotubes (BNNTs) representing NPs of different elemental composition (i.e., carbonaceous and ceramic) with different sizes and shapes (i.e., Nanotube, Nanoplatelets) are investigated. We utilize cellulose nanocrystals (CNCs) as a platform to make hybrid systems of CNC and the secondary NP (i.e., CNC-CNT, CNC-GNP, and CNC-BNNT). We then capitalize on fundamentally understanding the repulsive-attractive interactions in this hybrid system and their effects on the final pattern that is created. It is shown that the formation and thickness of deposited patterns of CNC-bonded CNTs, GNPs, and BNNTs after evaporation of nano-colloidal droplets depends only on the concentration and mass ratio of the NPs and not their shape and size or material that is utilized. This system involves non-toxic, abundant, and biocompatible agents such as water and CNC that promote its scalability. The proposed method enables new capabilities in the precisely controlled fabrication of engineered nanostructures, and programming smart self-assembly systems.

Fused Filament Fabrication Using a Diels-Alder Reversible Thermoset—Novel Isotropic 3D Printable Material with High Filler Content Piaoran Ye[1], Douglas A. Loy[2,1], Krishna Muralidharan[2] and Barrett G. Potter[2]; [1]University of Arizona, United States; [2]The University of Arizona, United States

A thermoreversible thermoset formed by Diels-Alder (DA) chem. was used in Fused Filament Fabrication (FFF) 3D printing to obtain a printable, elastic thermoset with isotropic mech. properties. FFF additive manufg. typically uses thermoplastics that are limited in the amt. of filler that can be incorporated in composite prints due to their high melt viscosities and often exhibit anisotropic strengths according to the print geometry. Thermoreversible thermosets with weak links based on cycloadducts between maleimide and furan groups can revert from crosslinked network to liq. oligomeric resins with heating above 100 °C. In this study, filaments with up to 60wt% tricalcium phosphate and silica particles were prepd. and used in FFF printing. Thermoreversible resins were prepd. by reacting 1,1'-(methylenedi-4,4'-phenylene)bismaleimide (MPB) with furfuryl group functionalized oligomeric Jeffamines. The resulting resins were then heated to mix with particle filler and extruded to afford 1.75 mm filament. Tensile test specimens were printed between 130-150 °C with varying printing geometries to establish that the thermoreversible thermosets displayed isotropic strength relative to print orientation. The resulting printed structures were readily recyclable by chopping into fragments and re-extruding as filament for addnl. printing. The resins can be recycled back into filament and then printed up to five times. Irreversible crosslinking, through reaction of free maleimides, occurs after 5 h at 140 °C but could be used to prevent thermoreversion. Properties of the resins could be tuned with filler content and with the mol. wt. of the jeffamine.

1:45 PM SF04.05.04
Highly Loaded Wood Flour Biocomposites for Large-Scale 3D Printing Xianhui Zhao[1], Katie Copenhaver[1], Yousoo Han[2], Lu Wang[2], Sanjita Wasti[3], Halil Tekinalp[1], Uday Vaidya[3], Douglas Gardner[2] and Soydan Ozcan[1]; [1]Oak Ridge National Laboratory, United States; [2]University of Maine, United States; [3]The University of Tennessee, Knoxville, United States

Biomass natural fibers have been commonly used for reinforcing polymers (e.g., polylactic acid [PLA]) because of their low cost, low density, abundance, and biodegradability. In this study, PLA/wood flour composites were produced with wood flour loading between 30 and 60 wt% to investigate the effect of wood flour loading on the composite performance. The composites obtained were characterized using dynamic mechanical analysis (DMA), tensile testing, thermogravimetric analysis (TGA), differential scanning calorimetry (DSC), scanning electron microscopy (SEM), and rheology. The rheological properties of these highly loaded composites were then modified using various coupling agents and viscosity modifiers to optimize the composites for large-scale additive manufacturing applications. The mechanism of the viscosity modification in the PLA/wood flour composites was investigated, and the chemical treatments were found to be effective in tuning the properties of the biocomposites for specific applications.

4D Printed Shape-Morphing Tissue Engineering Scaffolds with Enhanced Biocompatibility Xiaodie Chen, Jiahui Lai and Min Wang; Department of Mechanical Engineering, The University of Hong Kong, Hong Kong

3D printing is very attractive for fabricating tissue engineering scaffolds because it can produce either simple or complex scaffolds precisely and rapidly according to the scaffold design and custom-make scaffolds to meet the requirements for individual patients. However, 3D printed structures have static shapes and properties during their application and hence do not accurately imitate the dynamic nature of body tissues. Shapes, properties or functions of tissue engineering products should evolve along with the dynamic tissue regeneration process. Therefore, 4D printing, an emerging manufacturing platform through the integration of time with 3D printing, is now hotly pursued for fabricating dynamic structures which can change the shape, properties or functions over time under appropriate stimulus/stimuli such as temperature, pH, humidity, light, electricity, magnetic field, sound, or a combination of these stimuli. Currently, shape memory polymers are the most popular responsive materials for 4D printing in tissue engineering. However, most of them are synthetic polymers whose biocompatibility is not as desired. Combining a synthetic shape memory polymer with a biocompatible natural hydrogel is an effective way for obtaining a polymer blend with both shape memory ability and enhanced biocompatibility for 4D printing in tissue engineering. Poly(D,L-lactide-co-trimethylene carbonate) (PDLLA-*co*-TMC) is a popular synthetic shape memory polymer. Structures made of PDLLA-*co*-TMC with a DLLA-to-TMC ratio of 80:20 respond at 37 degrees Celsius for shape memory, suggesting its potential for shape-morphing scaffolds for human bodies. Gelatin methacryloyl (GelMA), a photopolymerizable hydrogel composed of natural gelatin functionalized with methacrylic anhydride, retains the functional amino acid sequence of gelatin and hence exhibits good biological activity. It is shown to promote cell adhesion and proliferation. In this study, 4D printing of shape-morphing scaffolds with improved biocompatibility was investigated using polymer blends of PDLLA-*co*-TMC (80:20) and GelMA. The 4D printing process involved four steps: (1) Pure PDLLA-*co*-TMC and PDLLA-*co*-TMC/GelMA blends at 1:1, 2:1 and 3:1 blend ratios were printed into planar structures; (2) the planar structures were shaped into tubes by using a glass rod at 80 degree Celsius; (3) the tubular structures were flattened at 25 degree Celsius; (4) the flattened scaffolds could self-fold into tubular structures at 37 degree Celsius within a minute in an aqueous environment. The influence of blend ratio on the shape memory ability and printability was studied and compared with pure PDLLA-*co*-TMC. Surface morphologies of the 4D printed pure PDLLA-*co*-TMC and PDLLA-*co*-TMC/GelMA scaffolds were observed under SEM. Also, the mechanical properties of pure PDLLA-*co*-TMC and PDLLA-*co*-TMC/GelMA blends were assessed via tensile tests. Finally, the viability, attachment and proliferation of cells seeded on 4D printed pure PDLLA-*co*-TMC scaffolds and PDLLA-*co*-TMC/GelMA scaffolds were studied. It was found that the addition of GelMA into PDLLA-*co*-TMC improved printability, stretchability, and biocompatibility while maintaining the shape memory property. 4D printed PDLLA-*co*-TMC/GelMA scaffolds

with desired functionalities such as biocompatibility and shape memory property have great potential for tissue engineering applications, especially for tubular tissues such as vasculature and gastrointestinal tract.

9:05 PM SF04.06.02
3D-Printed Monolithic Porous CO_2 Adsorbents from a Solution-Processible, Hypercrosslinkable, Functionalizable Polymer Junghyun Lee[1], Chong Yangh Chuah[1], Wen See Tan[1], Juha Song[1] and Tae-hyun Bae[2]; [1]Nanyang Technological University, Singapore; [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of)

In recent several decades, the global warming has been accelerating due to increasing carbon dioxide emissions, and accordingly various environmental problems are newly raised. Among the solutions to reduce CO_2 emissions, the adsorptive approaches have been actively progressing. Research on CO_2 adsorbent using 3D printing technology which is one of the most focused issues in the scientific community has been conducted recently, however, the approaches using the existing traditional concept using clay as a binder can cause limitation of adsorption capacity and preparation of feed for 3D printing. Herein, we present a new unconventional processable adsorbent fabrication method using 3D printing technology which starts with a widely used printable polymer. CO_2 adsorption capacity of 3D-printed polymers is imposed by post-treatment processes such as hypercrosslinking and amine-grafting. 3D-printed monolithic adsorbents showed significantly improved CO_2 adsorption capability and CO_2/N_2 selectivity due to the presence of microporosity and amine-functionality, compared with their original polymer form. Moreover, tests under dynamic flow in dry and humid condition demonstrated that the 3D monolithic adsorbents effectively captured CO_2 at an extremely low flow rate, while possessing good stability and regenerability. Based on the promising results presented in this proof-of-concept study, we are aiming to further improve the CO_2 capture capacity by increasing both porosity and amine loading in future work.

9:10 PM SF04.06.03
Hydrothermal Processing of Solid Waste Materials Shengfei Zhou, Sabrina Shen and Markus J. Buehler; Massachusetts Institute of Technology, United States

Hydrothermal processing (HTP) is a green method to convert biomass (such as algae) and solid waste into valuable materials. In this study, HTP is conducted to treat and valorize sewage sludge and food wastes into biocrude oil and biochar. The effects of process parameters including feedstock, solids load, HTP temperature, and reaction time, are investigated. Statistical model is created to predict the yields of the HTP products. A techno-economic analysis (TEA) of a continuous HTP process is developed, assuming the biocrude oil is used as asphalt binder additive. Biochar is characterized and assembled with fiber materials into composites, which might be used as electrodes for energy storage. Activated carbon is also prepared from the biochar, then used for 3D printing.

9:15 PM SF04.06.04
FDM 3D Printing of Epoxy-Polybenzoxazine Thermoset Composite E. A. Dineshi A. Peiris and Douglas A. Loy; The University of Arizona, United States

Fused Deposition Modeling (FDM) is the cheapest 3D printing technique centered around thermoplastic printing. However, the current usage of FDM 3D printing has been limited, especially in the applications where mechanical strength becomes crucial. The main reason for this limitation is the inherent anisotropic nature of the layered prints. Epoxy-benzoxazine based filaments can reduce this anisotropy effect by forming covalent crosslinking during the print. Polybenzoxazine and epoxies are major thermoset classes with excellent thermomechanical properties and rich molecular design flexibility. Blends of benzoxazine and epoxy resins exhibit a long shelf life at room temperature but will react at elevated temperatures to afford copolymers with superior properties. Here, thermoplastic filaments were prepared from epoxy-benzoxazine blends for FDM 3D printing that cure during printing to afford robust thermoset prints. The benzoxazine can polymerize by a base-catalyzed condensation reaction with itself and with the bisphenol A-based epoxide resin. Benzoxazine's tertiary amine group can also catalyze the reaction of alcohol hydroxy groups with epoxides in the epoxide resin. The thermoplastic blend was formulated from poly(bisphenol A glycidyl ether end-capped), a bisphenol A-based benzoxazine, and fumed silica. DSC analysis of the blend revealed that its cure temperatures are higher than the softening points of the epoxy polymer and the benzoxazine monomer, permitting the filament to be extruded below the cure temperature with no crosslinking. Printing of the blend-based filament at higher temperatures initiates the curing reactions that ultimately lead to 3D filament printed thermosets.

9:20 PM SF04.06.05
Topological Structure Enhanced Nanostructure of High Temperature Polymer Exhibiting Giant Dielectric Response Xin Chen and Qiming Zhang; The Pennsylvania State University, United States

Nanofillers in polymer composites will induce interface regions in the polymer with non-uniform nanostructures which can be approximated as multilayer shells surrounding nanofillers. This work studies topological nanostructures in polymers that interface with one-dimensional (1-D) and zero-dimensional (0-D) nanofillers. This new class of dielectric polymer nanocomposites involves nanofillers at ultra-low volume loading (< 1 volume percent) that generate large dielectric enhancement. The results show that the dipolar response of polyetherimide, a high temperature dielectric polymer, is increased by more than ten times with ultra-low (0.75 vol%) loading of 1-D nanofillers. The results reveal that 1-D nanofillers induce cylindrical shell-topology in the polymer matrix which is more effective in enhancing the high dielectric constant interfacial region than the spherical shell-topology generated by 0-D fillers. The cylindrical shells generated by 1-D fillers provide much higher dielectric enhancement over a broader interfacial region in the polymer matrix, as compared to the spherical shells induced by 0-D nanofillers.

9:25 PM SF04.06.06
Late News: A Flame Resistant, 3D Printed polyhydroxyalkanoate/ammonium Phosphate Biodegradable Polymer Blend Yiwei Fang[1], Ethan Zuo[2], Abhishek Vangipuram[3], Katerina Popova[4], Miffy Liu[5], Joshua Kaplan[6], Anna Cho[1], Krish Patel[1], Vikash Persaud[1] and Miriam Rafailovich[1]; [1]Stony Brook University, United States; [2]Saratoga High School, United States; [3]Novi High School, United States; [4]Hackley School, United States; [5]Shenzhen Middle School, China; [6]The Frisch School, United States

Polyhydroxyalkanoate (PHA), synthesized by certain bacteria like Cupriavidus necator, is an environmentally sustainable polymer that can be degraded by enzymes and microorganisms. As PHA has good processing property and biocompatibiliy, PHA is favored in many areas such as food packaging, biomedical engineering and 3D printing. However, the flammable nature of PHA limits its potential of being a substitute of conventional petroleum-based polymer. Ammonium polyphosphate (APP) is an effective flame retardant additive for polymer such as polylactic acid and polypropylene, which creates char layers as a physical barrier could stop the combustion. While the effect of APP in PHA has rarely been investigated yet. Here we combined APP and resorcinol bis(diphenyl phosphate) (RDP), which acts as a surfactant, with PHA by melt blending technique to enhance the flame resistance of PHA. The dense char formation shown in Thermogravimetric analysis (TGA) could possibly explain that even with a low loading of 5wt%APP and RDP could make PHA V-0 grade in UL-94 flame test. The fact that RDP as a surfactant

could increase the dispersion of APP in PHA is proven by SEM-EDS analysis. Heat effect and crystallization behavior was investigated by Differential Scanning Calorimetry (DSC). The chemical composition of the blend and char was investigated by Fourier Transform Infrared Spectroscopy (FTIR). As the Izod impact test and tensile test showed that APP reduces the strength of PHA due to its rigidity, it's essential to minimize the usage of APP to increase the 3D printing quality of PHA. Fiber drawing and comparison of the combustibility upon FDM printing will be discussed.

We gratefully acknowledge support from the Louis Morin Charitable Trust.

9:30 PM SF04.06.07
Cost-Effective Fabrication of High-Performance 3D Printed Composites Using Continuous Fiber by Modified Fused Deposition Modeling (FDM) Technology Patrapee Kungsadalpipob, Mostakima M. Lubna and Philip Bradford; North Carolina State University, United States

Additive manufacturing which is also known as Three-dimensional printing (3D printing) has become the most promising material fabrication approach for academic, R&D and industrial use. Among various types of 3D printing technology, Fused Deposition Modeling (FDM) is currently the most popular category because of its cost-effectiveness, high scalability and flexibility as well as minimal post-processing required. Unfortunately, it is still challenging to print continuous fiber reinforced structures due to various issues such as complex machine design, fiber flexibility and durability, as well as fiber-matrix incompatibility. Some companies have developed alternative 3D printers capable of printing carbon fiber composite, but the machine cost is still a hindrance for small scale use. Moreover, 3D printing with other types of continuous fibers has not been explored.

Our research aims to develop and modify a commercial desktop 3D printer to be capable of printing continuous carbon nanotubes (CNT) assemblies. In our lab we grow vertically aligned multiwalled carbon nanotubes (CNTs) using Chemical Vapor Deposition process (CVD). The resulting CNTs are called “Spinnable CNTs” because they can be spun continuously as yarns, sheets, and fibers which can be incorporated in other matrices. With their inclusion in polymers, CNT reinforcement not only leads to mechanical strength improvements, but also results in unique multi-functionalities such as electrical conductivity. We successfully impregnated CNT yarns onto the surface of the polylactic acid (PLA) filament. The binary solvent system with 2 %w/v of PLA has been used as a binder during filament feeding without applying additional pull forces. Moreover, different types of commodity and industrial yarns such as cotton, polyester as well as Zylon yarns have been printed and studied. The 3D printed composites are fabricated by ROBO 3D R1 plus FDM printer. The structure-property relationship of the printed parts were investigated by varying layer thickness, fill density, infill type, printing temperature, printing speed, and delay time.

Results revealed that a 210°C extruder temperature leads to the best printability in comparison against 190-205°C. Minimizing printing speed also results in better printability as it prevents the dragging and the peeling off of the reinforcement yarns. Mechanical performance is investigated through measuring the tensile strength. At the same fiber volume fraction, the 1 mm thickness 3D printed part containing Zylon yarn shows the highest tensile strength of 45MPa and modulus of 1.40 GPa, followed by the CNT yarn as reinforcement which presents tensile strength of 39 MPa and modulus of 1.27 GPa. Results showed that 3D printed PLA reinforced Zylon yarn has 7.1% higher in tensile strength and 0.72% higher in tensile modulus than 3D printed neat PLA. This demonstrated that different yarn strengths lead to varying degree of the printed composite strength.

Morphology, fiber orientation, and void formation of the printed parts were characterized by SEM, electrical properties, and thermal properties by DSC and TGA. For future work, we aim to modify commercial desktop 3D printer for more seamless integration of the continuous fiber with high fiber volume fraction. Enhancing printing productivity and broadening various types of continuous fiber also need to be developed. Successful development of this hybrid 3D printing technology will be useful in a broad range of applications such as electronics, automotive, and aerospace.
